older child includes painless rectal bleeding with stools described as bright or dark red with mucus or of a “currant jelly” appearance. Rectal bleeding in infants may be accompanied by pain. If Meckel diverticulum goes undetected, severe anemia and shock can occur.

DIAGNOSIS. Diagnosis in the child is based on history, physical examination, and radiography, specifically a nuclear medicine scan. A radionuclide scintigraphy or Meckel scan detects the presence of gastric mucosa and has an overall diagnostic accuracy of 90%. A radionuclide or Meckel scan is an imaging study that uses injection and detection of radioactive isotopes to create images of body parts (Venes, 2009). A Meckel scan is more effective in the identification of diverticulum, which may be difficult to visualize with plain films, CT, or barium studies. Abdominal radiographs and barium enema are not useful for diagnosis. The child should also be screened for anemia.

NURSING CARE. Treatment for symptomatic Meckel’s diverticulum involves surgical removal of the diverticulum or pouch to prevent hypovolemic shock from hemorrhage (Potts, 2002). Surgical repair is more common in children younger than 2 years of age, which accounts for 50% of those requiring surgery. Preoperative antibiotics may be ordered if diverticulitis (inflammation of the diverticulum [Venes, 2009]) has occurred. If obstruction has occurred, fluid and electrolyte imbalances are corrected before surgery.

Nursing care is similar to that of any child undergoing surgery as well as monitoring for shock and blood loss and providing rest. Postoperative care includes fluid replacement and gastric decompression and evacuation via nasogastric tube.

Functional Gastrointestinal Conditions

INFANTILE COLIC

The cause of infantile colic is unknown. Several factors have been implicated in the development of colic, including both physical and psychological factors such as allergy, cow’s milk intolerance, over or underfeeding, inadequate burping, cigarette smoke, maternal anxiety, and familial stress (Petersen-Smith, 2004). A stressful pregnancy and birth experience have also been suggested as potential underlying factors in the development of colic.

Signs and Symptoms

Colic is described as persistent, unexplained crying or fussing in infants younger than 3 months of age (Petersen-Smith, 2004). Episodes generally occur at the same time each day, usually during the late afternoon or evening. The infant is fussing and appears to be pulling both legs and arms into a flexed position.

Diagnosis

Diagnosis is based on a report of the symptoms occurring for more than 3 weeks, during which the crying episodes occurred for more than 3 days of the week with crying for 2 to 3 hours a day. The incidence of colic is estimated to be about one third of all infants (Petersen-Smith, 2004).

Box 25-1 Management Strategies for Infantile Colic

- Support parents.
- Assure parents that the child is in good health.
- Reinforce parents' efforts to comfort the child.
- Instruct parents on strategies to calm infant, such as swaddling, decreasing environmental stimulation, and rocking.
- Assess feeding techniques and instruct as needed.
- Provide an opportunity for parents to express frustrations.

Source: Petersen-Smith, A.M. (2004). Gastrointestinal disorders. In C.E. Burns, A.M. Dunn, M.A. Brady, N.B. Starr, & C.G. Blosser (Eds.). *Pediatric primary care: A handbook for nurse practitioners* (3rd ed.). St. Louis, MO: Elsevier, pp. 839–884.

Nursing Care

Management of colic begins with ruling out acute conditions that cause abdominal pain. The goal of treatment for infantile colic is to manage the situation until the symptoms resolve as no cure exists (Box 25-1). Though anticholinergics, barbiturates, motility enhancing agents, and antifatulents have been prescribed, practitioners generally avoid using these drugs because of their limited success and the lack of scientific data to support their effectiveness (Petersen-Smith, 2004).

**Ethnocultural Considerations— Israel**

Chamomile, vervain, licorice, fennel, and balm mint, which have antispasmodic properties are found in herbal teas and are used as a remedy for colic in Israel.

ACUTE DIARRHEA

Acute diarrhea also refers to acute enteritis or acute gastroenteritis (Jensen & Baltimore, 2006). Acute diarrhea is defined as excessive loss of fluid and electrolytes in the stool. Stool loss is considered excessive when it is more than 10 g/kg per day in infants and more than 200 g/day in children (Petersen-Smith, 2004, p. 875). Acute diarrhea with or without vomiting has multiple causes, which may include infections in or outside the intestinal tract, diet, medications, or toxic substances. Four kinds of diarrhea have been defined in the literature.

- “Osmotic diarrhea results when osmotically active particles in the intestine draw excess fluid into the stool; this condition occurs with dumping syndrome, lactose deficiency, overfeeding, malabsorption syndromes, and excess ingestion of hypertonic juices” (Petersen-Smith, 2004, p. 875).
- Secretory diarrhea happens when there is an increase in the active secretion, or there is an inhibition of absorption. The most common cause of this type of diarrhea is bacterial endotoxins that stimulate the secretion of chloride ions. There is little to no structural damage.
- “Motility disorders cause diarrhea but not malabsorption. Bile salt and pancreatic enzyme deficiency can cause diarrhea by deletion or inhibition of the normal absorption process” (Petersen-Smith, 2004, p. 875).

- “Inflammatory processes such as bacterial invasion, celiac sprue, and irritable bowel syndrome or surgical procedures can change the anatomy and functional ability of the intestine. Abnormal peristalsis for any reason can result in acute diarrhea” (Petersen-Smith, 2004, p. 875).

Infectious agents associated with diarrhea include bacteria: *Campylobacter jejuni*, *Clostridium difficile*, *Yersinia enterocolitica*, *Salmonella*, *Shigella*, enterohemorrhagic *Escherichia coli*, and viruses: human rotavirus and adenovirus (Petersen-Smith, 2004) (Table 25-1).

Approximately 20% of office visits of children younger than 2 years of age and eight of 1000 hospitalizations of children younger than 1 year of age are for acute diarrhea. Acute diarrhea causes 10% of preventable deaths in the United States, including 500 deaths in children between the ages of 1 and 4 (Petersen-Smith, 2004). The literature suggests that the cause of morbidity and mortality from this illness is related to poverty and poor access to care.

Signs and Symptoms

The clinical manifestations of diarrhea include increased frequency and fluid content of the stools with or without associated symptoms. Signs of systemic illness may also be evident. The caregiver should be asked about the presence of other signs and symptoms, such as vomiting, fever, and pain with special attention to the number of wet diapers within the previous 24-hour period.

Diagnosis

Diagnosis of diarrhea should include a history of recent travel, day care or school illness contacts, family members with similar illnesses, ingestion of medications and toxic substances, and a dietary history. In addition, information regarding the number of stools, frequency, and quality should be elicited and include when the symptoms began.

The physical examination focuses attention to the abdomen and perineum in addition to state of alertness, changes in the growth pattern, and the hydration status of the child. Laboratory tests are selected based on the suspected etiology and the overall health and appearance of the child. No blood tests may be indicated for an essentially well appearing child. For a child demonstrating symptoms of toxicity stool for culture and sensitivity (C & S), serum electrolytes and a complete blood count (CBC) with differential are suggested. Diarrhea with weight loss suggests the need for serum electrolytes and CBC with differential. Evidence of blood in the stool with or without a history of antibiotic use suggests a need to assess stool for C & S, CBC with differential, and serum electrolytes.

Nursing Care

Most incidences of acute diarrhea are self limiting. Management of viral and most bacterial causes is primarily supportive (Jensen & Baltimore, 2006). Treatment of acute diarrhea is determined by extent of the illness and the cause, with attention to hydration and dietary needs as appropriate and with prevention as a priority. Initially the priority is to restore and maintain hydration. Oral rehy-

Table 25-1 Rotavirus

Rotavirus	Incidence	Protecting Children	Dehydration Secondary to Gastroenteritis
<p>Viral gastroenteritis causes approximately 80% of all cases of diarrhea in children younger than 1 year with rotavirus, accounting for 50% of the cases of acute diarrhea in children</p> <p>Rotavirus is the most common cause of diarrhea illness among children worldwide and accounts for approximately one third of hospitalizations of children in industrialized countries.</p> <p>It is estimated that by 5 years of age, nearly every child will have had at least one episode of rotavirus-induced illness.</p> <p>Epidemiological studies conservatively estimate that rotavirus caused gastroenteritis is responsible for 352,000–592,000 deaths annually in children younger than 5 years, with 82% of these deaths occurring in the poorest of countries.</p> <p>The primary transmission of this virus is via the fecal–oral route; however, the virus is very hearty and stable on surfaces for long periods of time, increasing the risk for transmission through contaminated surfaces or food. In addition, the virus has been found in the respiratory tract of infected individuals, raising concern for transmission via infectious secretions.</p>	<p>The incidence for rotavirus does not vary between industrialized and developing countries, nor has incidence been shown to decrease with increased sanitation in developing nations.</p> <p>The incubation period for rotavirus is approximately 1–3 days. This is followed by a 3- to 8-day period of fever, vomiting, diarrhea, and abdominal pain. The disease is self-limiting. However, the vomiting and diarrhea in rotavirus may be severe enough to require intervention to prevent dehydration. A primary factor in survival of rotaviral induced gastroenteritis is access to adequate medical care.</p> <p>Worldwide children have limited access to rehydration therapy. Most often, therapy primarily consists of oral rehydration. In the case of rotavirus, vomiting may limit the usefulness of oral rehydration and in the absence of access to intravenous hydration, death occurs secondary to fluid and electrolyte imbalances.</p>	<p>Surviving an episode of rotaviral gastroenteritis confers partial immunity. Subsequent cases are possible but tend to be milder and less life-threatening. In 1998 a rotavirus vaccine was introduced, RotaShield. The vaccine was shown to be 100% effective in prevention of rotavirus infection but was quickly withdrawn after it was demonstrated that the vaccine was associated with a slightly higher risk of intussusception in infants.</p> <p>The recommended 2007 immunization schedule for 0–6 years of age now currently includes a recommendation for a three-dose series of rotavirus vaccine (Rota). The first dose is recommended to be administered between 6 and 12 weeks of age, with the initial dose not to be started later than age 12 weeks</p> <p>American Academy of Pediatrics Committee on Infectious Disease. (November, 2006).</p>	<p>Rotaviral gastroenteritis is a self-limiting disease.</p> <p>Deaths from rotavirus are due to dehydration.</p> <p>As most children with a diarrhea type illness are cared for in the home it is critical that the nurse educate the families on early signs of dehydration requiring medical treatment. Specific indicators of dehydration in infants include:</p> <ul style="list-style-type: none"> • Decreased number wet diapers • Sunken fontanel and eyes • Listlessness • Cool, pale skin. <p>Families should be given specific instructions regarding oral intake goals during treatment for rotavirus and instructed to return for follow-up if a child is unable to meet the goals or the appearance of any of the above symptoms of dehydration.</p>

dration is generally attempted before intravenous hydration is initiated and is again related to the acuity of the illness and its affect on the child. Recent trends in rehydration of the child who is not experiencing vomiting is to allow the child to drink what he or she desires, which may include formula or milk, although other authors may consider this controversial. Traditional treatment of children with mild to moderate dehydration (less than 10%) includes oral rehydration for 24 hours (Jensen & Baltimore, 2006). The rehydrating solutions generally recommended include glucose and electrolytes, such as Pedialyte and Infalyte. Fruit juices, soda, sports drinks, and powered drinks are generally not recommended by those employing traditional treatments. Returning to full-strength formula is recommended as quickly as possible. If the infant does not tolerate full-strength formula, a diluted formula (one-fourth to half strength) may be used for a short time, often 4 to 6 hours. Breast-fed infants may be fed more frequently for shorter periods of time.

Solid food is generally started within the first 24 to 48 hours and starts with bland, soft foods. Care needs to be taken to avoid foods with a high fat content and simple sugars. Foods generally well tolerated include vegetables, fruits, yogurt, complex carbohydrates, and lean meat.

Depending on the cause of the diarrhea, pharmacological treatment in general is not ordered for young children. Although antidiarrheals are generally not recommended they may be used with caution in older children if the diarrhea persists beyond the initial infection. The use of *Lactobacillus* (gram-positive, anaerobic, non-spore-forming bacilli) has been found to shorten the duration of the illness if used early in the process (Petersen-Smith, 2004).

Intravenous fluids are essential with “impaired circulation and possible shock; weight less than 8.8 to 11 lb (4 to 5 kg) or a child younger than 3 months; intractable diarrhea, lethargy, anatomic anomalies; failure to gain weight or continued weight loss despite oral fluids” (Petersen-Smith, 2004, p. 876).

Complementary Care: Diarrhea

Products containing *Lactobacillus acidophilus*, such as yogurt, can be used to decrease the incidence of rotavirus diarrhea in infants 5–24 months of age (Blosser, 2004). *Lactobacillus* is a nonpathogenic bacteria that produces lactic acid from carbohydrates and is normally found in milk, feces of infants fed by bottle, and adults. The addition of *Lactobacillus*

acidophilus to the diet changes the bacterial flora of the GI tract, hence treating the overgrowth of pathogenic or diarrhea-causing organisms in the GI tract.

Care of the child hospitalized for acute diarrhea includes monitoring fluid intake and output, observing for signs of dehydration, offering fluids as indicated, and monitoring intravenous infusions if ordered. The skin integrity of the perineal and buttock areas must be monitored for irritation related to frequent stooling and good perineal skin care provided. Nursing care also includes education on preventive measures. The child and caregivers need to be instructed on good hand washing in addition to appropriate care of soiled clothing and diapers. The nurse must reinforce proper hand washing to include not only that which follows toileting or diaper changes but also before and after eating and in the preparation of foods.

Across Care Settings: Schools, day care, and community

The most effective treatment for gastroenteritis is prevention through good hand washing.

CHRONIC DIARRHEA

Chronic diarrhea is defined as “one or more liquid to semiliquid stools passed per day for 14 days or longer” (Petersen-Smith, 2004, p. 878). Chronic diarrhea is usually associated with a chronic condition, such as inflammatory bowel disease, malabsorption syndromes, overfeeding, formula protein intolerance, lactose intolerance, food allergies, viral, bacterial or parasitic agents, radiation therapy, or immunodeficiencies (Jensen & Baltimore, 2006). Inadequate management of acute diarrhea can also lead to chronic diarrhea. Chronic nonspecific diarrhea (CNSD) or toddler’s diarrhea is the most common cause of chronic loose stools in childhood. The child with toddler’s diarrhea generally has a normal growth and weight gain. The cause of toddler’s diarrhea may be from “excessive intake of fruit juices which contain non-digestible carbohydrates” (Jensen & Baltimore, 2006, p. 587).

Signs and Symptoms

Clinical manifestations reflect the underlying pathology. The nurse should obtain information regarding the history of the diarrhea, including frequency and appearance. Information regarding weight loss, medications, and presence of associated symptoms should be determined. Special consideration needs to be taken to determine the dietary history with special attention to the amount of fruit juice ingested per day. The caregiver also should be asked whether the child has had stool incontinence and what treatments have been attempted at home in addition to recent travel and school exposure.

During the physical health assessment, the nurse should observe for evidence of abdominal distention or tenderness and the presence of hyperactive bowel sounds. Signs of weight loss and dehydration should also be included in addition to the condition of the perineal area. The child with toddler’s diarrhea has no evidence of mal-

nutrition or growth failure. Stools are described as loose and are often found to have undigested food particles present. There should be no evidence of blood in the stool of the child with toddler’s diarrhea.

Diagnosis

Diagnostic assessment may include stool for culture and sensitivity, ova and parasites, pH occult blood, fat stain, and Clinitest for reducing substances. A sweat chloride and lactose tolerance tests may be ordered to rule out cystic fibrosis or lactose intolerance. In addition, a CBC with differential, erythrocyte sedimentation rate (ESR), serum electrolytes, albumin level, and a urinalysis with culture as used as nonspecific indicators of illness (Procedure 25-1).

Nursing Care

Management of chronic diarrhea involves treating the underlying cause. Enteral (by the way of the intestine) or total parenteral nutrition (TPN) is provided for the child who is unable to maintain adequate oral nutritional intake (Petersen-Smith, 2004) (Fig. 25-4). The treatment for toddler’s diarrhea is a change or reduction in the child’s intake of fruit juices.

The general nursing care of the child with chronic diarrhea is similar to that of acute diarrhea with special focus related to the underlying cause. As with acute diarrhea the child and caregiver need to be educated on primary prevention.

VOMITING

Vomiting is the forceful expulsion of stomach contents. The type of emesis assists in identifying the cause. “Non-bilious vomit is generally caused by infection, metabolic, neurologic, or psychological problems” (Petersen-Smith, 2004, p. 842). Bilious (vomit containing bile) vomiting is more likely caused by an obstructive process. Bloody emesis is usually evidence of active bleeding in the GI tract. The nurse communicates to the family that nausea and retching often accompany vomiting. Regurgitation in contrast is a more passive and effortless phenomenon. Table 25-2 lists the most common causes of vomiting related to origin.

Signs and Symptoms

Specific manifestations and diagnosis vary as greatly as the causes and origin of the illness. A thorough history and assessment must include a description of the onset, duration, quality and quantity, appearance, presence of undigested food, odor, and evidence of a precipitating event. The child’s recent exposure to illness, injury, or stress in addition to family history of a similar illness needs to be determined. The caregiver or child should be asked about the relation of the vomiting to the time of day, meals, or other activities. Associated symptoms, such as fever, diarrhea, ear pain, headache, and signs of increased intracranial pressure or urinary tract infection should also be evaluated. Vomiting upon arising in the morning is often associated with neurological involvement. The nurse should also ask the caregiver or child about medications currently being taken to include over the counter, herbal, cultural, and homeopathic remedies (Petersen-Smith, 2004).

Procedure 25-1 Collecting Stool for Culture and Sensitivity and Ova and Parasites

Purpose

Collecting stool for culture and sensitivity and ova and parasites is used to detect the presence of bacterial overgrowth; to confirm bacterial gastroenteritis; and to assess sensitivity of specific antimicrobials.

Equipment

- Gloves
- Patient identification label
- Sterile culture tube and cotton swab to collect specimen
- Biohazard container

Steps

1. Don gloves.

RATIONALE: Prevents the spread of bacteria.

2. Using the sterile cotton swab collect (scrape) a fresh, warm specimen of stool from the diaper or stool receptacle and place it into the sterile culture tube.

3. Label both the sterile culture tube and the biohazard bag with the patient's identification information.

RATIONALE: Accurate labeling is essential for correct patient identification.

4. Place the sterile culture tube into the biohazard bag

RATIONALE: To ensure that the properly identified specimen is safely transported to the laboratory.

5. Deliver the fresh specimen of stool to the laboratory promptly after collection.

RATIONALE: Delays in transfer of the specimen may affect viability of the organism.

Clinical Alert

- Avoid external contamination of stool and deliver to laboratory promptly.
- Provide samples from several areas of the stool to ensure that organisms are isolated. Failure to do so may yield a false-negative result.
- Inform the lab of antimicrobial or antiamebic therapy within 10 days as it may yield false-negative results.
- Medications such as antacids, antibiotics, antidiarrheals, iron, and castor oil may interfere with analysis

Teach Parents

Teach the parents that a stool for culture and sensitivity is used to detect the presence of bacterial overgrowth; confirm bacterial gastroenteritis; and to assess sensitivity of specific antimicrobials.

Teach parents that a stool for ova and parasites (O & P is used to aid in diagnosis of parasites or their eggs).

Documentation

10/12/10 0900 Stool for culture and sensitivity and ova and parasites collected from the diaper, labeled, placed in biohazard bag and sent to laboratory via laboratory collection personnel.

N. Kramer, RN

Source: Schnell, Van Leeuwen, & Kranpitz (2003).

Figure 25-4 Total parenteral nutrition (TPN) is provided for the child who is unable to maintain adequate oral nutritional intake.

The nurse should assess the abdomen for the presence of distention, visible peristalsis, and presence of bowel sounds. Depending on the cause of the vomiting, bowel sounds may be hyperactive or hypoactive. With a history of persistent vomiting, it is essential for the nurse to assess the child's hydration status in addition to evidence of malnutrition.

Diagnosis

In addition to a thorough history and physical examination diagnostic studies may include urinalysis and culture, CBC, serum electrolytes, blood culture, liver function tests, and select abdominal imaging depending on suspected cause of the vomiting. Plain radiograph or ultrasonography of the abdomen may detect anatomic abnormalities. Endoscopy of the upper GI tract can be used if esophagitis is suspected. Further studies may include a toxicology screen, rapid strep test/throat culture, pregnancy test, or electroencephalogram depending on the suspected origin of the vomiting.

Table 25-2 Common Causes of Vomiting

Origin	Cause
Upper GI	<ul style="list-style-type: none"> • Gastritis • Esophagitis • Pyloric stenosis
Small intestine	<ul style="list-style-type: none"> • Intestinal malrotation with volvulus
Colon	<ul style="list-style-type: none"> • Hirschsprung's disease • Intussusception • Fecal impaction
Liver or pancreas	<ul style="list-style-type: none"> • Hepatobiliary dysfunction
Infections	<ul style="list-style-type: none"> • Bacterial enteritis • Otitis media • Urinary track infection • Viral gastroenteritis • Hepatitis • Sepsis
Neurologic	<ul style="list-style-type: none"> • Hydrocephalus • Brain tumor • Migraine headache • Head trauma • Congenital malformation
Other	<ul style="list-style-type: none"> • Cow's milk protein allergy • Maternal drug exposure and withdrawal • Toxic ingestion • Appendicitis • Inborn error of metabolism • Pneumonia • Drug or alcohol ingestion • Eating disorders • Pregnancy

Nursing Care

Management is directed toward the treatment of the cause and prevention of complications. The degree of dehydration is determined and treated. For self-limiting causes of vomiting in childhood the bowel is allowed to rest. Rehydration is generally initiated after 1 to 2 hours with nothing by mouth. Plain water, apple juice, soda, milk, and sports drinks are avoided. Breast fed infants may be nursed more frequently for shorter periods. Solids are avoided for 4 to 6 hours after which reintroduction is begun with bland solids, which may include complex carbohydrates, such as rice, wheat, cereals, yogurt, cooked vegetables, and lean meats. Fatty foods and those high in simple sugars are avoided. Though the recommendation is a change from the BRAT diet, which consisted of bananas, rice, applesauce, and toast, it is still well tolerated though low in density, fat, and protein sources.

When vomiting is of a limited duration and the cause is known, antiemetic drugs may be indicated. Adverse effects are rare with antiemetic use in children. Antiemetic drugs that block chemoreceptor triggers include ondansetron (Zofran) or trimethobenzamide (Tigan).

The nurse understands that metoclopramide (Reglan) enhances peristalsis and, therefore, gastric emptying. Phenothiazine (Phenergan) is used cautiously per rectum every 6 hours if vomiting is excessive, dehydration is imminent, and GI disease has been excluded.

Nursing care is determined by cause and generally focuses on careful observation and support. Care is taken to carefully position the child who is vomiting to prevent aspiration. The nurse assesses for signs of dehydration and carefully monitors fluid intake and output. Oral hygiene may include rinsing the mouth or brushing the teeth after vomiting to dilute the hydrochloric acid that comes in contact with the teeth. If vomiting has been determined to be related to improper feeding technique, the caregiver needs instruction on food or formula preparation and a demonstration of correct positioning during and after feeding in the care of an infant.

CYCLIC VOMITING SYNDROME

Cyclic vomiting syndrome (CVS) is a recurrent stereotypical spell of vomiting followed by periods of wellness. One third of recurrent vomiting in children is caused by CVS, with a female to male ratio of 5:4. The average age at onset is 5.3 years of age. Petersen-Smith (2004) suggests that it often takes more than 2 years to diagnosis and lasts on average 3.4 years. CVS is generally outgrown before or during the preteen years.

The typical child presents as well 90% of the time. However, during exacerbations significant costs are incurred and children miss an average of 20 days of school per year. Medical costs are related to intravenous rehydration, diagnostic studies, procedures, emergency room costs, and time taken off of from work by the caregiver.

Signs and Symptoms

The following diagnostic criteria were defined by the International Scientific Symposium on Cyclic Vomiting Syndrome as cited by Petersen-Smith (2004):

- Essential criteria include recurrent severe, discrete episodes of vomiting; varying intervals of normal health between episodes; duration of vomiting lasts hours to days; and there is no apparent cause of vomiting (negative laboratory, radiographic, and endoscopic testing).
- Supportive criteria include a pattern that is stereotypical (each episode is similar as to onset, intensity, duration, frequency, associated symptoms, and signs within individuals) and self-limited (episodes resolve spontaneously if left untreated).
- Associated symptoms include nausea, abdominal pain, headache, motion sickness, photophobia, and lethargy.
- Associated signs include fever, pallor, diarrhea, dehydration, excess salivation, and social withdrawal (p. 846).

The primary clinical manifestation is recurrent episodic vomiting, usually lasting 24 to 48 hours. The vomiting occurs at regular intervals, usually every 2 to 4 weeks. The condition may include a prodromal (initial or indicative of an approaching illness [Venes, 2009]) period during which the child may demonstrate signs of

pallor, anorexia, nausea, abdominal pain, and lethargy. Once the episode resolves a brief recovery period occurs during which the child returns to normal activities. Episodes generally occur in the middle of the night or early morning. Vomiting occurs as often as every 5 to 10 minutes. Seventy-six percent of the time the emesis is described as bilious with hematemesis (vomiting of blood) occurring approximately 32% of the time. Associated GI symptoms may include abdominal pain, retching, anorexia, nausea, or diarrhea. Systemic symptoms include headache, photophobia (light intolerance), phonophobia (intolerance or fear of sound), or vertigo (sensation of moving in space or having objects move). Infection, psychological stress, diet changes, or menstruation may be precipitating factors. A positive family history of migraine headaches may be present. On examination, the child may appear pale and listless, often lying in a position to decrease the pain, such as in fetal position. Dehydration may be evident.

Petersen-Smith (2004) describes three questions that are essential to make the diagnosis.

- Has the child had at least three episodes?
- Is the child completely asymptomatic between episodes?
- Are the episodes stereotypical? (p. 846)

Additional diagnostic red flags may include “severe headache, GI bleeding, unilateral abdominal pain, weight loss, failure to respond to any treatment, progressive worsening, prolonged episodes requiring repeat hospitalizations, and a change in pattern or symptoms” (Petersen-Smith, 2004, p. 846).

Diagnosis

Diagnostic studies are used to rule out other conditions. Laboratory studies may include CBC with differential, electrolytes, glucose, liver function tests, metabolic screening (lactate, ammonia, amino acids, and porphobilinogen), urinalysis, urine culture, and urine organic acids. Imaging studies may include small bowel radiography, abdominal ultrasound, MRI or CT of the head or sinuses and endoscopy.

Nursing Care

Management is generally supportive care and includes fluid replacement, rest, and pharmacotherapy as needed. Careful monitoring and documentation of fluid intake and output during vomiting episodes are essential. Accu-

rate assessment includes the type and appearance of the vomiting in addition to associated behavior. A calm stress-free environment should be provided. Although up to 28% of children with cyclic vomiting suffer with migraines as adolescents and adults, most children outgrow cyclic vomiting before or during the preadolescent years. A psychiatric evaluation may be indicated for cyclic vomiting as the symptoms can be associated with psychological stress.

CONSTIPATION

Constipation is the difficult or infrequent passage of hard stool, which is often associated with straining, abdominal pain, or withholding behaviors. Frequency alone is not a good diagnostic criterion as children vary greatly in their stooling frequency.

Constipation accounts for 3% of office visits and 25% of pediatric gastroenterologist visits (Potts, 2002). Constipation peaks between the ages of 2 and 4 and is more common in males than in females until adolescence, after which it is seen more frequently in females.

Constipation can occur secondary to an organic cause or in association with a systemic condition. Strictures and Hirschsprung disease are included among organic causes. Systemic conditions that may be a factor in the development of constipation include hypothyroidism, hypercalcemia caused by hyperparathyroidism or vitamin D excess, and chronic lead poisoning. Drugs such as antacids, diuretics, iron supplements, opioids, antihistamines, and antiepileptics are also associated with constipation as a side effect. Children with spinal cord pathology may experience a loss of rectal tone and sensation.

Most constipation is considered idiopathic or functional with no clear underlying cause. Environmental and/or psychosocial factors, such as travel, illness, dietary changes, and emotional factors may cause chronic constipation. Children may also experience constipation during toilet training, which is related to not wanting to take time from play or from overenthusiastic toilet training. Dilation and stretching of the rectum may come from repeated withholding. This leads to a decreased sensation or urge to pass stool.

Onset of constipation during infancy is generally associated with dietary causes. Constipation is less common in breast-fed infants. Environmental changes and attention to controlling the passage of stool are more common causes of constipation in early childhood. Any feeling of discomfort during stooling may lead the child to deliberately withhold stool in the future.

In the school-age child, organic and environmental factors are considered. Fear of using school restrooms or embarrassment in asking the teacher are common cause of constipation in early school age children. Separation, change in routine, change in eating and sleeping patterns may all contribute to the change seen in bowel habits. These children may try to “hold” their stool until a later time. When they do finally try to eliminate the stool, it may be very hard and painful. The longer the child holds the stool and delays elimination, the harder and larger the stool becomes and the more painful the process.

medication: Medications Used for Vomiting

A combination of medications is used for sedation and the relief of pain and nausea and vomiting, which may include a combination of diphenhydramine (Benadryl), lorazepam (Ativan), promethazine (Phenergan), and meperidine (Demerol). Metoclopramide (Reglan) is a prokinetic agent that accelerates gastric emptying. Migraine relief includes sumatriptan (Imitrex) for acute episodes; amitriptyline (Elavil), cyproheptadine (Periactin), phenobarbital (Luminal), propranolol (Inderal) for prophylaxis; and ethinyl estradiol (Loestrin) for menstrual pain relief. Erythromycin (E-Mycin, E.E.S., EryPed) as a prokinetic is not used much in children secondary to the gastric effects and questionable efficacy.

Nursing Insight— Constipation

The majority of children have idiopathic or functional constipation. This classification is used when there is no identifiable reason or underlying cause for their constipation.

Signs and Symptoms

The major symptoms associated with constipation are poor appetite and straining with stools. Soiling is more common with the diagnosis of encopresis. Stools are hard and blood may occasionally be seen in the outer surface of the stool. Additional signs include a potential for tenderness in the area of the colon and small intestines and rectal fissures.

Diagnosis

Diagnosis is based on the symptoms. An abdominal radiography and barium enema may be ordered for children who do not respond to treatment.

clinical alert

Abdominal pain

Most children who are constipated usually have some abdominal pain due to cramping. However, if the onset of constipation and severe abdominal pain is acute and/or accompanied by fever, vomiting or other symptoms, the child must be evaluated for a bowel obstruction.

Nursing Care

The management of simple constipation can generally be accomplished by focusing on dietary intake and keeping the bowel relatively empty. Occasional constipation caused by dietary intake can be treated with adequate intake of water and other fluids, which assist in regulating elimination. A regular diet, rich in all nutrients coupled with an adequate amount of water and other fluids, is the best way to ensure normal bowel elimination patterns. Fresh fruit adds fiber and can relieve constipation. Limiting dairy products such as cheese can also provide relief. However, many children can be “picky eaters” at times, preferring fast food or the same food for every meal. This type of eating can lead to disruptive bowel patterns including constipation. Occasionally, stool softeners may be needed to “train” the child and the bowels into a regular pattern of elimination. Giving the stool softener at bedtime allows it to work gently overnight to foster a morning elimination pattern. No medication should be used on a long-term basis without a physician’s prescription or health care provider’s guidance.

Nursing Insight— Constipation

Not all fruits contribute to soft stools. Applesauce and bananas are two fruits that can be used when children have diarrhea because they make stools firmer.

Chronic constipation may require strategies to restore a regular stooling pattern, hence shrinking the distended rectum to a normal size and promoting regular toileting

practices. Therapy for chronic constipation may include bowel cleansing and maintenance therapy to prevent further stool retention. Initial treatment of chronic constipation includes removing hard, impacted stool, which may be accomplished through use of “suppositories, enemas, and occasionally the use of polyethylene glycol electrolyte solution (GoLYTELY) administered orally or by NG tube”. A combination of mineral oil and enemas may be used for severe impaction for which suppositories are not effective. Rarely surgical removal is needed.

Once the impaction is removed, maintenance therapy includes use of mineral oil, stool softeners, and laxatives. Stool softeners may not be effective for severe constipation. The safest laxatives are milk of magnesia and polyethylene glycol (MiraLax).

Bowel retraining includes developing good toileting habits and reinforcement of sitting on the toilet for defecation. A regular toileting time should be established once or twice per day. The child should be allowed to sit on the toilet 5 to 10 minutes with positive behaviors reinforced.

Optimizing Outcomes— Constipation

A 2½-year-old child has not passed a stool in 5 days. The parents report that the child has been eating and growing well and has no other symptoms of illness. They report that the last stool passed was firm and appeared to cause the child some discomfort. The parents also report no evidence of blood has been noted in the stool. In addition, the parents began toilet training the child approximately 3 weeks ago.

The best outcome for the family is to understand that the child is normal. The nurse can discuss toilet training readiness to include not only physical readiness but also mental and psychological readiness. In addition, the nurse can include instructions regarding the importance of water and high-fiber in the diet and the avoidance of excessive refined carbohydrates.

Care of the child with constipation begins with a careful assessment of bowel patterns, diet history, drug history, and environmental factors. The nurse should ask the

Family Teaching Guidelines...

Dealing with Food Jags with Young Children

- ◆ Reassure the parents that food jags are normal at this age and that the tendencies will pass. Stress that a little patience will keep both parents and child from further gastrointestinal upsets.
- ◆ Suggest that the parents not force the child to eat foods he is not interested in but to provide a variety of nutritious foods during meals and for between meals snacks in the amount appropriate for the child’s age.
- ◆ Inform the family about treatments and when they need to seek additional help (www.nal.usda.gov/fnic/; www.mypyramid.gov; www.aap.org).

caregiver to describe the color, consistency, frequency, and characteristics of the stool. Caregiver education is an important part of nursing care and should include instruction on dietary needs, toileting practices, and bowel cleansing as needed.

Now Can You— Discuss functional gastrointestinal conditions?

1. Discuss functional gastrointestinal conditions?
2. Discuss signs and symptoms of functional gastrointestinal conditions?
3. Discuss nursing care for functional gastrointestinal conditions?

ENCOPRESIS

Encopresis is stool incontinence beyond the age when children should normally be able to control their bowels, which is usually beyond the age of 4. Encopresis is considered primary in children who have never obtained stool continence and secondary in the child who has been previously trained and then becomes incontinent of stool (Dunn, 2004). Encopresis is divided into two types: “encopresis with constipation, associated with stool retention, constipation, and incontinence and encopresis without constipation” (Dunn, 2004, p. 291). In encopresis with constipation, the pathophysiology is similar to that of regular constipation (i.e., stool retention leads to distention of the colon and stretching of the rectum). This distention is followed by ineffective peristalsis and decreased sensation to defecate, which can lead to impaction. Eventually the rectal and sphincter muscles become weakened. Once the rectum becomes impacted with hard stool semiformal or liquid stool from higher in the intestines may leak around the impacted stool and pass through the rectum causing soiling. Encopresis with constipation is involuntary and the child may be unaware of the passage of stool. Children with encopresis without constipation have voluntary stools in inappropriate places (Dunn, 2004).

Encopresis is more common in boys than in girls. The etiology is unclear and includes both physiological and psychosocial factors. Physiological factors may include inadequate fluid intake; dehydration (caused by illness, fever, or a active exercise during hot weather); dietary changes; inappropriate use of laxatives, suppositories or enema; and retention and constipation secondary to anal fissures, neurogenic conditions, medications, and painful stools. Psychosocial factors may include major family or life changes or loss; inappropriate toilet training techniques; and irregular toileting patterns; and physical and sexual abuse (Dunn, 2004).

Signs and Symptoms

Manifestations include a history of stained underwear, difficult or painful defecation, large and/or hard stools, reports of bloating or pain, streaks of bright blood, anorexia, evidence of attempts to retain stool (i.e., grimacing, shifting position or crossing legs, and urinary tract infection). Physical symptoms may include abdominal distention and tenderness, overflow soiling, impaction, a midline palpated mass, and anal fissures.

Diagnosis

Radiography and laboratory tests may be performed to rule out structural or organic causes though not routinely needed (Dunn, 2004).

Nursing Care

The nurse understands that the main goal of treatment is to establish regular bowel habits, is often multidisciplinary, and requires child and caregiver education. Basic treatment of encopresis without constipation includes dietary monitoring to ensure adequate fiber and water intake. Milk is decreased to 16 oz./day with limited cheese, rice, applesauce, and bananas. Stool softeners and laxatives are avoided. The child and caregiver are instructed on the need to establish a routine for toileting in addition to encouraging the child to take responsibility for his or her own toileting habits. Incentives or rewards may be used to reinforce positive behaviors.

Management of children with constipation is more complicated and begins with a catharsis phase, during which thorough bowel cleansing is accomplished through the use of enemas, suppositories, and laxatives. The catharsis phase takes approximately 2 weeks, after which a follow-up abdominal radiograph is done to confirm catharsis.

The catharsis phase is followed by a maintenance phase. The goals of maintenance include no soiling, regular, soft stools at least every other day to three-times/week, and increased awareness of the need to defecate. Laxatives may be substituted or alternated with stool softeners in order to maintain soft bowel movements. Toileting time should be planned around the times when the child is most likely to have a stool.

During the maintenance phase, behavioral changes are addressed, which include toilet sitting 3 to 4 times per day for 10 minutes (Dunn, 2004). An increase in physical activity is encouraged. Dietary changes include an increase in fluids other than milk, increase in fiber, and a decrease in constipating foods. Bowel movements are documented for time, quality, amount, and location. The maintenance phase may take up to 6 months before the bowel regains full function.

The follow-up phase involves regular visits from approximately every 4 to 10 weeks depending on the severity of the condition and the family need for support. Counseling or referral may be ordered for psychosocial and developmental needs as appropriate. The goals of follow-up visits are to monitor compliance, provide encouragement and support, and to detect and treat relapse.

Nursing care involves anticipatory guidance, child and caregiver support, and education. Instruction needs to be provided regarding appropriate dietary needs and toileting. The caregiver may need a demonstration on the use of enemas and suppositories if this is part of the treatment plan.

Collaboration in Caring— Encopresis

The school nurse needs to collaborate with the child, family, and teachers in setting up an effective plan of care for the child while he is attending school. School personnel should be instructed about the child's need for emotional support,

privacy, and timing of stool elimination. In addition, there should be sensitivity to the child's concerns about soiling and odors, allowing the child to attend to toileting needs as requested. Successful reconciliation of this disorder involves collaboration from the adults in the child's immediate environment.

GASTROESOPHAGEAL REFLUX AND GASTROESOPHAGEAL REFLUX DISEASE

Gastroesophageal reflux (GER) is the return of gastric contents from the stomach through the lower esophageal sphincter into the esophagus. Research suggests that up to “50% of infants younger than 2 months are reported to have symptoms of reflux, defined clinically as more than two episodes per day of regurgitation or emesis”.

Classifications of reflux include physiological, functional and pathological.

Physiological reflux or GRE is described as infrequent and episodic vomiting and is a common occurrence in many healthy infants. A decrease is seen as the esophagus elongates and matures. Suwandhi and colleagues (2006) suggest that the occurrence of physiological GER is present in 60% to 70% of infants ages 3 to 4 months and usually resolves by 1 year.

Nursing Insight— Functional GER

Functional GER involves painless, effortless vomiting with no physical sequelae (Petersen-Smith, 2004).

Pathological reflux or GERD is frequent with associated physical dysfunction. Though the diagnosis of GERD is generally considered when reflux persists beyond 18 months of age and involves an increased frequency and duration of episodes, GERD occurs in approximately 5% to 8% of all newborns and has been associated with apnea and other life-threatening events. GERD is often associated with esophagitis, failure to thrive, and aspiration pneumonia and noted after there is a pathological and/or histological change due to reflux (Potts, 2002). Children with GERD beyond 18 months are more likely to experience symptoms similar to an adult's.

The incidence of GER in healthy infants is approximately 40% to 50% as demonstrated by regurgitation followed by crying. The incidence of GER peaks at approximately 4 months of age, then steadily declines.

GERD is more common in premature infants and those born with neurological impairments (Potts, 2002). GERD can be identified in as many as 70% of low-birth-weight infants (≤ 1700 g) with up to 85% of those infants becoming symptom free by 1 year of age (Petersen-Smith, 2004). Up to 10% of very-low-birth-weight infants have reflux associated apnea, bradycardia, or bronchopulmonary dysplasia exacerbations. Reflux disease remains significant in 1% to 3% of older children.

The cause of GER is unknown and considered multifactorial. Neuromuscular immaturity of the lower esophagus, age, hormones, and intraabdominal pressure are suggested as factors in the development of GERD. The

following information will focus mainly on GER with some integration of information about GERD.

Signs and Symptoms

The most common symptoms of GER are vomiting and regurgitation that is nonbilious and includes undigested formula or food (Potts, 2002). The infant may also appear fussy related to irritation from the acidic gastric contents. The child may also refuse to feed because of the discomfort (Potts, 2002). Other manifestations include choking, coughing, wheezing, apnea, weight loss, frequent respiratory infections, and bloody vomit.

Diagnosis

Diagnosis of GER is through history and physical exam. An upper GI series may be used to rule out anatomical abnormalities but it does not provide information about the physiological function of the esophagus and is considered an unreliable diagnostic test for pathological GERD. Post-swallowing reflux can be observed through a barium swallow. A 24-hour intraesophageal pH monitoring study is essential in the diagnosis of GERD. If esophagitis, strictures, or Barrett esophagus are suspected, an endoscopy with biopsy may be completed to confirm the diagnosis.

case study Gastroesophageal Reflux

Two-month-old Ella was born via a normal spontaneous vaginal delivery. Her birth weight was 10 lb, 2 oz. (4.6 kg) and she was 22 inches (55.8 cm) long. Her parents are of Caucasian descent. Her mother's prenatal care was initiated during the third month of gestation and the pregnancy was uncomplicated. Her mother states that Ella spits up four or five times per day. She reports that Ella has four or five soft yellowish-brown stools daily. Ella is breast-fed and her mother reports that Ella nurses every 3–5 hours. No solids have been initiated.

Ella is awake and resting quietly in her mother's arms. During the initial assessment the nurse notes the following information: axillary temperature: 98.6°F (37°C); pulse, 106 beats per minute; respirations, 28 breaths per minute; weight is 13 lb. 10 oz. (6.2 kg); and length is 23.5 inches (59.7 cm). Ella appears pink, well nourished, and well hydrated. After the assessment, Ella began to fuss, at which time her mother offered her a bottle of Enfamil, which she takes eagerly. After completion of the bottle, Ella regurgitates a small amount of partially digested nonbilious liquid. Ella then closes her eyes and quietly falls asleep. The mother proceeds to tell the nurse that this is what normally occurs when Ella vomits.

1. Are these findings normal or pathological?
2. What actions should the nurse take?
3. What should be included in parent teaching?

◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

Nursing Care

Healthy, well-nourished infants need no treatment for physiological reflux. Common interventions include providing caregiver support and anticipatory guidance. The caregiver needs to be reassured that there is no underlying disease.

Steps in managing reflux with no underlying structural problems may begin with evaluating and changing the volume of the feeding such as offering small amounts more often and burping frequently. Thickening of feedings with cereal can provide sufficient calories while reducing the volume. One teaspoon per ounce of dry infant cereal may be added to 1 to 2 ounces of formula. Care must be taken when adding cereal to formula as it increases the caloric density of the formula and decreases the amount of fluid intake. Intra-abdominal pressure increase can be avoided by positioning the infant in an upright position (generally no higher than a 45 degree angle) after feeding. Several studies have reported that a prone position decreases episodes of reflux. Since prone positioning has been associated with sudden infant death syndrome (SIDS) this should only be considered with extreme caution and when complications from GER exceed the risk of SIDS. In addition, right side-lying positioning facilitates gastric emptying.

If the infant experiences complications, pharmacological therapy may be offered (Bishop, 2006). Proton-pump inhibitors, such as omeprazole (Losec) and lansoprazole (Prevacid), provide effective medical therapy for heartburn and esophagitis. H₂ inhibitors such as cimetidine (Tagamet) and ranitidine (Zantac) may also reduce heartburn though are considered less effective (Bishop, 2006). Prokinetic drugs, such as metoclopramide (Reglan), offer enhanced stomach emptying and increase lower esophageal sphincter control though the benefit is considered minimal (Bishop, 2006). Surgical treatment may be recommended for severe symptoms, such as those that are life threatening or unresponsive to nonsurgical interventions.

The surgical intervention of choice for the treatment of GERD is a **Nissen fundoplication** (wrapping the gastric cardia with adjacent portions of the gastric fundus) (Venes, 2009). A feeding jejunostomy (a surgical creation of an opening into the jejunum) may be used for infants with severe neurological defects who cannot tolerate oral or gastric tube feedings (Bishop, 2006).

Nursing care for either GER or GERD includes a thorough assessment of the infant's growth measurements and developmental patterns. Feeding patterns should be evaluated, and the amount, type, and frequency of feedings should be established with the pattern of regurgitation or emesis related to the feedings. In addition, information about positioning and burping after feedings should be determined. A baseline respiratory status is important because of the risk of aspiration associated with GERD (Potts, 2002). Much of the initial nursing management focuses on educating the caregiver regarding dietary modifications, positioning, and pharmacological therapy if prescribed. The importance of frequent burping and suggested positions for burping should also be discussed with the caregiver. Depending on the age of the child and the nature of the diet, education may also include information about dietary irritants (e.g., chocolate, caffeine products, citrus fruits, fruit drinks, tomatoes). If treatment includes use of thickened feedings, the nurse should demonstrate how to enlarge the hole in the nipple to better facilitate this type of feeding (Potts, 2002). Caregivers may also need to be reminded to avoid vigorous playing after feeding.

Nursing Insight—Gastroesophageal reflux

Frequent use of an infant seat for positioning should be avoided as it reduces truncal tone in infants and increases intraabdominal pressure, which can promote reflux (Potts, 2002).

nursing diagnoses The Child with Gastroesophageal Reflux GER and GERD

- Imbalanced Nutrition: Less than Body Requirements related to chronic vomiting or regurgitation
- Risk for Fluid Volume Deficit related to excessive losses through normal route.
- Risk for Aspiration related to increased intragastric pressure with an incompetent cardiac sphincter.
- Potential for Parental Knowledge Deficit related to lack of information concerning the child's care.

HIRSCHSPRUNG DISEASE

Hirschsprung disease, also known as congenital aganglionic megacolon, is caused by a congenital absence of Meissner's and Auerbach's autonomic plexus in the bowel wall. This absence of ganglion cells results in lack of motility in the affected portion of the bowel (Parks & Yetman, 2004). Hirschsprung disease is usually limited to the distal colon. The absence of ganglion cells in the affected portion of the bowel results in lack of nervous system stimulation to that portion of the colon. This leads to abnormal or absence of peristalsis in the involved segment and an inability of the internal sphincter to relax. A complete or partial bowel obstruction may occur as a result of this inability of the smooth muscles to relax. This in turn leads to an accumulation of bowel contents and an innervated bowel. The obstruction may extend proximally to involve varying portions of the colon.

The incidence of Hirschsprung disease is 1 in 5000 births. It is the most common cause of neonatal obstruction of the colon and accounts for up to 33% of all neonatal obstructions (Parks & Yetman, 2004). The condition is familial, four times more common in males, and more common in children with trisomy 21 (Down syndrome) (Parks & Yetman, 2004).

Signs and Symptoms

The history of the child with Hirschsprung disease may include a failure to pass meconium within the first 48 hours of life, failure to thrive, poor feeding, chronic constipation, and Down syndrome (Parks & Yetman, 2004). Physical findings include vomiting, abdominal obstruction, failure to pass stools, diarrhea, flatus, or explosive bowel movements. In older children, the initial symptom is chronic constipation (Potts, 2002). The child's stools may be described as ribbon or pellet shaped and foul smelling.

Enterocolitis (inflammation of the small intestine and colon) is the most ominous presentation of Hirschsprung disease. Enterocolitis may present in an otherwise well infant with a history of constipation. The child with

enterocolitis may present with an abrupt onset of foul-smelling diarrhea, abdominal distention, and fever. Rapid progression may indicate perforation of the bowel and sepsis. The major cause of death in Hirschsprung disease is related to enterocolitis and sepsis, accounting for up to 30% of cases (Potts, 2002).

Diagnosis

Diagnosis in the newborn is suspected based on clinical presentation or intestinal obstruction and failure to pass meconium. Radiographic studies show evidence of a dilated loop of bowel. A barium enema often demonstrates the transition between the dilated proximal colon and the aganglionic distal segment, though this may not be evident until age 2 months or later. Absence of ganglion cells is determined by a biopsy. Rectal manometry and rectal suction biopsy are the easiest and most reliable indicators of Hirschsprung disease. In anorectal manometry a balloon is distended in the rectum and measures the pressure of the internal anal sphincter. In normal patients, rectal distention initiates a reflex decline in internal sphincter pressure. In patients with Hirschsprung disease, the pressure fails to drop or there is a rise in pressure with rectal distension.

Nursing Care

Correction of Hirschsprung disease involves surgical resection of the affected bowel with or without a colostomy (Parks & Yetman, 2004). Surgical interventions generally include a temporary colostomy to be performed with an ostomy takedown and reanastomosis at age 6 to 12 months. Other surgical options include excising the aganglionic segment and anastomosing the normal proximal bowel to the rectum 1 to 2 cm above the dentate line.

Another procedure includes creating a neorectum. A neorectum involves bringing down normally innervated bowel behind the aganglionic rectum. The endorectal pull through procedure involves stripping the mucosa from the aganglionic rectum and bringing normally innervated colon through the residual muscular cuff. This bypasses the abnormal bowel from within. Advances in techniques have led to successful laparoscopic pull through (Potts, 2002).

Initial care of the child with Hirschsprung disease involves preoperative assessment of the child's fluid and electrolyte status. The child is placed NPO and a nasogastric tube is inserted. Intravenous fluids and electrolytes are administered to prevent and/or correct imbalances (Potts, 2002).

Postoperative care includes routine post-abdominal surgical intervention. Patency of the nasogastric tube is maintained along with monitoring for abdominal distention and assessing for return of bowel sounds. Proper placement of the NG tube can be checked by instillation of air and listening for a "pop" or aspiration of gastric contents. Accurate intake and output is maintained to include colostomy and nasogastric tube drainage.

The nurse must instruct the caregiver how to care for the temporary colostomy. The instructions should include care of the skin, appliance application, and referral to community resources. The caregiver also needs to be instructed on the symptoms of complications, such as

enterocolitis, leaks, and strictures at the site of anastomosis. Signs of leaks include abdominal distention and irritability. Constipation, vomiting, and diarrhea may indicate strictures (Potts, 2002). Signs of enterocolitis may include abdominal distention and pain in addition to fever, diarrhea, or shock-like symptoms (Lee & Kocoshis, 2005).

Malabsorption Disorders

LACTOSE INTOLERANCE

Lactose intolerance is an inability to digest milk and some dairy products, which leads to symptoms of bloating, cramping, and diarrhea (Venes, 2009). This condition results from a deficiency in the enzyme lactase, which is necessary for the digestion of lactose in the small intestine where lactose is hydrolyzed into glucose and galactose. Hydrolysis is a chemical decomposition in which a substance is split into simpler compounds by taking up the elements of water (Venes, 2009). Lactose intolerance can be categorized into at least three different entities. Congenital lactase deficiency is an inborn error of metabolism, which becomes evident once the newborn consumes a lactose containing product, such as human milk or formula products. This deficiency results from reduced or absence of lactase. Congenital lactase deficiency is rare and requires lifelong dietary restrictions.

Primary lactase deficiency, also referred to as late-onset lactase deficiency, is the most common type of lactose intolerance. Primary lactase deficiency usually becomes evident around the three to seven years of age.

Ethnocultural Considerations— Occurrence of Lactose Intolerance

Asians, southern Europeans, Arabs, Israelis, and African Americans experience a high incidence of primary lactase deficiency.

Secondary lactase deficiency, or lactose intolerance, can also occur secondary to intestinal lumen injury. Damage to the intestine can decrease or destroy the enzyme lactase. Temporary or permanent lactose intolerance can be caused by disorders such as cystic fibrosis, celiac disease, and kwashiorkor (severe protein-deficiency form of malnutrition of children), as can various infectious processes such as giardiasis (infection with a flagellate protozoan), rotavirus (a RNA virus), or HIV (human immunodeficiency virus).

Signs and Symptoms

The major symptoms of lactose intolerance are bloating, cramping, abdominal pain, and flatulence. Pain and diarrhea occur often within 30 minutes of the ingestion of lactose-containing products. Children with lactose intolerance may have a recent history of viral gastroenteritis. Signs in infants include vomiting, distention, abdominal pain after ingesting lactose-containing formula or the ingestion of cow's milk by the breast-feeding mother. Severe watery diarrhea with stools positive for reducing substance may be evident in infants with congenital lactase deficiency.

Diagnosis

Lactose intolerance is diagnosed on the basis of the history and a decrease in symptoms with elimination of lactose products from the diet. Diagnosis is further confirmed with the reintroduction of lactose-containing foods and a flare of symptoms. The nurse can communicate to the family that “the breath-hydrogen test is used to positively diagnose the condition”. The breath-hydrogen test measures hydrogen in the breath after a challenge with the ingestion of 50 grams of lactose (Venes, 2009).

Nursing Insight— Diagnosing lactose intolerance in infants and toddlers

An endoscopic visualization of the gastric mucosa and a digestive fluid sample may be needed with infants and toddlers due to the difficulty of performing the breath hydrogen test.

Nursing Care

Eliminating dairy products or the use of enzyme replacement may be used for the treatment of lactose intolerance. Reducing the amounts of dairy products instead of eliminating them is recommended by others. Soy-based formula can be substituted for formula or breast milk in infants. Most individuals can tolerate small amounts of lactose and should be encouraged to include it in their diets. Milk products are better tolerated when taken at meal times. Enzyme tablets, such as Lactaid, Lactrase, and Dairy Ease, can be used to predigest the lactose in milk or supplement the child’s own lactose. The enzyme tablets can be added to milk or sprinkled on dairy products.

critical nursing action Lactose Intolerance

The nurse understands that dairy products are a major source of calcium and that vitamin D supplements are needed to prevent deficiency. Hard cheese, cottage cheese, or yogurt may be taken in place of milk.

clinical alert

Probiotics

Concern regarding the potential for decreased bone mineral density and osteoporosis in children and adolescents with lactose intolerance reinforces the recommendations for the ingestion of small amounts of dairy products with meals. **Probiotics** (food preparations containing microorganism) such as *Lactobacillus* can improve lactose intolerance when live cultures are fermented in dairy products. *Lactobacillus* is a nonpathogenic bacteria that produces lactic acid from carbohydrates and is normally found in milk, feces of infants fed by bottle, and adults. The active culture in yogurt provides a source of calcium for persons with lactose intolerance in addition to producing some of the lactose enzyme required for proper digestions.

Care of the child and family dealing with lactose intolerance is primarily directed at diagnosis, support, and education. Dietary education should include identifica-

tion of the restrictions and alternative sources of dairy products, which can be included in the diet. Caregivers also need to be made aware of hidden sources of lactose such as its use as a bulk agent in certain medications. Caregivers need to consult with pharmacists regarding the avoidance of lactose-containing medications. The caregiver should be directed to alternative sources of calcium, such as yogurt, that are appropriate for the child’s diet.

CELIAC DISEASE

Celiac disease, also known as celiac sprue, gluten-induced enteropathy, and gluten-sensitive enteropathy, is a disorder in which the proximal small bowel mucosa is damaged as a result of dietary exposure to gluten and is the second only to cystic fibrosis as a cause of malabsorption disease in children (Bishop, 2006). The disorder does not present until gluten products have been introduced into the diet, usually between 6 months and 2 years of age as table foods are introduced into the diet. Celiac disease is a permanent intolerance to gluten. Gluten consists of two protein components, glutenin and gliadin. The toxic protein component is thought to be that of gliadin (Potts, 2002). Gluten is found in wheat, rye, barley, and related grains. Rice does not contain toxic gluten and can be eaten freely, as can a special preparation of oats (Bishop, 2006).

The pathology shown with celiac disease reveals a diffuse lesion of the upper small intestinal mucosa. Short, flat villi, deepened crypts, and irregular vacuolated surface epithelial layer and crypt hyperplasia are seen via light microscopy (Potts, 2002). As the villi flatten out and atrophy there is a decreased in the absorptive surface of the intestine. Malabsorption with a decreased fat absorption and eventually impacts the absorption of proteins; carbohydrates; and the fat-soluble vitamins A, D, E, and K (Potts, 2002).

It is estimated that approximately 1 in 250 and up to 1% of the population in the United States has celiac disease, of which only a few are diagnosed (Gelfond & Fasano, 2006). The disease is also more common in persons with type 1 diabetes, autoimmune thyroiditis, trisomy 21, Turner syndrome, and IgA deficiency (Bishop, 2006).

Ethnocultural Considerations— Occurrence of Celiac Disease

Celiac disease primarily affects people of northern European descent. The average incidence of celiac disease in Europe is 1:1,000 live births with a range of 1:250 in Sweden to 1:4,000 in Denmark (Potts, 2002).

Signs and Symptoms

Early manifestations of celiac disease are nonspecific and include anorexia, irritability, weight loss, and listlessness. Classic presentation in the pediatric population begins around age 6 months to 2 years and is characterized by gastrointestinal manifestations as gluten products are introduced into the diet. As the disease begins to progress, symptoms include diarrhea and abdominal distention. The diarrhea becomes chronic and is bulky, greasy, foul-smelling, and putty colored due to the large

amount of undigested fat content (Potts, 2002). The presence of high fat content in the stool is called steatorrhea and may also cause the stool to float. Due to protein losses the child develops a protuberant abdomen, loss of subcutaneous fat, hypotonia, anorexia, lethargy, and muscle wasting. Inadequate vitamin K absorption leads to the development anemia and bruising. Growth retardation and osteoporosis in addition to delayed puberty development are considered late signs. A less typical presentation occurs in children between ages 5 and 7 years and may include unusual intestinal complaints, such as recurrent abdominal pain, nausea, vomiting, bloating, constipation, and extraintestinal manifestations. In addition to delay in puberty and short stature the child may experience iron deficiency, abnormal liver function tests, and dental enamel defects. An atypical presentation of celiac disease may delay diagnosis until adult years as the extraintestinal manifestations overshadow the GI symptoms, which may be mild or entirely absent.

Diagnosis

The combination of clinical symptoms and serologic markers may suggest the diagnosis of celiac disease though a small bowel biopsy is essential to confirm the diagnosis and should be performed before gluten is eliminated from the diet (Bishop, 2006; Potts, 2002). A positive biopsy reveals atrophy of the villi and deep crypts on the intestinal mucosa is the definitive test (Potts, 2002). Laboratory tests can detect antigliadin and antiendomysial antibodies in addition to evidence of malabsorption and nutritional deficiencies. The nurse understands that “the presence of antigliadin and antiendomysial antibodies and their disappearance when gluten is removed from the diet are important findings in the diagnosis”.

Nursing Care

The treatment of celiac disease is a gluten-free diet. Since gluten is found mainly in wheat and rye and to a smaller extent in barley and oat products it is recommended that they be eliminated from the diet. Corn, rice, and millet are grains that are allowed in the diet. Dietary consultation is helpful as well as referral to a celiac support group (Bishop, 2006). The child and caregivers need to be instructed on the hidden sources of gluten, which may be found in many processed foods, such as thickening agents, soups, and luncheon meats. Gluten is added to many foods as hydrolyzed vegetable protein. Supplemental calories, vitamins, and minerals are recommended during the acute phase. The nurse should communicate to the caregiver that normal amounts of fat are suggested. Improvement is generally demonstrated within a week though complete recovery and histologic normality may require from 3 to 12 months (Sondheimer, 2007). Assessment of symptoms, growth, and adherence to the gluten-free diet (GFD) should be assessed monitored with periodic visits. “The Celiac Disease Guideline Committee recommends measurement of TTG after 6 months of treatment with a GFD to demonstrate a decrease in antibody titer as an indirect indicator of dietary adherence and recovery”.

Measurement of transglutaminase (TTG) levels is also recommended in individuals with recurrent or persistent symptoms at anytime after initiation of the GFD. Intervals of yearly or longer in the asymptomatic patient serve as a monitor of adherence to the GFD.

Optimizing Outcomes— Celiac disease

Best Outcome: Celiac disease requires a life-long commitment to diet control. Providing optimal outcomes for the child with celiac disease involves dietary guidance. Instruct the child and parents on the importance of carefully reading labels for hidden sources of gluten based products. These can often be found in common foods, such as ice cream, hot dogs, luncheon meats, soups, and cookies.

Children with more severe mucosal damage have impaired digestion of disaccharides, especially in relation to lactose. This may also necessitate the need for temporary lactose restriction in the diet. General dietary needs include high calories and proteins with simple carbohydrates, such as fruits and vegetables. High-fiber foods, such as raw vegetables and fruits with skins, nuts, and raisins are avoided until bowel inflammation has been reduced. It is important to stress the life-long need for diet control. Once the gluten-free diet has been introduced and symptoms are resolved the child and possibly the caregivers may believe that the condition has been corrected.

Be sure to— Obtain consent for genetic testing

In the case of genetic testing of children, the risks and benefits of testing should be discussed with the child as appropriate for their level of development. Most testing requires only a blood sample with little physical risk, although there can be psychological risks to the child that include decreased self-worth anxiety, and disruption of family bonds (Chasson, Gutt, & Ihlenfeld, 2002). The best interest of the child should be the primary consideration when genetic testing is ordered with counseling provided before the testing. Where possible both parents and the child should provide informed consent.

SHORT BOWEL SYNDROME

Short bowel syndrome (SBS) is a malabsorptive disorder that results from decreased mucosal surface area, which is usually caused by surgical resection of the small bowel. Factors such as dysmobility and overgrowth of bacteria can exacerbate the malabsorption. Volvulus, gastroschisis, necrotizing enterocolitis, and atresias are the most common causes of SBS in children. Crohn's disease is also a cause in older children. Trauma to the GI tract is a less common cause of SBS. The small intestine may be congenitally short in conditions in which bowel is lost in utero. Loss of a large portion of the bowel produces malabsorption and malnutrition. Short bowel syndrome results in compromised bowel function.

Signs and Symptoms

Malnutrition and diarrhea are the most common manifestations of SBS. Steatorrhea and carbohydrate malabsorption result in diarrhea and failure to thrive. The potential for dehydration, acidosis, hyponatremia, and hypokalemia results from an inadequacy of the short bowel to reabsorb fluid and electrolytes.

Nursing Insight— Short bowel syndrome

The major symptoms are diarrhea, malabsorption, malnutrition, and dehydration. Electrolytes are abnormal secondary to diarrhea and malabsorption.

Diagnosis

Diagnosis is confirmed by abdominal x-ray exam, abdominal ultrasound, endoscopy, colonoscopy, and complete blood count (CBC) that reveals anemia.

A stool sample may reveal presence of infection; blood, or nonabsorbed sugar, fats, and protein.

Nursing Care

Nursing care focuses on maintaining adequate nutrition and preventing complications (Potts, 2002). The use of total parenteral nutrition (TPN) via central line is part of the initial treatment of SBS. Enteral feedings are begun via nasogastric or gastrostomy tube (Potts, 2002). The nurse should communicate to the caregiver that the “main purpose of enteral nutrition is to stimulate the adaptive growth of the small intestine” (Potts, 2002, p. 692). Oral feedings may be started as tolerated in order for the infant to learn to suck and swallow. Pacifiers are also encouraged for this purpose. TPN may be gradually decreased as enteral and oral feedings are increased.

One main focus of nursing care includes administration and monitoring of the nutritional therapy. Care must be taken to avoid the complications of a central venous line (a venous access device inserted into the vena cava to infuse fluids and medicines) and TPN therapy (Venes, 2009).

clinical alert

Complications of a central venous line

When the child has a central line placement, the nurse observes the infusion site at least every 4 hours for complications such as infiltration, thrombophlebitis, fluid or electrolyte overload, or air embolism. The site dressing and administration set are also changed according to the institutions policies (Venes, 2009).

The care of enteral feeding tubes is also an important part of the nursing care. Care must be taken to observe for signs of dislodgement, infection, or occlusion.

Feeding tolerance must also be included as part of nursing care. Input, output, specific gravity, and weights are assessed daily by the nurse. Stools are tested for occult blood, pH, and reducing substances in addition to monitoring for vomiting, changes in the appearance of the stools, and abdominal distention.

With prolonged hospitalization, the nurse needs to consider the child’s emotional and developmental needs. Caregivers also need to be provided with psychosocial support and education to assist them in coping with the long-term affects of SBS. The plan of care should include attention to interventions to promote family adaptation.

Home-care services provide the opportunity for children with SBS to receive carefully monitored care at home. The nurse may serve as a resource for connecting the family to the appropriate home-care agencies, nutritional support services, and supply sources.

Hepatic Disorders

BILIARY ATRESIA

Biliary atresia, or extrahepatic biliary atresia (EHBA), is an idiopathic, progressive, inflammatory process that causes both intrahepatic and extrahepatic bile duct fibrosis and obstruction. Biliary atresia is the second most common liver disease diagnosed in infants with an incidence that ranges from 1 in 8000 to 21,000 live births and is fatal within the first 2 years of life if not corrected. The disease is more common in girls and premature infants. In the United States, the incidence is twice as high in African American infants as in Caucasian infants. The exact cause of biliary atresia is unknown. EHBA has two distinct presentations, postnatal and fetal, with differing mechanisms of development suggested. Infections and immune related mechanisms are implicated in postnatal EHBS, which represents 65% to 90% of cases. In the fetal form there is a congenital absence of patent biliary ducts.

Signs and Symptoms

The earliest clinical manifestations of EHBS and most outstanding features include jaundice, which can be first observed in the sclera. Jaundice may also be evident at birth but usually is not apparent until age 2 to 3 weeks of age. Urine is dark and stains the infant’s diaper. Stools are lighter than normal and often tan to white in color. The infant demonstrates poor weight gain and symptoms of failure to thrive resulting from poor fat metabolism. Pruritus (itching, burning or tingling of the skin) and irritability is present, which are often evident by an infant who is difficult to comfort. Hepatomegaly (enlarged liver) is an early symptom and the liver is firm upon palpation. Splenomegaly (enlargement of the spleen) occurs later.

Diagnosis

Early diagnosis is the key to survival of the child with EHBA. Infants who have surgery within the first 60 days of life have an 80% chance of establishing bile flow, with the potential for successful correction. CBC, electrolytes, bilirubin, and liver enzymes are included in the diagnostic workup as well as a TORCH titer (lab test for presence of antibodies for Toxoplasmosis, Other infections, Rubella, Cytomegalovirus, and Herpes simplex), urine cytomegalovirus, and sweat tests (measures electrolytes excreted in a sweat test to rule out cystic

fibrosis) are done to rule out other conditions with symptoms of jaundice and cholestasis. Biliary patency may be demonstrated by hepatobiliary scintigraphy (HIDA scan) but is not diagnostic. Endoscopic retrograde cholangiopancreatography (ERCP) can be performed in a very young infant and has an 80% accuracy. A percutaneous liver biopsy is also highly reliable.

Nursing Care

Medical care is primarily supportive and focuses on providing nutritional support. Formula with medium-chain triglycerides and essential fatty acids is recommended as well as supplemental minerals including iron, zinc, and selenium and the fat-soluble vitamins A, D, E, and K. For the infant with moderate to severe failure to thrive, aggressive nutritional support in the form of continuous tube feedings or TPN may be required. For advanced liver dysfunction, management is similar to that of the child with cirrhosis.

Management also involves surgical resection to correct the obstruction and provide for the drainage of bile from the liver into the intestines. The Kasai procedure, which is a hepatic portoenterostomy, may be performed to slow pathological changes that take place in the biliary duct (Potts, 2002). In surgery done before 8 weeks of age bile flow drainage is achieved approximately 90% of the time. A hepatic portoenterostomy involves resecting a section of the jejunum to the liver at the normal exit site of the hepatic duct to allow bile drainage into the small intestine. The jejunum may be looped to form a cutaneous double-barreled ostomy (Venes, 2009). Approximately one-third of infants regain normal liver function and become jaundice free after the Kasai procedure. A middle third demonstrate liver damage and must be supported by medical and nutritional interventions and the last third eventually require a liver transplant.

Preoperative care involves educating the family regarding the plan of care and the long-term nature of the condition. Nursing care immediately after a hepatic portoenterostomy is similar to that of the child following other major abdominal surgery. To help the child regain optimal health, providing nutritional support postoperatively involves special formulas, vitamins, and mineral supplements parenterally and through tube feedings. For the infant with a double-barreled ostomy bile is obtained from one site and refeed into the other site after feeding. The child's family needs to be instructed on and demonstrate skin and stoma care to be continued after discharge. The family also needs instruction on how to monitor and administer nutritional therapy. Side effects such as pruritus can be addressed through drug therapy and comfort measures. Postoperative risks and long-term complications should be explained to include symptoms to observe for such as indications of GI bleeding, ascites (accumulation of fluid in the peritoneal cavity), and cholangitis. Psychosocial support should be provided to the child and family to assist them in coping with the long-term nature of the condition, financial burden, uncertain prognosis, and potential waiting for transplant.

CIRRHOSIS

Cirrhosis is a pathological condition that occurs as an end stage to many liver and inflammatory conditions such as biliary atresia and chronic hepatitis (Potts, 2002). Auto-immune factors, infection, and chronic diseases such as hemophilia and cystic fibrosis can cause severe liver disease, which can lead to cirrhosis or irreversible damage. Cirrhosis is rare in the pediatric population but may develop as a result of chronic inflammation or disease, which causes scar tissue formation. Scar tissue leads to impaired intrahepatic blood flow and ongoing necrosis, which results in further cirrhotic changes.

Signs and Symptoms

Manifestations vary depending on the cause. General manifestations include jaundice, growth failure, muscle weakness, anorexia, and lethargy. Impaired intrahepatic blood flow leads to anemia, abdominal pain, edema, ascites, and GI bleeding. If the cirrhosis is secondary to a disorder of fat metabolism, steatorrhea may be observed (Potts, 2002). Portal hypertension and ascites are common symptoms of cirrhosis in the child with biliary anomalies. Splenomegaly is the most important sign of portal hypertension (Potts, 2002). Splenomegaly may be demonstrated by the presence of anemia, leukopenia, thrombocytopenia, and esophageal varices. These conditions lead to easy bruising, epistaxis, and GI hemorrhage (Potts, 2002). Jaundice, dark urine, and pruritis are symptoms of biliary obstruction.

Diagnosis

Diagnosis of cirrhosis is based on history, physical examination, laboratory values, and liver biopsy. Ascites, blood flow through the liver and spleen, and patency of the portal vein can be confirmed by Doppler ultrasonography of the liver and spleen. Laboratory evaluation includes liver function tests, such as bilirubin, aminotransferase, ammonia, albumin, cholesterol, and prothrombin time.

Nursing Care

Goals of care are directed at preventing and treating complications as there is no successful treatment of cirrhosis. Malabsorption problems are treated with nutritional support, such as a low-fat, low-protein diet and supplemental fat-soluble vitamins. Fluid restrictions, diuretics, and low-sodium diet are used to treat ascites. Blood and blood products are administered for the treatment of bleeding complications and hepatic encephalopathy is treated with reduced protein diet (Potts, 2002).

The only definitive treatment for end-stage liver disease and cirrhosis is a liver transplant, which improves the prognosis for many children (Potts, 2002). A 90% 1-year survival rate has occurred as a result of a combination of new surgical techniques and the use of immunosuppressive therapy.

Nursing care of the child with cirrhosis is similar to that of any child with a severe life-threatening disease. Interventions include monitoring for complications of malnutrition, hemorrhage, and hepatic failure in addition to providing comfort measures and emotional support.

HEPATITIS

Hepatitis may be acute or chronic and involves an inflammation of the liver. Hepatitis may be caused by virus or bacterial infections, fungal or parasitic infections, or chemical or drug toxicity (Potts, 2002). Six distinct viruses have been identified as causing hepatitis: hepatitis A virus (HAV), hepatitis B virus (HBV), and hepatitis C virus (HCV) in addition to hepatitis D virus (HDV), hepatitis E virus (HEV), and hepatitis G (HGV), which are not common (Potts, 2002). HAV, HEV, and HGV cause only acute infection. HBV and HCV cause chronic infections, whereas HDV has both acute and chronic forms. HAV and HEV are transmitted via the fecal–oral route, which is referred to as an enteral form of hepatitis (Potts, 2002). HBV, HCV, HDV, and HGV are transmitted via blood transfer or through intimate sexual contact, which is referred to as a parenteral form (Potts, 2002). Vaccines are available for the prevention of HAV and HBV. While each type of hepatitis has unique characteristics, assessment findings and treatments have many similarities (Table 25-3).

Most cases of hepatitis in children are caused by HAV and are most common in ages 5 to 14 years (Potts, 2002). HAV is found in the stool of infected individuals and transferred by oral ingestion, which is easily spread in areas with poor sanitation. Poor hygiene is also an important factor in the spread of HAV. High-risk areas also include settings where there are a number of children and infants in a common area, such as a day care center. Contact may occur directly through infected feces or indirectly through food and water contamination (Potts, 2002). Outbreaks have occurred in areas that have experienced sewage-contaminated water, infected food handlers with poor hygiene, and shellfish caught in water contaminated by sewage (Potts, 2002). The incubation period is 15 to 40 days (Sokol & Narkewicz, 2007).

HDV occurs only in patients with acute or chronic HBV infection, which causes it to be severe. The risk of HDV is reduced with hepatitis B vaccination. HDV is also more common in Mediterranean countries and among hemophiliacs and IV drug users. HEV is more common in

adults and uncommon in developed countries and is rare in the United States (Sokol & Narkewicz, 2007). High-epidemic areas include Southeast Asia; China; the Middle East; and parts of Africa, Mexico, and Central America (Sokol & Narkewicz, 2007). HEV produces a high incidence of mortality in pregnant women. The high-risk group for HGV includes transfusion recipients, IV drug users, and persons infected with HCV. Individuals infected with HGV are usually asymptomatic for liver involvement.

Signs and Symptoms

Characteristics for HAV, HBV, and HCV overlap considerably. Headache, anorexia, malaise, abdominal pain, nausea, and vomiting are characteristic of the preicteric phase, which lasts approximately 1 week and usually precedes the onset of clinically detectable disease (Jensen & Baltimore, 2006). Dark urine precedes the jaundice phase (Sokol & Narkewicz, 2007). The most common symptoms of the icteric phase are jaundice and hepatomegaly, which may last several weeks. Stools may appear clay-colored during this phase (Sokol & Narkewicz, 2007). Prodromal symptoms (initial stages of the disease) often decline in children during the icteric phase (Jensen & Baltimore, 2006). Young children are often asymptomatic or have a mild, nonspecific illness without icterus hepatitis A virus (HAV), hepatitis B virus (HBV), and hepatitis C virus (HCV) (Table 25-4).

Diagnosis

Diagnosis is based on history of exposure, symptoms, and serologic testing for markers of hepatitis A, B, and C, and liver function tests, specifically an elevation of ALT (alanine aminotransferase—an intracellular enzyme involved in amino acid and carbohydrate metabolism [Venes, 2009]), AST (aspartate aminotransferase—an intracellular enzyme involved in amino acid and carbohydrate metabolism [Venes, 2009]) and serum total bilirubin. Liver biopsy may be required to establish the diagnosis and degree of disease though rarely indicated in the diagnosis

Table 25-3 Hepatitis Viruses

	HAV	HBV	HCV	HDV	HEV
Type of Virus	Enterovirus	Hepadnavirus	Flavivirus	Incomplete	Calicivirus
Transmission	Fecal–oral	Parenteral, sexual, vertical	Parenteral, sexual, vertical	Parenteral, sexual	Fecal–oral
Incubation period	15–40 days	50–150 days	30–150 days	20–90 days	14–65 days
Diagnostic tests	Anti-HAV IgM	HBsAg, anti-HBc IgM	Anti-HCV, PCR-RNA test	Anti-HDV	Anti-HEV
Mortality rate	0.1–0.2%	0.5–2%	1–2%	2–20%	1–2% (20% in pregnant women)
Carrier state	No	Yes	Yes	Yes	No
Vaccine available	Yes	Yes	No	Yes (HBV)	No
Treatment	None	Interferon- α , nucleoside analogues (lamivudine, tenofovir, adefovir, entecavir)	Interferon- α (pegylated interferon in adults) plus ribavirin	Treatment for HBV	None

Table 25-4 Comparison of Hepatitis A (HAV), Hepatitis B (HBV), and Hepatitis C (HCV)

Clinical Features	HAV	HBV	HCV
• Onset	Usually rapid, acute	More insidious	Usually insidious
• Fever	Common and early	Less frequent	Less frequent
• Anorexia	Common	Mild to moderate	Mild to moderate
• Nausea & vomiting	Common	Sometimes present	Mild to moderate
• Rash	Rare	Common	Sometimes present
• Arthralgia	Rare	Common	Rare
• Pruritus	Rare	Sometimes present	Sometimes present
• Jaundice	Present	Present	Present

Source: Sokol, R.J., & Narkewicz, M.R. (2007). Liver and pancreas. In W.W. Hay, M.J. Levin, J.M. Sondheimer, & R.R. Deterding (Eds.). *Current diagnosis & treatment in pediatrics* (18th ed.). New York: Lange Medical Books/McGraw-Hill, pp. 638–683.

of HAV (Sokol & Narkewicz, 2007). The nurse understands that the presence of antigens or antibodies confirm and differentiate the diagnosis HAV, HBV, and HCV. “Serum immunological tests are not available to detect HAV, but there are two HAV antibody tests, anti-HAV IgG and immunoglobulin M (IgM)”. Anti-HAV is present at the onset and persists throughout life. A positive anti-HAV test indicates the presence of a current infection, immunity from a past infection or immunization.

Nursing Care

The goal for management of viral hepatitis includes early detection, support, and monitoring of the disease, recognition of chronic liver disease, and prevention of spread of the disease. Management of hepatitis is primarily supportive as there is no specific treatment (Potts, 2002). Management includes measures to provide rest to the liver, hydration, adequate nutrition, and the prevention of complications. Severe dehydration, vomiting, a prolonged prothrombin time, or signs of encephalopathy are indications for hospitalization (Jensen & Baltimore, 2006).

Immune globulin should be given to children who have been exposed to a person with HAV within 2 weeks of exposure. Immune globulin is up to 90% effective when given during this time period (Potts, 2002). The prognosis for children with hepatitis A virus (HAV) is usually good as most cases are mild and in most cases carrier states do not occur. Prevention of HBV infection after a one-time exposure such as a needle stick can be effectively prevented by the use of hepatitis B immune globulin (HBIG).

Nursing care is directed at maintaining comfort, providing adequate nutrition, and educating the family regarding prevention measures. Children with mild symptoms can be cared for at home, which necessitates the need to instruct the family regarding infection control, providing a well balanced diet, and providing rest. Children with hepatitis A virus (HAV) are not considered infectious within a week after the onset of jaundice and school attendance may be resumed. The family also needs to be instructed to avoid administering any medication to

the child since normal doses of drugs may become dangerous because of the liver’s inability to process them. Preventive measures include instructing the family on good hand washing (the single most effective preventive measure), food handling, and careful disposal of excreta and stool contaminated objects. Hepatitis A vaccine is recommended for children ages 2 through 18 years who may be living in high-risk communities (Potts, 2002).

critical nursing action Prevention of Hepatitis A and Hepatitis B

- Wash hands after changing diapers and using the toilet.
- Wash hands before food preparation and eating.
- Carefully dispose of soiled diapers.
- Wash linen or clothing contaminated with stool separately in hot water.
- Clean contaminated household surfaces with bleach and water (1/4 cup of bleach to 1 gallon of water).
- HAV and HBV vaccination.

Abdominal Trauma: Injuries

The leading cause of death in children and adolescents after the first year of life is caused by injuries. Injuries are responsible for more than 50% of all deaths in the 15- to 24-year age group (Brayden, Daley, & Brown, 2007). Motor vehicle injuries are the primary cause of accidental death in the United States with nearly 60% occurring with unrestrained children (Brayden et al., 2007). Ten percent of serious trauma to children occurs as a result of abdominal and genitourinary injury, which include contusion or laceration to liver, spleen, and kidneys (Ruddy, 2005) (Table 25-5). Injuries to hollow organs are increasing partly related to the increasing number of improperly restrained children involved in motor vehicle accidents (Ruddy, 2005).

Table 25-5 Injuries Caused by Abdominal Trauma

Organ	Incidence and Description	Management
Abdomen	<ul style="list-style-type: none"> • Approximately 8% of pediatric trauma • Risk of blunt trauma injuries increased because of relative size and close proximity of organs • Penetrating trauma accounts for <10% of pediatric abdominal trauma • Gunshot wounds involve multiple organs in 80% of the cases 	<ul style="list-style-type: none"> • Serial examination is primary in decisions regarding surgical interventions • Surgical intervention may be required if persistent unstable vital signs along with aggressive fluid replacement • Laparoscopy may be indicated with peritoneal irritation and abdominal wall discoloration • CT is valuable for assessing intra-abdominal trauma
Spleen	<ul style="list-style-type: none"> • Most frequently injured abdominal organ in children • Positive Kehr sign (pressure on the left upper quadrant eliciting left shoulder pain) related to diaphragmatic irritation from ruptured spleen • Spleen injury suspected with left upper quadrant abrasions or tenderness • Splenic injury may include capsular tear to a complete rupture 	<ul style="list-style-type: none"> • CT scan can be used to grade splenic injury • Treatment of choice is nonoperative management • Surgery indicated for blood loss greater than 40 mL/kg or transfused blood in 24–36 hours or evidence of hemodynamic instability • With splenectomy penicillin prophylaxis is recommended
Liver	<ul style="list-style-type: none"> • Accounts for 40% of all deaths associated with blunt abdominal trauma in children • Right lobe injuries are more common • Diagnosis based on Kehr sign (pressure on the right upper quadrant eliciting right shoulder pain) • Severe hemorrhage is more common with liver injury than with other abdominal organs 	<ul style="list-style-type: none"> • Conservative management is recommended with ongoing monitoring of blood loss, hepatic function, and liver structure with serial CR scans or ultrasound • Operative management is reserved for life-threatening situation
Pancreas and duodenum	<ul style="list-style-type: none"> • Less common in children than adults • Seen in bicycle handlebar injuries, motor vehicle crashes and nonaccidental trauma • Diagnosis difficult unless obvious injury to overlying structures • Diffuse abdominal tenderness, pain and vomiting accompanied by elevation of amylase and lipase may be indicative of injury though often does not occur for several days after injury • Duodenal injuries include hematomas and perforation • Perforations are difficult to diagnose 	<ul style="list-style-type: none"> • Management includes nasogastric suction and parenteral nutrition • Nonoperative management is appropriate for contusions • Surgical interventions may be required with distal transection • Perforation is not always obvious with a CT
Intestinal	<ul style="list-style-type: none"> • Injury occurs less often than with solid intra-abdominal organs • Risk varies with the amount of intestinal contents, i.e., a full bowel is likely to shear more easily than an empty bowel • Lap belt or seatbelt in a motor vehicle crash results in a sudden deceleration and increase in intraluminal pressure and can lead to perforation 	<ul style="list-style-type: none"> • Presence of a contusion over the seatbelt area and abdomen or back pain indicates a need to pursue the diagnosis of intestinal injury • Pneumoperitoneum in association with intestinal perforation occurs in about 20% of patients

Source: Marcante, K.J. (2006). The acutely ill or injured child. In R.M. Kliegman, K.J. Marcante, H.B. Jenson, & R.E. Behrman (Eds.). *Nelson: Essentials of pediatrics* (5th ed.). Philadelphia: Elsevier, pp. 179–216.

summary points

- ◆ The gastrointestinal (GI) system of the child is immature compared to that of an adult leading to variations in response to illnesses.
- ◆ Pyloric stenosis is characterized by projectile vomiting and a palpable olive-shaped mass in the epigastrium.
- ◆ One of the most common causes of intestinal obstruction in infancy is from intussusception.
- ◆ Anorectal malformations are usually evident at birth.
- ◆ The most common type of hernia in children is an umbilical hernia.
- ◆ Signs and symptoms of appendicitis include abdominal pain that begins in the periumbilical area and moves to the right lower quadrant, accompanied by a low grade fever, nausea, and occasionally vomiting.
- ◆ Treatment focus for inflammatory bowel disease includes medication, nutrition, and often surgery.

- ◆ Nursing care of the child with celiac disease includes education about the gluten free diet.
- ◆ The complications of peritonitis and perforation from appendicitis can be prevented by prompt recognition and diagnosis.
- ◆ Care of the child with gastroesophageal reflux (GER and GERD) can be managed by teaching the caregiver feeding and positioning methods to prevent or reduce reflux.
- ◆ Correction of Hirschsprung disease involves surgical resection of the affected bowel with or without a colostomy.
- ◆ Malabsorption disorders include lactose intolerance, celiac disease, and short bowel syndrome.
- ◆ Progressive cirrhosis and death occur from untreated biliary atresia in most children by age two.
- ◆ Cirrhosis is a pathological condition that occurs as an end stage to many liver and inflammatory conditions such as biliary atresia and chronic hepatitis.
- ◆ Hepatitis may be acute or chronic and involves an inflammation of the liver. Hepatitis may be caused by virus or bacterial infections, fungal or parasitic infections, or chemical and drug toxicity.
- ◆ Ten percent of serious trauma to children occurs as a result of abdominal and genitourinary injury, which include contusion or laceration to liver, spleen, and kidneys

review questions

Multiple Choice

1. A 6-week-old infant is admitted to the hospital with the possible diagnosis of pyloric stenosis. The nurse asks the parents about the infant's feeding history. Which of the following symptoms is most descriptive of pyloric stenosis in the infant?
 - A. Abdominal peristaltic waves passing from right to left
 - B. Frequently appearing hungry with projectile vomiting
 - C. Periodic bilious forceful vomiting after feedings
 - D. Decrease interest in feedings with weight loss
2. The pediatric nurse is monitoring a child for signs of bowel perforation. On assessment, the nurse notes which of the following as an important sign of bowel perforation?
 - A. Acute pain over the affected area
 - B. Frequent bradycardia
 - C. Increased urinary output
 - D. An episode of bloody diarrhea

Select All that Apply

3. It is important for the pediatric nurse to have keen assessment skills in order to monitor a child who may display signs of shock. Which signs should be immediately brought to the attention of the pediatrician?
 - A. Hypotension
 - B. Hypertension
 - C. Cyanosis
 - D. Tachycardia

Case Study

4. A 10-year-old boy is admitted to the pediatric unit where the nurse is suspicious of appendicitis. During the interview process, the child tells the nurse that the pain woke him up in the morning and that although he has not eaten in the past 24 hours, he does not feel hungry at all.

Which of the following signs are indicative of appendicitis?

 - A. Constant pain in the left lower quadrant
 - B. History of vomiting before the onset of the pain
 - C. History of pain around the umbilicus
 - D. History of diarrhea in the past 48 hours
5. Shortly after admission to the pediatric unit, the child complains of severe acute pain that spreads over the entire abdomen. On assessment, the pediatric nurse finds that the child has a rigid and tense abdomen. The child is also tachycardic and has a fever. Perforation of the appendix is suspected. The child is taken to the operating room immediately. Immediate post-operative care for appendectomy includes which of the following? (*Select all that apply.*)
 - A. A nasogastric tube is inserted to decompress the stomach.
 - B. Bowel sounds are assessed every 4 hours.
 - C. Fluids are given to the child when awake.
 - D. Strict intake and output assessments are completed.

True or False

6. The nurse teaches the mother of a newborn that her baby has been born with an absent vaginal opening and that this condition is called an imperforate anus.
7. A 14-year-old child has just been admitted to the emergency room. The pediatric nurse is teaching the family about peritonitis. The nurse explains that peritonitis in children includes moderate pain that worsens with movement.
8. A 12-year-old child has just been diagnosed with Crohn's disease. The nurse explains to the family that surgical treatment can cure the child.

Fill-in-the-Blank

9. During the abdominal assessment, the nurse is aware that a classic sign of pyloric stenosis is the _____ to _____ movement of peristalsis.
10. The nurse teaches the parents of a 3-month-old infant with gastroesophageal reflux to place the infant _____ following feedings ensuring that the infant is awake and well supervised.
11. When the pediatric nurse is assessing a child's _____, the nurse will gently gather a portion of the skin and then release the skin. If the child's skin remains suspended or _____ for 15 seconds, this indicates _____.
12. When comparing the adolescent with Crohn's disease to the adolescent with ulcerative colitis, the patient with _____ will have continuous patchy areas in the intestine, as opposed to the patient with _____ who will have diffuse, segmented areas of involvement.

CONCEPT MAP

Caring for the Child with an Immunological or Infectious Condition

Integrating the Science and Art of Nursing

Nursing is a learned profession built upon a core body of knowledge reflective of its dual components of science and art. Nursing requires judgment and skill based upon principles of the biological, physical, behavioral, and social sciences. Registered nurses use critical thinking to apply the best available evidence and research data to the processes of diagnosis and treatment. Nurses continually evaluate quality and effectiveness of nursing practice to seek to optimize outcomes.

—American Nurses Association (2004). *The Scope and Standards of Nursing*, p. 10.

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Discuss why infectious and immune diseases represent a significant pediatric health concern for the child, family, and public.
- ◆ Describe the body's first and second lines of defense.
- ◆ Explain the congenital immunodeficiency disorders.
- ◆ Examine the goals of treatment for HIV-positive children.
- ◆ Discuss why post-cell-transplant children are placed in a medically induced state of immunosuppression.
- ◆ Explore autoimmune disorders together with related nursing care.
- ◆ Discuss the three types of infections together with related nursing care.
- ◆ Describe the importance of immunizations and the role of the nurse.
- ◆ Explain why animals serve as a reservoir for certain infectious diseases.
- ◆ Describe possible solutions for the increase in the incidence of infections with antibiotic-resistant organisms.

moving toward evidence-based practice Maintaining Peripheral Intravenous Locks

Mok, E., Kwong, T.K., & Chan, M.F. (2007). A randomized controlled trial for maintaining peripheral intravenous lock in children. *International Journal of Nursing Practice*, 13, 33–45.

The purposes of this study were to compare the effectiveness and safety of three intravenous flush solutions in maintaining peripheral locks and to evaluate differences in the incidence of complications among them. The methods compared were a normal saline flush, a 1 unit/mL heparin–saline flush, and a 10 units/mL heparin–saline flush.

The study, conducted in a hospital pediatric unit, included a sample of 123 children whose ages ranged from 1 year to 10 years. The participants were randomly assigned to one of the

three treatment groups; each group consisted of 43 children. Each child was selected to receive one of the three flush solutions.

Study inclusion criteria included:

- Presence of a 22-gauge or a 24-gauge peripheral intravenous (IV) catheter that was anticipated to remain beyond the day of insertion
- IV flush or medication ordered every 6 or 8 hours
- Written consent obtained from a parent or guardian
- Verbal consent obtained from the patient as appropriate

(continued)

moving toward evidence-based practice (continued)

Study exclusion criteria included:

- Presence of a known bleeding disorder
- Abnormal platelet count or clotting factors
- Received medication that affected coagulation
- Received a transfusion of blood products or IV cytotoxic drugs.

The researchers developed an IV site assessment form that was used every 8 hours or with each administration of medication or IV flush through the peripheral lock. The form assessed the following signs of complications: redness, swelling, pain, coolness to the touch, and/or leakage at the insertion site.

Before the initiation of the study, the pediatric unit nurses who would be performing the peripheral flush and completing the IV site assessment form received education and hands-on practice on a standard method for flushing a peripheral lock.

All IV peripheral flushes were documented in the treatment records as Heparin Flush A or B or C. Since the study was a double-blind design, the nurse providing the flush only knew that the participant belonged to group A, group B, or group C and did not know the type of flush administered. All doses were prepared by two nurses who were not involved in the IV site assessments.

The study found no statistically significant differences among the three groups in:

- Length of catheter use
- Estimated catheter survival
- Incidence of intravenous complications
- Types of flushing solution in terms of the catheter longevity
- Incidence of intravenous complications

However, the researchers determined that children older than 2 years of age had a greater incidence of backflows (abnormal backward flow of fluid) that required additional flushes. This increase in incidence of backflows may be related to the child's mobility and play, which has been supported in the literature.

The researchers concluded that the type of flush used was not a significant predictor of catheter longevity and incidence of intravenous complications.

1. What might be considered as limitations to this study?
2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

Infectious and immune diseases represent a significant pediatric health concern for the child, family, and public. Prevention and control of infections and communicable diseases is a primary goal of national, state, and local health agencies, addressed largely through surveillance, public education, and immunization programs. Pediatric nurses are at the forefront of these efforts and are responsible for nursing care of children and families and in assisting families to become informed and educated so that they can take an active role in caring and advocating for their child.

Pediatric immune disorders are complex and require the pediatric nurse to work closely with the family to develop a plan of care that will promote healthy growth and development while addressing health needs related to the illness. An intact immune system has a profound effect on the vulnerability of the child to infectious disease. Disorders of the immune system in children, either absence of a component of immunity or a failure to differentiate self from nonself, may be either congenital or acquired.

The nurse's role in health promotion and prevention of immune and infectious diseases is explored, with an emphasis on the role of the nurse as caregiver and educator. Information on nurse–family partnership addresses immune system dysfunction in children.

The Immune System

The immune system protects the child from an attack of foreign intruders. Although the purpose of the immune system is identical for children and adults, in the child much of the immune response is as yet untested, or naive, making the response somewhat less efficient (Hoffjan et al., 2005).

A & P review An Important Line of Defense

The immune system is made up of cells, tissues, and organs that work in an organized manner to protect the body against invaders and infectious organisms.

The white blood cells (leukocytes) are part of the defense system. There are two basic types: phagocytes (neutrophils are the most common and fight bacteria) and lymphocytes (B lymphocytes and T lymphocytes), which seek out and destroy organisms that might cause disease.

Leukocytes are produced or stored in the lymphoid organs: lymph nodes, bone marrow, thymus, spleen, and tonsils. The leukocytes circulate throughout the body via the blood.

Antigens are foreign substances that invade the body. When an antigen is detected several types of cells work together to recognize and respond to the invader. Mature B lymphocytes independently identify foreign antigens and differentiate into antibody-producing plasma cells (memory cells). Once the B lymphocytes have produced antibodies, these antibodies remember so if the same antigen is presented to the immune system again, the antibodies can respond. Although antibodies can recognize an antigen they are not capable of destroying it without the help of mature T cells that are antigen specific.

Antibodies can also neutralize toxins and activate a group of proteins that assist in killing bacteria, viruses, or infected cells.

The protection offered by the immune system is called immunity. There are three types of immunity: innate, adaptive, and passive: Innate immunity (or natural) is a general protection and includes the physical barriers of the body, like the skin and mucous membranes. The skin is the first line of defense in preventing diseases from entering the body. Adaptive (or active) immunity develops as children are exposed to diseases or immunized

against diseases through vaccination. Passive immunity is acquired by the introduction of preformed antibodies into an unprotected individual and it lasts for a short period of time. For example, passive immunity can occur from antibodies that pass from the mother to the fetus through the placenta or newborns that acquire immunity through breastfeeding. ♦

The Body's Defense

The skin is the most important physical barrier and the body's first line of defense. It is the largest organ of the body and has several major functions:

1. Protects the deeper tissues from injury
2. Protects the body from foreign matter invasion
3. Regulates temperature
4. Aids in water retention
5. Aids in synthesis of vitamin D
6. Initiates the sensations of touch, pain, heat and cold
 - The mucous membranes provide a protective barrier against the entry of pathogens.

Mechanical and chemical barriers also help protect the child. For instance, tears, urine, vaginal secretions, and semen have a role in primary defense against infection. The nurse understands that the mechanical action of these fluids flowing out from the body carries with it unwanted intruders that may cause disease. An example of a chemical barrier is the acidic secretions of the stomach and digestive enzymes that serve to neutralize organisms taken into the body through the mouth. Chemical barriers in the gastrointestinal system can be maintained with good nutrition.

Clinical Alert

Increased risk for infection

The nurse understands that something as simple and common as diaper rash is more than a simple irritation; it is also as a potential portal entry for microorganisms.

The body's second line of defense is the **immune response**. The overall purpose of the immune response is to defend the body against microorganisms, parasites, and foreign cells such as cancer cells and transplanted cells. Key to a normal immune response is the body's ability to recognize foreign substances as nonself and then to mobilize defenses and attack the invaders. A deficiency in the immune response may lead to serious illness in the pediatric patient.

Nursing Insight— Immunoglobulins

Immunoglobulins, also known as antibodies, are substances made by the body's immune system in response to diseases and other insults. The major types of immunoglobulins are:

IgM is the first type of antibody made by the body in response to an infection. This antibody also helps other immune system cells destroy foreign substances. An adult level is attained by 9–12 months of age.

IgG antibodies are important in fighting bacterial and viral infections. An adult level is attained by 1 year of age.

IgA antibodies protect the body's surface from foreign substances. An adult level is attained by 5 years of age.

IgE causes the body to react against foreign substances such as fungus spores, animal dander, and pollen. An adult level is attained by early childhood

Nursing Insight— Children are more vulnerable to infection

There are important aspects about children that make them more vulnerable to infection:

1. The skin has a thinner texture that is more susceptible to external irritants and a greater risk for the absorption of microorganisms because of the greater body surface area
2. Immunoglobulin A (IgA) secreted by the epithelial cells of the mucous membranes does not reach adult levels until the child is 5 years of age, making children less resistant to organisms.
3. The endocrine glands that secrete sweat are not capable of mature function until 3 years of age, making children less able to regulate body temperature.

A way to help ensure a healthy immune system is to educate the family about the role of the immune system and the natural processes that help the body maintain resistance to disease. Nurses can support the child's immune system through nursing interventions, such as meticulous skin care and measures that target the maintenance of important barriers (Fig. 26-1).

Congenital Immunodeficiency Disorders

Congenital immunodeficiency disorders are rare but include more than 70 specific types of disorders that result in life-long impairment of immune system function. The impairment causes an increase in incidence, severity, and recurrence of infections.

Symptoms of congenital immunodeficiency disorders begin in infancy, and the actual onset of symptoms

Figure 26-1 Assessing and maintaining skin care is an important role of the nurse.

depends on the exact immune components involved. Specific disorders are grouped according to the component of the immune system that is affected (B cell, T cell, B lymphocytes, and combined). Children with immune system disorders are at risk for infection not only from outside pathogens, but also from their own normal flora.

B-CELL DISORDERS

In B-cell disorders, inadequate or a nearly absent number of immunoglobulins may be present. Maternal antibodies naturally protect newborns during the first few months of life; thus B-cell disorders do not become apparent until the third month of life. Most of the congenital immunodeficiency disorders (for example, selective IgA deficiency and common variable immunodeficiency) are genetically X-linked and are more likely in male children.

In B-cell disorders, the child usually has recurrent infections, beginning with respiratory infections. Infections of the skin and mucous membranes, typically seen in B-cell disorders, are generally more severe, and complications are frequent. Many children develop weight loss and fail to meet developmental milestones.

Specific treatment of B-cell disorders depends on the actual disorder. General treatment principles include supporting immune function through maintenance of barriers, providing good nutrition, preventing infection, administering prophylaxis antibiotics or antiviral agents, and administering selected vaccinations. Stem cell transplants are indicated for selected disorders.

T-CELL DISORDERS

Disorders affecting T lymphocytes are infections that begin in infants younger than 6 months of age. It is rare for a disorder of T lymphocytes to occur in isolation; generally abnormalities of T lymphocytes are either a component of a combined immune disorder or associated with a syndrome of congenital anomalies. For example, with DiGeorge syndrome, there is a constellation of congenital anomalies, including heart defects, absence of the parathyroid gland, abnormal facial characteristics, and an absent or underdeveloped thymus. These infants have a variety of clinical problems shortly after birth related to cardiac defects and disturbances in calcium regulation secondary to the parathyroid absence. The alteration in immune function is highly variable depending on whether there is a functioning thymus. Those without a functioning thymus have decreased counts of T lymphocytes and therefore have a limited ability to fight infection. These infants have both fungal and viral infections early in infancy. They are treated symptomatically and with antibiotic prophylaxis to prevent *Pneumocystis carinii* infection. Definitive treatment of the immunodeficiency includes thymus transplant and stem cell or histocompatibility antigen HLA-identical bone marrow transplant.

B-LYMPHOCYTE DISORDERS

Disorders affecting B lymphocytes and antibody production tend to occur in older infants and children. Specific B-lymphocyte disorders result in a failure to produce adequate numbers of antibodies. Passive protection from maternal antibodies masks these disorders during the first

few months of life. Children with B-lymphocyte disorders have multiple bacterial infections and failure to thrive. Treatment consists of the administration of specific immunoglobulins to replace missing factors and antibiotics that aggressively treat bacterial infections.

A specific B-lymphocyte disorder in children is transient hypogammaglobulinemia of infancy, in which the infant immune system is delayed in production of antibodies, sometimes until the child is 12 to 36 months of age. Support with immunoglobulin administration and antibiotics is needed until the child begins to produce antibodies. The condition is more common in premature infants and is self-limiting, resolving as the immune system matures and begins to produce antibodies.

COMBINED IMMUNODEFICIENCY DISORDERS

Combined immunodeficiency disorders affect multiple components of the immune system. They are more severe, occur in early infancy, and are often fatal during childhood. Severe combined immunodeficiency disease (SCID) is the most severe form of combined immunodeficiency. It is a congenital condition and results in absence or abnormal function of the B lymphocytes, T lymphocytes, and natural killer cells. The child with this disorder often has recurrent infections by the age of 3 months. Typical infections for SCIDs include otitis media, thrush, and pneumonia. The children often have diarrhea that contributes to failure to thrive. The infections are difficult to eliminate, tend to recur, and may be caused by unusual organisms such as *Pneumocystis carinii* or cytomegalovirus. Medical management includes antibiotics and immune globulin administration to control infections. A stem cell or bone marrow transplant is generally attempted. Without aggressive treatment, these children die before 2 years of age.

Nursing Insight— Wiskott–Aldrich syndrome

Wiskott–Aldrich syndrome is an example of a combined immunodeficiency syndrome. It results in thrombocytopenia, abnormal levels of B lymphocytes, and alteration in T-lymphocyte function. Wiskott–Aldrich syndrome is an X-linked congenital disorder, occurring only in boys. Typically, children have bloody diarrhea during infancy secondary to the platelet dysfunction. Other typical symptoms include eczema, recurrent infections, and failure to thrive. Children with Wiskott–Aldrich syndrome are at greater risk for lymphoma and leukemia. Medical management includes antibiotics, replacement of specific immunoglobulins, and eventual stem cell transplant.

Immunodeficiency Disorders

HUMAN IMMUNODEFICIENCY VIRUS

Human immunodeficiency virus (HIV) is caused by HIV-1 and is the primary cause of acquired immunodeficiency syndrome (AIDS) in infants and children. The HIV virus selectively targets and destroys T cells, thereby destroying cellular immunity. The child is virtually unprotected against a number of opportunistic infections and bacterial, fungal, and viral diseases. Every system is affected (Feeny, 2004).

Nursing Care Plan The Child with Immunosuppression

Nursing Diagnosis: Risk for infection related to immunosuppression

Measurable Short-term Goal: Child remains free from symptoms of infection.

Measurable Long-term Goal: Child regains natural resistance to infection.

NOC Outcomes:

- Immune Status (0702) Natural and acquired appropriately targeted resistance to internal and external antigens
- Infection Severity (0703) Severity of infection and associated symptoms

NIC Interventions:

- Infection Protection (6550)
- Infection Control (6540)

Nursing Interventions:

1. Institute universal precautions and designated isolation precautions as appropriate.

RATIONALE: Precautions protect the nurse, child, and family members from the transfer of microorganisms.
2. Demonstrate and instruct visitors to wash hands on entering and leaving the patient's room and to use protective equipment properly.

RATIONALE: Hand washing and proper use of gloves, masks, or cover gowns eliminates major transmission routes for many organisms.
3. Monitor for systemic and localized signs of infection every 2–4 hours when the child is hospitalized and at each interaction in providing community-based health care. Assess temperature, lung sounds, and condition of skin, as well as mucus membranes for pain, redness, and edema.

RATIONALE: Fever or respiratory symptoms may be the only overt signs of infection in an immunosuppressed child. Systematic monitoring allows early recognition and treatment of infection.
4. Monitor laboratory values as obtained: absolute granulocyte count, WBC count, and differential results.

RATIONALE: Changes in lab values alert the caregiver to developing infection. The immunosuppressed patient may not exhibit overt signs of an inflammatory response.
5. Promote a balanced diet of favorite foods, prepared and presented attractively. Allow only cooked fruits and vegetables if the child is neutropenic.

RATIONALE: Deficient intake of protein; vitamins A, C, or E; iron; or zinc may have a detrimental effect on the immune system and place the child at increased risk for infection. Cooking fruits and vegetables helps to eliminate harmful organisms.
6. Encourage rest and sleep by providing a quiet environment.

RATIONALE: Sufficient rest and sleep will help bolster the body's immune system.
7. Administer antibiotics and immunizations as prescribed, following CDC and AAP recommendations.

RATIONALE: Antibiotics may be prescribed prophylactically or to treat identified infections. Most children who are able to produce antibodies are given killed vaccines.

Centers for Disease Control and Prevention (CDC) data indicate that the route of infection for the majority children with AIDS younger than 15 years of age is prenatal transmission. Other sources of exposure are hemophilia/coagulation disorders, receipt of contaminated blood or tissue, and unidentified risk.

Prenatal transmission, also known as vertical transmission, occurs when an HIV-infected mother passes the virus on to her child. Vertical transmission may occur in utero, during birth via blood, from amniotic fluid and exposure to genital tract secretions, or after birth through the breast milk. Maternal factors, such as the stage of the illness and amount of virus in her system, affect the risk of transmission of the virus to the child. An example of an antiretroviral medication, zidovudine (AZT), given during pregnancy has demonstrated that the transmission of the virus can be prevented. This information has prompted CDC to make recommendations for pregnant women to

have voluntary prenatal testing. When a pregnant woman is HIV-positive, the infant is delivered by cesarean section and administered antiretroviral drug therapy soon after birth, which significantly reduce the risk of HIV infection in the neonate.

Before mandatory screening of blood and blood products in 1985, HIV was transmitted to children through blood transfusions. Most of the children infected with the virus were being treated for hemophilia. In the adolescent population, HIV infection occurs as a result of unprotected sexual activities and intravenous drug abuse. Prevention strategies in this age group focus on education about transmission and reduction in high-risk sexual practices.

The nurse understands that HIV selectively attacks a subset of T lymphocytes, the helper T cells. As the virus invades the helper T cells and takes over the cell for viral replication, the T cell becomes nonfunctional. A specific function of helper T cells is recognition of foreign cells; in

their absence, infection is more likely. HIV also affects B-lymphocyte function, adding to the difficulty in fighting infection.

When the HIV virus is present, there is an immediate drop in CD₄⁺ (helper T cell) levels. The drop is followed by an immune response, which then raises the levels and marks the beginning of a latent period that may last 10 years or longer. At some point the CD₄⁺ levels again decrease and when they reach critical levels the symptoms begin to appear, heralding the onset of AIDS. In children with prenatally acquired HIV, the latency period may be very short. In children who have visible symptoms during infancy an accelerated course of disease is typical and most of these children develop manifestations of AIDS by their first year of life. Their prognosis is very poor. The majority of HIV-infected children develop symptoms more slowly, initially developing clinically recognizable AIDS at 18 to 24 months of age.

Signs and Symptoms

Common clinical manifestations of HIV infection in children are lymphadenopathy, hepatosplenomegaly, chronic diarrhea, failure to thrive, oral thrush, skin infections, fevers, and recurrent infections. Chronic diarrhea with malabsorption of nutrients contributes to a failure to grow. A variety of chronic infections further complicate normal growth and developmental.

Diarrhea and poor nutritional status set the stage for skin breakdown that provides a portal of entry for opportunistic and bacterial infections. Infections of the mucous membranes also provide a site of entry for infection and pain from mucosal lesions further complicate nutritional status. Lymphadenopathy and hepatosplenomegaly are seen secondary to immune system involvement.

In addition, early onset of recurrent respiratory infections and progressive neurological involvement are common in children. The cumulative results of many serious infections are multiple developmental delays, with progressive impairment of motor skills and intellectual function.

Diagnosis

Diagnosis of HIV infection in children is necessary whenever there is a suspicion that the child may have the virus. Diagnosis of HIV infection in children requires a multi-pronged approach using appropriate testing and clinical observation. In infants, the diagnosis can be complicated by the transmission of maternal antibodies.

Diagnostic testing for infants with suspected or unknown prenatal exposure to the HIV virus should include a PCR test as soon as possible after birth. If the results of the test are positive, a repeat PCR test should be performed as soon as possible. Two positive PCR tests confirm the diagnosis. If there is still adequate enough suspicion that the infant may have HIV and the initial results are negative, the PCR test needs to be repeated again at 1 to 2 months of age, 3 to 6 months of age, and 15 to 18 months of age. Children with more than two negative tests results performed after the age of 6 months (and completed more than 1 month apart) may be considered HIV negative. For initial screening in children over the age of 18 months of age, the ELISA test may be used. Again, positive results should be confirmed by repeat testing.

Nursing Care

The primary concern for early and accurate identification of children with HIV infection is beginning treatment. The goals of treatment for HIV-positive children are to slow progression to AIDS, prevent further infections, promote normal growth and development, prevent complications including cancers, and prolong and improve quality of life.

Caring for children with HIV/AIDS is a multifaceted process and includes both psychological and physiological care. Because the diagnosis and treatment for HIV can be devastating, it is important for the nurse to provide psychological care. First, the nurse must assess the family's support systems and coping mechanisms. The nurse must also assess the family's ability, desire, and skills needed to care for the child. The nurse can ask about extended family or other avenues for support such as church groups, community agencies, and friends. If the mother is also infected with HIV, the nurse must determine the best way to care for both patients. It is critical to help the family access available resources such as social workers, pastors, insurance companies, and community health clinics. Often, the acute care setting nurse can initiate the coordination of ongoing care by contacting a case manager. The case manager can then assist the family through the complexities of the health care system.

Physiological nursing care for HIV is supportive, as there is no cure for infection with the virus. Priority nursing care focuses on decreasing the potential for opportunistic infection. The nurse must be ready to manage the infections that the child acquires. Often prompt and vigorous antimicrobial therapy for treatment of infections is needed. *Pneumocystis carinii* is a common infection that occurs in early infancy before absolute confirmation of HIV status. For this reason, according to current CDC guidelines, all infants born to HIV-infected mothers are routinely started on a prophylactic antibiotic regimen for this organism. Trimethoprim-sulfamethoxazole (TMP-SMZ) (Bactrim or Septra) is the agent of choice for this treatment. Intravenous immune globulin has also been used to prevent bacterial infections in children younger than the age of 2 year of age. In addition, the nurse can teach the family signs and symptoms of infection and encourage them to limit the child's exposure to large crowds of people and those with notable infections.

Labs: HIV Testing

There are two primary methods for confirming the diagnosis of HIV:

Enzyme-linked immunosorbent assay (ELISA) is a test that identifies the presence of HIV antibodies and is performed within 48 hours after birth. ELISA is fairly inexpensive, but is not as sensitive as polymerase chain reaction and sometimes produces some false-negative results. The use of ELISA is also ineffective in children younger than 18 months owing to the presence of maternal antibodies.

Polymerase chain reaction (PCR) is a test that identifies the proviral DNA specific to HIV. The PCR is more expensive but has greater sensitivity. However, the PCR has a greater number of false-positive results.

Labs: Blood Culture

Blood does not normally contain any bacteria or fungi. A simple blood culture can detect bacteria or fungi in the blood. Children with weakened immune systems (e.g., as a result of AIDS, cancer, chemotherapy, or medications such as corticosteroids) are more susceptible to an infection in the blood. To test for an infection in the blood, a phlebotomist draws a sample of blood from a vein. In the laboratory, the blood sample is mixed with substances that promote the growth of bacteria or fungus. In most cases, bacteria can be detected in the blood culture within 2–3 days. Some types of blood infections can take 10 days or longer to detect and results of tests for fungal infections in the blood can take up to 30 days. A normal blood culture (negative) result indicates that no bacteria or fungus has been found in the blood. An abnormal (positive) result indicates that bacteria or fungus have been found in the blood.

A significant concern in children with HIV is the risk of rapidly progressive disease with commensurate high mortality in infancy. There is no reliable indicator for which children will develop rapidly progressive disease and which children will have a slower course of disease progression. For children with the HIV virus, there are several recommendations for antiviral treatment that are in a constant state of revision and controversy. Following are the most recent recommendations from the National Guideline Clearinghouse (2008).

- Antiviral treatment is *initiated* for children under 1 year with known or suspected HIV and who have clinical symptoms
- Antiviral treatment is *considered* for children under 1 year who are asymptomatic
- Antiviral treatment is *initiated* in children older than 1 year with known or suspected HIV and who have clinical symptoms
- Antiviral treatment is *strongly recommended* for children with overt AIDS or severe depression of immune response, characterized by rapidly declining CD₄⁺ levels
- Antiviral treatment is *considered* in children with mild–moderate clinical symptoms with depressed but not rapidly declining CD₄⁺ levels
- Antiviral treatment *may be* postponed for those children who are asymptomatic

ANTIVIRAL THERAPY. Antiviral therapy includes nucleoside analogs or nucleoside reverse transcriptase inhibitors (NRTIs) such as zidovudine (AZT), didanosine (Videx), zalcitabine (Hivid), stavudine (Zerit), or lamivudine (Epivir) that inhibit the action of viral reverse transcriptase, an enzyme in the conversion for RNA to DNA. Common side effects of these medications include fever, headache, insomnia, myalgia, nausea, vomiting, diarrhea, anorexia, and bone marrow suppression. The nurse can help the family understand the importance of antiretroviral therapy and teach parents the common side effects. Other considerations for antiretroviral therapy include actual delivery of the medication to the child in a safe and effective manner, using the five rights of medication administration. It is important for the nurse to note that many antiretroviral medications are not well tolerated by children due to taste. In addition, the medication regimen can be quite complex, requiring the family to adhere to a complicated schedule of medication administration and

medication: Trimethoprim-Sulfamethoxazole (TMP-SMZ; Bactrim or Septra)

Trimethoprim-sulfamethoxazole (trye-**meth**-oh-prim/sul-fa-meth-ox-a-zole)

Indications: Prevention of *Pneumocystis carinii* pneumonia (PCP). Prevention of bacterial infections in an immunosuppressed child.

Actions: Combination inhibits the metabolism of folic acid in bacteria at two different points.

Therapeutic Effects: Bactericidal action against susceptible bacteria.

Pharmacokinetics:

Absorption: Well absorbed from the GI tract.

Contraindications and Precautions:

Contraindicated in: Hypersensitivity to sulfonamides or trimethoprim, megaloblastic anemia secondary to folate deficiency, severe renal impairment, and children younger than 2 months of age.

Adverse Reactions and Side Effects: Hepatic necrosis, nausea, vomiting, diarrhea, toxic epidermal necrolysis, Stevens–Johnson syndrome, erythema multiforme, rashes, agranulocytosis, aplastic anemia, and phlebitis with IV insertion.

Route and Dosage for PCP Prevention:

PO (CHILDREN): 75 mg/m³ TMP/325 mg/m³ SMZ q12h on 3 consecutive days/week. Not to exceed 320 mg TMP/1600 mg/SMZ per day.

Nursing Implications:

1. Assess child for infection. Advise the family to notify the health care provider for any signs of infection.
2. Assess for allergy to sulfonamides.
3. Monitor lab values periodically throughout therapy. May produce elevated serum bilirubin, creatinine, and alkaline phosphatase.

Data from Deglin, J.H., & Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

monitoring. The nurse can assist the family about how to understand the prescribed medicine routine by creating a written schedule of medications, common side effects, and when to call the physician.

SYMPTOMATIC AND SUPPORTIVE CARE. Symptomatic and supportive care of children with AIDS is similar to that for children with immunodeficiency conditions (see Nursing Care Plan: The Child with Immunosuppression). Essential in the child's care are palliative and comfort care measures. Proper hygiene, comfortable clothing, good nutrition, play, rest, and social interaction are all important aspects of care for the child. The nurse should ensure good communication between the family and health care professionals to facilitate a realistic ongoing treatment plan.

Adolescents present their own specific challenges when infected with HIV. Based on their desire to be independent, an adherence to complicated treatment regimens may be a struggle. The nurse must work closely with the adolescent to identify strategies for managing a complex medical illness with the need to be independent and socialize with peers. Often, referral to an adolescent support group is helpful for children in this age group.

Another aspect when caring for the HIV-positive child is immunizations. Immunization is usually not a controversial treatment component. In general, children should receive all immunizations including pneumococcal and influenza vaccines. Live vaccines, such as varicella and measles–mumps–rubella (MMR), can be administered if

the immunocompromise is not severe. Additional boosters may be needed for children with HIV due to decreased ability to produce antibodies.

PAIN MANAGEMENT. Pain management is a significant care concern for children with HIV. Pain in children can be multifactorial, resulting from inflammation, systemic manifestation of AIDS such as cardiomyopathy, drug toxicities, invasive secondary infections, and medical procedures used to monitor and treat the HIV infection. The majority of HIV-infected children report pain as a factor affecting their daily lives. Successful management of pain is based on the same principles of pain management found in other illnesses. Diligence in identification of pain, goals, and strategies to manage pain, implementation of nonpharmacological and pharmacological pain management strategies, and ongoing pain assessments are all-important in the plan of care. Pain control is a major factor in quality of life and hence a primary goal for the nurse.

Complementary Care: Nonpharmacological adjuncts to pain management

Pain management in children with HIV can be challenging. Proper pain management involves both pharmacological and nonpharmacological strategies. Nonpharmacological techniques are based on the child's own experiences and preferences. Some examples of nonpharmacological techniques include guided imagery, hypnosis, prayer, meditation, music or aromatherapy. Nonpharmacological techniques also promote *preparation*, *distraction*, and *relaxation* for the child.

Developmentally appropriate *preparation* before painful procedures has been shown to decrease the anticipation of pain, thus decreasing the pain experience. Child life specialists may assist the nurse to prepare the child for procedures. Preparation may include diagrams, pictures, handling equipment, meeting personnel, or visiting special rooms, such as recovery or the intensive care units.

Distraction can be useful, particularly for younger children. Techniques such as blowing bubbles, singing songs, blowing pinwheels, or reading a favorite book may turn their attention away from the procedure. Family members can be encouraged to participate in distraction by providing a favorite toy.

Relaxation can be effective in pain control and actually decreases pain in the child. Nurses can teach relaxation skills to parents early in the course of HIV. A deep sense of relaxation can be obtained through guided imagery or hypnosis. The nurse can encourage parents to purchase or borrow easy-to-read relaxation books that will help them direct the relaxation with their child.

TREATING MALNUTRITION. Malnutrition, associated with either weight loss or obesity, is a common problem in children with HIV and a contributing factor to immune dysfunction. AIDS-induced diarrhea, coupled with the common symptom of anorexia, may lead to deficiencies of micro- and macro-nutrients as well as an overall deficit in caloric intake. A new problem that has surfaced is children who have become obese. Obesity occurs secondary to the side effects of some of the medications commonly used to treat HIV coupled with decreased physical activity. Malnutrition in the form of either weight loss or

obesity leads to poor nutrition in HIV-infected children, underscoring the need for continuous assessment and attention. The nurse understands that early involvement of a nutritional expert to provide consultation with the family is beneficial. The nutritionist can address specific nutritional needs and provide education about healthy dietary choices. In addition, the nutritionist can perform a nutritional assessment that includes monitoring heights and weights, evaluating laboratory values, and screening for dietary difficulties.

The nurse must understand that early use of oral supplementation is recommended to proactively meet nutritional goals. The overall goal of oral supplementation is prevention of malnutrition. In addition, aggressive oral care is emphasized as important to prevent oral lesions that may add to decreased intake. Another way to ensure adequate nutrition is the initiation of parenteral (tube) feedings. Parenteral feeding is used for the most severe cases in which all attempts at normal oral nutrition have failed. The inherent risks of invasive oral or nasal catheters can negatively affect the already immunocompromised child, making this a high-risk course of treatment. However, parenteral nutrition may correct the nutritional deficiencies and therefore is a consideration when other routes have failed.

THE TEAM APPROACH. Care of the child with HIV/AIDS is complex and best managed through collaboration with the family and others (nurse, physician, pain specialist, psychologist, nutritionist, social worker, child life specialist, and schoolteacher). The family is encouraged to view the team members as a collaborative team of professionals and then see themselves as equal participants in their child's care.

Collaboration in Caring— Collaboration between the family and others

Nurse: Provides coordination of team and acts as the bridge between the family and others, assists family and child to assume an active role in the care, identifies conditions requiring intervention, provides treatments or referrals as needed, helps the family create a livable plan for their unique situation

Physician: Provides and directs all medical care and monitors infections/complications, and growth and development

Pharmacist: Provides the medication and acts as a resource to help the family understand drug actions, interactions, dosing parameters, and adverse side effects

Pain specialist: Provides management for acute and chronic pain

Psychologist: Assists the child and family to identify positive coping strategies for life with HIV/AIDS.

Nutritionist: Provides early and ongoing support for nutritional needs

Social worker: Provides support, community resources, and possible ways to manage finances

Child life specialist: Provides support for normal development and coping strategies

Schoolteacher: Assists family with a realistic educational plan through episodes of illness

Now Can You—Discuss human immunodeficiency virus (HIV)?

1. Describe the pathophysiology of HIV?
2. Differentiate between tests used to diagnose HIV infection?
3. Describe symptomatic and supportive care measures for children with HIV/AIDS.
4. Discuss the importance of treating malnutrition in children with HIV/AIDS.

Transplantation

Stem cell transplantation is the surgical removal of tissue from one part of the body (or individual) and its implantation into another part of the body (or individual). There are three types of stem cell transplants: autologous, isogeneic, and allogenic. In **autologous** transplant, the child's own cells are taken, stored, and reinfused after the child has received chemotherapy. In **isogeneic** transplantation, the cells are taken from an identical twin, and in **allogeneic** transplantation the cells are from a donor (family member) who has a compatible human leukocyte antigen. The National Marrow Donor Program is used when no relative is found to match the child.

NURSING CARE

After the surgery, post-transplant immunosuppression is critical. Children are placed in a medically induced state of immunosuppression to maintain sufficient immune system function to resist infection while at the same time suppressing the immune system just enough to decrease the possibility of tissue rejection.

Nursing Insight— Monoclonal antibody

A monoclonal antibody is a type of antibody that is highly specific to a single antigen. These antibodies are generated in a laboratory setting. They identify and target microorganism, white blood cells, hormones, and tumor antigen. Monoclonal antibody is used to treat transplant rejection, autoimmune diseases, and certain cancers.

Medically induced post-transplant immunosuppression is accomplished in three phases; induction, maintenance, and rejection. In the *induction phase*, the child is given medications to suppress immune function. In the *maintenance phase* a combination of medications is often given to provide the correct amount of immunosuppression that allows the graft to flourish but does not leave the child vulnerable to infections. In an acute *rejection phase*, episodes are treated with increased immunosuppression medications to stop immune system attack on the graft site.

Corticosteroids are the drug of choice for medically induced immunosuppression because they are potent anti-inflammatory agents and act to inhibit T-lymphocyte activation and cytokine (proteins produced primarily by white blood cells) production (Copenhaver et al., 2004). However, corticosteroids are nonspecific in their action, producing a generally less responsive state of immune function. This presents a delicate balance for any child

undergoing corticosteroid treatment. Although these medications are used primarily in post-transplant scenarios, it is important to recognize that children with other conditions are treated with corticosteroids, such as children with asthma or an autoimmune disorder such as systemic lupus erythematosus. It is important for the nurse to remember that any child taking corticosteroids to prevent post-transplant rejection or other illnesses is at higher risk for infections secondary to a slow and inefficient immune response.

Nursing care for children taking immunosuppressive medications includes prevention of infection by limiting exposure to overcrowded areas and infected individuals, promotion of good nutrition and general health, and maintenance of barriers, including skin and mucous membranes. Early identification and aggressive treatment for any infection is paramount.

clinical alert

Administration of steroids

The nurse or parents must *never* stop the administration of any steroids abruptly due to adrenal insufficiency. Although adrenal insufficiency is a risk at any time with systemic administration of steroids, the greatest risk comes with sudden withdraw of the medication. Clinical manifestations of adrenal insufficiency include hypotension, weight loss, weakness, nausea, vomiting, anorexia, lethargy, confusion, and restlessness. Nursing implications include assessing for signs and symptoms of adrenal insufficiency. In addition, educating parents about taking steroids as ordered is essential. Steroids come in a dose package that specifically gives correct dosage and the exact number of pills that are taken each day. Steroids must be tapered slowly when it is time to discontinue the medication.

Autoimmune Disorders

An **autoimmune disorder** is the immune response against one of the body's own tissues or cells. Autoimmunity results from the body's inability to distinguish self from nonself, wherein the immune system carries out immune responses against normal cells and tissues. The disorders can be organ specific or systemic, as in systemic lupus erythematosus, juvenile rheumatoid arthritis, immune-complex diseases, and anaphylaxis.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is a multisystem chronic autoimmune disorder of the blood vessels and connective tissue. The exact cause of SLE is unknown, although it is tied to genetic predisposition coupled with unidentified trigger(s) that cause the disease to activate. Suspected triggers include estrogen, infections, ultraviolet light, pregnancy, and certain drugs. The signs, symptoms, and course of disease are variable and dependent on the exact body systems that are affected, ranging from mild to life threatening. SLE has unpredictable periods of exacerbation (flares-ups) and remissions (lessening in intensity or degree). SLE is most common in adolescent and young adult females, African Americans, and Hispanics.

medication: Methylprednisolone (A-Methapred)

Methylprednisolone (meth-ill-pred-niss-oh-lone)

Indications: Anti-inflammatory or immunosuppressant agent

Actions: Suppress inflammation and the normal immune response.

Therapeutic Effects: Suppression of inflammation and modification of the normal immune response.

Pharmacokinetics:

ABSORPTION: Well absorbed after oral administration.

Contraindications and Precautions:

CONTRAINDICATED IN: Acute untreated infections.

CAUTIONS: Chronic use in children will result in decreased growth. During stress (surgery, infections) supplemental doses may be needed.

Adverse Reactions and Side Effects: Peptic ulceration, anorexia, nausea, acne, decreased wound healing, hirsutism, petechiae and bruising, muscle wasting, osteoporosis, cushingoid appearance, and thromboembolism.

Route and Dosage:

 PO (CHILDREN): 0.417 mg/kg–1.67 mg/kg (12.5–50 mg/m²)/day in 3–4 divided doses.

 RECT (CHILDREN): 0.5–1 mg/kg (15–30 mg/m²) daily or every other day for at least 1 week.

 IV, IM (CHILDREN): 139–835 mcg/kg (4.16–25 mg/m²) every 12–24 hours.

Nursing Implications:

1. Assess for signs and symptoms of adrenal insufficiency (hypotension, weight loss, weakness, nausea, vomiting, anorexia, lethargy, confusion, restlessness).
2. Monitor fluid status, daily weights.
3. Monitor electrolytes and glucose levels.
4. Administer oral medications with food.
5. Instruct family regarding need to take medications as ordered due to risk of adrenal insufficiency with sudden withdraw of medication.
6. Instruct family regarding possibility of immunosuppression, need to avoid ill contacts and report possible infections to health care provider immediately.
7. Instruct family to inform health care provider promptly for severe abdominal pain, tarry stools, increased bruising, nonhealing sores, sudden weight gain, or behavioral changes.
8. Immunizations should be discussed with the health care provider on an individual basis.

Data from Deglin, J.H., & Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

SLE may have either an acute or a vague onset. The basic pathophysiology of SLE includes autoantibodies that attach to the body proteins, creating antigen–antibody complexes. These antigen–antibody complexes are then deposited throughout the body, causing widespread tissue damage. Systems affected vary widely, but kidneys, spleen, joints, and heart are most frequently involved.

Signs and Symptoms

The symptoms are highly variable in both presentation and severity. Typical symptoms may include a fever, malaise, chills, fatigue, and weight loss. As the disease progresses symptoms may include a characteristic malar photosensitive rash (butterfly rash on the face); arthritis; photosensitivity; serositis; proteinuria; immunological and hematological disorders, such as hemolytic anemia, lymphocytopenia, thrombocytopenia, and vasculitis; and an abnormal antinuclear antibody (ANA).

Diagnosis

Definitive medical diagnosis is based on the presence of four or more of the aforementioned symptoms. Laboratory tests include a complete blood cell count with differential, metabolic chemistry panel, urinalysis, antinuclear antibody, anti-DNA antibody, complement 3 (C3), complement 4 (C4), quantitative immunoglobulins, rapid plasma reagin (RPR), lupus anticoagulant, and antiphospholipid antibodies (Lehman, 2002).

Nursing Care

Nursing care is based on managing pain and inflammation, treating symptoms, and preventing complications. Treatment of pain and inflammation in mild SLE is generally accomplished with nonsteroidal anti-inflammatory medications (NSAIDs). Antimalarial medications are also used in mild SLE to control symptoms of arthritis, skin rashes, mouth ulcers, fever, and fatigue. The nurse needs to tell parents that it sometimes takes a long time before the therapeutic effects of antimalarial medications are evident.

Nursing care for severe (increased inflammation), SLE requires the addition of corticosteroids. Corticosteroids are given to the child when the child does not respond to NSAIDs or antimalarial medications. Corticosteroids are highly effective in reducing inflammation and symptoms, although they also have the serious side effect of immunosuppression. During an exacerbation period, corticosteroids may be initiated in high doses. After symptoms are under control, the dose is tapered down to the lowest therapeutic level. It is important to tell the parents that steroids must be tapered slowly when it is time to discontinue the medication.

The most potent type of medication used to treat severe SLE includes immunosuppressive agents. These medications are used when the disease has reached a serious state in which severe signs and symptoms are present. Immunosuppressive agents may also be prescribed if there is a need to avoid corticosteroids. The decision to use immunosuppressives requires serious consideration due to significant side effects, primarily related to general immunosuppression. Examples of immunosuppressive agents used in treatment of SLE include azathioprine (Imuran), cyclophosphamide (Cytoxan), and methotrexate (Rheumatrex). Each medication has unique and serious risks such as bone marrow depression and hepatotoxicity. The nurse must reinforce information on the action of the medication as well as the side effects with the parents before administration of this medication.

In addition to medication, nursing care also focuses on palliative care and providing psychosocial support. It is important that the child maintain good nutrition, rest and exercise, avoid the sun, and encourage the expression of feelings about the condition. Although there is no specific diet for SLE, a balanced diet, low in salt (if the child becomes hypertensive or nephrotic) is encouraged. Rest and exercise include periods where the child is active during remissions and is resting during exacerbation. Avoidance of sun exposure is stressed because of the photosensitive rash that occurs with SLE. Use of sunscreen is important, and planning outdoor activities in the shade or staying indoors may be necessary. Because this condition may be difficult for the child and family to cope with and understand, encouraging the expression of feelings or

joining a support group is encouraged. Parents should notify teachers, coaches, and others about their child's condition so they can help monitor the child and obtain necessary treatment if needed. It is also the nurse's responsibility to help the child and family identify possible triggers, such as sunlight and emotional stress, and assist the family to find ways to avoid them.

clinical alert

Systemic lupus erythematosus

SLE is a condition with varying signs and symptoms that require continued careful assessment to ensure prompt recognition of an exacerbation. Prevention of exacerbations is the most important component of nursing care for children with SLE. It is important for the family to understand the importance of rest and adequate nutrition to help maximize immune system function. This disease often affects adolescents, so the facial rash, fatigue, and arthritic changes may put the child at risk for depression and altered body image. Referral to support groups helps the child to adjust to life with SLE.

Nursing Insight— SLE resources

The nurse can encourage an adolescent recently diagnosed with SLE to contact a local support group. In addition, several good resources are available online through the organizations located at the following Web sites:

- Lupus Foundation of America
<http://www.lupus.org/>
- National Institute of Arthritis and Musculoskeletal and Skin Disorders
<http://www.niams.nih.gov>
- SLE Foundation, Inc.
<http://www.lupusny.org/>
- Association of Rheumatology Health Professionals, American College of Rheumatology
<http://www.rheumatology.org/>
- Arthritis Foundation
<http://www.arthritis.org/>

JUVENILE RHEUMATOID ARTHRITIS

Juvenile rheumatoid arthritis (JRA) is a chronic autoimmune inflammatory disease and is the most common type of arthritis in children. There are three types of JRA:

- Pauciarticular: Affects the knees, ankles, and elbows; more frequent in females
- Systemic: Characterized by high fever, polyarthritis, rheumatoid rash, joints and internal organs; affects males and females equally
- Polyarticular: Involves five or more joints (usually small joints in the fingers and hands); may also involve ankles, knees, feet, hips, and neck

The cause of JRA is unknown, and it occurs in early (2 to 5 years of age) or later (9 to 12 years of age) childhood. If JRA has an early onset, there is better chance of complete recovery. This condition has typical cycles of remission and exacerbation. Remission can last for months

or years. During the active disease state, children experience decreased mobility, swelling, and pain due to joint inflammation. Scar tissue eventually develops, resulting in limited range of motion and interference with normal growth and development. Other organs such as the heart, lungs, liver, and eyes can eventually be affected.

Signs and Symptoms

Symptoms of JRA can be limited to a few joints or multiple joints. Initially, parents may notice the child limping, favoring a particular joint, complaining of pain, uneven growth in a limb, swelling in large joints (knees), loss of motion, and stiffness. Other symptoms include fever, rash, lymphadenopathy, hepatomegaly, and splenomegaly. The main complication for children with JRA is interference with growth and development.

Diagnosis

The physician bases diagnosis on the assessment findings, reported history, and laboratory tests such as rheumatoid factor, antinuclear antibody, and human leukocyte antigen (HLA).

Nursing Care

The priority nursing goal is to relieve pain and prevent contractures. Nursing care for the child with JRA includes guiding the family through medical appointments, drug therapy, physical therapy, other important care aspects, and surgery if necessary. The child with JRA can spend significant time in a physician's office. The nurse can provide parental support, answer questions, and communicate concerns and complications to the physician. Drug therapy includes the use of salicylates (aspirin) or nonsteroidal anti-inflammatory drugs such as Naproxen (Aleve), sulfasalazine (Salazopyrin), and methotrexate (Rheumatrex) may be prescribed if the child does not respond to salicylates. If the disease moves into a more severe state, steroids may be used.

A common treatment for JRA is ongoing physical therapy. The use of therapeutic exercise can restore or facilitate normal function or development in the child with JRA. Children should also be encouraged to perform activities of daily living. During bouts of pain and inflammation, warm compresses can be applied.

Other important care aspects include providing good nutrition, teaching the child and family how to manage the disease, offering support, devising proper school accommodations, and expressing the importance of routine medical visits. Some states offer summer camps for children with JRA. The camp environment gives the child a chance to have fun and the parent a needed respite. The web site: <http://www.arthritis.org/> offers essential information for children and families. In children with contractures, surgery may help relieve pain or improve joint function.

Nursing Insight— Immune-complex diseases

Immune-complex diseases occur when antibodies attach to antigens and destroy them. These complexes circulate in the blood and attach to the walls of blood vessels, producing a local inflammatory response. Examples of immune-complex diseases include glomerulonephritis, serum sickness, arthritis, and vasculitis (Venes, 2009).

Allergic Reaction

ANAPHYLAXIS

The body reacts to a foreign substance called an antigen (such as allergens, foods, animals, chemical agents, or fungal spores) that set off an allergic reaction (Venes, 2009). The most severe allergic reactions are associated with insect bites, latex products, penicillin medications immunizations, blood, or radiological contrast media. A severe allergic reaction is called anaphylaxis. **Anaphylaxis** is the immediate hypersensitivity reaction to an excessive release of chemical mediators affecting the entire body. Anaphylaxis is a medical emergency.

Signs and Symptoms

Signs and symptoms of anaphylaxis develop suddenly and require prompt recognition and treatment.

Nursing Insight— Signs and symptoms of anaphylaxis

Wheezing
Tachycardia
Hypotension
Cyanosis
Alteration in level of consciousness
Nasal congestion
Facial edema
Anxiety
Hives
Urticaria
Nausea and vomiting
Abdominal pain
Laryngospasm
A sense of impending doom
Vascular collapse and cardiac arrest

Diagnosis

Diagnosis of anaphylaxis is based on the exposure to the antigen and the signs and symptoms.

Nursing Care

Critical Nursing Action Anaphylaxis

Immediate nursing care for anaphylaxis includes the following actions:

- Perform cardiopulmonary resuscitation.
- Activate the emergency system.
- Ensure adequate airway—endotracheal intubation or oxygen.
- Administer epinephrine (adrenaline).
- Place a tourniquet proximal to the site of injection or insect sting.
- Keep the child lying flat, warm, and with feet slightly elevated.
- Administer corticosteroids and antihistamines.
- Determine the cause of the attack.

Basic life support must be initiated with support of airway, breathing, and circulation (ABCs). Administration of oxygen and initiation of an intravenous (IV) therapy with an isotonic crystalloid solution as soon as possible are

medication: Epinephrine (Adrenaline)

Epinephrine (e-pi-nef-rin)

Indications:

IV: Management of severe allergic reactions

Actions: Inhibits the release of mediators of immediate hypersensitivity reactions from mast cells.

Therapeutic Effects: Maintenance of heart rate and blood pressure.

Pharmacokinetics:

Absorption: Well absorbed.

Contraindications and Precautions:

CONTRAINDICATED IN: Hypersensitivity.

Adverse Reactions and Side Effects:

CNS: Nervousness, restlessness, tremor.

CV: Arrhythmias, hypertension, tachycardia.

Route and Dosage:

IV (SEVERE ANAPHYLAXIS): 0.1–0.25 mg q 5–15 min; may be followed by a 1–4 mcg/min continuous infusion (may be increased up to 1.5 mcg/kg per minute).

Nursing Implications:

1. Assess volume status. Hypovolemia should be corrected before administration of IV epinephrine.
2. Monitor blood pressure, perfusion, ECG, respiratory rate, and urine output during administration.
3. Assess for hypersensitivity reaction: rash, urticaria, swelling of face, lips, eyelids.
4. IV administration: Administer at a dilution of 1:10,000. This may be prepared through dilution of 1 mg of 1:1000 solution in at least 10 mL of 0.9% NaCl.
5. Administer each 1 mg of 1:10,000 solution over at least 1 minute.

Data from Deglin, J.H., & Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

standard treatment. Epinephrine (adrenaline) injection is administered intramuscularly or intravenously to provide reversal of pulmonary bronchospasm and constriction of blood vessels, thereby improving respiratory status and blood pressure. Ongoing assessment for shock is necessary and can be treated via IV fluid bolus. Occasionally antihistamines and corticosteroids may be added to further control symptoms after the initial stabilization. The majority of children respond positively to the treatment, with a full recovery.

For children who have experienced an anaphylaxis reaction the nurse must provide follow-up care to families to prevent recurrences. If the child has allergies that cannot be completely eliminated, a follow-up referral to an allergist for desensitization treatments or a self-administration epinephrine prescription, such as an EpiPen. It is important that parents are taught to recognize early indicators of anaphylaxis and are confident in their ability to act quickly on this assessment.

Collaboration in Caring— Peanut allergies in school

According to data from the National Institute of Allergy and Infectious Disease, approximately 3% of school-age children in the United States are affected by peanut allergies.

Exposure to peanuts for a sensitive child may result in symptoms ranging from simple hives and itching to anaphylaxis. For children with severe allergies a seemingly insignificant exposure, such as coming in contact with a cafeteria table that have been brought in contact with a peanut or oils from a peanut, may result in a rapidly progressive life-threatening reaction. The pediatric nurse plays a critical role in collaboration with the family and school personnel to create an environment for a child with peanut allergy to safely attend school. The nurse assists the family in establishing a coordinated plan including the following key components:

- Education of the school staff regarding peanut allergies. Include all staff who may be supervising this student and who may be in a position to recognize and intervene in an emergency.
- Outline an emergency plan specific for this student to include:
 - Specific instructions for staff in the event of a reaction
 - Location of emergency medications
 - Identification and elimination of risks
 - Emergency phone numbers
 - Establish a “peanut-free” zone in the cafeteria.
 - Send a letter to parents who may provide snacks to the child, such as parents of children in the same class, from a sports team, or a club, informing them of the presence of a child with severe peanut allergy.

medication: Diphenhydramine (Benadryl)

Diphenhydramine (dye-fen-**h**ye-dra-meen)

Indications: Relief of allergic symptoms caused by histamine release, including anaphylaxis, allergic rhinitis, allergic dermatoses. Relief of pruritus.

Actions: Antagonizes the effects of histamine at H₁-receptor sites. Significant CNS depressant and anticholinergic properties.

Therapeutic Effects: Decreased symptoms of histamine excess (sneezing, rhinorrhea, nasal and ocular pruritus, ocular tearing and redness, urticaria).

Pharmacokinetics:

ABSORPTION: Well absorbed after oral or IM administration.

Contraindications and Precautions:

CONTRAINDICATED IN: Hypersensitivity.

Adverse Reactions and Side Effects: Drowsiness, paradoxical excitation (more common in children), anorexia, dry mouth.

Route and Dosage:

PO (CHILDREN 6–12 YEARS): 12.5–25 mg q4–6 h.

PO (CHILDREN 2–6 YEARS): 6.25–12.5 mg q4–6 h.

IM/IV (CHILDREN): 1.25 mg/kg 4 times/day. Not to exceed 300 mg/day.

Nursing Implications:

1. Provide child and family education regarding medication, caution not to exceed recommended dose.
2. Inform parents that medication may cause drowsiness or excitability in child.
3. Provide education regarding common side effect of dry mouth. Management strategies include frequent mouth care and oral rinses.

Data from Deglin, J.H., & Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

Now Can You— Recognize and intervene in anaphylaxis?

1. Identify the life-threatening symptoms of an anaphylaxis reaction?
2. Prioritize interventions in treatment of an anaphylaxis reaction?

Infectious Diseases of Childhood

INFECTION

The occurrence of infectious disease in children is the result of an interaction between several factors including the child, the environment, and the agent causing the illness (Table 26-1). There are two main models used to illustrate this relationship, the most common being the epidemiological triangle (Fig. 26-2).

In the epidemiological triangle the host, environment, and agent make up the three sides of an equilateral triangle. The *host* is the organism from which a parasite obtains its nourishment, the *environment* is the surroundings or conditions that influence the organism, and the *agent* causes the actual effect (disease) (Venes, 2009). This model illustrates the codependence that these three factors have on one another and recognizes that change in any one of the three factors will influence the risk or probability of a child contracting the disease.

Many factors unique to the pediatric population such as age, sex, physical, and psychosocial factors all play a role in the susceptibility of the host to an infectious disease. The normal development of the child's immune system is also a major factor in many infectious diseases especially during the early childhood years.

The final element in the triangle, the agent contains specific information, including infectivity, pathogenicity, and virulence, that assists the nurse in developing the appropriate plan of care. Infectivity is the mode of transmission, incubation period, and communicable period. The mode of transmission is how the pathogen actually gains access to the body. With this knowledge, the nurse can plan care to eliminate unnecessary portals of entry (multiple IV sites) and thoroughly inspect the skin on a routine basis. Knowledge about the incubation period (onset of symptoms) to the actual illness or the

Table 26-1 Communicable Diseases in Childhood

Disease	Clinical	Treatment	Complications
<p>Chickenpox (Viral)</p>  <p><i>Causative Agent</i> Varicella-zoster virus, a herpes virus.</p> <p><i>Epidemiology</i> Highly contagious disease Peak incidence in spring</p> <p><i>Mode of Transmission</i> Airborne and spread through contact with respiratory secretions and contact with lesions</p> <p><i>Infection Control</i> Incubation period from 13 to 17 days. Children are considered contagious 1 day before the eruption of lesions to the time when all lesions have crusted, or up to 6 days after appearance of the rash. The period of communicability may be prolonged in children who are immunocompromised. Airborne and contact precautions are needed for hospitalized children during the period of communicability.</p>	<p>Manifestations</p> <p>Acute onset of malaise, fever, and irritability followed by rash</p> <p>Rash described as a “tear drop on a rose petal.” Begins with a macule on a red base, this progresses to a clear vesicle, later forms a crust. The lesions are severely pruritic and eruptions may continue to occur for up to 5 days.</p> <p>Generally first appears on the face and trunk, but may spread anywhere on the body.</p>	<p>Supportive</p> <p>Varicella zoster immune globulin (VZIG) may be given to within 72 hours of exposure to immunocompromised children following exposure with the goal of preventing the disease. VZIG provides only temporary immunity so is reserved only for high risk individuals who are unable to receive vaccine.</p> <p>Acyclovir used for immunocompromised child presenting with chickenpox.</p> <p>Must be used within 24 hours of onset to be effective</p> <p>Oral antihistamines, baking soda, oatmeal baths, and calamine lotion to manage itching</p>	<p>10% of the children with chickenpox develop a complication.</p> <p>Immunocompromised children have high risk for complications (including those on steroids for treatment of asthma).</p> <p>Most common complications are bacterial superinfections of lesions, encephalitis, varicella pneumonia, and thrombocytopenia. Use of aspirin-containing medications has been linked with Reye syndrome in children with chickenpox</p>
<p>Diphtheria (Bacterial)</p>  <p><i>Causative Agent</i> <i>Corynebacterium diphtheriae</i> bacillus</p> <p><i>Epidemiology</i> Occurs mostly in fall and winter and in unimmunized or partially immunized persons</p>	<p>Gradual onset of symptoms with a low-grade fever, anorexia, malaise, rhinorrhea, cough, hoarseness, stridor, cervical lymphadenitis, and pharyngitis</p> <p>Hallmark sign is fuzzy gray or black covering over the tonsils, hard and soft palates, and posterior pharynx</p> <p>May produce profound difficulty breathing due to narrowing of the upper airway.</p>	<p>IV antitoxin and antibiotics within 3 days of onset of symptoms (IV sensitivity testing must be done before administration)</p> <p>Oral antihistamines, baking soda or oatmeal baths, and calamine lotion to help control itching</p> <p>All contacts are given prophylactic antibiotic treatment and immunization boosters</p>	<p>Respiratory compromise secondary to the endotoxin produced membrane covering much of the upper airway</p> <p>Membrane may require removal, but bleeding may result in the endotoxin spreading beyond the respiratory tract to cause myocarditis, peripheral neuropathy, or an ascending paralysis similar to Guillain-Barré.</p>

Table 26-1 Communicable Diseases in Childhood—cont'd

Disease	Clinical	Treatment	Complications
<p><i>Mode of Transmission:</i> Transmitted through airborne droplets, contact with respiratory secretions, contact with contaminated household articles, close personal contact with infected persons.</p> <p><i>Infection Control</i> 2–7 days incubation period (may be longer) If not treated may remain contagious for up to 4 weeks Contagious for 4 days after antibiotic treatment instituted droplet and contact precautions used for hospitalized children</p>			
<p>Infectious Mononucleosis (Viral) <i>Causative Agent</i> Epstein–Barr virus (EBV). <i>Epidemiology</i> Most persons become infected with EBV sometime during their life (usually adolescence or young adulthood) Infection with EBV during this time of life causes symptoms of infectious mononucleosis 35%–50% of the time. <i>Mode of Transmission</i> Transmitted via intimate contact with the saliva of an infected individual <i>Infection Control</i> Incubation period is 4–6 weeks. Infected persons may shed virus intermittently and without symptoms throughout life No isolation beyond standard precautions needed</p>	<p>Fever, pharyngitis, and lymphadenopathy lasting from 1 to 4 weeks Fatigue and some degree of hepatosplenomegaly</p>	<p>Steroids may be considered in the case of respiratory difficulty secondary to swelling of the upper airways</p>	<p>Respiratory compromise secondary to airway swelling and exudative pharyngitis, aseptic meningitis, encephalitis. Rarely splenic rupture Possible thrombocytopenia and agranulocytosis.</p>
<p>Fifth Disease (Erythema Infectiosum) (Viral)</p>  <p><i>Causative Agent</i> Human parvovirus B19 <i>Epidemiology</i> Children 5–14 years of age, most often during spring <i>Mode of Transmission</i> Transmission via contact with respiratory secretions <i>Infection Control</i> Incubation period for 4–14 days. Contagious before onset of rash. No isolation required</p>	<p>Stage 1: 2–3 days, mild systemic symptoms that mimic flu Stage 2: deep red rash appears on cheeks, circumoral pallor; 1–4 days later a symmetric, lacy red rash appears on the trunk and limb Stage 3: lasts 1–3 weeks, the rash disappears, but may reappear after exposure to sunlight or heat</p>	<p>Treatment is symptomatic.</p>	<p>Arthralgia and arthritis are the most common complications in otherwise healthy children. Children with underlying hemolytic conditions may experience transient aplastic crisis requiring hospitalization Fetal death may occur if mother is infected during pregnancy Exposure to sunlight and heat may exacerbate the rash</p>

Disease	Clinical	Treatment	Complications
<p>Scarlet Fever (Bacterial)</p>  <p><i>Causative Agent</i> Group A beta-hemolytic streptococci (GAS)</p> <p><i>Epidemiology</i> Occurs secondary to a pharyngeal infection with GAS. This is seen most frequently in late fall through spring.</p> <p><i>Mode of Transmission</i> Spread through direct contact with infectious respiratory secretions</p> <p><i>Infection Control</i> Incubation period is 2–5 days Children with untreated infections remain contagious for weeks with the highest risk of transmission during the acute phase of the illness. Children should remain home from school until both 24 hours and initiation of treatment and afebrile.</p>	<p>Acute onset of fever, sore throat, rhinitis, headache, and tender cervical nodes</p> <p>Sandpaper-like rash appears 12–48 hours after onset of symptoms, rash is most prominent in creases and blanches to touch</p> <p>In 3–4 days, the rash begins to fade and the tips of toes and fingers begin to peel. On day 4–5 bright red strawberry tongue develops.</p>	<p>Antibiotics</p> <p>Supportive care for throat pain and fever</p>	<p>Untreated strep infections may lead to retropharyngeal abscess, acute rheumatic fever, acute glomerulonephritis, toxic shock syndrome, bacteremia, and necrotizing fasciitis</p>
<p>Tetanus (Bacterial)</p>  <p><i>Causative Agent</i> <i>Clostridium tetani</i>.</p> <p><i>Epidemiology</i> Not transmitted person to person</p> <p><i>Mode of Transmission</i> Occurs in humans through wounds which come in contact with soil contaminated with the <i>Clostridium tetani</i> bacillus Most common in children this is secondary to a cut or deep puncture wound Neonatal tetanus occurs in newborns delivered in unsanitary conditions</p> <p><i>Infection Control</i> The incubation period for tetanus is 2–14 days Prevention is immunization and postexposure prophylaxis. Neonatal tetanus prevented through improved sanitation of delivery condition.</p>	<p><i>Clostridium tetani</i> produces a neurotoxin that affects the muscles and nerves</p> <p>Early signs are headache and restlessness, followed by stiffness of the neck and jaw. This stiffness progresses to painful spasms of the masticatory muscles accompanied by difficulty opening the mouth and dysphagia. Localized painful muscle spasm may begin to occur at the site of the wound. This eventually progresses up the trunk to the point of opisthotonos, a severe spasm of back muscles, causing the back to arch acutely</p> <p>As the neurotoxin spreads widely throughout the body, seizures are possible</p>	<p>Administer tetanus immune globulin (TIG) to neutralize the neurotoxin Antibiotics eliminate the bacillus from the body</p> <p>Surgical débridement of the wound to control infection Antispasmodic agents, such as diazepam (Valium) to reduce spasms.</p>	<p>Potential for spasms in all muscle groups</p> <p>Laryngospasm</p> <p>Respiratory muscle spasms (may compromise breathing and lead to death)</p>

time that the child is able to transmit the pathogen to others (communicable period or portal of exit) allows the nurse to alert others that the child is infectious and isolate the child for a certain period.

Pathogenicity is the percentage of those children exposed to the pathogen that will eventually develop the disease. This information is helpful to the nurse in the community when assessing citywide outbreaks. The nurse can notify schools, community centers, churches, shopping malls, and other public places that an outbreak exists and that it is best to avoid these areas, especially for high-risk children. **Virulence** is the severity of the health problems caused by the agent. The more virulent the disease the more necessary it is to curtail its the spread. For example, in winter, during an influenza outbreak, a number of schools close so they can be thoroughly cleaned and sanitized. Pathogenicity and virulence are often key considerations in development and implementation of public health programs.

Although the epidemiological triangle is useful in understanding the interdependence of factors involved in infection, understanding the Chain of Infection Model is also important (Fig. 26-3). The model illustrates the steps that must occur for transmission as well as demonstrating possible ways to stop transmission of the disease. For instance, a pathogenic microorganism or a disease-causing agent is present. The agent must have a reservoir where the pathogen can grow. Reservoirs may be human hosts, animals, and the soil. With knowledge about the reservoir, the nurse can eliminate it to break the chain. A mosquito abatement program to control West Nile virus is an example about of an attempt to alter the chain of infection via reservoir elimination.

Public health immunization campaigns are another example of a way to decrease the reservoir for diseases. The next three links in the chain involve the escape of the pathogen from the reservoir into the host. Knowledge about the routes of transmission (contact, droplet, airborne) enables the nurse to initiate appropriate isolation precautions. The final link involves a susceptible host. Susceptibility is decreased mainly via good general health practices such as good hygiene, nutrition, and decrease in stress.

Figure 26-3 Chain of infection model.

Nursing Insight—Infections

There are three types of infections: bacterial, viral, or fungal.

- Bacterial infections are caused by single-celled living microorganisms and include *Streptococcus*, *Staphylococcus*, and *Escherichia coli*. Common bacterial infections are described in Chapter 24.
- Viruses (e.g., influenza, HIV) are not living organisms and require living hosts (such as people, plants, or animals) to multiply. Some viral infections are contagious while others are not.
- Fungal infections are pathological invasions of the body by yeast or other fungi (e.g., athlete's foot, yeast infections). Fungal infections are most likely to occur in children with a compromised immune system (Venes, 2009).

It is important to understand the differentiation between bacterial, viral, and fungal infections so the proper medication is given. Antibacterial antibiotics treat bacterial infections, antiviral antibiotics are available to treat some types of viral infections, and antifungal agents are used to treat fungal infections.

Signs and Symptoms

Although each infectious condition has unique signs and symptoms, several symptoms are common in varying degrees among several illnesses. Common signs and symptoms can include fever, malaise, anorexia, and pruritus (itching) from rashes.

Diagnosis

Diagnosis of an infectious disease is confirmed by type of infection, signs and symptoms, along with various diagnostic means.

diagnostic tools Identification of an Infectious Disease

- Complete blood count (CBC) with differential
- Urinalysis (UA)
- Spinal fluid analysis
- Cultures from fluids, secretions, drainage
- Pulse oximetry
- Chest radiograph
- Computerized tomography

Nursing Care

Building on the scientific foundation of immunology, the pediatric nurse can provide specific care measures to promote immune function and to provide education to families.

critical nursing action Skin Care and Nutritional Support

Simple nursing actions such as good skin care and nutrition help maintain the barriers and the natural immune response. The skin can be maintained by good hygiene measures such as hand washing and paying attention to any breaks or openings on the skin surface. Through good nutrition, the innate physical, chemical, and mechanical barriers are preserved and the risk for infection is decreased. Adequate nutrition also promotes prompt healing and decreases the potential for skin breakdown. Maintaining barriers and the immune response is particularly important in children whose immune system is not yet fully mature and for children who are at risk for immunosuppression.

An important topic in education is promoting stress reduction in children. Stress in children may also negatively affect the immune system and is associated with increased risk for infections. Recent advances in science support the connection between daily life stress and immune function in children. Although the exact mechanism is unknown, more than one negative life event positively correlated with a significant drop in helper T cells in children with AIDS (Howland et al., 2000). This kind of information can help the nurse promote optimal immune function through minimizing negative life events for children.

Nursing care for the child with an infectious disease also centers on accurate assessment, prevention of disease transmission, treating the signs and symptoms, teaching families about universal precautions, and preventing complications.

assessment tools Key Components of Physical Assessment for the Child with an Infectious Disease

Vital Signs

- Temperature
- Heart rate
- Respiratory rate
- Blood pressure
- Pain

Respiratory Assessment

- Upper respiratory infection symptoms
- Breath sounds
- Work of breathing
- Pulse oximeter reading
- Skin/mucous membrane color
- Secretions; color, character, amount

Neurological Assessment

- Febrile seizures
- Early identification of neurological complications
- Level of consciousness

Gastrointestinal Assessment

- Fluid intake
- Presence of vomiting or diarrhea

Skin

- Presence of rash, pruritus, lesions

Across Care Settings: Caring for the child with an infectious disease

The majority of children with an infectious disease are cared for in the home or by a child care provider.

Nursing care for the children and their families includes prevention of common illnesses along with their complications. Prevention of disease transmission within the family or community is essential. Key points to prevent transmission include:

- Good hand washing practices
- Covering the mouth and nose when coughing or sneezing
- Disposal or cleansing of articles contaminated with respiratory or gastric secretions such as tissues, blankets, and toys
- Early identification of illness, with isolation from other children during infectious stages

The nurse can assist families in managing the signs and symptoms. Fever is common. The nurse can teach parents about the use of acetaminophen (Children's Tylenol) or ibuprofen (Children's Advil) for treatment of fevers. It is essential that parents follow the directions on the medication label. Cool moist compresses to the head, as well as sponging or tepid baths can reduce the fever.

Nursing Insight— Pathophysiology of a fever

The hypothalamus is the thermostat of the body. As blood circulates through the hypothalamus, it directs the various body organs to either conserve or dissipate the heat (depending on the blood's temperature). If the body temperature is lower than normal, vasoconstriction is initiated to conserve heat or shivering/chills occurs that increases heat production. When a child has a fever (excess heat) the body's temperature, heart, and respiratory rates increase. Vasodilatation occurs and the skin becomes flushed and warm to the touch. When the fever "breaks" the child may start to perspire and the heart and respirator rates return to normal.

clinical alert

Reye syndrome risk with use of aspirin

The administration of salicylates (aspirin) to children with acute viral illness is linked to Reye syndrome. It is critical that nurses teach parents about Reye syndrome and provide education regarding use of aspirin-free medications for control of fever in children (National Reye Syndrome Foundation: www.reyessyndrome.org/).

Common medications that contain salicylates (aspirin) are:

- | | |
|---|----------------------------|
| • Alka-Seltzer | • Ecotrin |
| • Anacin | • Excedrin |
| • Ascriptin | • Kaopectate |
| • Bayer Arthritis Pain and Aspirin preparations | • Pamprin |
| • Bufferin | • Pepto-Bismol |
| • Doan's | • Sine-Off Sinus Medicaine |
| • Dristan | • St. Joseph Adult Aspirin |
| | • Vanquish |

Malaise (weakness) tends to correlate with fevers and providing a quiet, restful environment during the acute phase of illness may assist in the management of this symptom. If the child is anorexic, offering small amounts of fluids frequently helps keep the child hydrated. Sometimes a room temperature lemon-lime soft drink or ice-pop will taste good to the child. Also offering small amounts of favorite foods, soft foods, or bland foods may help with the anorexia. If the anorexia becomes worrisome to parents, the nurse can encourage them to contact their health care provider.

Pruritus is associated with many of the common infectious diseases and can be a source of distress for the child and a potential site for secondary infection due to skin breakdown. Educating the family about how to effectively control the itching is an important part of the nursing care plan. Parents may be advised to keep the child's fingernails short and place soft mittens on younger children to prevent scratching. Oatmeal or Aveeno baths may provide some

relief, as does Caladryl lotion. Parents are advised to change bed linens frequently and avoid use of harsh soaps during the time of illness to avoid further irritation. Light clothing often helps keep perspiration and heat rashes to a minimum. An oral antihistamine such as diphenhydramine (Benadryl) may be useful in cases of severe pruritus.

The pediatric nurse can educate families and day care providers about universal precautions. Emphasize hand washing, cleaning of toys and surfaces, and proper disposal of diapers. The pediatric nurse also provides education to families about the importance of excluding the child from school and other activities during the illness. Sound knowledge about the routes of transmission assists the nurse in developing a plan of care for the hospitalized child that includes environmental precautions that minimize the risk of transmission.

Optimizing Outcomes— Children with infectious diseases

The best outcome for the child with an infectious disease is the prevention and early identification of complications. The nurse must pay careful attention to fluid deficit, upper respiratory tract infection, and neurological difficulties.

Although potential complications are specific to each illness, there are general symptoms that are associated with many of the infectious diseases. Children with infectious disease often are at risk for developing a fluid deficit due to a combination of anorexia, nausea, vomiting, and sore throat. The nurse can assist families in managing fluid deficit by offering the child small amounts of liquids frequently and offering favorite fluids to the child such as juice, soda, or water. Respiratory infections are also common. A cool steamer, decongestants, or gentle nasal suctioning with a bulb syringe may help diminish respiratory difficulty. Neurological symptoms include general lethargy (sluggishness or tiredness) that may progress to decreased responsiveness. Generalized irritability that progresses to inconsolable crying, seizures, or meningeal symptoms, including stiff neck and photophobia, may be present. Parents must be instructed call the health care if these neurological symptoms occur or the child is unresponsive.

critical nursing action Seeking Immediate Help

Respiratory symptoms are a major component of many of the common infectious illnesses of childhood. Respiratory symptoms of concern include increased work of breathing; inability to swallow, including drooling of saliva; muffled voice; or very rapid or slow respirations. The nurse must instruct the family to seek help immediately if the child exhibits any of these signs of respiratory deterioration.

Common Viral Infections

There are more than 400 types of viruses, which are the smallest infectious agents known today. When a virus enters a cell, it can trigger a disease process immediately or remain dormant for many years. The virus can enter any organ of the body by attaching to the cell membrane,

assembling the cells into a more mature form that is then capable of affecting other cells and taking over cellular function. Viruses are responsible for such diseases as cytomegalovirus (CMV), herpes zoster, small pox (variola), and infectious mononucleosis.

CYTOMEGALOVIRUS INFECTIONS

Cytomegalovirus (CMV) is a member of the herpes family, infecting up to 85% of the population of the United States by the age of 40. CMV is transmitted via close contact with body fluids of an infected person. The disease is not highly contagious and transmission is easily prevented with good hand washing. Young children in daycare are a major reservoir for this disease. For non-immunocompromised children who acquire CMV after birth there are few symptoms and no long-term health consequences.

Signs and Symptoms

A few children will have symptoms similar to those of mononucleosis with a prolonged fever and mild hepatitis. Disease in a non-compromised host is self-limiting and requires no more than symptomatic support. After the initial infection with CMV the virus remains dormant in body cells. The virus may be reactivated with impairment in the body's immune system.

A very small percentage of pregnant women acquiring a primary CMV infection during their pregnancy will give birth to an infant suffering from congenital CMV disease. These infants are at risk for long-term hearing or vision deficits and varying degrees of mental retardation.

CMV infection is a significant risk for unborn and immunocompromised children. Common manifestations of CMV infection in this population are pneumonia, retinitis, and symptoms of gastrointestinal dysfunction.

Diagnosis

Urine, saliva, blood, and biopsy samples can be used for virus isolation to make a diagnosis. CMV pneumonia is suggested by radiograph and lung CT scan.

Nursing Care

CMV is a major cause of morbidity and mortality in immunocompromised children. Whenever possible, exposure to the CMV virus via blood products should be avoided. Ganciclovir (Cytovene), an antiviral agent, is used in the treatment of life-threatening CMV in this population. The most common symptom after resolution of the acute phase of the infection is fatigue, which may be present for as long as 18 months after the primary infection. The nurse teaches the patient that the average time to recovery from fatigue is 1 to 2 months. Patients should resume activity as tolerated.

clinical alert

Preventing CMV infection in immunocompromised children

CMV infection is a source of significant morbidity and mortality in immunocompromised children. Good handwashing is the best preventive measure. Disposable gloves should be worn when handling linen or underclothes soiled with feces or urine. CMV-negative blood should be provided to immunocompromised children.

**medication:** Ganciclovir (Cytovene)Ganciclovir (gan-**sy**e-kloe-vir)**Indications:**

Treatment of CMV retinitis in immunocompromised children.
Prevention of CMV infection in transplant children at risk.

Actions: CMV converts ganciclovir to its active form inside the host cell, where it inhibits viral DNA polymerase.

Therapeutic Effects: Antiviral effect directed against CMV-infected cells.

Pharmacokinetics:

ABSORPTION: 5–9% absorbed with oral administration. IV administration results in complete bioavailability.

Contraindications and Precautions:

CONTRAINDICATED IN: Hypersensitivity to ganciclovir or acyclovir.

Adverse Reactions and Side Effects:

Seizures, headache, malaise, drowsiness, ataxia,
GI bleeding, nausea, vomiting, increased liver enzymes
Neutropenia, thrombocytopenia, anemia
Hypotension, hypertension
Renal toxicity

Route and Dosage:

Pediatric doses not established.

IV (ADULTS): Induction 5 mg/kg q12h for 14–21 days

MAINTENANCE: 5 mg/kg/day or 6 mg/kg for 5 days/week; may increase to q12h.

PO (ADULTS): Maintenance: 1000 mg 3 times/day or 500 mg 6 times/day

Nursing Implications:

1. Pediatric dose not established.
2. Increased risk of bone marrow depression when used with antineoplastics or zidovudine.
3. Assess child during treatment of signs of infection, bleeding, or development of CMV retinitis.
4. Administer IV at slow rate, using in-line filter.
5. Advise child/family to notify health care provider for any signs of bleeding.

Data from Deglin, J.H., & Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

HERPES ZOSTER

The varicella-zoster virus (the same virus that causes chickenpox) causes herpes zoster. This virus is seen in older children and young adults. The first time the child is exposed to this virus, he or she contracts chickenpox. On a subsequent exposure, due to reactivation of the virus, herpes zoster occurs.

Signs and Symptoms

Initial signs and symptoms include cutaneous vesicular lesions that follow the nerve pattern on the face, trunk, and upper back area. It is important to note that the child will experience pain from the nerve involvement.

Diagnosis

Diagnosis of herpes zoster is based on patient history and physical examination findings.

Nursing Care

Nursing care includes measures to decrease the itching and pain. Acetaminophen (Children's Tylenol) may be given for pain. Acyclovir (Zovirax) is administered because

it inhibits viral DNA synthesis, thus limiting the disease. Cool water compresses, cool baths, and calamine lotion can relieve the itching.

SMALLPOX

Smallpox (variola) has been eradicated since 1995 but is stored in laboratories worldwide and has a mortality rate of 50%. It is spread easily from one person to another via direct or indirect contact. The period of communicability is from the time of rash onset until all the lesions have been crusted over and shed.

Signs and Symptoms

Similar to chickenpox, smallpox has lesions, but can be differentiated as the smallpox lesions produce pus. Other signs and symptoms are chills, fever, headache, and vomiting.

Diagnosis

Smallpox is diagnosed based on the patient's history and clinical signs and symptoms. The disease can be definitively diagnosed by isolation of the virus from the blood or lesions, or by identification of antibodies in the blood made in response to the virus. Smallpox is diagnosed in specialized laboratories with appropriate testing techniques and measures to protect the laboratory workers.

Nursing Care

Nursing care includes isolation until all lesions have been shed, treating the signs and symptoms, and possibly administering an antibiotic to prevent a secondary condition. Passive immunity includes the administration of vaccinia immune globulin (VIG). Active artificial immunity is not recommended.

INFECTIOUS MONONUCLEOSIS

The Epstein–Barr virus is responsible for infectious mononucleosis, which is communicable during the actual phase of the illness (7 to 10 days). Historically, infectious mononucleosis was first discovered as a disease that was transmitted through kissing. Although it can occur at any age, the disease most commonly found in adolescents and young adults.

Signs and Symptoms

The cervical lymph nodes become swollen, firm, and tender. Other symptoms are chills, fever (103.3°F [39.6°C]), headache, anorexia, and malaise. Also during the initial disease phase, the spleen may become enlarged. Because rupture is possible, the nurse must not palpate the spleen or place any pressure over the area.

Diagnosis

The monospot test was designed to detect the disease. A positive test result confirms the disease. If necessary, a blood test can be drawn to confirm the presence of Epstein–Barr virus.

Nursing Care

The nurse must communicate to the parents the importance of bed rest, maintaining hydration, decreasing fever, and isolation during the acute phase. Sharing drinking

cups with family members and peers is not advisable. Children can experience general fatigue or weakness for up to 6 weeks after the acute phase. It is important that they continue to include rest periods and fluids during their normal daily routine.

Common Fungal Infections

Any disease introduced by a fungus is called a mycosis. Fungi are either unicellular (yeasts) or multicellular (molds) and larger than bacteria. Fungal diseases are categorized according to the particular body tissue they affect. Most infections in children are superficial subcutaneous infections of the skin, hair, nails, or mucous membranes associated with either overgrowth of fungi normally present or introduced through breaks in the skin. Superficial findings include slight itching, red or gray patches, dryness, and brittle hair. Transmission is by the inhalation of spores. There are four superficial fungal infections seen in children: tinea capitis, pedis, cruris, and corporis (Table 26-2).

CANDIDA ALBICANS (ORAL THRUSH)

Most infants have natural yeast in their mouths called *Candida albicans*. Owing to the immature immune system in infants, the yeast in their mouths can overgrow and lead to an infection called oral thrush.

Signs and Symptoms

Signs and symptoms of oral thrush include white plaques on the surface of the tongue and the buccal (cheek) membranes.

Diagnosis

Candida albicans is diagnosed via a microscopic examination of the plaques (Venes, 2009).

Nursing Care

Maintaining nutrition is a priority nursing care measure of the child. This fungal infection is painful and the child may not eat well. Nystatin (Mycostatin) is the medication that effectively treats thrush. It is administered with a gloved finger using a swab placed on the buccal membranes. The medication must be administered after feedings so it will remain in contact with the fungi rather than being washed away immediately during the feeding.

The nurse can also educate the parents about the prevention of oral thrush. If the infant is bottle fed oral thrush can be prevented by thoroughly cleaning the bottle nipples in hot water. If the infant is breastfed and the mother's nipples are sore and reddened the nurse can encourage the mother to contact the physician about possible use of an antifungal ointment on the nipples while the infant is also treated with Nystatin (Mycostatin). Pacifiers can be thoroughly cleaned in hot water also.

Nursing Insight—Candidal organisms in the diaper area

Candida can also grow in the diaper area, causing a bright red diaper rash. Changing diapers frequently, exposing the area to air, and applying Nystatin (Mycostatin) ointment is prescribed. The nurse must be aware that candidiasis can be a generalized infection, especially in newborns. It must be treated immediately to prevent it from becoming systemic.

Table 26-2 Fungal Infections

Fungal Infection	Location	Treatment	Parent Information
Tinea Capitis (Ringworm)	Begins as an infection of a single hair follicle but spreads rapidly in a circular pattern and produces a one inch in diameter lesion. The circular pattern becomes filled with dirty-appearing scales and the hairs involved break off.	Oral Griseofulvin (Fluicyn)	Adolescents warned not to use alcohol due to tachycardia Children do not need to be kept home from school Family members must not share towels or combs
Tinea Pedis (Athlete's Foot)	Skin lesions between the toes and on the plantar surface of the foot	Liquid preparations of Clotrimazole (Lotrimin)	Antiseptic foot baths Do not let others share personal items such as foot wear, towels, clothes or sports equipment Wear thongs or swim shoes in public showers and stocking/shoes in locker rooms
Tinea Cruris (Jock Itch)	Found on the inner aspects of thighs and scrotum	Liquid or powder preparations of Clotrimazole (Lotrimin)	Shower or bathe frequently if necessary Dry scrotal area thoroughly when damp Wear cotton underwear Do not let others share personal items such as foot wear, towels, clothes or sports equipment
Tinea Corporis (Epidermal Layer of the Skin)	Fungal infection of the epidermal layer of the skin that has a circular lesion with a clear center and scaly inflammation	Topical Clotrimazole (Lotrimin)	Do not let others share personal items such as foot wear, towels, clothes or sports equipment

Nursing Insight— Systemic fungal infection

A systemic fungal infection, known as systemic mycosis, occurs primarily through inhalation of fungal spores. The specific fungal agent determines the course and severity of the infection. Systemic mycosis is not transmitted from person to person. One type of systemic mycotic infection is aspergillosis, which is found in airborne dust particles, compost heaps, or air vents. The condition usually manifests in children who already have a weakened immune system. Aspergillosis usually affects open spaces in the body, such as cavities that have formed in the lungs from preexisting lung diseases. It is characterized by a slow progression chronic illness and spreads rapidly through the bloodstream to the brain and kidneys. This infection is very serious and difficult to treat. The main medical treatment for aspergillosis is the administration of intravenous amphotericin B (Amphocin) and supportive management for complications from either the active disease or subsequent treatment.

medication: Amphotericin B (Amphocin)

Amphotericin (am-foe-ter-i-sin)

Indications: Treatment of active, progressive, potentially fatal fungal infections.

Actions: Binds to fungal cell membrane, allowing leakage of cellular contents.

Therapeutic Effects: Fungistatic action.

Pharmacokinetics:

ABSORPTION: Not absorbed orally.

Contraindications and Precautions:

CONTRAINDICATED IN: Hypersensitivity.

Adverse Reactions and Side Effects: Headache, hypotension, diarrhea, nausea, vomiting, nephrotoxicity, hypokalemia, chills, fever, and hypersensitivity reactions.

Route and Dosage: Specific dosage and duration of therapy depend on infection being treated.

Amphotericin deoxycholate:

IV (CHILDREN): 0.25 mg/kg infused initially; increase by 0.25 mg/kg every other day to a maximum of 1 mg/kg per day.

Amphotericin B cholesteryl sulfate:

IV (CHILDREN): 3–4 mg/kg per day

Amphotericin B lipid complex:

IV (CHILDREN): 5 mg/kg per day

Amphotericin B liposome:

IV (CHILDREN): 3–5 mg/kg q24h

Nursing Implications:

1. Premedication with antipyretics, corticosteroids, antihistamines, and antiemetics may reduce incidence of fever, chills, headache, nausea, or vomiting.
2. Monitor VS and above noted symptoms every 15–30 minutes during test dose and every 30 minutes for 2–4 hours after the test dose.
3. Monitor VS and the aforementioned symptoms closely for the first 1–2 hours of each subsequent dose.
4. Monitor for thrombophlebitis as drug is highly irritating to tissues.
5. Monitor CBC and platelet counts weekly, BUN and serum creatinine every other day while increasing dose then twice weekly. Monitor potassium and magnesium levels biweekly.
6. Ensure resuscitation equipment readily available before administration.

Data from Deglin, J.H., & Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

nursing diagnoses The Child with an Infectious Disease

- Hyperthermia related to disease process
- Risk for Fluid Volume Deficit, related to decreased intake
- Impaired Skin Integrity, related to pruritis
- Deficient Knowledge, related to disease process and self-care

case study Infant with Pertussis

A 3-month-old infant is admitted with a history of “cold” symptoms for the last 2 weeks. The parents report the symptoms of fever, malaise, and a hacking cough that seems much worse at night. The cough tends to come in clusters and has been increasing in intensity over the past 3 days. The parents have brought the infant into the emergency room because he is now vomiting during the coughing spells and then turns blue around his mouth. An initial diagnosis of pertussis is made.

Critical Thinking Questions

1. The parents ask about transmission of pertussis for themselves and for the other children. How would the nurse best respond?
 2. What preparations should the nurse take now to prevent the spread of this disease?
 3. What actions should the nurse take during a coughing spell?
 4. The family asks about the length of the illnesses. What is the nurse’s response?
- ◆ See Suggested Answers to Case Studies in the text on the Electronic Study Guide or DavisPlus

Immunizations

The cornerstone of infectious disease prevention in pediatrics is an immunization program in which the child receives the necessary vaccines. Vaccines are produced by using weakened or killed microbes, inactivated toxins, or subunits of disease-causing microbes. The goal of an immunization program is to bring about active immunity to guard against the onset of a specific antigen. The immune system response occurs through an exposure to a naturally occurring antigen or artificially through a vaccine-mediated exposure.

Nursing Insight— Vaccine

The general requirements for development and implementation of a vaccine are:

- There must be a risk of the disease for the individual or population.
- The risk of the vaccine itself must be minimal and outweighed by the risk of the disease.
- The vaccine must be given at a time when it is effective.
- The immunization itself must be effective in promoting an immune response (National Institutes of Health. (2003). *Understanding Vaccines: What They Are and How They Work*. <http://niaid.nih.gov/> NIH publication No. 03-4219.)

An understanding about the different types of vaccines can assist the nurse in planning care that maximizes the effectiveness of vaccine and anticipates possible complica-

tions that can occur. Traditional vaccines include inactivated vaccines, live attenuated vaccines (weakened), and toxoids. *Inactivated vaccines* are produced when the disease-causing microbe is killed but is still capable of inducing the human body to produce antibodies (e.g., inactivated poliovirus vaccine). They are very safe and require little special handling. These types of vaccines stimulate a relatively weak immune response. For this reason, repeated boosters are required. The *live virus (attenuated) vaccine* is made by using a disease-causing organism that is not killed, but is grown under special conditions designed to decrease virulence (e.g., measles vaccine). Vaccines made with live organisms require special care, such as refrigeration. Live vaccines have the potential for mutation, allowing the organism to revert to a more virulent form. Due to the increased risk of mutation, live vaccines are not recommended for children (or adults who have close proximity to the child) with compromised immune systems. A *toxoid vaccine* is used in an inactivated form and is effective in producing an immune response geared toward a toxin-producing organism. The toxoid has been treated with either heat or a chemical to weaken its toxic effect but retains its antigenicity (e.g., tetanus toxoid).

More recent vaccine development has produced subunit vaccines, polysaccharide vaccines, conjugate vaccines, and recombinant vaccines. *Subunit vaccines* use only a portion of the virus or bacterium to produce the desired immunological response without the undesirable effects that occur with some of the other surface antigens (e.g., *Bordetella pertussis* vaccine included in the acellular DPT). This subunit vaccine produces immunity to *Bordetella pertussis* with less risk so it may be more safely given to infants and young children.

Some bacteria possess a polysaccharide outer capsule that protects them from recognition and phagocytosis by the immune system. Organisms with this coating include *Haemophilus influenzae* B (HiB), *Streptococcus pneumoniae*, and *Neisseria meningitidis*, each of which may produce a very serious case of pneumonia or meningitis in an infant or young children. *Polysaccharide vaccines* (Pneumovax), made from portions of the polysaccharides making up the protective capsule of these organisms, have long been available and are effective in producing immunity in children older than the age of 2 years. At exposure the polysaccharide capsule does not elicit a T-cell response, the duration of immunity is variable and not life long. In addition, these antigenic components are not recognized by the immune system of children younger than 2 years of age and it is children in this age group who are at highest risk for serious pulmonary or neurological infection resulting from these bacteria.

The development of *conjugate vaccines* has provided an option for protecting infants and young children. The conjugate vaccine links a recognizable antigen with the “hidden” bacterial antigen, thereby enabling the immature immune system to identify the bacteria as nonself and respond. In this way, the infant’s T cells may identify the otherwise unrecognizable antigen, providing both an improved primary response and conferring immunological memory. An example of a conjugate vaccine used in children younger than 2 years of age is the *Haemophilus influenzae* type b (Hib) vaccine. Before the advent of this vaccination, pediatric meningitis resulting from Hib infection was a common cause of morbidity in infants.

Production of the *recombinant vaccine* uses genetic engineering to insert the genes for production of the antigens desired into a low virulent vector. The vector then can be used to easily produce quantities of the antigen for further purification into a subunit vaccine. The only recombinant vaccine currently used is hepatitis B virus (HBV). The HBV surface antigen is injected into yeast cells that produce quantities of the antigen for use in vaccination against hepatitis B.

Nursing Insight— The role of the nurse with immunizations

The primary nursing goal is up-to-date immunizations for all children based on their particular health status. The pediatric nurse has several roles in the area of immunization. Addressing family concerns regarding immunizations is an important role of the nurse. The nurse also plays a key role in organizing and carrying out vaccination programs and distributing accurate and timely information regarding childhood immunizations. In addition, the nurse must use the current immunization schedule (www.cdc.gov/vaccines/recs/schedules) and recognize that the complicated schedule may pose some challenges for parents. The nurse can ensure that the parent has a vaccine information sheet (VIS) that records the immunizations. The nurse must also remind parents when the next immunizations are due. The nurse must recognize that explosion of information about immunizations available via the World Wide Web has both benefits and disadvantages. Through the Web, parents are bombarded with information regarding the types and safety of immunizations. The nurse must stay abreast of current information and discuss the parents’ concerns. The nurse must also attempt to contact and immunize high-risk unimmunized children such as children who are homeless, immigrant, refugee, home schooled, frequently mobile, or who have a chronic or life-threatening illnesses. The pediatric nurse is also actively involved in statewide reporting of adverse effects of the vaccine.

Be sure to— Be aware of legal considerations in immunization education

The National Childhood Vaccine Injury Act of 1986 provides that parents or legal representatives of children receiving immunizations must be given a VIS developed by the Centers for Disease Control and Prevention (CDC) before immunization. The purpose of the VIS is to ensure uniform education regarding vaccines. The VIS must be used with the following vaccinations: DTaP, Td, MMR, polio, hepatitis B, Hib, varicella, and pneumococcal conjugate.

Full compliance with this law requires the nurse to:

- Provide the parent or legal guardian with the appropriate VIS before immunization.
- Record on the medical record the date that the VIS was given, the date of publication for the VIS, the name, address, and title of the person giving the vaccine, the date of administration of the vaccine, the manufacturer of the vaccine, and the vaccine lot number.
- The VIS must not be altered in any way.
- VIS forms (in many languages) may be accessed at www.cdc.gov/nip or www.immunize.org

- Hardcopies may be ordered through the CDC Web site: www.cdc.gov/nip/publications
- Individual state health departments with camera-ready copies can be obtained.
- Additional resources and additional education provided to the parent must also be recorded

Note: Additional VISs are available for use with other common childhood vaccines, although use with other vaccines is strongly encouraged.

NURSING CARE

Nursing care for the child receiving immunizations requires the integration of several nursing roles. The nurse must be diligent in maintaining current knowledge about the medication's action and potential side effects and any contraindications to immunizations. In addition, the pediatric nurse must remain abreast about the current immunization schedule as well as being skilled in the actual administration of the vaccine. Setting up immunization clinics and long-term tracking of children who have and have not received immunizations are important, as well as accurate documentation and follow-up care. The pediatric nurse who works in the infectious disease area must cultivate specific channels for keeping up to date. The Department of Health and Human Services: Centers for Disease Control and Prevention <http://www.cdc.gov/vaccines/> has updated information. The pediatric nurse uses current information to discuss the immunization plan and concerns with the family, prior to immunization (Diekeman, 2005).

Family Teaching Guidelines... Immunizations

How To: Increasing immunization administration and compliance requires that the nurse work with the family to address the administration of the vaccine as well as their educational concerns.

Essential Information: When working with families the nurse can:

1. Discuss the actual administration and potential side effects of the vaccine with the parents.
2. Develop programs and materials that educate parents about immunizations.
3. Identify opportunities for administering immunizations by providing immunization clinics in nontraditional settings such as churches, synagogues, mosques, community centers, or shopping malls.
4. Provide opportunities and encourage parents to communicate their concerns about immunizations.
5. Encourage parents to investigate immunizations using reputable Web sites and other resources.
6. Assist the parents in understanding how to keep track of immunizations and when the next immunizations are due.
7. Assist parents in investigating funding resources for immunizations (this is a possible barrier to immunization for many families).

critical nursing action Identifying Contraindications to Immunizations

A contraindication to vaccine administration indicates that the child has an increased risk of serious side effects from the vaccine and therefore should not receive that vaccine. There are very few real contraindications to vaccinations. Only one universal contraindication exists to all vaccines:

- Previous severe allergic reaction (anaphylaxis) to the vaccine or its component of vaccine.

Individual vaccines carry additional contraindications:

- Diphtheria, Tetanus, and Pertussis (DTaP) vaccine: Progressive neurological disease, i.e., infantile spasms, encephalopathy
- Measles, Mumps, and Rubella (MMR) vaccine: Pregnancy, severe immunodeficiency
- Varicella: Severe immunosuppression

Circumstances requiring postponement of vaccine administration include:

- Moderate to severe illness
- Administration of Immunoglobulin within last 3–11 months (precise period depends on specific immunoglobulin)

Note: Individual vaccines may have additional contraindications and precautions. Safe administration of vaccines requires the nurse to screen for contraindications and precautions prior to administration.

clinical alert

Adverse effects of immunizations

- Local effects are mild and occur most frequently (soreness, redness, and pain at the site of injection). These effects can be managed through local application of heat or ice to the site.
- Systemic effects are less frequent and include fever and mild irritability. These are managed with acetaminophen (Children's Tylenol) administration before immunization, continuing every 4 hours as needed for 24 hours.
- An allergic reaction is rare but serious. The pediatric nurse and parents should watch for signs of an allergic response and seek medical assistance immediately should their child exhibit any of the following symptoms: high fever; altered mental status, including excessive irritability, lethargy, nonresponsiveness, or seizures; increased work to breathe; hoarseness or wheezing when breathing; hives; or pale or cool skin.

The immunizations are administered according to manufacturers' recommendations. During the immunization process, the nurse takes the time to address the unique concerns of each family. The parent's role after immunization is to understand and treat side effects. It is important for the nurse to communicate to parents when to call the physician. Once parental concerns have been addressed, the child can be released from the clinic when there are no signs of adverse reaction and the family understands when to notify the care provider (an allergic reaction).

Now Can You— Safely give immunizations?

1. Identify contraindications to immunizations?
2. Discuss three strategies for increasing the administration of immunizations in children?
3. Identify key points of family education regarding immunization?

Animal-Borne Infectious Diseases

Animals serve as a reservoir for certain infectious diseases, including rabies, West Nile virus, and avian influenza. Nurses participate in prevention of these diseases through education for families about strategies that minimize exposure to infected animals, mosquitos, and infected birds.

Teaching children about animal safety is also important. The nurse can proactively talk to families and children about the risk of approaching unknown animals. Typically, rabies is not readily noticed through behavior of infected animals; for this reason children should be warned to be wary of unfamiliar animals.

Nurses can strategize with families about ways to avoid mosquito bites in areas where these insect diseases are common. Protection from exposure includes protective clothing, minimizing exposure of the skin, and use of insect repellents such as diethyltoluamide (DEET) sprayed on the clothing of children older than 1 year of age. It is important to emphasize to parents the potential for anything applied directly to the skin to be absorbed systemically in young children. Due to the risk of systemic absorption, safe use of insect repellents requires application to clothing rather than the child directly.

RABIES

Rabies is an acute viral infection of the nervous system caused by rhabdoviridae lyssavirus. The primary agent for this virus is carnivorous wild animals. Transmission of this disease occurs through direct contact with the brain tissue or the saliva from infected animals. The nurse must remember that untreated or inadequately treated rabies is fatal in humans (Hanlon, Niezgodna, Morrill, & Rupprecht, 2000).

The typical incubation period for rabies is 3 to 8 weeks but may extend for several months. The highest incidence of this disease occurs in children younger than 15 years of age. Only a small percentage, 10% to 15%, of persons with exposure to rabies goes on to develop the disease. However, the disease carries 100% mortality once symptoms are present. Treatment must be initiated as soon as possible after exposure and before the onset of symptoms.

Signs and Symptoms

Typical signs and symptoms of rabies include an initial period of generalized flu symptoms, including malaise, fever, and sore throat. The disease then progresses to alterations in mental status including seizures and hyperexcitability. The respiratory tract is then affected, leading to spasms that cause severe impairment of respiratory function, including respiratory arrest.

Diagnosis

Tests are performed on samples of saliva, serum, spinal fluid, and skin biopsies of hair follicles at the nape of the neck for rabies antigen.

Nursing Care

The nurse knows that postexposure treatment for rabies includes wound cleansing with a virucidal agent, administration of human rabies immune globulin (HRIG), and administration of a rabies vaccine series. HRIG is typically

given in a total dose of 20 IU/kg body weight. A portion of the total dose is given into the tissue surrounding the wound through a series of injections given all around the wound borders. Depending on the volume of medication to be given and the size of the wound, there may be medication remaining after the wound has been encircled with the HRIG. Any remaining medication is given IM at a site distant from the wound. For example, if the child is being treated for a small bite wound on the right forearm, the prescribed volume and dose of HRIG would be given in small injections all around the wound. If on completion of this process there remained 0.5 mL of HRIG it could be given IM in the left vastus lateralis. As with other types of immune globulins, the primary goal of administration of the HRIG is to provide a rapid, short-term passive immunity.

Active immunity is provided postexposure through completion of a rabies vaccine series using human diploid cell rabies vaccine (HDCV). This medication is given IM at the same time as HRIG (day 0) and again on days 3, 7, 14, and 28. Some sources recommend another dose on day 90. The HRIG and HDCV are well tolerated in children. Support is needed due to the frightening nature of the disease, the urgency of the treatment, and the need for multiple injections (Jackson, Warrell, & Rupprecht, 2003).

clinical alert

Postexposure treatment for rabies

Owing to the traumatic nature of treatment postexposure, seriousness of rabies, and poor prognosis, exercising caution with unknown animals is essential. Most exposures to rabies occur through bites of wild animals, which allow contaminated saliva to enter the bite wound. If an animal has injured a child, the parents must contact their health care provider immediately!

WEST NILE VIRUS

West Nile virus causes an infection that is spread by mosquitoes that become infected when they bite infected birds (Morse, 2003). Infected mosquitoes then may spread the virus to children. West Nile virus infection has been documented in children as young as 1 month of age. The incidence of severe disease in children is rare (O'Leary et al., 2004). The incubation period for West Nile virus is from 3 to 14 days.

Signs and Symptoms

Most of the time West Nile virus causes few symptoms lasting 3 to 6 days, or the symptoms are so mild children do not realize they have been infected. Typical symptoms include headache, malaise, anorexia, nausea, vomiting, myalgia, eye pain, generalized lymphadenopathy, and a maculopapular rash found on the trunk, neck, and extremities. In rare cases, the virus can lead to encephalitis or meningitis.

Diagnosis

Diagnosis of West Nile virus is confirmed by specific IgM antibody in cerebrospinal fluid. Because IgM antibody does not readily cross the blood-brain barrier, IgM antibody in CSF strongly suggests acute CNS infection (Campbell, Marfin, Lanciotti, & Gubler, 2002).

Nursing Care

Nursing care of children with West Nile virus includes education about the disease itself and its prevention. Treatment is supportive based on the signs and symptoms. Nurses can also provide information about the relative infrequency of severe disease in children. Responding to parental concerns, nurses can help them plan strategies for minimizing exposure to mosquito bites. Of particular concern is also minimizing possible side effects related to systemic absorption of insect repellents.

“What to say” — Use of insect repellents

Concerned about exposure to insect bites and the possibility of infectious disease transmitted through this route, parents at times apply insect repellents such as diethyltoluamide (DEET) directly on their children. Although the nurse must provide education to change this behavior, it is important to support the parents' intent of decreasing the risk of infection in their child. The nurse can appraise the parents about the intent of the action while providing them with the correct information that the insect repellent must be applied to the child's clothing. Applying the insect repellent to the clothing decreases the chance of systemic absorption (through the skin) of a potentially harmful substance.

AVIAN INFLUENZA

Influenza pandemics are recurring events. In this past century influenza pandemics occurred in 1918, 1957, and 1968. Recently, one particular strain of the Avian Influenza, H5N1, has been identified by the World Health Organization (WHO) as a strain with this potential (WHO, 2006a).

Avian influenza, known commonly as bird flu, refers to an influenza virus that occurs naturally in birds worldwide. Although occurring chiefly in birds, certain subtypes of the virus may mutate and transfer to humans. Because this strain of virus has not been previously circulated in the human population, the potential for an influenza pandemic is present. This particular influenza virus is transmitted via the respiratory route and the resulting infection is likely to be more severe than typical influenza, as the human immune system currently lacks the ability to respond swiftly to this new threat.

Currently transmission is thought to occur primarily through direct contact with infected birds or the secretions or excretions of the infected animals. Confirmed cases of avian influenza in humans have occurred in those with contact with domestic birds, primarily poultry, infected with the virus. Known cases have been confined to Asia and Europe.

Person-to-person spread has been reported very rarely and is limited to one direct, close contact. In 2006, the WHO reported 228 confirmed human cases of the H5N1 strain of avian influenza, and documented with 130 deaths. (World Health Organization, 2006a). As of Wednesday, May 16, 2007, in Indonesia, WHO confirmed 15 additional cases, including 13 deaths, of human infection with H5N1 avian influenza (WHO, 2007).

clinical alert

Clusters of human H5N1 cases

As reported on the CDC Web site (<http://www.cdc.gov/flu/avian/outbreaks/current.htm>), “Clusters of human H5N1 cases ranging from 2–8 cases per cluster have been identified in most countries that have reported H5N1 cases. Nearly all of the cluster cases have occurred among blood-related family members living in the same household. Whether such clusters are related to genetic or other factors is unknown. While most people in these clusters have been infected with H5N1 virus through direct contact with sick or dead poultry or wild birds, limited human-to-human transmission of H5N1 virus cannot be excluded in some clusters.”

The WHO is working closely with health departments worldwide to coordinate surveillance and pandemic preparation in an attempt to avert or lessen the expected impact of the threatening pandemic. Avian influenza should be considered in a child with moderate to severe respiratory symptoms who meets one of the following criteria: has traveled to an area with known outbreaks of avian influenza in the domestic poultry, has had contact with infected birds, or has had close contact with a person infected with avian influenza.

Signs and Symptoms

Symptoms of avian influenza in humans have ranged from typical symptoms of influenza, such as cough, sore throat, fever, and myalgia to severe pneumonia and acute respiratory distress.

Diagnosis

Avian influenza cannot be diagnosed on the basis of symptoms alone. It is usually diagnosed by collecting a swab from the nose or throat during the first few days of illness to test for avian influenza virus.

Nursing Care

Treatment includes supportive and symptomatic care, including aggressive treatment of complications such as pneumonia. Antiviral medications may also be used. There are four antiviral medications: amantadine (Symmetrel), rimantadine (Flumadine), oseltamivir (Tamiflu), and zanamivir (Relenza) currently approved for use in treatment of influenza in humans. Effectiveness varies with the particular strain of virus.

The H5N1 virus seen in human cases in Asia has proven to be resistant to amantadine (Symmetrel) and rimantadine (Flumadine). CDC does not recommend use of these agents. The latest (2006b) WHO guidelines suggest the use of oseltamivir (Tamiflu) as the first-line antiviral treatment if it is available but note this recommendation is based on very few cases and lacks strong evidence. WHO and CDC continue to monitor the cases of avian influenza in humans and provide updates on recommendations for specific treatment. Research focused on development of a vaccine to protect against H5N1 virus has been underway since April 2005 and clinical trials are ongoing.

Family Teaching Guidelines... Preparing for an Influenza Pandemic

How To: Actions taken by individuals and communities helps to decrease the impact of an influenza pandemic. Nurses can work with families to provide them the information needed to prepare adequately.

Essential Information: When working with families the nurse can:

1. Discuss the differences between seasonal flu and pandemic flu.
2. Describe actions being taken by the health care community to monitor and prepare for the pandemic and encourage families to take an active role.
3. Assist families to establish their own plan for care in the event of a pandemic including:
 - Storage of a 2-week supply of food and water for the family.
 - Maintenance of a supply of needed medications.
 - Maintenance of a supply of over-the-counter medications needed to treat symptoms of flu.
 - Establish a plan for family members living alone.
4. Encourage families to become involved with community groups to help prepare and plan for the pandemic.
5. Reinforce basic infection control techniques to limit spread of influenza.
6. Provide families with links to CDC resources with preparation checklists. Encourage them to utilize the checklists to assist in preparation.

An Emerging Issue in Infectious Disease: Resistant Organisms

In recent years, there has been a steady increase in the incidence of infections with antibiotic-resistant organisms in the United States and in many countries around the world. Several factors have been associated with the genesis and spread of these organisms. On a global scale, bacterial resistance, due to misuse, is an escalating problem in many countries providing an ever-increasing reservoir for resistant organisms to thrive.

Ethnocultural Considerations— Antibiotic Use Around the World

Further increasing the likelihood of inadequate treatment is the common cultural practice in many countries of taking an incomplete course of treatment. Conditions for the development of antibiotic-resistant organisms include overcrowded living conditions and lack of potable water and basic sanitation. In many developing countries, the likelihood of transmission of resistant organisms from person to person is high. Inadequate equipment or surveillance furthers the problem of antibiotic resistance around the world. In the era of global travel, the increase in community acquired antibiotic resistant organisms in any part of the world becomes a necessary component of the discussion of infection control policies worldwide.

Overuse of antibiotics is the primary factor for the development of antibiotic resistance as well as noncompliance with a prescribed course of treatment. Person-to-person transmission of antibiotic-resistant organisms occurs primarily through nosocomial transmission in hospitalized children and now also may be occurring in the community at large.

The costs, both human and monetary, of antimicrobial resistance are large (McGowan, 2001). Specific strategies directed at control of antimicrobial resistant organisms are development of new antimicrobial agents and surveillance programs to identify incidence of current misuse. Isolation measures to prevent the spread infection in both the hospital and broader community, education of health care professionals about the increased incidence of resistant organisms, and improving correct use and compliance of antibiotics is necessary.

Within both the acute care environment and in the community nurses can promote public awareness and develop strategies to decrease the transmission of antibiotic resistant organisms. Specifically, nurses can spread the word about overuse and provide family education about completing a prescribed course of treatment. Measures that help nurses provide effective antibiotic therapy are knowledge about exact dosing, medications that decrease efficacy, and duration of treatment. The nurse must also maintain updated knowledge of current practices in infection control. Consult an infection control specialist and decrease the spread of nosocomial transmission in the hospital. Nurses are the bridge between the actual infection and public health awareness.

Now Can You— Describe the role of the nurse in antibiotic-resistant organisms?

1. Identify conditions for the development of antibiotic-resistant organisms?
2. Discuss ways that nurses can promote public awareness about antibiotic overuse?

ANTIBIOTIC ALTERNATIVES

As concerns about antibiotic-resistant organisms increase, alternatives for prevention of disease are being pursued with increased vigor. Monoclonal and probiotics antibodies are now considered for the future in the control of infectious disease in children. Monoclonal antibodies are based on the same premise as passive immunity and have demonstrated effectiveness in passive immunity for a large number of infectious diseases acquired in childhood. Monoclonal antibodies are applied to mucosal surfaces to prevent disease transmission at the site of entry. The main drawback of this type of protection is the cost and time associated with production of sufficient amounts of antibodies. However, advances in technology will soon shorten the availability time and resources needed to manufacture new monoclonal antibody preparations. Since monoclonal antibodies produce only passive immunity, much more emphasis has gone into development of vaccines for stimulating active immunity.

Probiotics are another new area of research. Probiotics are bacteria that colonize in the intestine and participate

in the intestinal microenvironment in such a way as to improve immune function. To be effective, probiotics must be able to survive the trip through the digestive tract and colonize primarily in the colon. It is believed that once in the colon, the probiotics act to reinforce the mucosal barrier through reducing gut permeability and enhancing local immune response, such as IgA release. It is unclear about the role that probiotics will play in the prevention of illness.

Nursing Insight— Probiotics

Children with rotaviral gastroenteritis who received the probiotic *Lactobacillus* had reduced severity and duration of acute diarrhea.

“What to say” — Home care instructions

The nurse is providing home care instructions to the parents of a 2-year-old child presenting with symptoms of a viral illness. The parents tell the nurse they are unhappy with the physician's decision not to prescribe antibiotics. The nurse responds by asking:

- Tell me more. What has been your past experience with treating similar illnesses?
- What are your concerns with this illness? What do you believe will happen if antibiotics are prescribed to treat your child at this time?
- What are your plans to care for your child? Under what circumstances will you contact your health care provider to discuss a change in treatment plan?

summary points

- ◆ Infectious and immune diseases represent a significant pediatric health concern for the child, family, and public.
- ◆ The body's first line of defense is the skin and the second is the immune response.
- ◆ Congenital immunodeficiency disorders are rare but include more than 70 specific types of disorders. These conditions result in life-long impairment of immune system function. This impairment then results in an increase in incidence, severity, and recurrence of infections.
- ◆ The goals of treatment for HIV positive children are to slow progression of AIDS, prevent further infections, promote normal growth and development, prevent complications including cancers, and prolong and improve quality of life.
- ◆ After the surgery, post-transplant immunosuppression is critical and children are placed in a medically induced state of immunosuppression.
- ◆ An autoimmune disorder is the immune response against one of the body's own tissues or cells. Examples of autoimmune disorders are systemic lupus erythematosus, juvenile rheumatoid arthritis, and anaphylaxis.
- ◆ There are three types of infections (bacterial, viral, and fungal). Although each infectious condition has unique signs and symptoms, several symptoms are common in

varying degrees among several illnesses. Common signs and symptoms include fever, malaise, anorexia, and pruritus from rashes.

- ◆ The cornerstone of infectious disease prevention in pediatrics is an immunization program where the child receives necessary vaccines.
- ◆ Animals serve as a reservoir for certain infectious diseases, including rabies, West Nile virus, and avian influenza. Nurses participate in prevention of these diseases by educating families about strategies that minimize exposure to infected animals, mosquitoes, and infected birds.
- ◆ There has been a steady increase in the incidence of infections with antibiotic-resistant organisms in the United States and in many countries around the world.

review questions

Multiple Choice

1. The pediatric nurse provides health prevention teaching to a group of parents in a community clinic regarding communicable diseases. Teaching should include:
 - A. Administering salicylates (aspirin) for fever
 - B. Bathing the child with harsh soap to prevent the spread of the disease
 - C. The application of soft mittens to prevent scratching
 - D. Providing layers of clothing to keep the child warm
2. A 4-month-old girl is admitted to the pediatric unit with a diagnosis of pertussis. Upon assessment, the nurse records a history of severe coughing spells which progress to vomiting, a decreased interest in feeding, and inspiratory stridor. The nursing plan of care includes:
 - A. Monitoring pulse oximetry every 12 hours
 - B. Maintaining suction and oxygen equipment at the bedside
 - C. Performing a respiratory assessment once a day
 - D. Feeding formula every 2 hours to prevent dehydration
3. The pediatric nurse provides patient education to the parents of a child with chickenpox. The teaching should include the potential complications that may come about secondary to this illness. All of the following are common complications EXCEPT:
 - A. Febrile seizures
 - B. Encephalitis
 - C. Reye syndrome
 - D. Thrombocytopenia

True or False

4. One of the major roles of the pediatric nurse in health promotion includes assisting families in becoming advocates for their children.
5. The pediatric nurse correctly teaches parents that disorders of the immune system are always acquired.
6. When caring for a child with an immune disorder the nurse correctly explains to parents that antibiotics

reinforce the mucosal barrier by reducing gut permeability and enhancing local immune response.

7. When conducting patient teaching, the nurse will communicate that the child who is infected with the HIV virus will have a decreased CD4 or helper T-cell count.

Fill-in-the-Blank

8. When teaching parents about the immune system, the nurse stresses that the main purpose of the immune response is to _____ the body against microorganisms, parasites, and foreign cells like cancer cells.
9. An HIV-infected mother has been admitted to the hospital in labor. The nurse bases the plan of care upon the understanding that initiation of _____ and delivery via _____ reduce the risk of HIV infection in the neonate.
10. The pediatric nurse administers _____, the medication of choice in preventing *Pneumocystis carinii* pneumonia (PCP).

Case Study

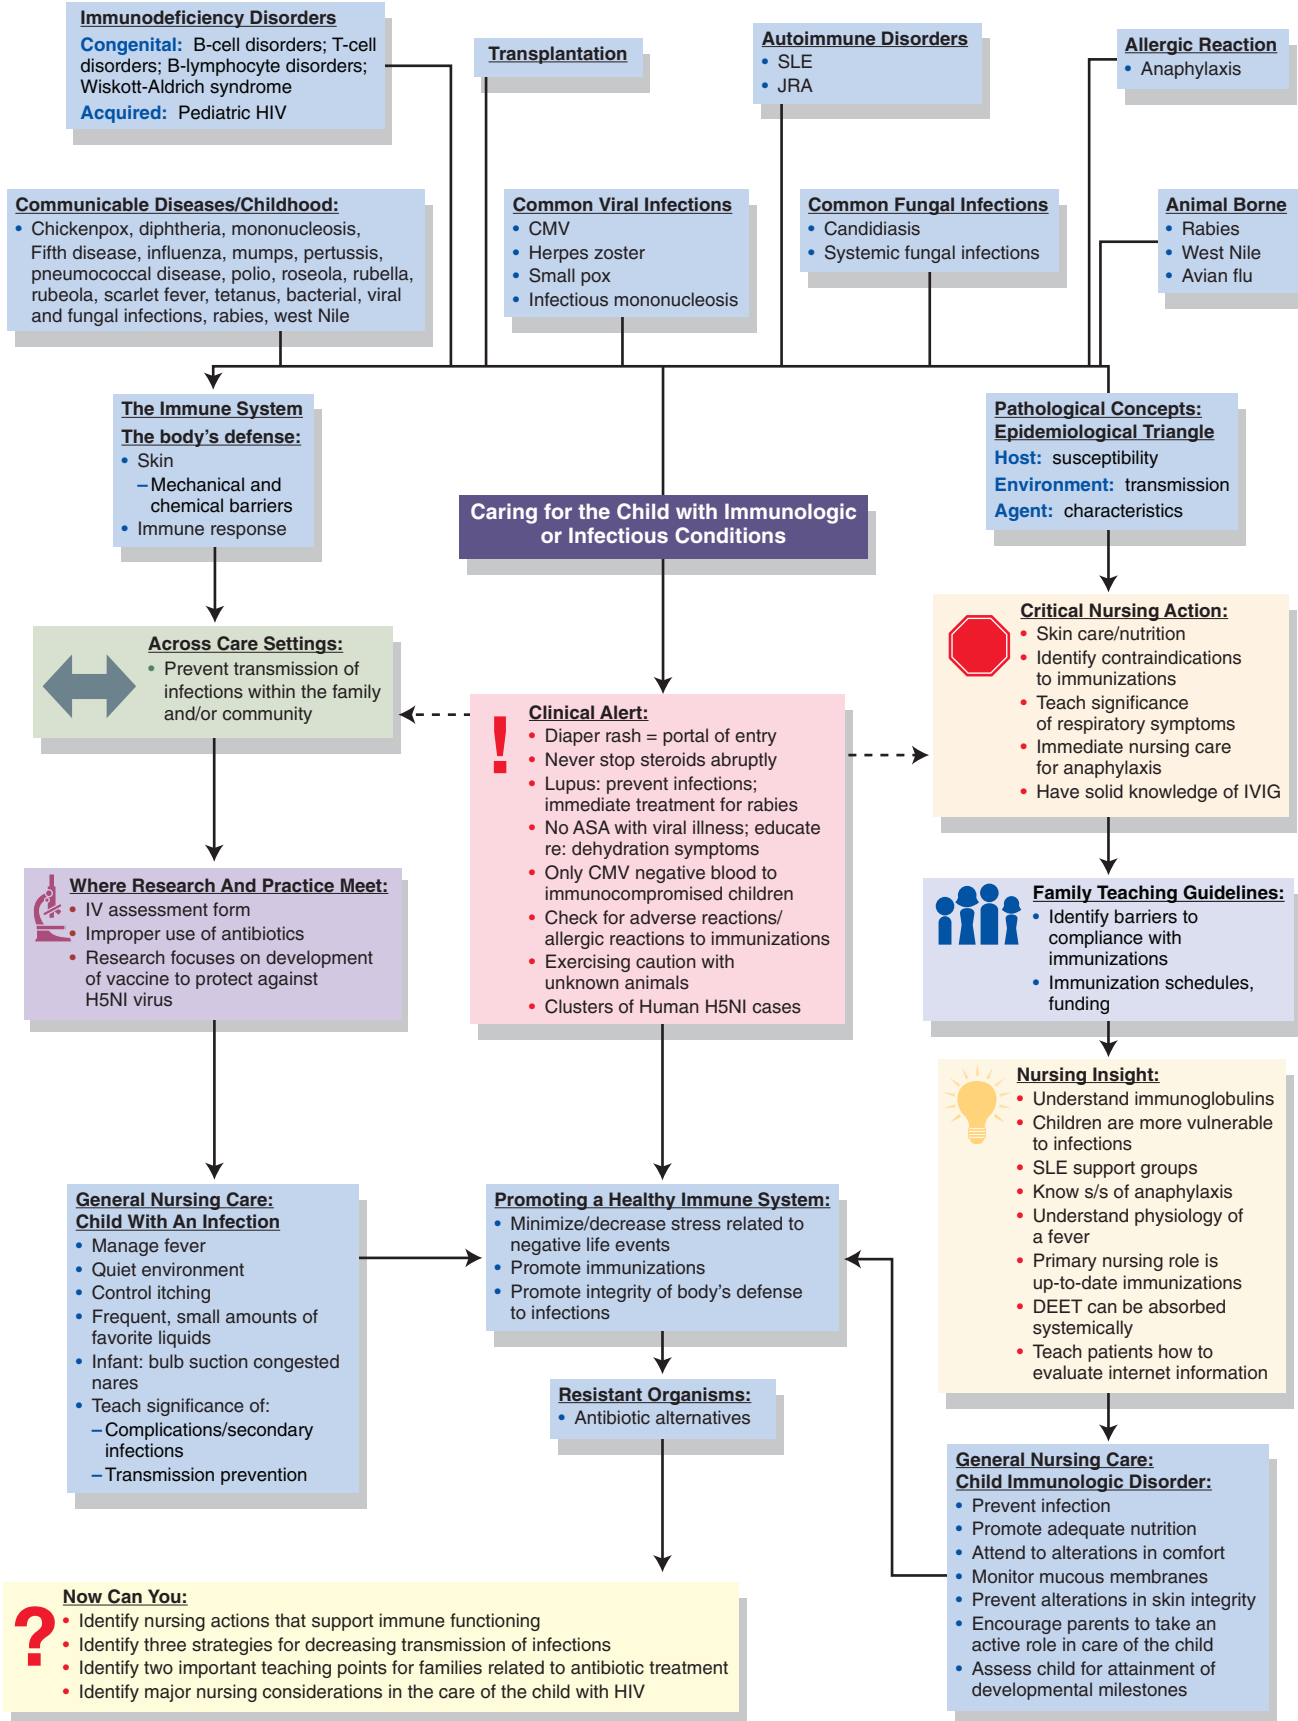

11. A 2-year-old is admitted with a history of fever, severe diarrhea, vomiting and abdominal pain for the past 3 days. The stool culture is positive for rotavirus. Which of the following nursing assessments indicate that the child is dehydrated?
 - A. Urine specific gravity of 1.010
 - B. Irritability and crying
 - C. Warm skin and red cheeks
 - D. Decreased number of wet diapers
12. The nurse is preparing to administer *Lactobacillus* (*L. acidophilus*) to a 4-year-old patient. The parent asks the nurse why the child is receiving this medication. The nurse's best reply is:
 - A. "I'm not sure but I'll ask the doctor to come and speak with you."
 - B. "It's an antibiotic to help clear up the infection."
 - C. "It's an electrolyte to help treat the dehydration."
 - D. "It's a medication that helps reduce the severity and duration of the diarrhea."

CONCEPT MAP

Caring for the Child with a Cardiovascular Condition

chapter 27

I dedicate this chapter to the children with cardiac disease who I have cared for over the last 25 years in the Pediatric ICU, Cardiology, and Cardiovascular surgery. There are so many children, such as; Anthony, Jonathan, Elizabeth, Timmy, Kerrie Ann and Megan. Some children see immediate and lasting results from treatment (those are the ones I rarely see in follow-up) and then there are those I see chronically, year after year, perhaps since infancy, who have grown to college age. These children have the strength to survive and to live day to day with the constant reminder of their illness. They live with tachycardia, cyanosis, shortness of breath and poor growth patterns and low exercise tolerance. Year after year, month and month, or even week after week these children return for blood tests, electrocardiograms, echocardiograms and invasive procedures such as cardiac catheterizations and multiple surgeries. They give me strength.

—Judy Marshall

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Understand the anatomy and physiology of the heart.
- ◆ Discuss congenital heart disease (heart defects) and the effect on children.
- ◆ Recognize major cardiac diseases and conditions together with related nursing care measures.
- ◆ Identify the importance of closure devices in the care of children with cardiac conditions.
- ◆ Describe important surgical interventions and postoperative management used for children with a cardiac condition.
- ◆ Develop a nursing care plan for caring for a child with cardiac conditions.
- ◆ Explain nursing care for the child in the Pediatric Intensive Care Unit (PICU) and surgical/medical unit.
- ◆ Describe how to care for children with cardiac conditions across care settings.

moving toward evidence-based practice Development risks in participants with Hypoplastic Left Heart Syndrome and Transposition of the Great Arteries

Brosig, C.L., Mussatto, K.A., Kuhn, E.M., & Tweddell, J.S. (2007). Neurodevelopmental outcome in preschool survivors of complex congenital heart disease: implications for clinical practice. *Journal of Pediatric Health Care, 21*(1), 3–12.

The purpose of this study was to compare the neurodevelopmental outcome of preschool children who had surgical repair for hypoplastic left heart syndrome (HLHS) with those who had surgical repair for transposition of the great arteries (TGA).

Past research has suggested that neurodevelopmental delays in individuals with congestive heart disease (CHD) are related to chronic hypoxia, inadequate cerebral perfusion, and decreased

systematic oxygen delivery, which may be experienced during the preoperative, perioperative, and postoperative periods.

The researchers of this investigation contend that diagnostic and surgical advances in the past 10 years have improved the neurodevelopmental outcomes of persons undergoing HLHS and TGA repair procedures. Surgical repair for HLHS is associated with multiple risks due to “deep hypothermic circulatory
(continued)

moving toward evidence-based practice (continued)

arrest (DHCA), the prolonged effects of hypoxia at a time of critical brain growth, and the stress of multiple surgical procedures spaced over a 2- to 4-year interval" (p. 4).

Persons with TGA generally undergo one surgical procedure, the arterial switch operation (ASO), which provides complete repair of the defect and maintains normal anatomy and oxygen saturation.

The study sample was selected from two cohort groups: one group included children ages 3–6 "who survived the Norwood procedure for HLHS or other" forms of congenital heart disease (CHD) that produced "significant obstruction to the systemic" circulation (p. 4). The second group was selected from children ages 3–6, who survived the arterial switch operation for transposition of the great arteries.

All participants received surgical care between 1996 and 1999 at a Midwestern hospital. All procedures were performed by the same cardiac surgeons. Study eligibility requirements included meeting the age and diagnostic criteria and coming from a primarily English-speaking family. Children who had other major congenital anomalies, medical conditions, or treatments deemed to exert an adverse impact on development were excluded.

The final sample included 13 participants in each group. All chart reviews were completed by one investigator. The neurodevelopmental assessment was performed by a pediatric psychologist who was unaware of the child's cardiac diagnosis and surgical history.

Several instruments, including McCarthy Scales of Participant's Abilities, Woodcock Johnson III Tests of Achievement, Developmental Test of Visual–Motor Integration, Receptive Once-Word Vocabulary Test, Expressive One-Word Vocabulary Test, and Child Behavior Checklists were used. The tools were selected based on findings from previous studies.

Analysis of demographic data revealed the following:

- The mean age of the participants was 4.7 years.
- The mean age of the TGA group was 4.6 years; the mean age of the HLHS group was 3.9 years.

- Ninety-six percent of the participants were Caucasian; 73% were male.
- All participants were considered to be from middle-class families.
- Twelve percent of the participants were enrolled in special education services.

Analysis of surgical data revealed the following:

- Participants in the HLHS cohort experienced longer hospital stays after surgery (mean = 26 days) vs. 16.5 days for the participants in the TGA cohort.
- Participants in the HLHS cohort experienced a longer duration of time (mean = 282 minutes) on cardiopulmonary bypass than did the TGA cohort (mean = 200 minutes).
- Participants in the HLHS group experienced an average of 65 minutes on deep hypothermic circulatory arrest; the TGA cohort experienced an average of 14 minutes on deep hypothermic circulatory arrest. Hypothermic circulatory arrest involves an induced state of hypothermia combined with use of extracorporeal circulation and anesthesia management, the purpose of which is to rest the heart and decrease myocardial oxygen requirements while surgical repair is completed.
- Participants in the HLHS group had an average of three surgeries; those in the TGA cohort had an average of one surgery.

Analysis of cohort scores on the various testing instruments revealed that, in general, the HLHS cohort demonstrated more difficulties with visual–motor skills, expressive language, attention, and externalizing behavior than did the TGA group.

1. What might be considered as limitations to this study?
2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

Children with cardiac problems are a complex population of patients. The heart is integral to all other bodily systems. Whereas a child can survive on one kidney or one lung, heart disease is not self limited and affects most other bodily systems. The nurse must understand various cardiac diseases and problems; treatment of cardiac disease; and care measures for an infant, child, or adolescent with cardiac conditions. Cardiac defects are often associated with other syndromes (Table 27-1).

A & P review Understanding the Heart

Anatomy

A child's heart contracts 60–180 times per minute depending on his or her age. The heart never stops beating although it decelerates during rest and sleep and accelerates during excitement, exercise, or illness.

Chambers

The heart consists of four chambers, two of which act as reservoirs (atria) and two as pumping chambers (ventricles) (Fig. 27-1).

The right atrium is a reservoir or collecting chamber for the peripheral venous return. The right atrium receives deoxygenated blood from the entire body (except lungs) through the superior and inferior venae cavae and coronary sinus with an approximate oxygen saturation of 70%.

The left atrium receives fully oxygenated blood from the lungs through the pulmonary veins, with an approximate oxygen saturation of 100% (Venes, 2009). The ventricles are the remaining two chambers in the heart. From the atria, blood empties into the ventricles through atrioventricular valves. The right ventricle has smaller muscle mass with trabeculated surfaces. The right ventricle receives blood from the right atrium and pumps it into the lungs via the pulmonary artery.

Table 27-1 Syndromes Associated with Cardiac Disease

Syndrome/Disease/ Chromosomal Aberrations	Cardiac Defect/Condition	Other Physical Findings
Down Syndrome	AV canal, VSD	Down's facies, developmental delay
Noonan Syndrome	Pulmonic valve stenosis, LVH	Elfin facies, pectus deformity, joint laxity, undescended testes, spine abnormalities, hypotonia, seizures
Williams Syndrome	Supravalvular aortic stenosis, PA stenosis	Williams' facies: include a small upturned nose, long philtrum (upper lip length), wide mouth, full lips, small chin, and puffiness around the eyes. Hypercalcemia, dental abnormalities, renal problems, sensitive hearing, hypotonia, joint laxity, overly friendly personality.
DiGeorge or Velo-cardio-facial Chromosome	Interrupted aortic arch, truncus arteriosus, VSD, PDA, TOF	Decreased immune response, low set ears, palate problems, hypoparathyroidism and hypocalcemia
Duchenne's Muscular Dystrophy	Cardiomyopathy	Generalized weakness and muscle wasting first affecting the muscles of the hips, pelvic area, thighs and shoulders. Calves are often enlarged.
Marfan Syndrome	Aortic aneurism, aortic and/or mitral regurgitation	Arms disproportionately long, tall thin with laxity of joints, dislocation of lenses, spinal problems, stretch marks, hernia, pectus abnormalities, restrictive lung disease
Trisomy 18	VSD, PDA, PS	Multiple joint contractures, spina bifida, hearing loss, radial aplasia (underdevelopment or missing radial bone of forearm), cleft lip, birth defects of the eye
Trisomy 13	VSD, PDA, dextrocardia	Omphalocele, holoprosencephaly (an anatomic defect of the brain involving failure of the forebrain to divide properly), kidney defects, skin defects of the scalp
CHARGE	TOF, truncus arteriosus, vascular ring, interrupted aortic arch	Coloboma of the eye, Heart defects, Atresia of the choanae, Retardation of Growth and development, and Ear abnormalities and deafness.
Fetal Alcohol Syndrome	VSD, PDA, ASD, TOF	Growth deficiencies, skeletal deformities, facial abnormalities, organ deformities: genital malformations; kidney and urinary defects, central nervous system handicaps
VATER (VACTERLS)	VSD and others	Vertebral anomalies, vascular anomalies, Anal atresia, Cardiac anomalies, Tracheo-esophageal (T-E) fistula, Esophageal atresia, Renal anomalies, radial dysplasia, Limb anomalies, Single umbilical artery
Turner Syndrome	CoA, ASD, AS	Kidney problems, high blood pressure, overweight, hearing difficulties, diabetes, cataracts, and thyroid problems, lack of sexual development, a "webbed" neck, a low hairline at the back of the neck, drooping of the eyelids, dysmorphic, low set ears, abnormal bone development, multiple moles

The left ventricle typically is thicker with a smooth interior. The left ventricle receives blood from the left atrium and pumps it into the systemic circulation via the aorta (Venes, 2009).

Valves

There are four valves in the heart. Two are atrioventricular (AV) valves connecting the atria and ventricles (Fig. 27-2). The tricuspid valve connects the right atrium to the right ventricle and is so named because it consists of three cusps or "doors" that open to allow blood flow into the adjoining chamber and shut to prevent backflow. The mitral valve, called the bicuspid valve for its two cusps, connects the left atrium to the left ventricle. The aortic and pulmonary valves are both tricuspid and are called semilunar valves because the cusps look like a half-moon. The pulmonary valve is located at the junction of the right ventricle and pulmonary artery. It prevents regurgitation of blood from the pulmonary artery to the right ventricle. The aortic valve, located at the junction of the left ventricle and the ascending aorta, also prevents regurgitation (Venes, 2009).

Vessels

Aside from the chambers and the valves in the heart, there are major vessels that lead to and from the heart. The vena cava carries the blood from body tissues to the right atrium. The superior vena cava lies above the heart and carries blood from the head, arms, and upper body. The inferior vena cava lies below the heart and carries blood from the legs, abdominal organs, and lower part of the body. The pulmonary artery is the only named artery in the body that carries deoxygenated blood. It is called an artery because it carries blood away from the heart, but since it arises from the right ventricle, it carries deoxygenated blood. It carries this blood to the pulmonary capillary bed, where it interfaces with the alveoli in the lungs and "picks up" oxygen. From the lungs, the blood returns to the heart through the pulmonary veins into the left atrium (the only veins that carry oxygenated blood). The blood leaves the left ventricle through the aortic valve, through the aorta and out to the body (Fig. 27-3).

Figure 27-1 Chambers of the heart.

Figure 27-3 Vessels of the heart.

Figure 27-2 Valves of the heart.

Figure 27-4 Normal blood flow.

Normal Flow

It is important to understand the flow of blood through the cardiovascular system because an interruption in any one of the vessels, valves, or chambers causes a disruption in the cardiac output. Venous system, venae cavae, right atrium, tricuspid valve, right ventricle, pulmonary valve, pulmonary artery, and lungs pick up O_2 . The pulmonary veins, left atrium, mitral valve, left ventricle, aortic valve, aorta, and arteriole system delivers O_2 via the blood to the cells of the body (Fig. 27-4).

Physiology

The simplest way to understand the physiology of the heart is to comprehend that the purpose of the heart is to pump blood. This vital pumping function provides a means to carry oxygen via the hemoglobin to the tissues. Without oxygen delivery, cells die and ultimately body systems fail. The heart must maintain a cardiac output at all times. The components of cardiac output (CO) are cardiac output and stroke volume.

Cardiac output is the amount of blood discharged from the left or right ventricle per minute (Venes, 2009). Cardiac output is the product of stroke volume (SV) and heart rate (HR).

Stroke volume is the amount of blood ejected by the left ventricle with each heartbeat (Venes, 2009). Stroke volume is the product of preload, after-load, and contractility (inotropy) ($CO = SV \times HR$).

An altered cardiac output limits the blood's ability to provide oxygen to the tissues. Since heart rate and the size of the heart vary with the size of the child, the volume of cardiac output will vary accordingly. A variety of methods measure cardiac output, with varying degrees of accuracy. The Fick calculation is the most accurate way to measure cardiac output (Fig. 27-5). ♦

$$\text{Pulmonary flow } (Q_p) = \frac{VO_2}{C_{PV} - C_{PA}}$$

$$\text{Systemic flow } (Q_s) = \frac{VO_2}{C_{AO} - C_{MV}}$$

Figure 27-5 Fick calculation.

Nursing Insight— Congestive heart failure

Many congenital and acquired cardiac conditions result in congestive heart failure (CHF). Much of the basic nursing care of a patient with a cardiac condition is dependent on the degree of the CHF.

Cardiac failure occurs when the heart can no longer fully accomplish its intended purpose. CHF, or called simply heart failure, is characterized by the inability of the cardiac muscle to perform its proper function of moving blood forward. Blood is “congested” in a backward direction. The heart’s pumping action is lost so the blood backs up into other areas of the body such as the lungs or the liver. This backward congestion of fluid eventually fills into the periphery.

Signs and Symptoms

The signs and symptoms of CHF vary with age and whether the fluid is more congested on the right or left side. Infants present with poor feeding, poor growth, irritability, shortness of breath (SOB), or excessive sweating. In advanced stages an enlarged liver or edema develops. Older children show poor growth, shortness of breath, and exercise intolerance. Peripheral edema in children does not present in the same way as in adults. Ascites rarely occurs in children except in the most dramatic cases and more often in teenagers. Babies and toddlers exhibit puffy eyelids, swelling of hands and feet, and the fontanel may be bulging. Congenital heart disease (CHD), arrhythmias, or other cardiac diseases such as cardiomyopathy (CM) or Kawasaki disease can lead to CHF.

Diagnosis

Diagnosis includes patient history and physical examination findings including vital signs (blood pressure and pulses may be diminished), weight gain, or changes in breath sounds. Diagnostic measures include chest x-ray exam, exercise test, echocardiogram, magnetic resonance imaging (MRI), and cardiac catheterization.

Nursing Care

CHF is treated with medications or, if due to some congenital defects, surgery. Positive inotropes such as digoxin (Lanoxin) or even the stronger dopamine drugs are used when poor contractility is the cause of CHF. If increased preload is the cause, then diuretics such as furosemide (Lasix) or hydrochlorothiazide (Aquazide) may be used. Vasodilators such as captopril (Capoten) or enalapril (Vasotec) are prescribed if increased afterload is the causative factor. Often all three are used in conjunction. Because of the risk of dehydration, fluid restriction is not often used in pediatrics except in the worst cases.

Congenital Heart Disease

Congenital heart disease is a defect in the heart, great vessels, or a noted disease pattern after birth. Congenital heart defects occur in approximately 1% of all pregnancies and 1 in 170 live births (Neilson & Robin, 2002). There are various ways by which the nurse can recognize a congenital heart defect, including recognizing the shunting pattern and recognizing cyanotic versus acyanotic congenital heart defects.

CYANOTIC VERSUS ACYANOTIC CONGENITAL HEART DEFECTS

Congenital heart defects are classified as cyanotic versus acyanotic: many, but not all, cardiac defects involve mixing of blood. If the blood from the right side of the heart or venous blood is forced into the left side of the heart, as in right-to-left shunting, the overall oxygen saturation of the blood ranges from normal (96-100%) to as low as 70%.

In the presence of normal hemoglobin, a decrease in the oxygen saturation to 85% will cause an outward sign of cyanosis (bluish coloration) that appears around the lips, nose, and mouth of babies and toddlers and in the nail beds of older children. If the decreased oxygen state is chronic, the child eventually will develop clubbing of the fingernails. The longer and lower the oxygen saturation the more evident the clubbing. The physiological explanation for this change is that the capillaries enlarge to accommodate the low saturation in an attempt to deliver more blood to the periphery.

Another long-term effect of low oxygenation is polycythemia. Polycythemia is the increase in the red blood cell production in response to the low oxygen output. The patient has hemoglobin (Hgb) levels greater than 15 (g/dL). The condition also causes thickening of the blood and predisposes the child to thrombi and stroke.

Nursing care entails monitoring and maintaining the child’s oxygen and nutritional status. The nurse educates the family regarding rest periods and managing the child’s fatigue.

Now Can You— Understand the heart?

1. Discuss the anatomy and physiology of the heart?
2. Identify signs and symptoms in a child with congenital heart disease?

Segmental Classification of Congenital Heart Defects

In the United States, cardiac defects occur in 8 to 12 per 1000 (1%) live births (Park, 2003). Several types of cardiac defects may be responsible for CHD (Table 27-2). The nurse may best understand the cardiac defects via a segmental approach organized by the type of defective physical structure. Cardiac defects are those of the septum or septae [pl] (chamber walls), vessels and valves, conotruncal defects, as well as combination defects.

DEFECTS IN THE SEPTUM

Atrial Septal Defect

Atrial septal defect (ASD) is a simple defect of the atria. During fetal development, the septal wall forms between the 4th and 8th week of life when two septae, the primum and secundum, stretch around the center of the common atrium (Fig. 27-6). Eventually these septae overlap and form an area called the foramen ovale. The foramen ovale is a necessary structure during fetal life, but should close within hours after birth. Sometimes the foramen ovale may persist until 1 year of life. An ASD results when the two septae fail to form properly. Primum ASD and secundum

Table 27-2 Classification of Cardiac Defects

Class	Name	Prevalence (% of all defects)	Types or Forms	Associated Defects
L–R Shunt	Atrial–septal defect	5–10 (50–100)	Secundum or primum or sinus venosus	PAPVR or MVP
	Ventricular septal defect	20–25 (200–250)	Perimembranous, muscular, multiple	PDA, CoA, AV prolapse
	Patent ductus arteriosus	5–10 (50–100)	Large shunt or small	
	AV canal	0.02 (0.20)	Complete or partial; balanced or unbalanced	AV regurgitation. 30% of cases occur with Down syndrome
	Partial anomalous pulmonary venous return	<1 (10)	TAPVR	ASD
Obstructive Lesions	Pulmonary stenosis	5–8 (50–80)	Valvular, subvalvular, supra-ventricular (PA)	VSD, Noonan syndrome
	Aortic stenosis	0.05 (0.50)	Valvular, subvalvular, supra-ventricular	Bicuspid aortic valve, Williams syndrome, IHSS
	Coarctation of the aorta	5–10 (50–100)	Preductal, postductal, ascending aorta, descending aorta	Bicuspid AV, aortic hypoplasia, VSD, PDA, abnormal MV
	Interrupted aortic arch	0.01 (0.10)	Type of coarctation, types A, B, C	PDA, VSD, bicuspid AV, MV deformity, truncus arteriosus, subaortic stenosis
Cyanotic Defects	Transposition of the great arteries	0.05 (0.50)	D-type, L-type,	ASD, VSD, PDA, PS
	Tetralogy of Fallot	0.10 (1.00)	PS or PA or absent PV with PS	May be cyanotic or acyanotic if PS is mild
	Total anomalous pulmonary venous return	0.01 (0.10)	Supracardiac, cardiac draining into RA, cardiac draining into the coronary sinus, infracardiac; obstructive	ASD or PFO
	Tricuspid atresia	1–2 (10–20)		ASD, VSD, PDA, CoA, TGA
	Pulmonary atresia	<1 (10)	Variable RV sizes	ASD, PFO or PDA
	Epstein's anomaly	<1 (10)	Variable degrees of displacement	WPW, RA hypertrophy, ASD
	Truncus arteriosus	<1 (10)	Types I-IV showing various placements of PA arising from the aorta	Large VSD, right Ao arch, DiGeorge syndrome
	Single ventricle	<1 (10)	DILV or RV	ASD, PS, PA, CoA, VSD, asplenia, polysplenia, TGV
	Double outlet right ventricle	<1 (10)	Types are by the position of the VSD: subaortic VSD, subpulmonary VSD, remote VSD, subaortic VSD with PS, doubly committed VSD	VSD, PS
	Splenic syndromes	<1 (10)	Asplenia and polysplenia	Various redundant cardiac structures or absence of structures

The numbers in parentheses indicate the number of infants born with defects out of 100,000 live births.

© Judith M. Marshall, 2006.

ASD are two variations of the defect, which differ in the location of the defect on the septal wall.

SIGNS AND SYMPTOMS. A murmur may or may not be present and the child may or may not have a right ventricle (RV) heave or a thrill (abnormal tremor accompanying a vascular or cardiac murmur felt on palpation) (Venes, 2009). At worst case, the ASD in the child is the source of right atrial enlargement caused by fluid overload from left to right shunting through the opening in the atrial wall. This fluid overload can extend to the right ventricle, which is the source of the RV heave and show an axis change on an ECG.

It also produces a fixed split second heart sound. The liver becomes engorged as result of this fluid overload. Other signs and symptoms of cardiac failure such as shortness of breath, respiratory distress, periorbital edema, failure to thrive, and increased respiratory infections may be noted. These signs gradually worsen with time unless the defect is repaired. An ASD along with atrial fibrillation may predispose the child to stroke due to the tendency of blood pooling and risk of thrombus formation.

DIAGNOSIS. ASD is confirmed by chest x-ray exam, echocardiography, cardiac catheterization, and ECG.

Figure 27-6 Atrial septal defect.

NURSING CARE. Without treatment, certain types of ASDs may close spontaneously in the first year of life and the child typically shows no outward signs of a malformation. The ASD, if not closed spontaneously, may be closed with a surgical procedure or interventional cardiology where a closure device is inserted. Nursing care focuses on postoperative management of the child.

critical nursing action Postoperative management

Provide immediate postoperative care in the intensive care unit:

- Record the vital signs frequently until the child is stable.
- Maintain “lines” (there may be several):
 - A peripheral IV line is used to administer fluid and medications.
 - A central venous pressure (CVP) line is inserted in a large vessel in the neck and is used to measure central venous pressure.
 - Intracardiac lines are inserted in the right atrium, left atrium, and pulmonary artery and are used to measure the pressures inside the cardiac chambers that provide essential information about cardiac output, blood volume, pulmonary pressures, ventricular function, and drug therapy response.
- Assess and maintain respiratory status. Respiratory assessment is done frequently and oxygen is given via mechanical ventilation.
- Monitor fluid status. Accurately measure the intake and output of all fluids.
- Assess for signs and symptoms of infection.

clinical alert

Renal failure

Renal failure is considered when the output is less than 1 mL/kg per hour along with an elevation in serum creatinine and blood urea nitrogen.

- Monitor blood lab values for postoperative bleeding and post-pump electrolyte imbalances.
- Suction secretions.
- Maintain chest tubes that remove secretions and re-expand the lungs. Check drainage for quantity and color.

clinical alert

Postoperative hemorrhage

Postoperative hemorrhage is considered when there is excessive chest tube drainage greater 5–10 mL/kg in 1 hour or more than 3 mL/kg per hour in 3 consecutive hours.

- Assess for complications such as cardiac, neurological, pulmonary, or hematological changes; infection; and delayed growth and development.
- Consider the child’s level of development in order to provide developmentally appropriate care.
- Ensure rest, which is essential to promote healing and decrease the work load of the heart.
- Manage pain via comfort measures and the administration of medication.
- Group nursing care to avoid imposing unnecessary fatigue and weakness.
- Provide emotional support and information about home care.

Ventricular Septal Defect

A ventricular septal defect (VSD) is the most common congenital heart defect. Fortunately, it is one of the mildest. A VSD forms much the same way as an ASD. In fetal development at the approximate gestational age of 4 to 8 weeks, the wall is formed when a superior and inferior limb (like a divider) of tissue come together to create a wall between the two chambers (Fig. 27-7). The wall can have a single opening or be fraught with multiple defects, sometimes called a Swiss cheese VSD.

The defect may be located anywhere on the ventricular septal wall. Usually those in the muscular septum close spontaneously. If left alone, individuals can live a long normal life. At the worst case, the child suffers from right ventricular overload from left-to-right (acyanotic) shunting of blood due to the high-pressure gradient from the left to the right side. Generally, a VSD is repaired surgically. However, in the future, the use of a transcatheter closer device may be used.

SIGNS AND SYMPTOMS. Most patients with VSDs are asymptomatic. If the VSD is large and there is a heavy left to right shunt, the patient develops signs of right ventricular

Figure 27-7 Ventricular septal defect.

failure, such as shortness of breath, feeding difficulties, poor growth, easy fatigability, and recurrent pulmonary infections. Typically, a harsh murmur along with a thrill at the lower left sternal border is detected at the well baby check-ups.

DIAGNOSIS. Diagnosis is based on an audible heart murmur along with other signs and symptoms. A chest radiograph, ECG, echocardiogram, or cardiac catheterization may help confirm the diagnosis.

NURSING CARE. Care of the child with VSD is similar to that of the child with ASD. Nursing care focuses on post-operative management of the child.

Atrioventricular Canal Defect

An atrioventricular canal defect (AVC) is also known as complete AVC or endocardial cushion defect (ECD). This defect is somewhat of a combination of an ASD and VSD. However, it is much more than that, as it involves the valves. In its simplest definition, an AVC is a large hole in the center of the heart. The endocardial cushion fails to form properly. There are openings on the atrial wall and the ventricular wall, and the tricuspid and mitral valve come together to form one large valve (Fig. 27-8). These defects are often seen in children with Down syndrome, although 70% of AV canal defects are seen in children who have no other anomalies. This defect must be repaired surgically if the child is to live a normal life span. Although the blood is mixed through this large open space, the shunt is left to right and the child is not cyanotic.

SIGNS AND SYMPTOMS. Signs and symptoms of cardiac failure such as shortness of breath, respiratory distress, periorbital edema, failure to thrive, increased respiratory infections, and distended liver may be noted. These signs will gradually worsen with time unless the defect is repaired. There are many variations of this defect including partial ECD.

DIAGNOSIS. A complete physical examination, listening to the heart and lungs, help in the diagnosis. A heart murmur is verified. Additional tests such as chest x-ray, ECG, echocardiogram, cardiac catheterization, and cardiac magnetic resonance imaging (MRI) confirms the diagnosis.

Figure 27-8 Atrioventricular canal defect.

NURSING CARE. Care of the child with AVC is similar to that of the child with ASD and VSD. Prior to surgery, nursing care is geared toward optimizing the cardiac output and ensuring adequate weight gain. Nursing care focuses on post-operative management of the child.

Nursing Insight— Care of the child with congenital heart defects

The hospital nurse most often cares for a child with a congenital heart defect when the child is admitted for surgery. Occasionally, a child with a defect may be admitted for reasons not related to the heart. The child should always be monitored for signs of CHF and measures taken to prevent fatigue, fluid overload, or infections.

The school nurse may also have students with congenital heart defects. Typically, the cardiologist or cardiology nurse practitioner submits letters to the school that outline the plan of care and any physical or activity restrictions. Anyone caring for a child who is taking cardiac medications must understand the effects, side effects, and proper dosing.

DEFECTS OF THE VESSELS AND VALVES

Patent Ductus Arteriosus

A patent ductus arteriosus is probably the simplest form of vessel defect (Fig. 27-9). Remember that the ductus arteriosus is a normal structure during fetal life. In utero, the pulmonary resistance is high because the lungs are filled with fluid and not air. The blood is oxygenated through the placenta by the umbilical vein. Instead of the blood moving from the pulmonary artery (PA) to the lungs, the ductus is a pop-off valve for the large volume of fluid. As the blood flow follows the “path of least resistance,” the blood moves through the ductus, into the aorta, and out to the body tissues. Directly after birth and the baby’s first breaths, the pulmonary resistance starts to drop and the blood flow goes from the PA into the lungs. Since there is decreased flow through the PDA, the duct starts to close. Changes in prostaglandin level assist the closure as well. In 8 to 10% of the population, the PDA remains open (Park, 2003). It can take as long as 1 year for the PDA to close completely. The

Figure 27-9 Patent ductus arteriosus.

pediatric cardiologist monitors the asymptomatic child up to 1 year for spontaneous closure of the PDA.

If a large PDA is not closed, severe long-term sequelae may ensue. At birth, the pulmonary resistance is higher than the left-sided pressures. As this gradient reverses, the left-sided pressure forces blood toward the right side through the PDA. Eventually, the fluid congests the right side of the heart and the pulmonary bed. The right ventricle hypertrophies in an attempt to mobilize fluid forward. The defect occurs alone, or in combination with coarctation of the aorta.

SIGNS AND SYMPTOMS. The PDA murmur is distinctive in sound and location. Other symptoms include frequent colds and susceptibility to RSV, fatigue, poor feeding, and poor growth pattern.

DIAGNOSIS. The presence of the characteristic machine-like murmur under the left clavicle along with symptoms of heart failure leads to the diagnosis of patent ductus arteriosus. Chest radiograph shows an enlarged heart and evidence of an excessive amount of blood flow to the lungs. An echocardiogram confirms the diagnosis, demonstrating the size of the ductus arteriosus and enlargement of heart chambers due to the extra blood flow.

NURSING CARE. A PDA may be closed surgically or with a transcatheter device. The PDA may also be “forced” closed using the medication indomethacin (Indocin). Nursing care focuses on postsurgical measures, such as care of the wound, monitoring vital signs, and ensuring adequate hydration and nutrition.

Nursing Insight— Subacute bacterial endocarditis prophylaxis (SBE)

If the child has a high risk for bacterial endocarditis, the physician may prescribe antibiotics before dental work and surgery. The child may require this for only 6 months after the defect is repaired. Each case is treated individually according to published American Heart Association guidelines.

Pulmonic Stenosis

Pulmonic stenosis or pulmonic valve stenosis (PS or PVS) is a malformation of the pulmonary artery or pulmonic valve. The narrowing of the valve causes an increased workload on the right ventricle (Fig. 27-10), which in turn leads to congestive heart failure (CHF) with symptoms such as hepatomegaly. This condition is frequently associated with Noonan syndrome and is part of the combination condition called tetralogy of Fallot.

Nursing Insight— An insufficient valve

Valves may be congenitally malformed, or become physically altered because of disease. If the valve does not close properly, there may be leakage called regurgitation or insufficiency when the valve is stiff or stenotic. When the valve is insufficient, the ventricle must pump with greater force to push blood through a stiff or “sticky” door. Because of the backflow of blood, the ventricle pumps with a greater force of contraction because there is more volume (Starling’s law). This constant added force eventually wears on the cardiac muscle.

Figure 27-10 Pulmonary stenosis.

SIGNS AND SYMPTOMS. A heart murmur is the most common sign of pulmonic stenosis. During periods of increased blood pressure such as with excitement, exercise, and crying, the child may experience dyspnea (breathlessness) or in the most severe cases, brief moments of cyanosis when the blood flow does not reach the pulmonary bed.

DIAGNOSIS. Diagnosis is confirmed by presence of heart murmur, electrocardiogram, and echocardiogram. Cardiac catheterization measures the degree of pulmonary stenosis.

NURSING CARE. Depending on the gradient (difference in the pressure measurements), the cardiologist may choose to observe the child over time before deciding to treat or to treat immediately. Treatments include balloon angioplasty or valvuloplasty (a procedure that reopens narrowed blood vessels and restores forward blood flow) or open heart surgical intervention. Since this valve is in an area of low flow and low pressure, these children often do well with one intervention, but should be monitored over time for restenosis. Care measures help the patient to reduce stressful situations that may cause high blood pressure.

Nursing Insight— Pulmonary atresia

Pulmonary atresia is a dramatic fatal defect if not corrected or palliated (treated to reduce effect) early in life. Pulmonary atresia is absence of the pulmonary valve, pulmonary artery, or both (Fig. 27-11). The child must have an ASD or patent foramen ovale (PFO), the opening present in utero and at birth which closes spontaneously and/or a PDA in order to survive. If these are not present, emergency procedures are performed to save the child’s life. Initially prostaglandin (PGE₁) is infused to maintain patency (free flow) of the PDA. A balloon atrial septostomy (formation of an opening in a septum) is performed to create an ASD (Venes, 2009). Initial surgical repair includes a shunt (diversion) or a conduit (channel). Later, a Fontan procedure (a procedure used to repair complex single ventricle type congenital heart defects) may be needed.

Figure 27-11 Pulmonary atresia.

Aortic Stenosis

Aortic stenosis or aortic valve stenosis (AS or AVS) is a malformation and narrowing in the aorta or around the aortic valve (Fig. 27-12). A narrowing in this area causes an increased workload on the left ventricle and eventually leads to hypertrophy (increase in size) and heart failure. This condition may also be acquired.

SIGNS AND SYMPTOMS. In children with aortic stenosis, a murmur may be audible during the systolic phase of the cardiac cycle. A click may be heard and a thrill may be noted. The child may have chest pain or fatigue and syncope on exertion. Critical AS causes heart failure in neonates. Variations of this defect are supra- and subvalvar stenosis and an association with bicuspid aortic valve.

DIAGNOSIS. Diagnosis is based on the clinical findings, chest x-ray exam, and echocardiogram. An ECG may show left ventricular hypertrophy. Cardiac catheterization is the definitive test, also measuring the exact gradient.

NURSING CARE. In critical situations with very narrow valves, preload and afterload reduction medication is indicated. Since this valve is in a high-flow high-pressure area,

Figure 27-12 Aortic stenosis.

it is more critical to correct. An angioplasty or valvuloplasty is performed to open the narrow area with a balloon. Another treatment mode is surgical intervention to repair or replace the valve. Nursing care is based on medical and/or postoperative management. Aortic stenosis requires life-long monitoring.

Coarctation of the Aorta

Coarctation of the aorta (CoA) is a narrowing or stricture of the descending aorta distal to the carotid arteries. The coarctation is classified by its location: preductal, ductal, or postductal.

SIGNS AND SYMPTOMS. Normally, blood pressure in the legs should be higher or equal to that in the arms. When a BP in the lower extremities measures >10 mm Hg less than that in the upper extremities, the practitioner suspects a CoA (Park, 2003). Occasionally, the BP in the right arm is higher than in the left. This usually occurs with a preductal coarctation in which the blood flow to the left arm is supplied by the flow of blood through the ductus, which is a lower pressure system. For this reason, if only one upper extremity is used as comparison to the lower extremities, it should be the right arm. If a child is hypertensive, the nurse should suspect CoA. The child may show signs of CHF. The child may have pain in the legs or cyanotic lower extremities.

DIAGNOSIS. The classic diagnostic feature of this defect is a high gradient, which is the difference in the pressure measurements between the arms and legs (Fig. 27-13).

NURSING CARE. Surgery is always indicated for this condition. Nonsurgical treatment for older infants and adolescents involves a balloon angioplasty and stent placement. Nursing care focuses on postoperative management of the child. The child is seen in follow-up for evidence of restenosis.

Tricuspid Atresia

Tricuspid atresia (TA) occurs when there is an error of the formation of the tricuspid valve. As a single defect, this condition is incompatible with life, since no blood from the RA reaches the RV and thus the right ventricular

Figure 27-13 Coarctation of the aorta.

Figure 27-14 Tricuspid atresia.

outflow tract (RVOT) leading to the PA and the lungs. For this reason, most children born with TA also have comorbidity with a septal defect such as ASD or VSD as well as a PDA. The deoxygenated blood must reach the pulmonary bed to sustain life (Fig. 27-14).

SIGNS AND SYMPTOMS. The initial signs are dramatic as the PDA starts to close in the hours after birth, the child becomes severely cyanotic, tachycardiac, and dyspneic. A heart murmur is generally present.

DIAGNOSIS. Tricuspid atresia may be discovered during a routine prenatal ultrasound imaging or at birth based on the signs and symptoms. Diagnostic testing includes ECG, echocardiogram, chest radiograph, and cardiac catheterization.

NURSING CARE. Tricuspid atresia requires emergency intervention. Initially, the neonate is given PGE₁ to keep the PDA from closing. In addition, if there is no ASD or PFO, an emergent balloon atrial septostomy is performed to ensure survival. The next step is to perform a systemic–pulmonary (SP) shunt if the pulmonary blood flow is deficient or a PA band if the pulmonary blood flow is excessive. Eventually a Glenn procedure may be done and Fontan procedure is the definitive surgery. Nursing care focuses on postoperative management of the child.

clinical alert

Survival

With any congenital defect, as long as there is mixing of oxygenated and deoxygenated blood, the child survives. A more definitive surgery such as a Fontan procedure is performed at a later date to correct the condition.

Nursing Insight— Epstein's malformation

Epstein's malformation occurs when the tricuspid valve is displaced into the right ventricle (Fig. 27-15). Typically, in this condition, an ASD is present. The ventricle and the

Figure 27-15 Epstein's malformation.

atria may become hypertrophied and this condition is often associated with supraventricular arrhythmias, particularly Wolff–Parkinson–White syndrome. With Epstein's malformation the child may live normally or require treatment. Surgical intervention is the treatment of choice.

Total Anomalous Pulmonary Venous Return

Total anomalous pulmonary venous return (TAPVR) is a condition in which the pulmonary blood flow returns to the heart through the right atrium rather than the left (Fig. 27-16). The child usually has an ASD, allowing the blood to flow back to the left ventricle and out to the body tissues. As a consequence of ASD, mixing of venous blood with arterial blood may occur, causing a cyanotic condition. One problem for a child with TAPVR is that a high volume of blood returns to the right side of the heart, causing right-sided hypertrophy and enlargement. If an ASD is not present, one needs to be created with a balloon septostomy. A variation of this condition is partial anomalous pulmonary venous return (PAPVR), in which two of the veins return blood to the left side and two of the veins return blood to the right side. Other variations are simply in routing of the blood flow back to the heart.

Figure 27-16 Total anomalous venous return.

SIGNS AND SYMPTOMS. The child has cyanosis, respiratory distress, lethargy, poor and rapid breathing, poor feeding, frequent respiratory infections, and signs of heart failure.

DIAGNOSIS. Diagnosis is based on signs and symptoms and diagnostic testing including ECG, echocardiogram, chest x-ray exam, and cardiac catheterization.

NURSING CARE. The treatment for TAPVR is complete surgical repair. Post-surgery, the child can live a full normal life, but should be followed routinely (every 1 to 2 years) for any reoccurring stenosis. Nursing care focuses on post-operative management of the child.

CONAL-TRUNCAL DEFECTS

Conal-truncal defects develop during the formation of the trunk dissection. Embryologically, the pulmonary artery and the aorta begin as a large “trunk.” The ventricles then fold on themselves, the atria rise into position, and the great vessels form when the trunk twists around and septates (having a dividing wall). Transposition of the great vessels and truncus arteriosus occur in children when there is a disruption in this process.

Transposition of the Great Arteries or Vessels

Transposition of the great arteries or vessels (TGA or TGV) occurs in utero when the signals cross and instead of twisting there is simply a septation and the aorta arises from the right side of the heart and the pulmonary artery arises from the left (Fig. 27-17).

SIGNS AND SYMPTOMS. Symptoms appear at birth or soon afterwards and include cyanosis, shortness of breath, poor feeding, and clubbing of the fingers and toes.

DIAGNOSIS. Diagnosis is based on signs and diagnostic testing including pulse oximetry, ECG, echocardiogram, chest x-ray exam, and cardiac catheterization. If an echocardiogram is done before birth, it is called a fetal echocardiogram.

NURSING CARE. The severity of the signs and symptoms of this condition direct the exact treatment for the child. TGA in all cases must be surgically corrected, typically

Figure 27-17 Transposition of the great vessels.

where research and practice meet: Repair of Transposition of the Great Vessels or Arteries

Until approximately 1975, TGV or TGA was corrected through a palliative procedure called a Mustard or Senning in which a tunnel or baffle was created in the right atria shunting blood to the left atria, then the left ventricle and therefore out the aorta. This was not a definitive repair and the children were often cyanotic and many times did not survive into adulthood. In 1975 a surgical procedure called arterial switch was first performed. By 1985, this procedure had replaced the Mustard and Senning as the treatment of choice (Park, 2003). In surgery the position of the aorta and the PA are permanently switched. Arterial switch is not without long-term side effects, but after surgery the child can lead a full, normal acyanotic life.

with an arterial switch operation This is considered a definitive repair and the prognosis is good. Nursing care focuses on postoperative management of the child.

Truncus Arteriosus

Truncus arteriosus is a complicated cyanotic lesion with a poor prognosis if not treated surgically. In truncus arteriosus, the trunk has not twisted or septated. There are multiple variations of the condition, classed I to IV, but the general physiology is that the aorta and pulmonary arteries (PAs) are combined, with full mixing of blood (Fig. 27-18). Sometimes the PAs arise from the aorta, either ascending or descending.

SIGNS AND SYMPTOMS. Clinical signs and symptoms of truncus arteriosus include cyanosis, congestive heart failure, and low cardiac output.

DIAGNOSIS. Diagnosis is based on signs and diagnostic testing that includes pulse oximetry, ECG, echocardiogram, chest radiograph, and cardiac catheterization.

NURSING CARE. This condition requires palliative and complete surgical repair. Treatment for children includes aggressive medical regimen with inotropic medications along with preload and afterload reduction. Nursing care focuses on postoperative management of the child.

Figure 27-18 Truncus arteriosus.

COMBINATION DEFECTS

Tetralogy of Fallot

Tetralogy of Fallot (TOF) is a condition always seen in combination with multiple defects. *Tetra* is from the Latin root “four” and Fallot is the name of the physician who defined it as a syndrome or common grouping. There are always four associated conditions: VSD, overriding aorta, hypertrophic RV, and pulmonary stenosis or atresia. With advanced technology and early screening, this condition is diagnosed at an early age. As recently as the 1980s TOF was undetected for many years, and in developing countries remains so even today.

SIGNS AND SYMPTOMS. In TOF, a stenotic vessel and high pulmonary vascular resistance (PVR) cause the right ventricle to hypertrophy (Fig. 27-19).

clinical alert

Tetralogy of Fallot

The hallmark sign of TOF is cyanosis with crying or playing, which is relieved by squatting or drawing up the legs. These episodes are called “TET” spells—cyanotic events exacerbated by excitement and crying, then relieved by a decrease in pulmonary vascular resistance.

DIAGNOSIS. Diagnosis of TOF is based on signs and symptoms such as cyanosis, breathing difficulties, fainting, fatigue and weakness, slow growth, or developmental delay. Tests including ECG, echocardiogram, chest x-ray exam, and cardiac catheterization confirm the diagnosis.

NURSING CARE. Nursing care focuses on postoperative management of the child because the treatment for TOF is surgical repair. Presurgical care involves preventing or minimizing symptoms associated with the defect.

Nursing Insight— A way to remember cyanotic defects

The nurse can remember that all defects starting with a “T” are cyanotic defects. There is no special reason why; it is just a convenient way to remember which defects are cyanotic.

Complex or Single Ventricle Type Defects

Complex single ventricle defects are most often cyanotic conditions with full mixing of oxygenated and deoxygenated blood. The main problem in these defects is that there is only one physiological pumping chamber or ventricle. A VSD may be present. In these conditions, palliative procedures allow the child to grow until a definitive repair may be performed. Hypoplastic left heart syndrome is a condition in this category.

Nursing Insight— Hypoplastic left heart syndrome

Hypoplastic left heart syndrome is a life-threatening defect that must be treated shortly after birth in order to sustain life. The defect is one in which the left ventricle is extremely small or hypoplastic and unable to maintain an adequate cardiac

output. The right ventricle must act quickly as the primary pumping mechanism of the cardiac system (Fig. 27-20). This is possible only if there is a left-to-right connection. Occasionally, an ASD is present, but many times an artificial shunt or pathway must be created shortly after birth. Prostaglandin (PGE₁) is given to keep the PDA open. A Norwood procedure is the first stage in the process along with a Blalock-Taussig (BT) shunt. Eventually a Glenn procedure provides more blood flow and ultimately a Fontan procedure is performed. The only other option for treatment is a cardiac transplantation. Otherwise, the family can take the child home and provide palliative care measures.

nursing diagnoses Congenital Heart Defects

- Decreased cardiac output related to structural factors of congenital heart defect and ineffective contraction of the cardiac muscle
- Ineffective breathing pattern related to pulmonary congestion and decreased cardiac output
- Activity intolerance related to decreased cardiac output
- Risk for infection related to debilitated state, decreased oxygenation, decreased cardiac output

Figure 27-19 Tetralogy of Fallot.

Figure 27-20 Hypoplastic left heart syndrome.

case study Infant with a Heart Murmur

Abby, a 1-month-old infant, is seen in the community clinic for a heart murmur that was heard at birth. The clinic nurse obtains a history from the mother about the infant's weight gain, feeding patterns, and behavior. The mother reports that the baby has "gained some weight, tires when feeding, and sleeps most of the time." The nurse then performs a complete physical assessment and hears an aortic murmur. This type of murmur is detected as an abnormal, soft blowing sound heard during the systolic phase of the cardiac cycle. The nurse understands the murmur may be a sign of aortic valvular disease such as aortic stenosis.

critical thinking questions

1. What suggestions can the nurse give Abby's mother about feeding the baby?
 2. Discuss important aspects about oral medication administration?
- ◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

Cardiac Diseases

Children with cardiac diseases are at risk for alterations in health such as growth and development, nutrition, psychosocial functioning, and schooling, as well as at an increased risk for infection, acquiring other diseases, and even cardiopulmonary arrest. Sometimes these children have significantly altered life styles and undergo constant medical treatment. The nurse must have a good understanding of common cardiac diseases in children and be prepared to provide essential nursing care measures.

SUBACUTE BACTERIAL ENDOCARDITIS

Subacute bacterial endocarditis (SBE) occurs subsequent to a bacterial infection or introduction of an infective agent into the child's blood stream. The infection may be caused by an invasive procedure such as surgery, urological procedures, or most often dental cleaning. The bacterium in the blood stream adheres to a rough area in the heart such as a stenotic valve or an area of turbulent flow. The bacterium colonizes and causes tissue destruction. SBE is most commonly seen in patients with an unrepaired congenital heart defect or valve disease, but can also occur in normal hearts.

SIGNS AND SYMPTOMS. Initially, vague symptoms may include a low-grade fever, malaise, loss of appetite, and muscle aches. A high fever, chills, sweating, stiff joints, or back pain can indicate that acute illness has occurred. As the condition worsens, symptoms of heart failure occur (Venes, 2009).

DIAGNOSIS. A thorough medical history and a physical exam are essential to diagnosis. The history includes symptoms, questions about a heart murmur or valve replacement, surgery, as well as any recent risk factors for a bacterial or fungal infection (dental procedures or catheter for dialysis), recent fever, chills, or flulike symptoms lasting more than 2 weeks. A physical exam may reveal eye hemorrhage petechiae, fluid in the lungs, or signs of a

stroke. Blood cultures to identify bacteria or fungi in the bloodstream may detect endocarditis.

NURSING CARE. SBE is treated with antibiotics, but the most effective approach is prevention. The guidelines for administration and dosage of prophylactic antibiotics are determined by the American Dental Association (ADA) and the American Heart Association (AHA). Guidelines for prescribing prophylaxis treatment were updated in April 2007:

- Patients with prosthetic cardiac valve
- Patients who previously had endocarditis
- Patients with congenital heart disease only in the following categories:
 - Unrepaired cyanotic congenital heart disease, including those with palliative shunts and conduits
 - Completely repaired congenital heart disease with prosthetic material or device, whether placed by surgery or catheter intervention, during the first 6 months after the procedure
 - Repaired congenital heart disease with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
- Cardiac transplantation recipients with cardiac valvular disease

If valve destruction occurs, the valve may need to be repaired or replaced.

KAWASAKI DISEASE

Kawasaki disease, also known as mucocutaneous lymph node syndrome, is a multi system disease affecting the cardiovascular system. The cause is unknown, but a defective immune response to an infectious process is thought to be responsible. Kawasaki disease is not congenital or contagious. During the acute phase, diffuse vasculitis leads to long-term cardiovascular problems in possibly one out of every five patients affected. The nurse understands that one long-term sequel of Kawasaki disease is aneurysm formation in arterial vessels (all aneurysms are concerning but most worrisome are those of the coronary arteries). Other sequelae are myocarditis or rhythm disturbances.

SIGNS AND SYMPTOMS. Signs and symptoms of Kawasaki disease are the result of vasculitis affecting all organ systems.

clinical alert

Kawasaki disease

There is no specific test to detect Kawasaki disease. The diagnosis is based on symptoms. Together with persistent fever (5 days or more spiking to 104°F [40°C]), if the patient has four of the five signs listed below a Kawasaki diagnosis may be made:

- Skin rash
- Cervical lymphadenopathy, typically unilateral, greater than 1.5 mm in diameter
- Edema and erythema of hands and feet with eventual peeling of skin
- Irritation and inflammation of the mouth with "strawberry tongue," erythema, and cracking lips
- Conjunctivitis without exudate.

DIAGNOSIS. Children with fever and fewer than four signs in the presence of vessel aneurysm can also be diagnosed with Kawasaki disease. Other inflammatory diseases such as Rocky Mountain spotted fever, scarlet fever, or toxoplasmosis should be ruled out. Complete blood count (CBC), erythrocyte sedimentation rate (ESR), electrocardiogram, and echocardiogram help to confirm diagnosis.

NURSING CARE. Nursing care begins with the administration of IV immunoglobulin (IVIG) and aspirin (ASA), which are used primarily for their anti-inflammatory effects. Other treatments such as steroids, plasma exchange, or cytotoxic agents may be used if this initial therapy is ineffective (AHA, 2006).

clinical alert

Thrombus formation

Children with aneurysm formation as a result of Kawasaki disease also require long-term follow-up for continued assessment related to other vascular changes such as stenosis or tortuosity (twisting) (AHA, 2006; Park, 2003). Occasionally, cardiac catheterization is indicated to diagnose aneurysm formation. In the event of thrombus (blood clot) formation, the nurse understands that the treatment is the same as any patient who is at risk for a myocardial infarction. Thrombotic agents such as streptokinase (Streptase), urokinase (Abbokinase), and alteplase (Activase) has been used with some success in thrombus formation. Long-term use of anti-coagulants such as warfarin (Coumadin) or clopidogrel (Plavix) may be used to prevent thrombus formation in the engorged or aneurysmal vessels.

Across Care Settings: American Heart Association

The American Heart Association has complete up-to-date information about diagnosis and treatment of Kawasaki disease (<http://www.americanheart.org>).

The nurse can communicate to the family that the frequency of follow-up visits to the physician is usually determined by the initial episode and how fast initial treatment was delivered. Often these children undergo a dobutamine (Dobutrex) or exercise stress test to assess the vascular response to exercise. Coronary bypass surgery is rarely needed and a very small number of children with Kawasaki disease-related complications require a cardiac transplantation.

CARDIOMYOPATHY

Cardiomyopathy (CM) is a condition in which the cardiac muscle becomes dilated, hypertrophied, stiff, or inflamed. There are various classifications and causes, but the end result is the same. The cardiac muscle no longer functions adequately and treatment must ensue to sustain life.

SIGNS AND SYMPTOMS. Generally, the child with CM has a variety of sometimes vague symptoms such as weakness,

excessive tiredness, shortness of breath, exercise intolerance, heart palpitations, chest pain, poor feeding, and slow weight gain. The child may also experience fainting or lightheadedness.

Nursing Insight— Three classes of cardiomyopathy

Dilated (DCM) or congestive cardiomyopathy is the most common form and is due to weakened contractions leading to dilation of all four chambers of the heart. The weakened contractions are thought to be caused by myocardial damage, as a result of toxic agents. Dilated cardiomyopathy is caused by myocardial damage from chemotherapy, microbes, bacteria, viruses, immunological defects, or nutritional disorders.

Hypertrophic cardiomyopathy (HCM) is usually a familial disorder. It is a condition in which the ventricle is hypertrophied, swollen, or thickened in the absence of other cardiac conditions. The pumping mechanism of the ventricle is usually hyperdynamic, but the filling is hindered because of thickening of the ventricle.

Restrictive (RCM) is the least occurring type of cardiomyopathy and is characterized by unusually noncompliant ventricular walls that fail to relax. The size of the ventricle is normal, but the atria are enlarged because of the impaired diastolic filling due to stiffness in the ventricle (Park, 2003).

DIAGNOSIS. Diagnosis includes a complete physical examination that may reveal a murmur, gallop, and venous congestion as demonstrated by hepatomegaly or distended neck veins. An electrocardiogram may show right- or left-sided enlargement and possible Q waves. Tachycardia, cardiac rhythm disturbances, or ventricular ectopy is often seen. The nurse understands that an echocardiogram provides the exact diagnosis. A family history of cardiomyopathy or sudden death of unknown causes in a family member may also alert the practitioner to seek a definitive diagnosis for CM.

NURSING CARE. Nursing care includes a medication regimen that is aimed at improving function of the cardiac muscle. Medications in the angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers have positive inotropic properties influencing the force of muscular contractility (Venes, 2009) and must be continued until the muscle becomes stronger; the need for them may be life long. Other treatment includes beta-blocker therapy and nutritional supplementation particularly with carnitine (Carnitor or L-carnitine). Diuretic and inotropic therapy is also recommended, except in the case of hypertrophic CM.

After the diagnosis, the child with CM must be followed closely for further complications, preferably in a recognized cardiomyopathy program. The nurse can communicate to the family that frequent echocardiograms are warranted to assess the size and function of the ventricular wall as well as to note improvement or deterioration of the condition. The family must also understand that the child is placed on activity restrictions to prevent overstimulation of the heart muscle (Park, 2003). The ultimate treatment quite often is cardiac transplantation.

**medication:** CarvedilolCarvedilol (kar-**ve**-dil-ole)Beta (β)-Adrenoreceptor blocker, α -adrenergic**Pregnancy Category:** C**Indications:** Carvedilol is indicated for the treatment of mild-to-severe heart failure of ischemic or cardiomyopathic origin.**Actions:** Beta blockers slow tachycardia, vasodilation, decreases peripheral vascular resistance, decreases renal vascular resistance, reduces plasma renin levels, increases atrial natriuretic peptide levels**Therapeutic Effects:** Increases stroke volume, decreases blood pressure and improves renal flow, decreases heart rate.**Pharmacokinetics:**

Bioavailability 25–35%

Onset of effect: 1–2 hours

Half-life: 7–10 hours

Contraindications and Precautions: Monitor for possible deterioration of CHF, liver injury, bronchospastic disease, thyrotoxicosis.**Adverse Reactions and Side Effects:** Chest pain, dizziness, hyperglycemia, bradycardia, nausea**Route and Dosage:**

Oral: 0.07 mg/kg per dose

Maximum dose: 0.5 mg/kg

Once or twice daily dosing

Reduce dose for bradycardia <55 beats per minute

Nursing Implications:

1. Initiate with low dose and titrate up as tolerated.
2. Monitor blood pressure for 1 hour after initial dosing
3. Monitor blood pressure, pulse, and ECG frequently.
4. Take with food.

Data from Deglin, J.H., & Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

trauma. Damage to the heart muscle also occurs as the result of a direct blow to the thorax overlying the heart (e.g., a baseball or steering wheel). Electrocutation (injury from electricity) can also cause damage to the cardiac muscle. In cardiac trauma, the particular damage to the heart can be a ventricular rupture, a great vessel tear, damage to the pericardial sac or coronary arteries, cardiac tamponade, myocardial infarction, or arrhythmias.

SIGNS AND SYMPTOMS. The signs and symptoms are related to the type of cardiac trauma sustained.

DIAGNOSIS. The diagnosis of cardiac trauma is made with electrocardiogram (ECG), echocardiogram, and chest x-ray exam.

NURSING CARE. Nursing care is based on the extent and exact type of the injury. The nurse understands that essential nursing care includes bed rest. Activity restrictions must also be enforced until the cardiac muscle heals. In addition, antiarrhythmics, inotropic agents, and pericardiocentesis (aspiration of fluid from the pericardial sac) may be required. A cardiac rehabilitation program can be recommended.

**Nursing Insight— Cardiac tumors**

Cardiac tumors are rare in children and are almost exclusively rhabdomyomas (Park, 2003). Other tumors are teratomas, fibromas, and myxomas. Most of the tumors are benign but significant because they occupy space in the heart and may restrict the normal flow of blood. Surgical removal is the treatment of choice for cardiac tumors. At times, rhabdomyomas may regress; therefore intervention may be delayed. At times, it is surgically unsafe to remove the tumor and a cardiac transplant is needed. A long-term consequence of cardiac tumors includes scar tissue formation, which in turn may lead to arrhythmias.

**Nursing Insight— Rheumatic fever**

Rheumatic fever (RF) is a group-A hemolytic streptococcal infection affecting multiple bodily systems such as the heart, the joints, subcutaneous tissue, and at times the nervous system. During the acute phase of rheumatic fever, the entire heart may suffer due to vegetations or deposits of the offending organism that grow on the valves of the heart causing permanent damage. The aortic and mitral valves are most often valves involved. The mitral damage may result in mitral stenosis (MS) or mitral regurgitation (MR). Aortic regurgitation (AR) also results from rheumatic fever (AHA, 2006; Parillo, 2006).

Often individuals who have had rheumatic fever as children require a valve replacement at some time in their lives. The nurse understands that when a valve is replaced in infancy or childhood, it must be replaced every 5 years to accommodate the child's growth. Valves replaced during adolescence can last up to 10 years.

**Nursing Insight— Hypercholesterolemia–hyperlipidemia**

The etiology for hypercholesterolemia–hyperlipidemia in children is classified as primary and secondary. A primary cause is hereditary predisposition (Park, 2003) and children may develop atherosclerotic lesions as early as infancy.

Hypercholesterolemia is more often due to secondary causes. Secondary causes are exogenous (originating outside an organ), endocrine, or metabolic disorders; liver diseases; renal diseases; or other miscellaneous reasons such as anorexia nervosa or collagen diseases. Children with cardiac transplant have a high incidence of hyperlipidemia because of the immunosuppressant drug cyclosporine-A (Neoral). In addition, children with cardiac transplant form atherosclerotic lesions at a very rapid rate and the child risks facing coronary artery bypass graft (CABG), or worse, a second transplant surgery. The nurse can communicate to the family that treatment of hyperlipidemia for children with a transplanted heart is more aggressive than for the general population.

Additional Cardiac Conditions

CARDIAC TRAUMA

Cardiac trauma can result from a variety of injuries such as a motor vehicle accidents or sports activity. Even a child wearing a seat belt in a car can sustain cardiac

Family Teaching Guidelines... Hypercholesterolemia–Hyperlipidemia

ESSENTIAL INFORMATION

There are two types of primary hypercholesterolemia–hyperlipidemia: familial hypercholesterolemia and familial combined hyperlipidemia. The standards for childhood cholesterol levels are different from those for adults (Table 27-3).

Although the standard levels are different, the treatment goals are similar to those for adults and include diet modification, exercise, and medication. A recommended balanced nutrition is one that provides less than 10% of total calories from saturated fatty acids, 30% or less of total calories from fat, less than 300 mg of cholesterol each day. The nurse can help the family decrease the fat and cholesterol intake to 7% of fatty acids, 25% or less total calories from fat, and less than 200 mg of cholesterol per day. Pharmacological treatment is recommended for children older than 10 years whose LDL cholesterol is greater than 190 mg/dL.

Recommendations for testing children at age 2 or older are:

- ◆ At least one parent with high cholesterol (240 mg/dL or greater)
- ◆ A family history of early heart disease such as a male parent or grandparent with CHD before age 55 or a female parent or grandparent with CHD before age 65
- ◆ Diabetes
- ◆ Obesity
- ◆ Immunosuppressant drug use (AHA, 2005)

Table 27-3 Cholesterol Levels in Children

	Desirable	Borderline	Associated with Higher Risk
Total cholesterol	Less than 170	170–199	200 or more
LDL cholesterol	Less than 110	110–129	130 or more

HYPERTENSION

High blood pressure or hypertension (HTN) is an elevated blood pressure and is uncommon in children.

SIGNS AND SYMPTOMS. Signs and symptoms depend on the underlying causes. Elevated blood pressure (not in the recommended range) is a key sign (see Table 21-2). A young child may be irritable where an older child may complain of changes in vision, dizziness, or headaches.

DIAGNOSIS. Taking a detailed medical and thorough family history is important in the diagnosis of hypertension. A child is hypertensive if the blood pressure is above the 95th percentile for age, height, and gender. As a screening tool, the nurse should consider any reading greater than 20 mm Hg above normal blood pressure for

the child's age as high. A teenager is considered an adult for treatment purposes and follows the same guidelines as adults. The extent of further testing is based on the degree of blood pressure elevation. The nurse knows that high blood pressure or hypertension may indicate a coarctation of the aorta, kidney disease, left ventricular hypertrophy (LVH), or early-onset familial hypertension. Some cardiology centers conduct hypertension follow-up for families with a strong history.

NURSING CARE. Nursing care for the child with hypertension is based on education about the condition, diet, exercise, lifestyle modification, and medication. Medications for high blood pressure or hypertension include beta-blockers and ACE inhibitors.

Ethnocultural Considerations—Hypertension

Based on familial predisposition, hypertension has a higher incidence among black children than in other ethnic groups. Nursing care for this group of children includes educating the child and family about the condition, promoting a reasonable sodium intake, and teaching the family how to reduce the saturated fat and cholesterol in their diet.

IDIOPATHIC PULMONARY ARTERIAL HYPERTENSION

Idiopathic pulmonary arterial hypertension (IPAH) is a condition of high blood pressure in the lungs. It may result from cardiac defects or may be idiopathic (without recognizable cause). It is a severe disease resulting in death if not treated. Normally, the desired pulmonary blood pressure is low, allowing blood to flow easily from the right side of the heart. The pressure in the right side of the heart is lower than in the left (the left reflecting the systemic blood pressure). If the pressure in the lungs is high, as with IPAH, the right ventricle must pump harder to force the blood to the lungs. Over time, this wears on the ventricle and causes right ventricular hypertrophy (RVH). Eventually, the heart fails and congestive symptoms develop.

SIGNS AND SYMPTOMS. Symptoms of IPAH include shortness of breath (dyspnea), especially during exercise; chest pain; weakness; fatigue; dizziness; leg swelling; and fainting episodes.

DIAGNOSIS. In the early stages of the disease, a physical exam may be normal because diagnosis of IPAH may take several months. However, as the condition progresses, a physical exam shows a heart murmur, enlargement of the neck veins, liver and spleen enlargement, leg swelling, parasternal heave, ascites, and clubbing.

Diagnostic tests such as a pulmonary arteriogram, echocardiogram, chest radiograph, cardiac catheterization, and pulmonary function tests may help confirm the diagnosis.

NURSING CARE. Until recently, treatment for idiopathic pulmonary arterial hypertension included oxygen, which relaxes the arteries of the lungs, calcium channel blockers that relax the blood vessels, and diuretics which decrease the volume in the vessels. However, these treatments may also have an untoward effect of lowering the overall blood pressure. Newer, innovative treatments are outlined next.

where research and practice meet: Innovative Treatment Strategies for Idiopathic Pulmonary Arterial Hypertension

Innovative treatment strategies that are producing promising results for idiopathic pulmonary arterial hypertension include:

- Prostacyclin (Flolan) dilates blood vessels and decreases pulmonary vascular resistance.
- Inhaled nitric oxide relaxes pulmonary, but not systemic blood vessels.
- Sildenafil (Revatio) decreases pulmonary artery pressures and bosentan (Tracleer) blocks endothelin-1 (hormone that causes vasoconstriction). (<http://www.revatio.com/>; www.tracleer.com)

The nurse must remember that the treatment for IPAH is complicated, ongoing, and the condition has no cure. The only definitive treatment is a lung or heart–lung transplant, the latter because there is already heart damage to the right ventricle. Treatment for IPAH caused by cardiac defects is aimed at the cause of the defect.

NEURALLY MEDIATED SYNCOPE

Neurally mediated syncope (NMS) is a condition caused by an exaggerated response to a normal bodily function. It is also called vasovagal syncope. The baroreceptors in the carotid artery act as a regulator of blood pressure during certain situations. If the system is stressed such as during extreme heat, pain, fright, or prolonged standing, the initial response is a release of epinephrine, stimulating the sympathetic nervous system. This stimulation in turn raises the blood pressure. The baroreceptors send messages to control the blood pressure. In neurally mediated syncope (NMS), the response is exaggerated and the blood pressure, and often the heart rate, drop significantly and suddenly.

SIGNS AND SYMPTOMS. The main sign is a temporary loss of consciousness (a fainting spell). Occasionally, the response is so dramatic that the child may experience a seizure.

DIAGNOSIS. Definitive diagnosis of neurally mediated syncope is made via the tilt test.

diagnostic tools Tilt Test

Neurally mediated syncope (NMS) is diagnosed via a simple test called a tilt table test. The nurse assists by placing the child in a supine position on a table equipped with a foot board. The table may be tilted on an upright position anywhere between 45 and 90 degrees. After a short time, the table is tilted to a full 90 degree angle so that the child stands upright. The tilting may or may not reproduce the body response. If the tilt test is positive, the nurse will see a remarkable drop in blood pressure or heart rate and the child will experience syncope or pre-syncope (dizziness or lightheadedness). If the child does not exhibit any symptoms, such as syncope or lightheadedness, the table is laid flat again and isoproterenol (Isuprel) is administered to stimulate a fast heart rate. This chemical mimics the fight or flight (fear, pain, anxiety) response that may occur before episodes of syncope. The table is then tilted again to elicit a syncopal response or a drop in the blood pressure. If there is no response or change in vital signs, the test is considered negative and other causative factors are evaluated.

NURSING CARE. Nursing care for NMS may be as simple as increasing the child's sodium and water intake. An adrenocorticosteroid such as fludrocortisone (Florinef) may be given to retain fluid. The next level of treatment is

a beta-blocker, which regulates the exaggerated response. The nurse monitors for frequency, severity, and precipitating factors of syncope.

“What to say” — *Neurally mediated syncope (NMS)*

It is important that the nurse communicate to the family that NMS is concerning based on the potential for injury if the child loses consciousness. If a teen with syncope is of driving age, he or she must be syncope free for 6 months in some states before the teen may drive again.

LONG Q-T SYNDROME

Long Q-T syndrome (LQTS) is an electrophysiological condition predisposing the child to fatal arrhythmias such as ventricular tachycardia (VT), torsade de pointes, and ventricular fibrillation (VF) (Fig. 27-21). LQTS is a familial disorder, and if one child is affected, all siblings, parents, and possibly cousins should be tested. There are a variety of known factors and genetic chromosomal markers in a person with LQTS. Long QT syndrome is among a group of defects of the ion channels (channelopathies) on the cardiac cell membrane. Currently genetic researchers are studying this phenomenon in hopes of developing a cure. A prolonged QT interval can also be acquired from medications and various toxins.

SIGNS AND SYMPTOMS. A nursing assessment includes a history of fainting triggered by intense emotions, vigorous physical activity, swimming, auditory stimuli (such as a school bell), and upon awakening. Other signs and symptoms of LQTS are palpitations, seizure, or sudden death. The child and family most likely are unaware that they have this problem. Because sudden death is one of the symptoms, the child's first episode may be the last.

DIAGNOSIS. An ECG should be performed in all children with seizures of sudden onset, fainting, or near drowning episodes. The child may be asymptomatic and may present at routine exam with a prolonged QT on ECG.

Figure 27-21 Long QT syndrome.

NURSING CARE. The nurse understands that the primary treatment is medication. The most frequently used medications are beta-blockers. Treatment also includes pacemaker-defibrillator insertion or left cardiac sympathetic denervation. It is important that the nurse communicates to the family that the most common cause of treatment failure is noncompliance with medication (Moss & Robinson, 2002).

Rhythm Disturbances

Nursing Insight— Electrocardiogram

The abbreviations ECG/EKG are used interchangeably. (The K is the abbreviation for the German *kardio* [cardiac].) An ECG is a graphic display of electrical activity produced by changes in the intracellular charge of the cardiac muscles. The components of an ECG are marked with the letters PQRST (Fig. 27-22).

Collaboration in Caring: Nurses caring for children with heart arrhythmias

The nurse working in a cardiac area with children who experience arrhythmias and require cardiac telemetry can acquire specific knowledge about the ECG and learn about basic arrhythmia interpretation. The nurse who cares for children on a cardiac floor or in the intensive care unit (ICU) can acquire more advanced information through a course on 12-lead ECG. Pediatric Advanced Life Support (PALS) and a pediatric emergency course are essential.

Optimizing Outcomes— Rhythm disturbances

The nurse who can determine the baseline rhythm and recognize changes will facilitate the best outcome for a child with an arrhythmia. The nurse must know the ramifications of these changes. Important questions the nurse can ask about rhythm disturbances are:

Is the rhythm potentially fatal?
Will it alter the cardiac output?

Nursing Insight— Rhythm disturbances and the effect on cardiac output

Tachycardia is the name for a fast heart rate. It describes any condition in which the heart beats faster than the standard pediatric heart rate values and includes sinus tachycardia, supraventricular tachycardia, atrial tachycardia, atrial flutter, atrial fibrillation, junctional tachycardia, and ventricular tachycardia (see Table 21-2). If the heart rate is too fast, the diastolic phase shortens in relation to the length of the full cardiac cycle. The ventricle is not allowed enough filling time; therefore the stroke volume is less, decreasing the cardiac output.

Bradycardia is the name for a slow heart rate. This is any condition where the heart beats slower than the standard

pediatric heart rate values. This type of arrhythmia includes sinus bradycardia, junctional and idioventricular rhythms, and the slow phase of sick sinus syndrome. In a bradycardic child, the cardiac output is affected because the heart rate is slow. Initially, the body tries to compensate by increasing the contractile force, thus increasing the stroke volume (SV). Eventually, this will plateau or the cardiac muscle may not be strong enough to compensate as in congestive heart failure (CHF) or cardiomyopathy.

Blocks are disruptions in the flow of electrical current throughout the heart. They include bundle branch block (BBB) and first-, second-, and third-degree blocks. First- and second-degree type I blocks may incur no interference in the cardiac output, whereas second- and third-degree blocks are more severe and require intervention in order to maintain adequate circulation.

Lethal rhythms are those producing little or no cardiac output and include ventricular tachycardia, ventricular fibrillation, torsades de pointes, pulseless electrical activity (PEA; formerly known as electromechanical dissociation [EMD]), or asystole.

Nursing Insight— Sinus arrhythmias

A normal irregular rhythm in which the rhythm varies with respiration is called sinus arrhythmia. Sinus arrhythmia has no adverse effect on the cardiac output.

- The heart rate increases with inspiration. (Remember: “Inspiration” and “Increase” both start with an “I”.)
- The heart rate decreases with expiration.

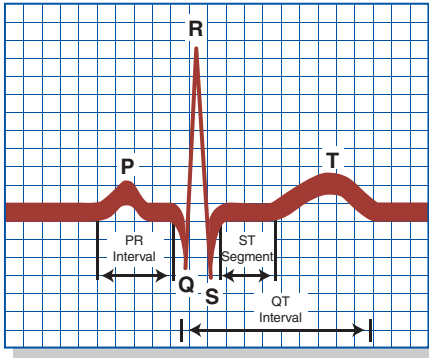

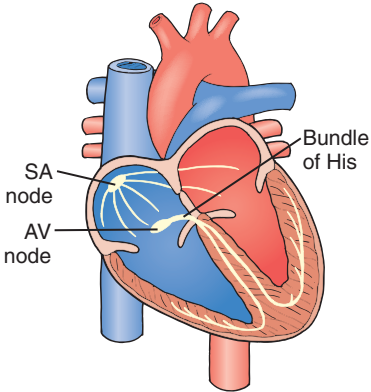

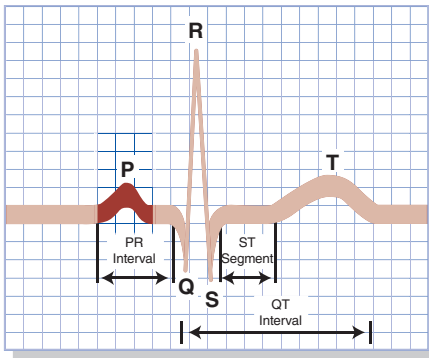

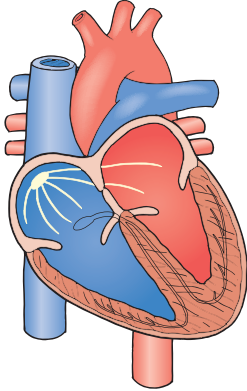

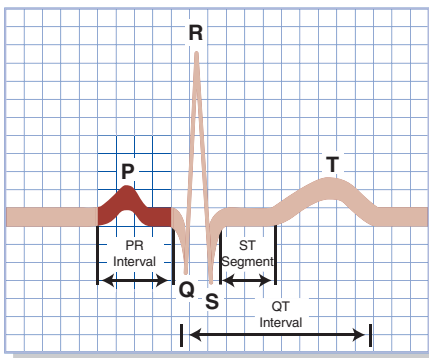

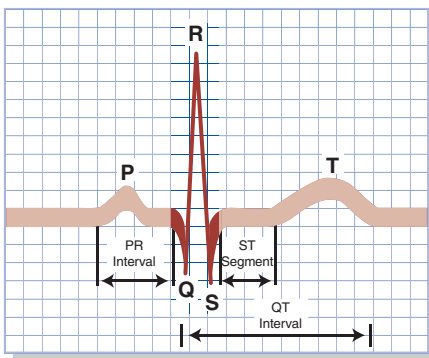

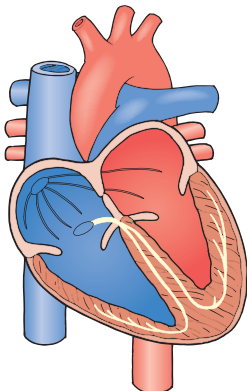

Invasive Tests

CARDIAC CATHETERIZATION

Cardiac catheterization is an invasive test performed for a number of reasons. The purpose of the cardiac catheterization is to determine the pressures within the child’s heart, vessels and to provide a radiographic picture of the anatomy by measuring the size and shape of vessels, valves, and ventricles. A cardiac catheterization is necessary to perform a myocardial biopsy. Corrective procedures, called interventional catheterizations, may be performed in the cardiac catheterization lab.

diagnostic tools Cardiac Catheterization

The cardiac catheterization procedure takes place in a cardiac catheterization lab where the child is sedated or anesthetized. First, an introducing sheath is placed in a major vessel such as the femoral vein or artery. Next, a long hollow tube or catheter is threaded through this sheath and into the heart. The physician uses real-time radiographic study or fluoroscopy to monitor the movement of the catheter and to prevent perforation. During a cardiac catheterization, pressure is measured in the ventricles and the vessels. The normal pressure of the left ventricle correlates with the normal blood pressure for age. The normal pressures in the right ventricle and right and left atrium are similar to those of an adult patient. Elevated pressures can indicate a variety of illnesses and will usually support or refute the suspicions of the diagnostician. For example, high pressure in the right ventricle may indicate a ventricular septal defect (VSD) with left-to-right shunting or pulmonary artery

stenosis or pulmonary hypertension. Radio-opaque dye is injected through the catheter and the flow of the dye is observed on fluoroscopy. The “shape” the dye is the shape of the inside of the heart, giving a picture of the anatomy of the ventricle, valves, vessels, and any defects that may be present.

The overall risks for the child undergoing a cardiac catheterization are minimal. Because this is an invasive procedure, the nurse must explain the risks of bleeding, infection, thrombus, arrhythmia, perforation, stroke, or even death (resulting from previous named risks) to the parent or legal guardian.

clinical alert

Postcatheterization

The nurse must monitor pressure dressing in the groin, heart rate, respirations and blood pressure.

ANGIOGRAPHY

Angiography visualizes the structure and function of the ventricles, the vessels, and the valves. It is also useful to determine size and location of septal defects. After

placement of the catheter in the heart, radio-opaque contrast medium is injected into the chambers and vessels of the heart. If there is a defect, the contrast highlights septal openings, narrow vessels, and extra vessels. An angiography gives the cardiologist and the cardiovascular surgeon important information to direct the medical treatment.

BIOPSY

Biopsy of the myocardium is performed routinely for children who have had a cardiac transplant. Children with cardiac transplant undergo routine biopsies to assess for rejection. Several small pieces of myocardial tissue are removed and then analyzed by a laboratory specialist for cellular changes. The sample may also contain microbial organisms responsible for the cellular changes seen in cardiomyopathy.

CLOSURE DEVICES

The nurse understands that it is possible to close simple congenital intracardiac communications or shunts in the cardiac catheterization laboratory rather than with major surgery (e.g., atrial septal defects and an opening called a patent foramen ovale are closed with transseptal closure devices). The cardiologist places these transseptal closure devices across the septum, through the defect, and deploys the device to form a seal around the opening. In the case of a PDA closure, a plug type device is used.

Over a period of approximately 6 weeks to 6 months after the closure device is placed, the child's own tissue grows over the device, creating a permanent seal (endothelialization). In addition, yearly follow-up visits to the cardiologist are recommended along with an ECG, an echocardiogram, and possibly a chest radiograph. The nurse will also explain to the caregivers that there is the risk of embolization of the device placed. Embolization occurs when the device becomes dislodged from its intended location, migrating to the atria, pulmonary artery, the ventricle, or aorta.

OPENING DEVICES

Angioplasty or Valvuloplasty

Narrow vessels or valves may be opened or dilated with a balloon angioplasty or valvuloplasty as an initial treatment or a stent may be placed in a vessel as a long-term treatment (Fig. 27-23). This treatment is performed during a

Figure 27-23 Balloon angioplasty with stent.

cardiac catheterization procedure. A special catheter with a balloon (similar to a Foley balloon) catheter is passed into the heart and into the narrow vessel. The balloon is then inflated, causing the stenotic area to expand. Sometimes the stenosis recoils days, months, or years after the balloon procedure. The procedure may then be repeated but this time a stent (a wire mesh tube) is placed over the balloon. The balloon is again inflated and the stent is left in place. This repair is permanent and requires surgical extraction if removal is necessary.

Balloon Atrial Septostomy

Balloon atrial septostomy is an emergent palliative procedure necessary to keep the child alive when the heart has no means of blood flow to the pulmonary system or body such as in tricuspid atresia or hypoplastic left heart. A catheter with a balloon is passed into the right atrium, pushed across the foramen ovale (PFO), and an entry way to the left atrium is created. The balloon is inflated and then pulled forcefully across to the right atrium, creating a hole large enough to accommodate blood flow. Infusion of prostaglandin is a palliative treatment until septostomy occurs to keep the PDA open and blood flowing to the pulmonary system or body.

NURSING CARE

The nurse must be aware of specific aspects of caring for a child who is post-cardiac catheterization (Box 27-1). The post-cardiac catheterization child has a pressure dressing in the groin (inguinal area of the leg) used for the insertion site. If an internal jugular vein is used, a small bandage covers the site on the neck.

The nurse monitors the heart rate, respirations, and blood pressure and makes note that it is in the same range as measured precatheterization. If tachycardia is identified postcatheterization, the nurse should suspect pain or dehydration. Acetaminophen (Children's Tylenol) is given for the pain. If the child is dehydrated, the nurse can administer fluid boluses. Signs of infection are rare in the first few hours postcatheterization.

The nurse must remember that children with cardiac disease may be cyanotic. It is important to obtain a baseline oxygen saturation and monitor the child with that number in mind. Some children normally have a value as low as 85%. The nurse should confirm the range of normal oximeter readings with the practitioner.

Box 27-1 Typical Post Cardiac Catheterization Medical Orders

- Admit to postsurgical observation unit.
- VS q15min \times 4, then q1hr \times 2, then q2hr \times 2, then q4hr
- Check pulses with vital signs, especially on affected extremity.
- Keep O₂ saturation above _____.
- Call house officer for heart rate > _____, blood pressure > _____ (age and baseline dependent) and temperature > _____.
- Give acetaminophen (Children's Tylenol) for pain.
- Keep flat in bed for 6 hours.
- Check pressure dressing with vital signs for bleeding.
- Call house officer for complaints of abdominal pain or no urine output.
- Increase diet as tolerated.
- Give antiemetics for nausea.

The child may be placed on cardiac telemetry if arrhythmias were induced during the catheterization. Normally, if the child has a non-electrophysiological diagnosis, any arrhythmias seen during the procedure disappear when the catheters are removed, but subsequent monitoring may be required.

There are specific growth and development issues to consider postcatheterization. After a cardiac catheterization, a child is required to lie flat for up to 6 hours depending on the insertion site of the catheter. The supine position minimizes the risk of bleeding through the insertion site. A younger child may need to be restrained with leg immobilization devices to keep the leg straight. Older children or adolescents are usually cooperative unless they are developmentally delayed. Sometimes the nurse may need to administer sedation to keep the child still, but this only delays the discharge and holds certain risks. Generally, an infant or child does well if the mother is allowed to stay at the bedside or hold the child. Allowing the infant to feed also calms him or her.

The nurse can communicate to the family that after a cardiac catheterization, the child will be on the same medications as before. Specifically, for any devices left in the body such as closure devices or stents, the child will be on a baby aspirin (ASA) for 6 months after the procedure. The aspirin prevents clot formation while endothelialization (growth of new tissue) occurs around the artificial device. Subacute bacterial endocarditis prophylaxis (SBE) precautions should be followed for 6 months for device placement patients. The nurse can tell the family that after 6 months of placement of the device, no special precautions are needed.

clinical alert

Blood pressure postinterventional catheterization

The child's blood pressure should remain within normal limits. One specific measurement the nurse must watch is the pulse pressure; which is the difference between the systolic and diastolic blood pressure. A normal pulse pressure range is <40 mm Hg.

Children with PDA have a wide pulse pressure (>40 mm Hg). After the closure of a PDA, the pulse pressure should be within normal range. A sudden widening of the pulse pressure postprocedure may indicate a dislodged or embolized device. This event requires urgent measures by the physician or resident in house, who must be contacted immediately. Embolization of the device can cause stroke, thromboembolic events, or death.

The nurse can communicate to the family that the child's growth must be considered before placing a stent. Some stents are expandable and must be redilated at a later date to accommodate for the growth of the child. If it is known that a child must have a more definitive surgery, a stent may be placed, knowing that it will be extracted at a later date. Risks include vascular tear or embolization of the device. Absorbable stents are in the experimental phase.

Surgical Interventions

Surgical repair may be palliative repair or complete anatomical repair. Palliative repair is usually considered when the child is very young and the complete anatomical

repair is too complex for him or her to tolerate. The surgeons perform a temporary, palliative repair, to allow the child time to grow and develop to a point when the more definitive procedure may be tolerated. The child may be cyanotic after a palliative repair, but less cyanotic than if the surgery was delayed. These children are followed closely by the cardiologist until the time when a complete repair may be done. A complete repair is considered a cure or definitive treatment. However, as the child grows or hemodynamic requirements change, a complete repair may have to be revised (Table 27-4).

PACEMAKERS

Pacemakers are used to treat cardiac conditions such as heart block or severe bradycardia, sick sinus syndrome, and junctional or idioventricular rhythms. Pacemaker therapy may be internal or external, temporary or permanent. The nurse understands that external pacing is always temporary. The surgeon may elect to place temporary pacing wires if the child has complications of heart block during surgery, or if the surgical area is near or on the conduction tissue.

“What to say” — Pacemakers

The nurse communicates to parents that permanent pacemakers may be placed in the abdomen in younger children and in the subclavicular area in older children. Consideration is taken for children who are athletic, as the pacemaker generator must be protected. Care is taken when deciding to place a permanent pacemaker.

Pacemaker generators must be replaced every 5–10 years. When a pacemaker is placed in an infant, a replacement may be necessary 15 times in his or her lifetime. Pacemaker insertion for vasovagal syncope is controversial. Currently the AHA and American College of Cardiology (ACC) do not recommend pacemaker placement for neurally mediated syncope.

NURSING CARE. Nursing care of the pacemaker postoperative patient is the same as for any surgical procedure, including watching for signs of infection and ensuring the incision remains intact. The nurse communicates to the family that follow-up care requires routine pacemaker testing as recommended by the pacemaker center placing the device. Essential information for the family is to understand that after initial follow-up procedures, evaluation of the pacemaker is usually performed every 6 months to 1 year, but can be as often as every 3 months.

CARDIAC TRANSPLANTATION

Cardiac transplantation requires complex multidisciplinary management and is used as a treatment for severe, life-threatening cardiac conditions. Although still rare, there were 5767 reported pediatric cardiac transplants performed across the nation between 1982 and 2003 (Boucek et al., 2006). Transplantation is performed only under the most grave of circumstances, in situations in which the child would otherwise die.

A progressive heart transplantation program includes a cardiomyopathy treatment program to prevent the need for transplantation. The transplantation team

Table 27-4 Surgical Repairs of Cardiac Defects

Repair and Intended Effect	Defects	Potential Long-term Implications and Sequelae
Palliative Repairs PA banding: <ul style="list-style-type: none"> • A restrictive band is placed around the main pulmonary artery to decrease uncontrolled pulmonary blood flow and prevent the development of pulmonary hypertension and eventual right heart failure. 	VSD, single ventricle, tricuspid atresia	Eventual decreased O ₂ saturations with growth/aging, right ventricular hypertrophy, if the band becomes too tight with growth of the child. Excessive flow to left pulmonary artery and left pulmonary HTN r/t stenosis of the right pulmonary artery, related to possible migration and encroachment on the right PA. Possible revision of banding.
Blalock–Taussig shunt (modified) <ul style="list-style-type: none"> • A Gore-Tex graft conduit is placed between the right or left subclavian artery and the ipsilateral pulmonary artery to provide controlled pulmonary blood flow. 	Cyanotic heart defects such as HLHS, TOF, pulmonary atresia, tricuspid atresia	Mild pulmonary artery distortion at site of anastomosis, Inability of shunt size to increase with growth/aging, Thrombus formation on graft site, Potential coronary ischemia r/t pulmonary “steal” of blood flow during diastole.
<ul style="list-style-type: none"> • Sano shunt • A Gore-Tex graft conduit is placed between the single ventricle and the pulmonary artery to provide controlled pulmonary blood flow. 	Cyanotic heart defects such as HLHS, pulmonary atresia, tricuspid atresia, single ventricle defects	Mild pulmonary artery distortion at site of anastomosis, Thrombus formation on graft site, Inability of shunt size to increase with growth/aging.
<ul style="list-style-type: none"> • Atrial septectomy • A communication is surgically created by tearing a hole or incision in between the left and right atria. This encourages mixing of blood flow at the atrial level and encourages pulmonary blood flow. More invasive than ballooning of septum as seen in Rashkind procedure. Considered to be a palliative procedure prior to complete repair. 	Single ventricle physiology with intact atrial septum, unrepaired TGA.	Eventual development of heart failure if further palliation/repair is not sought.
Definitive (or Complete) Repairs Patch closures <ul style="list-style-type: none"> • Native cardiac tissue (pericardium) or a prosthetic patch is sutured in place over a septal defect to effectively close the communication between the atria or ventricles. 	ASD, VSD, AV canal	Incomplete closure of defect, arrhythmia, potential for patch dehiscence, AV block (VSD closures)
<ul style="list-style-type: none"> • Ductal ligation • A tie or clip is placed around the patent ductus arteriosus and tightened to prevent excessive pulmonary blood flow from the aorta. 	PDA	Incomplete closure of ductus and associated residual pulmonary shunting, mobilization of device.
<ul style="list-style-type: none"> • COA repair • Narrowing in the proximal, distal, or arch of the aorta is reduced or eliminated via surgical resection of stenosed area, patch placement to increase aortic diameter, subclavian flap aortoplasty or bypass grafting. 	Coarctation of aorta	Restenosis or recoarctation of affected portion of aorta, Transient spinal ischemia and associated paraplegia, Paradoxical hypertension, Possible need for re-repair or angioplasty
Valvuloplasty <ul style="list-style-type: none"> • A malformed, damaged, or stenotic valve is surgically revised to correct the associated malfunction. 	Destructive endocarditis, Valvular stenosis.	Incomplete or unsuccessful revision of affected valve; thromboemboli formation, additional valvular damage and possible need for valve replacement.
<ul style="list-style-type: none"> • Artificial valve replacement • A faulty or damaged native valve is replaced with a valve made of either human or animal tissue or a mechanical valve. 	Endocarditis, failed Ross, Valvular stenosis	Need for a lifetime of replacement prosthetic valve procedures, Need for long-term oral anticoagulation, Thromboemboli formation, aortic or pulmonary insufficiency.
Ross procedure <ul style="list-style-type: none"> • A damaged or dysfunctional aortic valve is removed and replaced with the patient’s pulmonic valve, which is then replaced with a donor homograft valve. 	Destructive endocarditis, Valvular aortic stenosis.	Aortic/pulmonary valve stenosis, Gross valvular dysfunction, Aortic or pulmonary insufficiency, Potential for a lifetime of possible prosthetic valve replacements, risk for heart block.

Table 27-4 Surgical Repairs of Cardiac Defects—cont'd

Repair and Intended Effect	Defects	Potential Long-term Implications and Sequelae
<p>Konno procedure</p> <ul style="list-style-type: none"> A faulty aortic valve is replaced with a prosthetic valve while the narrowed aortic root is enlarged via patch placement to increase systemic blood flow. Ross-Konno procedure combines replacement of aortic valve with native pulmonary valve and aortic root enlargement 	<p>Any left ventricular outflow tract obstruction such as aortic valve hypoplasia, sub-aortic stenosis</p>	<p>Potential failure of aortic valve graft and persistent aortic stenosis, Thromboemboli formation on grafted valves, Potential need for life-long oral anticoagulation, potential for development of heart block, aortic insufficiency</p>
<p>Damus–Kaye–Stansel</p> <ul style="list-style-type: none"> Prosthetic conduits are placed between the proximal main pulmonary artery and the aorta and between the right ventricle and the distal pulmonary artery. Existing VSD is closed and the existing aortic valve may be closed or left unclosed. This procedure attempts to reroute in appropriate pulmonary and systemic blood flow 	<p>TGA with VSD; DORV with VSD.</p>	<p>Aortic insufficiency, thromboemboli formation in cases of complete aortic valve closure, need for periodic surgical conduit replacements, coronary ischemia.</p>
<p>Rastelli</p> <ul style="list-style-type: none"> The main pulmonary artery is divided from its incorrect origin on the LV and is re-attached to the RV using a prosthetic conduit. A tunnel is then created between the existent VSD and aorta, effectively re-routing blood from the LV to systemic outflow. 	<p>DORV, TGA + VSD + sub-aortic stenosis/pulmonic stenosis truncus arteriosus type I.</p>	<p>Conduit obstruction and resultant heart failure, arrhythmia, thromboemboli formation, failure of prosthetic conduits to allow increased flow with growth/aging, implicit need for eventual RV-PA conduit replacements.</p>
<p>Arterial switch (ASO)</p> <ul style="list-style-type: none"> The great arteries (main pulmonary artery and aorta) are divided from the LV and RV respectively and reattached to their appropriate locations on the RV (MPA) and LV (aorta). The coronary arteries are also divided from the MPA and transplanted to the neo-aorta. 	<p>TGA</p>	<p>Arrhythmia, coronary artery obstruction, LV ischemia and dysfunction, aortic insufficiency, supravalvular pulmonic stenosis, branch pulmonary artery stenosis.</p>
Staged Repairs		
<p>Modified Norwood</p> <ul style="list-style-type: none"> The main pulmonary artery is divided from the branch pulmonary arteries and patched to the hypoplastic aortic arch, creating a hybrid systemic arterial outflow from the RV. An atrial septectomy is created via catheterization or surgical incision to allow for left to right shunting, so that oxygenated pulmonary venous blood is directed toward systemic outflow. A systemic–pulmonary shunt (Sano or Blalock–Taussig) is created to allow pulmonary arterial blood flow, as the creation of single ventricle physiology only has a direct connection to systemic outflow. This stage creates a single ventricle that is responsible for pulmonary and systemic circulation. 	<p>Stage 1 repair for HLHS</p>	<p>Coronary ischemia due to diastolic “steal” of aortopulmonary shunt if BT shunt is used, pulmonary artery distortion, cyanosis, aortic outflow obstruction, tricuspid insufficiency, potential stenosis of systemic-pulmonary shunt, FTT, feeding difficulties, arrhythmia.</p>
<p>Glenn</p> <ul style="list-style-type: none"> The systemic–pulmonary (BT or Sano) is taken down or ligated with clips. The SVC is connected to the branch pulmonary arteries. The existent ASD is enlarged if necessary to allow for continued left to right shunting of oxygenated blood into the systemic outflow. This stage attempts to reduce the workload of the heart so that the single ventricle is only pumping to the systemic circulation. 	<p>Stage 2 repair for HLHS, tricuspid atresia</p>	<p>Elevated upper body venous pressures related to increased PVR, hypoxemia, upper body swelling, headache, arrhythmia, stenosis at area of SVC-PA anastomosis, development of aortopulmonary collateral vessels</p>
<p>Fontan</p> <ul style="list-style-type: none"> The procedure attempts to establish separate pulmonary and systemic circulations by attaching the IVC directly to the RPA-SVC anastomosis with a Gore-Tex extracardiac conduit. This allows for passive flow of systemic venous return directly to the pulmonary arteries and completely bypasses the RA. The existent single ventricle continues to receive pulmonary arterial flow and pump to the systemic circulation via the neo-aorta constructed in Stage 1 repair. 	<p>Stage 3 repair for HLHS, tricuspid atresia</p>	<p>Obstruction of conduit leading to systemic venous pooling, thromboemboli formation, arrhythmia, systemic venous hypertension, protein-losing enteropathy, right heart failure leading to hepatosplenomegaly</p>
<p>Other Fontan techniques route caval flow through a conduit partly routed through the RA, which may lead to complications. Newer techniques bypass the RA completely. Occasionally, fenestrations or holes are created between the IVC-RPA conduit and the RA to allow for a “pop-off” of extra fluid, which is thought to prevent some post-operative complications.</p>

attempts to correct the condition early on and to prevent the child's condition from progressing to the point of no return. It is certainly more desirable to perform a transplant long before the child is gravely ill, but it is also difficult to justify the need for transplantation to a family whose child is playful and seems “normal” to them. Although survival rates continue to improve, there are limitations.

clinical alert

Complications of cardiac transplantation

The four main complications of cardiac transplantation are:

- Rejection
- Infection
- Posttransplant lymphoproliferative disorder (PTLD)
- Transplant coronary artery disease (TCAD)

Although transplantation saves lives and greatly improves the quality of life, it is often said that transplantation is exchanging one disease for another. Living with a transplanted heart is considered a chronic condition, but it is manageable. The child and his or her family must follow a strict regimen of medication, diagnostic tests, blood tests, and clinic follow-up.

Across Care Settings: The transplantation team

The cardiac transplantation team consists of nurse practitioners, physicians, surgeons, nurses, social workers, medical psychologists, religious leaders, school nurses, and school officials. Most important, the child and his or her parents, and extended family are involved in the caretaking decisions. The child and his or her family must be hypercompliant with the regimen in order to prevent rejection of the cardiac muscle.

NURSING CARE. The priority nursing intervention is to help the family understand the importance of medication compliance. There is no room for a less than rigorous approach when administering the medications. This is a difficult endeavor, but the positive aspect is that the child will live. The medication regimen includes up to three anti-rejection medications (immunosuppressants), antihypertensive drugs, electrolyte supplements, diuretics, anticoagulants, and antihyperlipidemics. These medications, particularly the immunosuppressant drugs, must be given every day, sometimes twice (and rarely three times) per day within a 1-hour window of time. The immunosuppressants prevent the body's immune system from rejecting the transplanted heart muscle.

Another important nursing intervention is communicating to the family about the frequent follow-up visits to the clinic, which will help ensure close monitoring by the cardiac transplantation team. Sometimes the child will come to the hospital as frequently as every week for follow-up care.

Following the transplant, the nurse can educate the family about cardiac catheterization with myocardial biopsy that is performed as often as every 2 weeks in the initial postoperative phase and during times of rejection. The family also must understand that every year coronary angiography is performed with cardiac catheterization to assess for coronary atherosclerosis, a side effect of the immunosuppressant drugs. Although it is difficult, the nurse must talk to the family about myocardial rejection. Myocardial rejection is the most severe, concerning consequence of cardiac transplant. Myocardial rejection can lead to systemic failure, and depending on the grade, usually requires hospitalization. This necessitates frequent follow-up and biopsies.

Children who have received a transplanted heart are subject to many emotional and psychological issues. As it is difficult to live one's life with any heart defect or other chronic defects, imagine a life of a child locked into this intensive medical regimen. Children who received their transplant as infants or toddlers may be more adjusted psychologically (because it is the only life they know), but may suffer more developmental delays. These children may have suffered brain anoxia, or are delayed because of frequent hospitalizations. Most children do well, attending school and continuing on to college. Psychosocial adjustment depends on the coping skills and support systems of the child and the family. In addition, physical growth can be stunted because of frequent prednisone dosing. Alterations in growth and development also have an emotional impact on the child's life.

Nursing Care for the Child with a Cardiac Condition

The nursing plan of care for the child with a cardiac condition consists of assessment, outcomes, intervention, and evaluation.

CARING FOR THE CHILD IN THE PEDIATRIC INTENSIVE CARE UNIT

Postcardiac surgical patients generally require admission to a pediatric intensive care unit (PICU) for recovery. PICU admission requires specific care by highly trained

nurses. The child generally stays on the unit for approximately 2 to 3 days for simple repairs and 5 to 10 days for more complicated repairs. The child is then transferred to a cardiac step-down or cardiac care unit. If the child has other body system issues or does not respond well to the surgery, very lengthy postoperative PICU admissions may ensue. The PICU stay is also influenced by the child's condition before surgery or any perioperative complications. The patient in the PICU most likely is intubated, has chest tubes, a nasogastric tube, and Foley catheter. There are multiple peripheral and central intravenous lines. The nurse may encounter temporary pacemaker wires. Postsurgical patients have a large dressing on the surgical site (mid-sternum or lateral). When this dressing is removed, there are usually steri-strips or Dermabond™ on the skin.

Nursing care for the child in the PICU includes important concepts such as assessment, nutrition, hygiene, activity and psychosocial care. Emphasis for care also includes taking vital signs, maintaining growth and development, administering medications, performing lab tests, and interpreting an ECG.

clinical alert

Postoperative Vital Signs

The routine for vital signs (VS) in the PICU is much more rigorous than on a general or telemetry floor. Typically, recovery of cardiac surgical patients takes place in the ICU rather than in the postanesthesia unit. These patients may be very sick and require close monitoring and a one-on-one patient assignment. The VS should be taken every (q) 15 minutes for the first few hours then q30min, then q1hr until the child is stable. The nurse can adjust the frequency depending on the stability of the patient. All changes in VS, no matter how subtle, should be documented and reported to the physician or practitioner.

Growth and development is a consideration for any hospital admission. Often PICU patients postcardiac surgery are heavily sedated or chemically paralyzed to maintain a stable environment. When caring for a sick child, the nurse should consider the child's level of development. Soft music can be played for any child, and older children should be talked to and explanations given for any touching or procedures. The nurse should encourage the parents to talk to the child as well. It has been documented that after sedated or chemically paralyzed patients are brought to consciousness, they can tell their caretakers about events and conversations heard throughout the day. Never assume that your patient cannot hear what is said (The Joint Commission, 2004).

Be sure to— Administer medication properly

It is crucial for the nurse to understand the desired and undesired effects of the child's medication. Before giving any medication, the nurse must check the proper dosage (with calculations) and route. At times, medications are given in very small amounts and an error in decimal placement can mean a fatal overdose or other detrimental effects. Be sure to use the 5 rights of medication administration.

Nursing Care Plan The Child with a Cardiac Condition

Nursing Diagnosis: Decreased cardiac output related to alterations in preload, afterload and inotropic function of the heart

Measurable Short-term Goal: The child will maintain heart rate, respirations, and blood pressure within acceptable limits (specify).

Measurable Long-term Goal: The child will tolerate daily activity without signs of cardiac decompensation

NOC Outcomes:

- Cardiac Pump Effectiveness (0400) Adequacy of blood volume ejected from the left ventricle to support systemic perfusion pressure.
- Vital Signs (0802) Extent to which temperature, pulse, respiration, and blood pressure are within normal range

NIC Interventions:

- Cardiac Care: Acute (4044)
- Fluid/Electrolyte Management (2080)
- Medication Administration (2300)
- Vital Signs Monitoring (6680)

Nursing Interventions:

1. Assess vital signs: blood pressure, respirations, lung sounds, and apical and peripheral heart rate for a full minute (specify frequency). Monitor temperature every 4 hours.
RATIONALE: Changes in cardiac output will be reflected in changes in blood pressure, respiratory status, and heart rate. Fever and infectious processes increase cardiac workload.
2. Provide continuous cardio-respiratory monitoring and evaluation of oxygen saturation levels as ordered
RATIONALE: Continuous cardiac monitoring provides objective data about cardiac functioning. Oxygen saturation above 95% indicates adequate respiratory status.
3. Weigh the child daily at the same time, on the same scale, and dressed in the same manner.
RATIONALE: Congestive heart failure results in fluid accumulation reflected by weight gain. Decreased weight may indicate therapeutic effects of treatment.
4. Administer supplemental humidified oxygen as ordered.
RATIONALE: Adequate oxygenation enhances tissue perfusion and decreases tachypnea and metabolic demands. Humidification moistens secretions to keep the airway clear.
4. Administer cardiac, diuretic, and other medications as ordered by care giver (specify drug, dose, route, and times).
RATIONALE: (Specify the action of the particular drug related to cardiac output.)
5. Promote adequate rest and uninterrupted sleep by clustering nursing care. Collaborate with parents to reduce stress for child.
RATIONALE: Rest and stress reduction reduce the work of the heart.
6. Position the child upright at a 30- or 60-degree angle (semi-Fowler's position)
RATIONALE: Elevating the head of the bed enhances lung expansion, decreases venous return to the heart, redistributes blood to dependent areas, and relieves pressure on the diaphragm.
7. Monitor fluid and electrolytes as obtained. Maintain fluid restrictions if ordered (specify).
RATIONALE: Excess fluid volume increases the work of the heart, while electrolyte alterations interfere with the electrophysiology and function of the cardiac muscle.
8. Provide ongoing education and support to the family. Encourage verbalization of concerns, feelings and questions.
RATIONALE: Adequate knowledge and emotional support lessens the family and child's anxiety levels.

Labs: Laboratory Values

Laboratory values are unstable and close monitoring is necessary. Electrolyte measurement, particularly potassium, is perhaps the most critical lab test in the initial postoperative period because the cardiac bypass machine hemolyzes the cells, thus creating a high concentration of extracellular potassium. Hemoglobin and hematocrit tests check for possible bleeding and coagulation factors can be affected by pump time. The child will probably be on a ventilator and arterial blood gases must be assessed frequently to determine the concentration of the gases like carbon dioxide and oxygen.

The patient is on a cardiac monitor and the nurse should observe for both subtle and obvious changes. Postoperative arrhythmias may be caused by electrolyte disturbances or trauma caused by surgery.

TRANSFERRING THE STABLE CHILD TO A SURGICAL OR MEDICAL UNIT

When the postsurgical child becomes more stable, he is transferred to the surgical or cardiac floor. Commonly, a pediatric patient with a newly diagnosed cardiac condition

is transferred to a tertiary care center for more definitive treatment. The nurses on this type of unit are trained in caring for cardiac patients. These units are usually equipped with telemetry monitoring.

On most telemetry units, vital signs are taken frequently, but not as often as in the PICU. The stable child requires less frequent vital signs monitoring. Typically, most telemetry units require measurement of vital signs every 4 hours.

Optimizing Outcomes— Waking the child during the night for vital signs

The best outcome for a child with a cardiac condition is proper healing along with adequate growth and development. Studies now show that sleep is necessary for proper healing and that a full sleep cycle allows certain hormones and chemicals necessary for healing and growth. The nurse should assess if the child needs to be awakened during the night for vital signs or can be allowed to sleep.

The nurse must consider the child's growth and developmental needs when assigning him or her to a room. Many hospital rooms are now private, but some older hospitals still have double rooms and even multibed wards. If this is the case, the nurse must take care to keep similar aged and same gender children in the same room.

Medications given to patients on the medical/surgical unit usually do not require constant monitoring or adjusting. Some children are admitted to a medical/surgical unit for the sole purpose of starting a new medication and monitoring its effects. These children are not "sick" per se, but the medications can cause such adverse effects that close monitoring is necessary.

Although it is important to draw blood for laboratory analysis at specific times, it is not always possible on the medical/surgical unit where the phlebotomist may make rounds only at certain times of the day. Often it may be necessary for the nurse to draw the blood. The nurse understands that lab tests on the surgical/medical unit are necessary to follow-up on certain conditions that may affect the cardiac system such as anemia or coagulopathies. Nurses caring for children on ECG monitoring should understand the basics of the ECG recording.

CARING FOR CHILDREN WITH CARDIAC CONDITIONS ACROSS CARE SETTINGS

The homebound child or one who visits the cardiac clinic may require specific nursing care. Often, his parents or other primary caregivers extend care into the home or community. One philosophy of family-centered care is that the parent or primary care taker always knows the child best and the nurse should rely on their judgment if they call with changes or concerns.

Across Care Settings: The clinic

Caring for the child with a cardiac condition in a clinic includes:

- The nurse must monitor HR, BP, RR and pulse oximeter. Compare these vital signs values to previous visits or values from the parents or home health nurse.

- Review medications and changes noted by the caregiver. The clinic nurse verifies medications and provides proper teaching. Ensure that the family has enough refills and of the proper dosage. Occasionally medications are adjusted during a phone triage visit. This needs to be properly documented in the record. Medications are frequently altered at clinic visits related to growth of the child.
- Laboratory tests may be performed in conjunction with the clinic visit. Ordering of these tests may be related to the previous lab values and the medications taken. Many children require warfarin (Coumadin) to prevent thrombus. The prothrombin time (PT) and international normalized ratio (INR) should be checked on a routine basis. The nurse must also note if any changes have been made to the warfarin (Coumadin) dosage. The clinic nurse must remember that shortly after initiation of warfarin (Coumadin) the PT/INR is checked frequently until stabilized. After stabilization, the follow-up is usually 4 weeks to 3 months. The nurse must communicate to the family that the response to Coumadin (warfarin) is affected by diet. The present recommendations are to adjust the Coumadin (warfarin) dosage rather than the diet, as families will be more compliant (Ansell et al., 2004; http://chestjournal.org/cgi/content/abstract/126/3_suppl/2045). There is a commercially available home monitoring device for these patients, which is a good option for those with unstable values.
- Electrogram monitoring usually includes a 12-lead ECG that provides a snapshot view of potential or existing arrhythmias and estimated chamber size or strain on the heart muscle. Often Holter monitors or event recorders are applied in the clinic setting. Parents may be given other recording devices for home use such as an apnea monitor or pulse oximeter. Parents should be advised not to become too preoccupied with these devices and learn to rely on their own instincts or assessment skills.

Inevitably, the cardiac pediatric patient will attend school. Frequently, the school nurse or other school official will be called upon to provide care for this child. At the minimum, schools should have an automatic external defibrillator device installed. Personnel with direct contact with the child should complete a CPR course. Often it is the school nurse who first identifies a cardiac problem, hearing a murmur on a routine visit to the office or the child has a syncopal or palpitation episode. A child with long QT syndrome may have a first event while participating in school activities such as physical education, swimming, or even when the school bell is sounded. The school nurse should be prepared.

The school nurse also has other responsibilities. Typically vital signs in the school setting will coincide with administration of medication or an untoward event. If there is an event, the school nurse is responsible for stabilization until EMS arrives on the scene. Children may be taking medication frequently during the day, which necessitates administration by the school nurse. The nurse

Family Teaching Guidelines... Caring for the Child with a Cardiac Condition

HOW TO:

Teaching the child and family about the cardiac condition is essential to help ensure good growth and development as well as helping the child achieve his or her highest level of health. Essential information includes cardiopulmonary resuscitation, vital signs, medications, the disease entity, and resources.

ESSENTIAL INFORMATION

Vital Signs: Often it is noted that a parent is waking during the night to take VS, as is done in the hospital setting. One philosophy is that the child at home should lead as normal a life as possible and not become a cardiac cripple. There is rarely a need for a full-time nurse for cardiac reasons alone, but a home health nurse may evaluate the child at intervals to see if help at home is needed.

Medication: Often, children with cardiac disease require lifelong medication administration. Some require medication only until the surgery is completed and within the initial postoperative period. As in the case with cardiac transplant child, the family must receive crucial information related to the timing and the routine of medication administration. In other cases, the cardiac drugs may be given safely with just basic instruction. The nurse can also teach the family that one of the most important aspects of medication administration is proper dosing. Many of the medications are given in a liquid form. The medication dosing should always be in milliliters (mL) or cubic centimeters (cc) and not tsp or other household measures, as the family may use a kitchen teaspoon instead of 5 mL.

Disease Entity: It is important to educate the family about the disease entity itself. Because there are many resources in print and on the Internet, it is important to ensure that the child and family is receiving and reading the most up-to-date and accurate information possible. An informed family and child will be less anxious and perhaps more compliant. Educating families also builds a relationship necessary for a team approach in treating the cardiac disease.

The following are resources for families and children:

should understand the actions, interactions, and side effects of medications the students are taking even if not given in school.

Typically the school nurse does not perform lab tests in the school setting. In addition, there will be no electrogram equipment in the school, although if the child has a Holter monitor or event recorder in place, the school nurse may be responsible for reapplying electrodes or helping to fill out the diary. The school nurse should understand the purpose of these recordings and must be familiar with the location and use of any defibrillation equipment placed in the school.

summary points

- ◆ Congenital heart disease describes a congenital defect in the heart, valves or great vessels. Congenital heart defects occur in about 1% of all pregnancies and in 1 in 170 live births.
- ◆ Children with cardiac diseases are at risk for alterations in health such as growth and development, nutrition, psychosocial implications, schooling as well as being at an increased risk for infection, acquiring other diseases, and even cardiopulmonary arrest. Sometimes these children have significantly altered lifestyles and undergo constant medical treatment. The nurse must have a good understanding of common cardiac diseases in children and be able to provide essential nursing care measures.
- ◆ The nurse provides nursing care to the child who has undergone procedural treatments with closure devices or surgery.
- ◆ The nursing plan of care for the child with a cardiac condition consists of assessment, outcomes, intervention, and evaluation.
- ◆ Postcardiac surgical patients generally require admission to a pediatric intensive care unit for recovery. Pediatric intensive care unit (PICU) admission requires specific care by highly trained nurses.
- ◆ When the postsurgical child becomes more stable, he or she is then transferred to the surgical or cardiac floor.
- ◆ Often, the parents or other primary caregivers extend care into the home or community.
- ◆ Teaching the child and family about the cardiac condition is essential to help ensure good growth and development as well as helping the child achieve their highest level of health. Essential information includes cardiopulmonary resuscitation, vital signs, medications, the disease entity, and resources.

review questions

Multiple Choice

1. When the heart condition coarctation of the aorta is suspected, the pediatric nurse will include which of

the following in the nursing assessment? (*Select all that apply.*)

- A. Take the child's blood pressures in all four extremities.
 - B. Have the child lie down while taking the blood pressure.
 - C. Encourage the child to play with a toy during the blood pressure assessment.
 - D. Encourage the pediatrician to order Acetaminophen (Children's Tylenol) to sedate the child.
2. The pediatric nurse recognizes that a possible long-term condition associated with Kawasaki disease is:
 - A. Cervical lymphadenopathy
 - B. Aneurysm formation
 - C. Shortness of breath
 - D. Mitral valve damage
 3. The cardiac condition tetralogy of Fallot includes which of the following defects? (*Select all that apply.*)
 - A. Pulmonary stenosis or atresia
 - B. Ventricular septal defect
 - C. Overriding aorta
 - D. Hypertrophic right ventricle
 4. A 14-year-old child with a history of rheumatic fever is being discharged to home after a heart valve replacement. What information would be important for the pediatric nurse to communicate to the family during discharge teaching?
 - A. "The heart valve will last the child's entire lifetime."
 - B. "The child will be on thrombotic agents for life."
 - C. "The child may be at risk for frequent fainting episodes."
 - D. "Approximately every 10 years the heart valve may need to be replaced."
 5. What is the priority nursing intervention for the child who has undergone an interventional cardiac catheterization procedure?
 - A. Administer morphine sulfate (Astramorph) for pain.
 - B. Compare preintervention saturation levels with post intervention saturation levels.
 - C. Ensure that the head of the bed is elevated to a 30-degree angle at all times.
 - D. Remove the pressure dressing 1 to 2 hours post-cardiac catheterization

True or False

6. The nurse understands that at this time there is no cure for idiopathic pulmonary arterial hypertension.
7. The pediatric nurse understands that a blood pressure greater than 20 mm Hg above the normal blood pressure for the child's age is considered as a high blood pressure reading.
8. The pediatric nurse recognizes that a lung or heart-lung transplant is the only definitive treatment for primary pulmonary hypertension.

9. The pediatric nurse must teach the parents of any child with an unrepaired cyanotic heart defect about the need for subacute bacterial endocarditis prophylaxis (SBE) therapy.

Fill-in-the-Blank

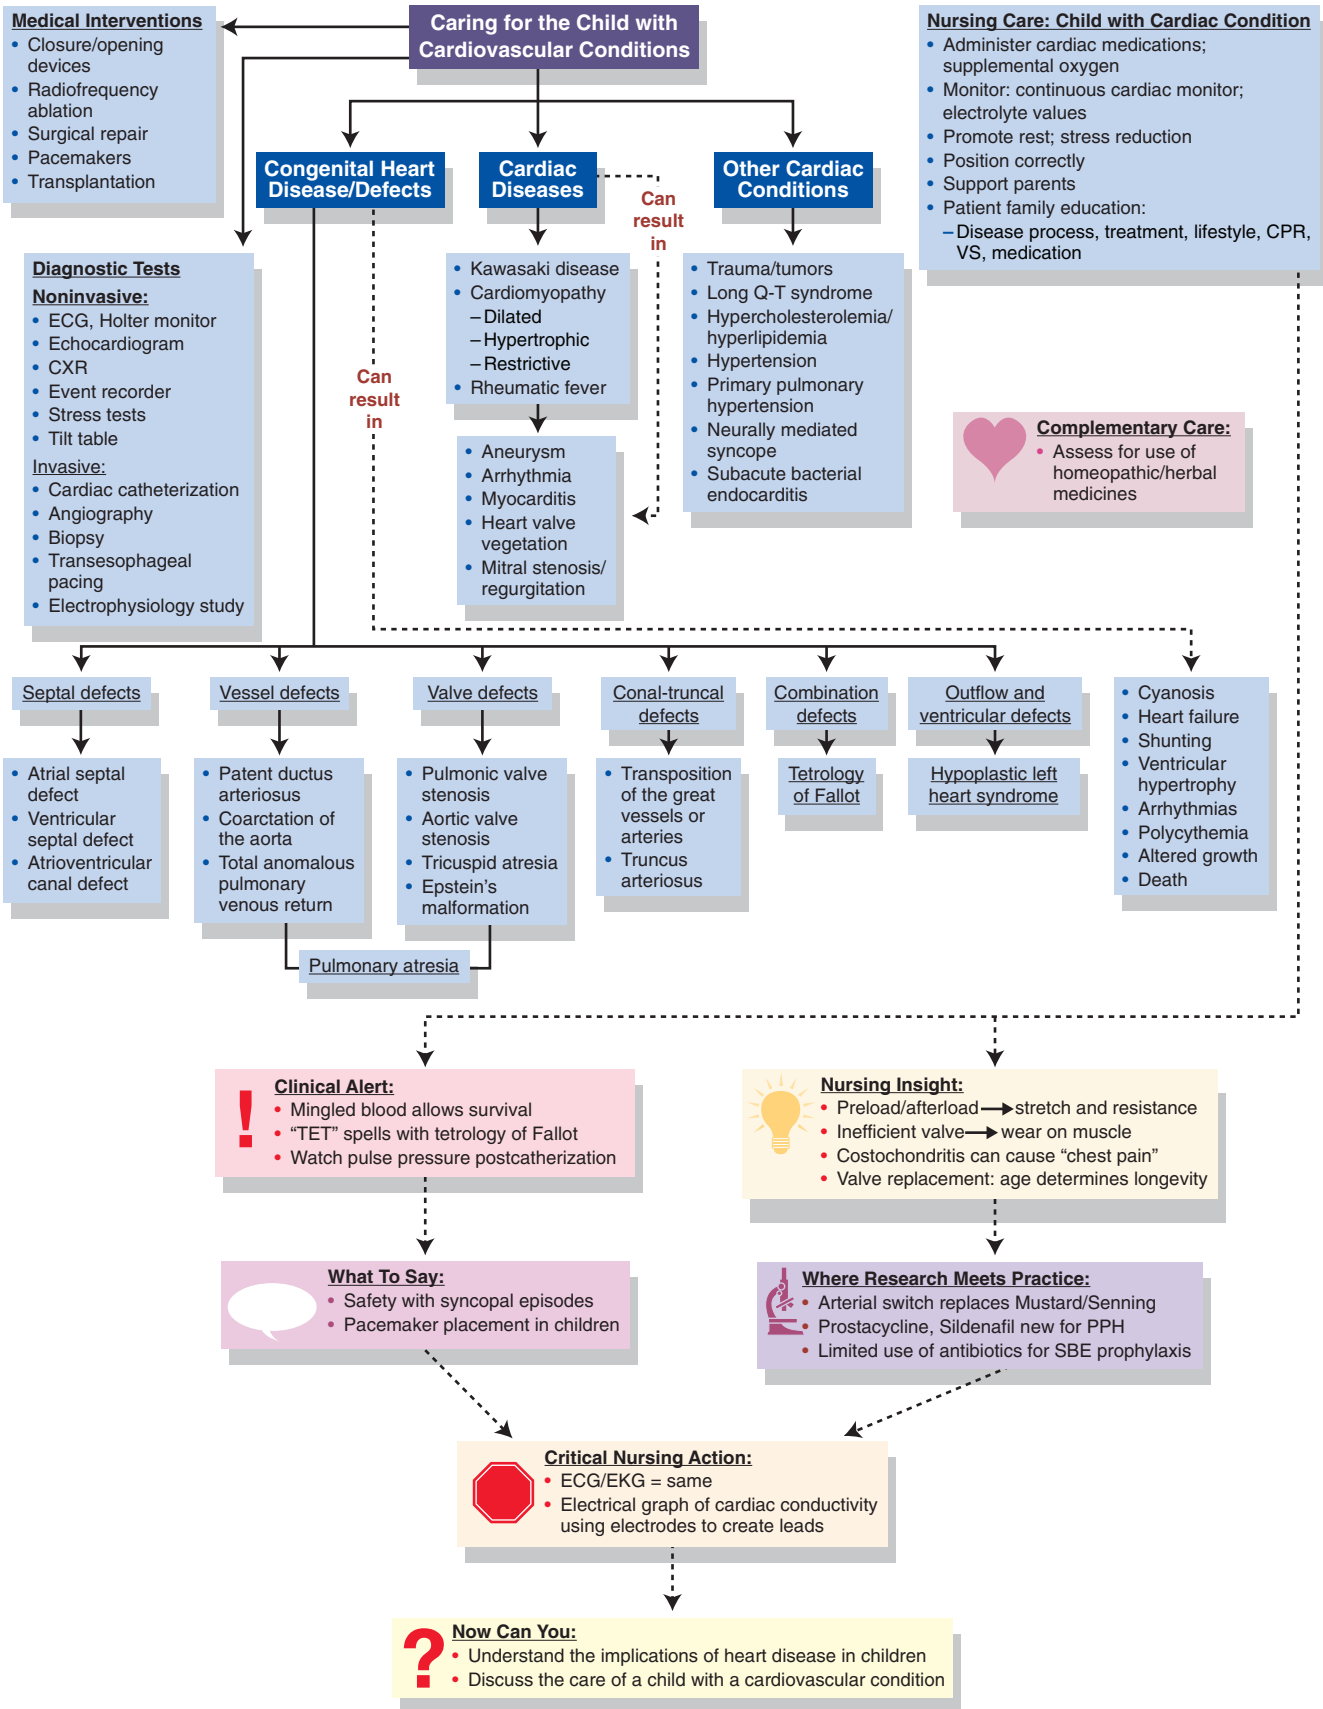

10. The child with an atrial septal defect has _____ to _____ shunting because the pressure is _____ on the _____ side of the heart.
11. In the cardiac condition, transposition of the great vessels, the _____ arises from the _____ ventricle of the heart and the _____ arises from the _____ ventricle of the heart.

CONCEPT MAP

Caring for the Child with an Endocrinological or Metabolic Condition

No More Sweets for Me

No more sweets for me
today, I must abstain; not to overindulge.
Tomorrow I can have some more
If I have one I'm still ok,
If I choose two I should be all right
If I take three I better be careful
I don't want to over due it

I don't like Halloween, too much candy for me
I want, but can't have dessert, and birthday cake
I don't want to complain, but some days it just doesn't seem fair
But in the end I'll be happier,
at least that's what you keep telling me.

—Nicholas Zahara-Such

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Describe the anatomy and normal function of the endocrine system.
- ◆ Recognize pathophysiological conditions of the endocrine system.
- ◆ Identify nursing insights necessary for the holistic care of a child with an endocrine or metabolic condition.
- ◆ Plan collaborative care for a child with an endocrine or metabolic condition.
- ◆ Identify complementary measures to provide alternatives to care within the child's culture.
- ◆ Define pharmacological and therapeutic measures to treat a child with an endocrine condition.
- ◆ Develop family teaching plans to optimize outcomes in a child with a chronic endocrine or metabolic condition.
- ◆ Use critical thinking measures to evaluate care of a child with an endocrine or metabolic condition.

moving toward evidence-based practice Glycemic Control of Children with Diabetes

Stallwood, L. (2005). Influence of caregiver stress and coping on glycemic control of young children with diabetes. *Journal of Pediatric Health Care, 19*(5), 293–300.

The purpose of this study was to examine the influence of caregiver stress, perceived stress and coping during the management and glycemic control of young diabetic children.

Current literature stresses the importance of maintaining acceptable glucose levels to avoid diabetic complications. Control is accomplished through adherence to a prescribed

management regimen. Previous research supports the notion that diabetes-related stress is a major contributor to decreased success in the home management of diabetes.

This investigation was part of a larger project that focused on the "relationships of the caregiver's diabetes-related stress, perceived stress, and coping with home management and

(continued)

moving toward evidence-based practice (continued)

glycemic control” (p. 295). Measures of stress, perception of stress, coping, and adaptation, as described in the Double ABCX Model of Family Adaptation, provided the framework for the study.

A cross-sectional correlational design was used. The convenience sample consisted of 73 primary caregivers of children younger than 9 years who were present in a children’s hospital diabetes clinic waiting room.

To be eligible for inclusion in the study, the primary caregiver was required to meet the following criteria:

- Function as “the primary caregiver of diabetes-related home management for a child younger than 9 years of age, and
- Able to speak and understand English” (p. 295).

The children of the caregivers were required to meet the following criteria:

- A diagnosis of “Type-1 diabetes for a minimum of 3 months
- Taking a combination of short-acting and long-acting insulin in 2–4 daily injections, and
- Free of a major co-morbid chronic illness” (p. 295).

Data collection took place before the primary caregiver was seen by the diabetes health care team.

Level of stress, defined as “pressures that accompany the stress of home management,” was measured by the Problem Areas in Diabetes (PAID) scale. The tool used a 5-point Likert type scale where 1 was ‘not a problem’ and 5 was ‘a serious problem.’

The Appraisal of Diabetes Scale (ADS) was used to measure the perception of stress, defined as “the meaning the caregiver assigns to the situation.” This instrument used a 5-point Likert-type scale and included questions such as: “How upsetting is your child’s diabetes for you?” and “How much control over your child’s diabetes do you have?” Higher scores were indicative of higher levels of perceived stress.

The Coping Health Inventory for Parents (CHIP) scale was used to measure coping. This instrument consisted of 45 self-report items to evaluate the caregiver’s perceptions of methods currently used to manage the child with a chronic condition. Three types of coping patterns were examined: family life, external relationships, and relationships with health care providers and other persons who provide care to children with chronic illnesses.

Hemoglobin A_{1c} (Hgb A_{1c}) was used to assess level of glycemic control. Target ranges of the A_{1c} (Hgb A_{1c}) for the diabetic clinic were >7 mg/dL to <9 mg/dL. Increased levels of Hgb A_{1c} are associated with increased blood sugar levels: with each 1.0 increase in the Hgb A_{1c}, there is an average mean blood glucose change of 30 mg/dL.

The Diabetes Self-Management Profile (DSMP) was used to assess home diabetes management. This instrument assessed

the following five domains over the previous 3 months: exercise frequency; hypoglycemia awareness and preparedness; food measurement and diet alterations based on activity and insulin administration; frequency of blood glucose testing and timing and technique of insulin administration.” Higher scores on the DSMP were indicative of better home diabetes management.

Analysis of the data revealed the following findings:

- The caregivers’ ages ranged from 19 to 66 years; mean age 35 years.
- The caregivers’ levels of education ranged from 10 to >16 years.
- Of those who reported income, 43 had an annual income of <\$50,000.
- The average length of time since receiving a diagnosis of diabetes was 2.5 years, with a range of 3 months to 7 years.
- Thirty-seven of the caregivers were Caucasian and 29 African American. Sixty-two of the primary caregivers identified themselves as the child’s mother; 8 identified themselves as the child’s father.

Results from the Hgb A_{1c} reports revealed that 33 children scored within an acceptable range, 35 scored outside of the acceptable range, and no data were available for 5 children.

The researcher concluded that increased levels of caregiver stress as indicated by the Problem Areas in Diabetes (PAID) scale were associated with higher levels of perceived stress as measured by the Appraisal of Diabetes Scale (ADS) scale. This finding may point to a direct relationship between stress and the perception of diabetes related stress.

A negative relationship was found between perceived stress on the Appraisal of Diabetes Scale (ADS) and the Hgb A_{1c} levels, which may be interpreted that the role of stress may be a motivator for attaining glycemic control.

A negative relationship was also found between home management and Hgb A_{1c} levels, suggesting that children of caregivers with a higher level of home management were better able to attain acceptable Hgb A_{1c} levels.

A negative relationship was also noted in relation to the child’s age and the PAID score, which might suggest the presence of higher levels of stress in families with younger diabetic children.

The researcher reported that no significance relationship was found between data from the Diabetes Self-Management Profile (DSMP) and the Coping Health Inventory for Parents (CHIP) scale.

1. What might be considered as limitations to this study?
2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

The endocrine system consists of multiple organs throughout the body. One of the main purposes of these organs is to secrete hormones that regulate various bodily functions. Hormones are chemicals that the body creates, such as proteins consisting of amino acid chains or steroids derived from fatty (cholesterol derived) substances. Although their derivations can vary, hormones act solely as “messengers,” moving from system to system coordinating the functions of many parts of the body.

In the care of children, it is important to remember that the endocrine system controls growth and development as well as energy use and energy stores; it also controls levels of sugar, salt, and fluids in the bloodstream. While hormones regulate a child’s response to stress or physical trauma, they play a vital role in sexual development as well.

This chapter provides a review about the anatomy and physiology of the endocrine system as well as the hormones it produces and the conditions that are commonly seen in children with endocrine or metabolic conditions. Current treatments and nursing strategies to augment the treatment and care of the child are discussed. Complementary care measures are included for the nurse to gain a repertoire of care modalities.

A & P review Organs of the Endocrine System

The hypothalamus is located in the center of the brain and is one of the main control centers of the body. Its main function is to communicate the messages of the central autonomic nervous system to the organs/glands of the endocrine system, thus working to create and maintain homeostasis throughout the body.

The pineal body is a photosensitive gland that receives light through the optic nerve. The pituitary gland is connected to the hypothalamus by a stem-like structure. It has two parts: the anterior and the posterior pituitary. It is said that the pituitary gland is the “master” because of its effect on growth and the functions of other glands in the body. The thyroid gland is located in the front of the neck just below the larynx. The two lobes of the thyroid are connected by an isthmus, which is a small band of tissue. The thyroid produces two hormones called thyroxin (T_4) and triiodothyronine (T_3).

There are four parathyroid glands, two embedded on the posterior side of each lobe of the thyroid gland. The parathyroid glands produce parathyroid hormone (PTH). The adrenal glands are located on the top of each kidney. Each gland has an outer (cortex) portion and an inner (medulla) portion. The hypothalamus has control on the adrenal glands by causing the anterior pituitary to release adrenocorticotropic hormone (ACTH) releasing hormone. Each part of the adrenal cortex produces different hormones. The pancreas is located in the abdomen, just behind the stomach near the duodenum. It functions as both an endocrine (without ducts) gland by secreting hormones and also as an exocrine (with ducts) gland. As an exocrine gland, it produces and secretes digestive enzymes directly into

the small intestine through ducts. As an endocrine gland, it produces both insulin and glucagon which in turn are carried to the body through the bloodstream. These hormones are antagonistic and have opposite effects on metabolism.

The gonads, namely the ovaries in females and the testes in males, produce several steroidal sex hormones. Generally, these sex hormones produce and regulate changes in the male and female body at puberty. ♦

Pathophysiological Conditions of the Endocrine System

CONDITIONS OF THE ANTERIOR PITUITARY

Since the anterior pituitary gland is responsible for the production of many hormones that influence and regulate growth, metabolic activity, and eventually sexual development, conditions of the anterior pituitary are a result of either an over or underproduction of their essential hormones. These conditions include growth hormone deficiency, precocious puberty, and acromegaly.

Hypopituitary

Hypopituitary or growth hormone deficiency (GHD) is an endocrine condition that is generally due to a decreased production of GH by the anterior pituitary gland. It is seen in children who present with short stature (below the 3rd or 5th percentile) and is characterized by delayed skeletal growth.

The incidence of GHD has not yet been established with 100% certainty, but generally, its prevalence has been reported to be about 1 out of every 3500 children. Boys are referred more often than girls for short stature because it is believed that small females are more accepted in our society. Incidence among boys and girls is about equal.

Recent studies have tried to isolate the cause of hypopituitarism. Some cases, which have been spontaneous in nature, have led to the identification and characterization of numerous genes and factors as the causes. Generally, the majority of the cases are still considered to have no known cause and idiopathic in nature. In addition there are many other causes including genetic, congenital, acquired (due to trauma or CNS infections), tumors in the region of the hypothalamus or pituitary, as well as secondary causes such as cranial irradiation and transient causes such as psychosocial deprivation.

SIGNS AND SYMPTOMS. Usually in the neonatal period, infants with GHD are of normal birth weight and length. The delayed or absent growth begins to be assessed in the first 2 years of life. Delayed growth of less than 2 inches (4 to 5 centimeters) in a year should be evaluated further. Assessment must be done carefully and consistently at each visit to the pediatrician. The rate of growth can be measured using the metric system to increase the preciseness of the measurement. If a child is seen to have “fallen off” the growth chart, height or weight plateaus, stays the same, or dramatically is less than last visit, further evaluation is warranted.

critical nursing action Proper Growth Assessment

It is imperative that the nurse plot the child's height and weight accurately at each outpatient visit on the appropriate growth chart (Fig. 28-1). If the child is of short stature (below the 3rd or 5th percentile) and is not chartable on the usual chart or has Down syndrome, the pediatric nurse should go to the Center of Disease Control Web site for the most appropriate chart, located at <http://www.cdc.gov/nchs/about/major/nhanes/growthcharts/charts.htm>. It is important to use the same one growth chart at each visit. The nurse must remember to weigh an infant completely undressed (including diaper) and young child in underwear with socks only.

Other signs and symptoms include delayed closure of the anterior fontanel, delayed dental eruption, greater weight to height ratio with increased abdominal (truncal) fat, decreased muscle mass, poor development of bridge of nose giving a child-like appearance, protrusion of the frontal skull bones, delayed puberty, including high pitched voice and a small penis or testes in boys, and hypoglycemia.

It is important to also note and alert the physician about episodes of frequent or recurrent hypoglycemia, prolonged jaundice, or micropenis in the neonatal period, as these may indicate the possibility of congenital hypopituitarism (Allen, 2006).

DIAGNOSIS. A diagnostic work-up begins with a review of all previous growth charts to determine the rate of growth. Special attention is given to children in the less than 3rd or 5th percentile or to any child whose growth has ceased. Bone age determination by radiograph of the wrist, knee, or hand is usually less than the child's chronological age, thus indicating a delayed skeletal maturation. Magnetic resonance imaging (MRI) of the brain is also performed. Baseline blood tests and pituitary function tests are needed to confirm the diagnosis. Various pituitary function tests are given to stimulate growth hormone (GH) release. The GH stimulants are medications that include insulin, glucagon, clonidine, arginine, or L-dopa. One or more of these may be administered during testing

Figure 28-1 The nurse is measuring the child's height to ensure growth and development are on target.

to stimulate a rapid release of GH. Small percentages of children do not respond to these pituitary tests and must be retested. When peak GH levels are less than 10 nanograms per liter (ng/L) the diagnosis is confirmed.

NURSING CARE. The nurse assists the child in reaching the goals of treatment, which are that the child achieves a normal growth rate and eventually reaches a normal adult height. Treatment is considered simple with the administration of human recombinant GH (replacement therapy with daily subcutaneous injections).

Although significant side effects of GH are rare, it is important to know that they may include increased intracranial pressure (ICP), gynecomastia, arthralgia, and edema. Children who complain of a headache must be carefully monitored because this may be the only sign of ICP. Managing these side effects may mean that the GH dose is temporarily reduced or stopped. GH therapy can also decrease a child's sensitivity to insulin, but there are few reported cases of diabetes mellitus while the child is on GH treatment. Recombinant human GH is a safe treatment for children with idiopathic short stature. Studies that assess the frequency of rare side effects and long-term follow up are necessary (Quigley et al., 2005).

When a child is diagnosed with GHD, careful and consistent growth measurements are as essential as plotting the measurements on the appropriate growth chart. Children should be measured and weighed no less than once every 6 months on an outpatient basis.

critical nursing action Daily Weights to Ensure Accurate Medication Doses

When the child is hospitalized, the nurse must be conscientious and recalculate medication dosages with every weight variance. Physicians must be notified if the dose ordered is now inaccurate based on the most current weight. Daily weight measures using kilograms ensures that accurate medication dosages are calculated and given.

Parents need to be given as many supportive resources as possible. Specific foundations have Web sites that will link the family with other families going through the same treatment. Some reliable resources that parents could be referred to include: the Human Growth Foundation <http://www.hgfound.org/>, the Short Stature Foundation <http://www.kumc.edu/gec/support/dwarfism.html>, or the Magic Foundation <http://www.magicfoundation.org/www>.

These Web sites may also help parents find financial support as the GH treatments can be expensive and sometimes insurance does not cover the condition. The drug companies that produce GH also have programs that can assist families who cannot pay for the treatments.

Children with GHD can be small framed and of short stature. It is important to stress to the families to treat the child for their age, not their size. Frequently, teachers or other adults treat a child with GHD differently than a child of the same age and normal size. Children with GHD should be encouraged to play sports that do not involve size, such as swimming, ice skating, dancing, and gymnastics. They should also be encouraged to dress age-appropriately. Supporting the family to help the child attain a positive self-image is of the utmost importance. The nurse should help

the child realize that self-determination and confidence, not height, achieve goals. Classmates can be insensitive to the child's feelings and can even tease the untreated short child. Adolescence, with the focus on body image, can be an especially difficult time. It is best to begin treatment as early as possible when a near normal height can be reached and before the psychological effects of short stature harm the child.

Another important aspect of nursing care includes patient and family teaching about the condition, its treatment, and providing as much support as possible. Parents need to be taught about GH replacement therapy, its preparation, and administration of the subcutaneous injections. Just as with other daily subcutaneous injections, rotating sites, potential side effects, and actions to take if necessary must be taught to the parents. Parents should be prompted to think of ideas that would decrease the child's stress regarding the daily injections.

The nurse can also remember to encourage the parents to take the child with GHD to the dentist regularly because the GH treatments cause the child's teeth to be softer and much more susceptible to cavities.

“What to say” — Helping children express themselves

Children can be apprehensive about daily injections of any kind. It is important for the nurse to be as honest as possible regarding the GH treatments. The nurse can refer the family to the Magic Foundation Web site for on-line videos that address this topic. The nurse can help the child express answers to the following questions:

“How do you feel?”

“What do you tell your friends about your condition and the GH medication?”

“How have you changed since the GH treatments began?”

“What advice do you have for other children beginning GH treatment?”

Complementary Care: Therapeutic touch

Therapeutic touch (TT) or massage is a form of energy therapy that helps the body release endorphins. Endorphins (or more correctly endomorphines) are *endogenous opioid* biochemical compounds. Endorphins are peptides produced by the pituitary gland and the hypothalamus and resemble the opiates in their abilities to produce analgesia and a sense of well-being. In other words, endorphins work as “natural pain killers.” Using drugs may increase the effects of the endorphins (A.D.A.M., 2006). Energy therapy does not promote GH release and therefore would not replace conventional GH treatments, but it certainly can be used to adjunct the GH therapy.

The nurse should constantly be aware of individual patient goals and the progress made toward achievement, that is, to know and accurately communicate the growth status of the child and the child's psychological acceptance of his body image. The nurse must ascertain the status of these vital outcomes. The pediatric nurse should be alert to facial expressions of uncertainty. Sometimes families are afraid to ask or fear that the question is unintelligent.

Collaboration in Caring— A team approach

The nurse can make referrals for psychological counseling for the child or family if warranted. Even when the pediatric nurse is not certain about the child's psyche, the referral should be made and the decision left to the specialist.

Pituitary Hyperfunction

Pituitary hyperfunction or precocious puberty (early or premature) is a condition that occurs with hyperfunction of the pituitary gland. Generally, puberty occurs between 8 and 13 years of age in girls and between 9 1/2 and 14 in boys. In girls, precocious puberty is when any of the following secondary sexual characteristics develop before 8 years of age: breasts, armpit or pubic hair, mature external genitalia, and the first menstruation. In boys, precocious puberty is when any of the following secondary sexual characteristics such as mature external genitalia, growth of body hair, including facial, underarm, abdominal, chest, and pubic hair, increase in size and mass of muscles, deepening of the voice and changing the shape of the face and skeleton before 9 years of age.

Most often precocious puberty is idiopathic in girls and the incidence is about five times higher than in boys (Traggiai & Stanhope, 2003). In males, it is usually due to central nervous system (CNS) abnormalities, or lesions such as a benign hypothalamic tumor, brain injury, or another type of brain tumor. Other known causes include post infections-encephalitis or meningitis, congenital adrenal hyperplasia, tumors of the ovary, adrenal gland or testicle, exogenous sources or androgens.

SIGNS AND SYMPTOMS. Similar characteristics of precocious puberty appear in boys and girls, as well as ones specific to each sex. In boys, the following signs and symptoms may be seen: facial hair, penile growth, increased masculinity, testicular enlargement, and voice changes. In girls these characteristic signs and symptoms are likely: breast development onset of menarche, ovary enlargement, and cysts on ovaries. Commonly seen in both boys and girls are the following: armpit hair, pubic hair, body odor, acne, emotional lability and mood swings, and growth spurts in height. Advanced bone age equals increased skeletal growth which in turn equals increased height initially. If untreated, epiphyseal plates (growth plates) close early and growth stops.

DIAGNOSIS. The nurse understands that blood tests include measurement of luteinizing hormone (LH), follicle-stimulating hormone (FSH), testosterone, or estradiol. Testing to stimulate the release of gonadotropins confirm the diagnosis. In addition, radiological studies should be done to calculate the child's bone age. Because of the high incidence of CNS involvement in males, skull CT and/or MRI is usually indicated.

The pediatric nurse must perform a complete history and assessment of the child's pubertal status including a Tanner staging of sexual maturation. Growth charts should also be completed to determine the exact age that linear growth spiked. Breast, genital, pubic hair, and testicular development should be documented. The nursing history should include exposure to hormones, CNS infection or trauma, and the family history of the age at puberty onset.

clinical alert

Exogenous hormones

Many commercially purchased female products contain estrogen. Facial creams, hair products, and other “beauty” aids can contain hormones or placenta extracts. Some shampoos specifically marketed to African Americans have been found to contain hormones. Children can readily absorb enough of these exogenous hormones to present with precocious puberty. The nurse can refer parents the Web site on Organic Parenting http://www.primalspirit.com/ps3_1lyn-piluso.htm

The nurse must alert parents of the dangers of hidden toxins in everyday products that can harm their children. The nurse must also be cognizant of “endocrine disruptors,” and can refer families to <http://www.mindfully.org/Pesticide/EDs-PWG-16jun01.htm>

NURSING CARE. The nurse assists in providing treatment for precocious puberty. Treatment includes gonadotropin-releasing hormone (GnRH) agonists (Kaplowitz, 2006) which can be given via subcutaneous injection daily or as a depot injection once every 3 to 4 weeks or has been given intranasally two to three times daily. Initially the treatments stimulate gonadotropin release, but when given over the long term it suppresses the release of gonadotropins by acting on the pituitary gland.

Treatments cause a decrease in growth rate and a stabilization or regression in development of secondary sexual characteristics. Sizes of breasts, ovaries, the uterus, and testes as well as erection frequency all decrease. The success of the treatment is measured via growth charts and blood levels of gonadotropins and sex steroids. When treatments are stopped, puberty promptly begins.

Consistent, accurate record keeping of child’s growth rate must be documented because while on treatment the child’s growth rate declines. The nurse must continue to assess and document the progression or regression of the child’s secondary sex characteristics. Nursing care must also focus on the accuracy of medication delivery. The pediatric nurse should provide accurate information to both the child and the family about medication preparation, action, and administration techniques.

It is important to approach the child in a manner appropriate to his or her level of emotional and cognitive development. Information provided to both the child and family should include the physical changes that the child is experiencing as well as on the child’s disturbed body image. The nurse understands that help should be given to the child and family regarding manner of dress. Loosely fitting clothing may help to conceal the abruptly changing body image. The nurse can also make referrals to counseling.

Depending on the age of the child, the child should be included in the teaching as much as appropriate. Providing information about normal development during puberty helps the caregivers and the child understand the physical and emotional changes that occur with the early onset of puberty. In addition, the nurse understands that decreased stress and low-fat diets are some of the latest discoveries related to decrease premature sexual maturation. In other words, obesity, especially in females, and stress are the newest suspected causes of early puberty. Pediatric nurses must stay critically aware of the child’s feelings and help the parents develop ways to stay “connected” to their child with precocious puberty.

Optimizing Outcomes— Financial Resources

Helping the parents identify financial resources for assistance if necessary ensures the best outcomes of the care and treatments given. GnRH analog depot treatments are very costly and can range from \$700 to \$1000 per injection. These treatments are usually covered by the insurance companies, but some require the injection to be given in the physician’s office. For those with limited insurance resources, some pharmaceutical companies provide assistance and give treatments at limited or no cost.

Across Care Settings: A team approach

Precocious puberty has its greatest effect on the child and family both psychologically and psychosocially. It is to the child and family’s best interest for the primary care pediatrician to make referrals to an endocrinologist and psychologist as soon as possible. Especially in very young children, early referrals can help to prevent serious psychological trauma and help the child begin to adjust to his or her changing body. Communication among members of the entire team is essential for ongoing collaboration and the best possible outcomes.

Acromegaly and Gigantism

The term “acromegaly” comes from the Greek words *acro* (extremities) and *megaly* (enlargement). Acromegaly can be recognized by abnormal or overgrowth of the hands and feet, as well as other signs such as enlargement of the facial features in an adult. Although both acromegaly and gigantism have a similar cause, they are different. Acromegaly occurs in adulthood, when the long bones of the legs and arms have stopped growing (Understanding Acromegaly <http://www.acromegalyinfo.com/info/understanding/home.jsp>).

In children, before closure of the bone growth plates, the condition is known as gigantism. Gigantism caused by large amounts of GH results in excessive growth of the long bones in a child. Children affected by gigantism can grow to extraordinary heights. It also affects the child’s muscle and organ growth, making the child look very large for his or her age. It may be noted as early as the sixth to ninth month of life. Whether acromegaly or gigantism, these conditions involve changes in the way the body functions and can delay puberty. Over time, these changes can cause complications (such as cardiomegaly or diabetes) that can be life threatening. It is imperative to obtain an early diagnosis and initiate a treatment plan as soon as the condition has been discovered. Early treatment can prevent irreversible changes that can ultimately lead to a premature death. Mortality rates can be two to fourfold higher in these patients because of the strain this excessive growth has on the vital organs such as the heart and pancreas.

Acromegaly/gigantism is a rare disease that affects about three to six out of every million people in the United States. Acromegaly/gigantism is caused by the uncontrolled hypersecretion of GH by the pituitary. In most cases, the cause of this excessive production of GH

is a noncancerous tumor on the pituitary. Gigantism may also be caused by multiple endocrine neoplasms, McCune Albright syndrome (MAS), neurofibromatosis, or Carney complex.

Nursing Insight— *Understanding acromegaly/gigantism*

To understand the causes and treatment of acromegaly/gigantism, the nurse needs to understand the three important hormones that circulate throughout the body to regulate many of the body's most basic activities:

- Growth hormone (GH)
 - The pituitary releases GH in short spurts throughout the day and night, resulting in constantly varying GH levels.
 - When a person has acromegaly/gigantism, abnormally high levels of GH are released by the pituitary. Too much GH causes changes in physical characteristics and other aspects of your body.
- Insulin-like growth factor (IGF-1): IGF-1 levels rise whenever GH levels rise, but IGF-1 is released more evenly than GH, and IGF-1 levels remain higher longer. Researchers believe that elevated IGF-1 levels probably cause most of the changes to one's body that are associated with acromegaly.
- Somatostatin: One of the main effects of somatostatin is its ability to control the amount of GH in the body. Researchers have taken advantage of this knowledge in developing treatments for acromegaly. Natural somatostatin is broken down by the body in a matter of minutes, whereas treatments based on somatostatin remain active much longer.

SIGNS AND SYMPTOMS. The signs and symptoms of acromegaly/gigantism may include gradual enlargement of the hands and feet in adults (may be indicated by increased ring or shoe size), and rapid growth during childhood (giantism in children). There may be swelling of soft tissue, skin tags, thyroid disorders, muscle weakness, and fatigue. Skin changes (thickening, oiliness, and acne, hirsutism) and coarsening of facial features, including forehead, nose, lips, tongue, and jaw, are common.

These changes do not appear in adults until 30 or 40 years of age, whereas in children, a rapid increase in skeletal growth would be seen each time the child is plotted on the appropriate growth chart.

Beside the changes in appearance, acromegaly/gigantism produces body function changes. These symptoms are listed in the order of most frequent to least frequent and become more pronounced as the child becomes older: arthralgia (arthritis-like joint pain), delayed onset of puberty or amenorrhea or irregular menstruation in women, excessive perspiration, sleep apnea, headaches, paresthesia or carpal tunnel syndrome, loss of libido or impotence, hypertension, goiter, and visual field defects.

DIAGNOSIS. The best way to diagnose acromegaly is to measure serum GH levels after an overnight fast and then again after giving a glucose drink (oral glucose tolerance test). A glucose ingestion of 75 grams would lower a healthy person's GH level to less than 2 ng/mL. In a child with gigantism and an overproduction of GH, this reduction would not be seen.

As a response to increases in GH, insulin-like growth factor (IGF-1), produced in the liver, also increases. IGF-1 levels are much more stable over time than GH, therefore, it provides a more reliable test than GH levels.

Since more than 90% of children with acromegaly/gigantism suffer from benign tumors of the pituitary gland (an adenoma), other tests, such as head scans by MRI or by computed tomography (CT), look specifically for a pituitary growths or tumors. These tumors are usually the source of the excessive GH secretion.

NURSING CARE. Nursing care includes assisting in providing treatments that are aimed toward curing the cause. If there is a tumor, surgical removal is warranted. It has been found that surgery is the curative treatment of choice in 80% of the cases. Unfortunately, there are cases in which the surgical procedures cannot completely remove the tumor.

In these instances, medications are the treatments of choice. Somatostatin analogs or dopamine agonists are effective in reducing the release of GH secretion. The dopamine agonists are usually less effective medications but are usually the first drug of choice because they are easy to administer orally. Somatostatin analogs must be administered by a subcutaneous injection every 8 hours and are more rigorous treatments and can be difficult to administer.

In 2003, pegvisomant (Somavert) (a new drug class, GH receptor antagonist) became available. Traditionally, reducing pituitary tumor secretion of GH has been the treatment of choice, thus lowering serum IGF-I levels. Pegvisomant (Somavert) blocks the actions of circulating GH excess, but does not lower serum GH levels (Freda, 2006). Although dosages are not clearly identified for children (Schwartz, 2007), this medication is easy to administer and can be given once every 24 hours by subcutaneous injection.

Another attempt to slow GH release has been with radiation therapy. This is the slowest course of treatment in that it can take 5 to 10 years to see the full effects and almost always affects the proper excretion of other hormones as well. Many other hormones can be affected resulting in hypothyroidism, adrenal insufficiency, hypogonadism, and rarely diabetes insipidus. Radiation therapy has many side effects in children, such as learning disabilities, obesity, and emotional changes. Most experts use radiation only when all other treatments fail.

Nursing care should focus on the initial aspects of accurate assessment of growth by using the correct growth chart and by meticulously documenting height and weight at each outpatient visit. When a child is affected with gigantism, the patterns of abnormal growth are quite recognizable. Rather than just unusual tallness, there is a characteristic body build consisting of heavy thick bones, especially jaw, and unusually large hands and feet. Careful physical assessment is important to observe and document, as is the cognizance of laboratory values. Clinically an accurate assessment is one of the most important aspects of care.

In addition to assessment, the pediatric nurse should focus on the medication that the child receives. Medication regimens should be followed thoroughly and patient family teaching is of utmost importance. Medication regimens,

including the administration of subcutaneous injections, and regular physician visits are extremely important. Follow-up home care may be needed in some cases depending on the status of the child's health and the resources available to the family. In the first few weeks of treatment, home health nursing visits would benefit the family by reinforcing the discharge teaching and by giving them a sense of confidence regarding the medication delivery and care of the child.

Postsurgical care after pituitary tumor excision requires precise critical neurosurgical care. Neurological and vital signs must be taken frequently. Depending on the surgical site (sometimes it is removed through the nose), care must include observations and documentation of dressing, wound, and drainage. Usually the first dressing is changed by the surgeon or advanced practice nurse. It is necessary to follow hospital protocols and physician's orders with regard to the appropriate care to give postoperatively.

Complications of this condition are numerous, and the focus of care should be measures to intervene and prevent them. The nurse must remember that a lifelong monitoring and evaluation is vital in order to maintain optimal health. This is a very rare disorder, with little clinical experience in children. Multi-team efforts can help to extend and normalize life as much as possible. The earliest interventions can help prevent many serious complications that can lead to a premature death. Progressive, untreated disease can cause serious complications, such as hypertension, cardiomyopathy, and subsequent cardiovascular disease, osteoarthritis, diabetes mellitus, polyps of colon, sleep apnea, carpal tunnel syndrome, hypopituitarism, uterine fibroid tumors, spinal cord compression, and vision loss.

CONDITIONS OF THE POSTERIOR PITUITARY

Diabetes Insipidus

Diabetes insipidus is caused when there is an insufficient production of antidiuretic hormone (ADH). ADH acts on the kidneys to conserve water by controlling the kidneys' urine output. ADH is secreted by the hypothalamus and stored in the posterior pituitary gland before it is released into the bloodstream. When sufficient ADH is secreted, the amount of urine output is decreased to avoid dehydration. When a child has diabetes insipidus, there is insufficient ADH resulting in excessive production of extremely dilute urine. This causes the child to be excessively thirsty. In simple terms, diabetes insipidus can be called a disease of water regulation, causing the child to exhibit polydipsia (extreme thirst) and polyuria (excessive urination). Diabetes insipidus is categorized into two groups:

Central diabetes insipidus (*or neurogenic*), the production or secretion of ADH is insufficient. It can be caused by damage directly to the pituitary gland, such as head injury, neurosurgery, a genetic disorder, and other diseases.

Nephrogenic diabetes insipidus, the lack of the kidney's appropriate response to normal levels of ADH. It can be caused by drugs or chronic disorders, such as kidney failure, sickle cell disease, or polycystic kidney disease.

Generally occurring *suddenly*, diabetes insipidus can be due to many medical or surgical conditions:

Surgical (most common causes):

- Damage due to neurosurgery (i.e., hypothalamus or pituitary gland)
- Brain injury or tumor excision

Medical:

- Hypothalamus malfunction (insufficient ADH production)
- Pituitary gland malfunction (ADH is not released into the bloodstream)
- Vascular abnormalities or cerebral vascular accident (CVA) or "stroke"
- Infection
 - Encephalitis—brain inflammation
 - Meningitis—inflammation of meninges
 - Sarcoidosis—inflammation of the lymph nodes and other tissues throughout the body
 - Tuberculosis—infectious disease
- Family heredity—genetic defect (Chan & Roth, 2006)

SIGNS AND SYMPTOMS. Children experience and verbalize symptoms of the disease very differently. Infants are very difficult to assess because verbalization is through crying no matter what the problem is. It is helpful to separate signs and symptoms of diabetes insipidus into infant and child categories to accurately ascertain which symptom the pediatric patient is manifesting.

assessment tools Signs and Symptoms of Diabetes Insipidus

Infant can manifest the following: Irritability Poor feeding (<i>despite vigorous suck</i>) Failure to grow/thrive Vomiting Constipation High fevers	Child may experience these symptoms: Excessive thirst (polydipsia) Excessive urine production (polyuria) Enuresis (nocturnal bed wetting)
---	--

clinical alert

Dehydration

Dehydration can be seen in all cases, causing the infant/child to be irritable with many other manifestations, including dry mucous membranes, decreased skin turgor, decreased tears when crying, sunken fontanel and tachycardia. If dehydration is severe, the child's pulse may be thready and very rapid. Hypotension may also be present and could lead to hypovolemic shock. If dehydration occurs, it is important to administer IV fluids.

DIAGNOSIS. After a complete history, physical examination, and daily log of fluid and dietary intake and output patterns, the first morning urine is usually collected and subsequently tested for specific gravity, osmolality, and sodium. Ideally, the morning urine would be collected after an overnight fast. If the urine is dilute (specific gravity of 1.005 or less) and the osmolality (greater than 300 Osmol/kg) and sodium (as high as 170 mEq/L) are elevated, the

diagnosis can be effectively confirmed. Diagnosis can be difficult in infants because they excrete dilute urine naturally.

diagnostic tools Diagnosis of Diabetes Insipidus

The diagnosis of diabetes insipidus, including type (neurogenic central or nephrogenic) can be given definitively after a water deprivation test. This test is done under close supervision of the patient's vital signs. Urine and blood are collected early in the day and tested for osmolality and electrolytes. The child is then deprived of water until significant dehydration occurs. The child is weighed every 2 hours until 2%–5% of body weight is lost. Urine specific gravity is monitored hourly; this test can be stopped if the specific gravity is 1.014 or higher. Urine and blood specimens can be sent for osmolality midway through the deprivation test, i.e., 2 hours in an infant and 4 hours in a child. This water deprivation test should never be longer than a total of 4 hours in an infant and 7 hours in a child. During this test, the child may become febrile and develop hypotension. Vital signs should be watched very closely and taken every hour if necessary. A 24-hour urine collection may also be ordered to determine total daily urine output.

NURSING CARE. It is essential to differentiate between central (neurogenic) and nephrogenic diabetes insipidus before decisions are made regarding treatments and nursing care. For central diabetes insipidus, when polyuria is persistent, intranasal, parenteral, or oral doses of desmopressin (DDAVP) are the treatments of choice. Desmopressin (DDAVP) is a synthetic vasopressin analogue (Children's Hospitals and Clinics of Minnesota, 2007b). The diuretic chlorothiazide (Diuril) is given to decrease urine volume by up to 75%.

Nephrogenic diabetes insipidus cannot be effectively treated with DDAVP because of the lack of effective receptor sites, thus making the kidney unresponsive. Diuretics, amiloride (Midamor) (potassium-sparing diuretic) and indomethacin (Indocin) (nonsteroidal prostaglandin) or aspirin are all useful to help treat the child.

Nursing Insight— Action of diuretics on the kidney

Diuretics impede the sodium chloride reabsorption that occurs in the distal tubule of the kidney. This reduces the loss of free water and increases the concentration of the child's urine. Reduction in urine volume derives from a concomitant action on the proximal tubule, which causes reabsorption of sodium chloride from the glomerular filtrate, thus drawing additional water along. This results in both a smaller volume and a higher concentration of the urine (Chan & Roth, 2006).

It is important for the nurse to remember that a diet low in solutes helps this condition. Generally, infants should be given breast milk because it is naturally low in solutes. Protein content in diets should be about 6% of an infant's diet and only 8% of a young child's diet. This should be enough to allow normal growth but not cause a solute excess.

The nurse should observe the child and closely monitor urine output. In addition, the nurse must keep very close track of fluid balance. The best way to measure fluid balance is by weighing the patient daily. Daily weights should be done using exact conditions (i.e., same scale, infants completely undressed including diaper, young child in underwear with socks only). Output measurements must also be exact and include weighing diapers in grams for infants. All output voided into the toilet or into a urinal

should be caught in a container to enable precise measurement of urine in milliliters. Record keeping and communication to the rest of the health care team should emphasize exact amounts taken in and excreted. The pediatric nurse should closely monitor the child for subtle signs of impending dehydration or fluid imbalance.

Caring for a child with diabetes insipidus can be difficult during the water deprivation test. The child becomes very irritable due to thirst and it may be difficult for the child to understand why he or she cannot drink. The child becomes more and more irritable, which is frustrating for the parents to deal with as well. Extreme patience is necessary to help the child and parents during this time. The nurse and parents can alternate holding and comforting the child as well as using distraction methods.

Accurate administration of medications is also a key factor when providing nursing care. The intranasal form of desmopressin (DDAVP) may be difficult to give and special care should be taken to give the medication accurately and also teach the parents proper administration.

Patient and parent teaching, as with most conditions, is of utmost importance. Parents must be taught to replace fluids in the very young child or infant because these patients cannot be relied on to accurately express thirst nor can these patients obtain a drink on their own without help from an adult. Also, common gastrointestinal illnesses that either increase fluid needs or decrease intake must be identified and the nurse must alert parents to the seriousness of these conditions that can lead to life-threatening fluid and electrolyte imbalances (Chan & Roth, 2006). Early discovery and care of the child with diabetes insipidus is important. This condition demands close monitoring of the fluid and electrolyte balance to prevent complications (Hudson, 2007). Family involvement is the key to successful home management. Helping the family by beginning a log of accurate intake, output, and daily weight while the child is hospitalized can be the greatest asset and optimize outcomes to this very challenging care situation.

clinical alert

Critical thinking question

Will you always see poor skin turgor or tenting of abdominal skin? The answer is *no*. When the child has hypernatremic dehydration, skin turgor is not decreased despite the state of dehydration (Chan & Roth, 2006).

This state of hypernatremia places the child at an increased risk for seizures. If left untreated, diabetes insipidus can cause a child to have brain damage and impaired mental function such as retardation or attention-deficit/hyperactive disorder (ADHD), short attention span, or restlessness (Children's Hospital Boston, 2007).

medication: Accurate Administration of Intranasal Medication Doses

Intranasal DDAVP is administered through a rhinal tube. Ensure the child blows his or her nose before the medication is given. Positioning the child on the side the medication is given enhances the absorption of the medication. Instructions to parents should be as clear as possible. Refer to the Family Resource Center Library at www.childrensmn.org for explicit patient family education materials.

where research and practice meet: Alternative Measures for Diabetes Insipidus

Alternative measures could be significant in treating the common childhood illnesses such as the vomiting and diarrhea that can be fatal in a child with diabetes insipidus. In all instances, it is crucial to prevent dehydration. There are many homeopathic therapies that treat diarrhea that have been proven to be more effective than some conventional treatments. Homeopathy is defined as stimulating the natural healing abilities of the body to cure the disease.

In a recent study of children with acute diarrhea, those who received individualized homeopathic treatment for 5 days had a significantly shorter duration of diarrhea than children who received placebo. Some of the most effective homeopathic remedies are listed below. An experienced homeopath assesses the physical, emotional, and intellectual make-up when determining the most appropriate remedy for a particular individual (A.D.A.M., 2004).

Arsenicum album—used for foul-smelling diarrhea from food poisoning or traveler's diarrhea with burning sensation in the abdomen and around the anus. This remedy is most appropriate for individuals who feel exhausted yet restless and whose symptoms tend to worsen in the cold and improve with warmth. Vomiting may also occur. *Arsenicum* may also be used to prevent diarrhea when traveling

Chamomilla—used for greenish, frothy stool that smells like rotten eggs; used primarily for children, especially those who are irritable, argumentative, and difficult to console; commonly recommended for colicky or teething infants

Calcarea carbonica—used for children who fear being in the dark or alone and who perspire heavily while sleeping; stools have a sour odor

Mercurius—used for foul-smelling diarrhea that may have streaks of blood accompanied by a sensation of incomplete emptying; this remedy is most appropriate for individuals who tend to feel exhausted after bowel movements, experience extreme changes in body temperatures, perspire heavily, and have a thirst for cold fluids

Podophyllum—used for explosive, gushing, painless diarrhea that becomes worse after eating or drinking; exhaustion often follows bowel movements and the individual for whom this remedy is appropriate may experience painful cramps in lower extremities; often used in infants for diarrhea experienced from teething

Pulsatilla—used for diarrhea that occurs after consuming too much fruit or rich, greasy food; stools are greenish in infants and of changing consistencies in older children

Sulfur—used for irritable and crying children; may have a red ring around the anus and diarrhea with the odor of rotten eggs

Veratrum album—used for profuse, watery diarrhea accompanied by stomach cramps, bloated abdomen, vomiting, exhaustion, and chills; the diarrhea is worsened by fruit, and the individual craves cold liquids (A.D.A.M., 2006).

Therapies such as acupuncture (used with children in China but not used for diarrhea in the United States), hypnosis, relaxation therapy as well as conditioning have been used and found to be useful in the treatment of vomiting.

Collaboration in Caring— Collaboration with parents

Collaboration with the parents helps to manage this child's care at home. It is important to also keep the physician alerted to any dehydration states the child may acquire. Early recognition of the disease in addition to recognizing excessive fluid losses, as well as the ability to replace excessive losses, is the key to long-term survival. A dietician or pediatric endocrinologist may also work closely with the primary pediatrician and the family to care for this child.

Syndrome of Inappropriate Antidiuretic Hormone

Although syndrome of inappropriate antidiuretic hormone (SIADH) is rare in children, it can be caused when excessive levels of antidiuretic hormones (ADH) are produced. Without ADH the kidneys and body cannot conserve the correct amount of water. The syndrome causes the body to retain water and causes levels of certain electrolytes (sodium) in the blood to decrease. Despite this decrease in osmolarity and electrolytes, the kidneys respond to the excessive ADH by causing more water reabsorption. Eventually this results in water intoxication, which is a large amount of water to a decreased amount of sodium in the extracellular fluid. Hyponatremia results with cellular edema.

SIADH occurs most frequently in children with CNS infections, intrathoracic disease, and can occur in postoperative patients. Among premature neonates, the syndrome most often accompanies brain injury and is closely associated with intracranial hemorrhage (Ferry, 2006). It can also be caused by hypoxia and positive pressure ventilation. In other cases, some medications (diuretics) and chemotherapy may produce the antidiuretic hormone. Other causes may include the following: meningitis, encephalitis, brain tumors, psychosis, lung diseases, head trauma, Guillain-Barré syndrome (GBS), certain medications such as diuretics or chemotherapy, damage to the hypothalamus or pituitary gland during surgery, as well as positive pressure ventilation.

SIGNS AND SYMPTOMS. Every child experiences and expresses symptoms quite differently. Symptoms in more severe cases of SIADH may include nausea and vomiting, seizures, personality changes such as irritability, combativeness, confusion, and hallucinations as well as stupor and coma (Lucile Packard Children's Hospital at Stanford, 2007).

Other signs and symptoms may include increased blood pressure, weight gain with no externally visible edema, decreased urine output despite a high specific gravity, and fluid and electrolyte imbalance. As the electrolyte (especially sodium) levels decrease the child becomes lethargic and confused. Often, if the child is old enough, complaints of a headache are also common. Eventually, altered levels consciousness followed by seizures and coma can be seen.

DIAGNOSIS. SIADH is diagnosed through serum level tests.

diagnostic tools Serum Levels

Laboratory serum levels are monitored. Diagnosis is confirmed when the following values are found:

- High urine osmolarity (greater than 1200 Osmol/kg)
- High urine specific gravity (greater than 1.030)
- Low serum osmolarity (less than 275 mOsmol/kg)
- Low serum sodium (less than 125 mEq/L)
- Decreased BUN (less than 10 mg/dL)
- Decreased hematocrit

NURSING CARE. Fluid restriction is the cornerstone of care for a child with SIADH. The fluid restriction is begun at 75% of maintenance and decreased further to half of maintenance only if there is no improvement within 4 to 6 hours. Hypertonic sodium chloride solution is given if severe hyponatremia and severe neurological disease are

present. Corticosteroids are given only when adrenal insufficiency is present. Vasopressin analogs are still experimental treatments.

Fluid restriction is the most difficult aspect of nursing care. This restriction can be challenging to maintain, especially if the child is old enough to reach the sink or water fountain. Fluid intake by all routes must be recorded as intake. The pediatric nurse must meticulously monitor and record all intake and output. Sometimes, the placement of a Foley catheter is necessary or weighing soiled diapers in grams is needed to ensure accurate measurements of output. The nurse must remember to obtain the weight of a clean diaper so that it can be subtracted from that of the soiled diaper weight before recording the output.

Medications should be given with meals to prevent any unnecessary fluid intake. If the child is thirsty, he or she can be offered hard candy to suck, providing the child's medical condition does not contraindicate the sugar. To prevent water reabsorption in the intestines, tap water and saline enemas should be avoided. Irrigate all oral tubes with normal saline rather than with water to prevent pulling of sodium thus creating an even greater electrolyte imbalance. Oral mucous membranes can be kept moist by providing frequent mouth care. Avoid alcohol-based mouth washes as these dry out the mucous membranes. The nurse must also monitor the child's nutritional status. A diet high in sodium and protein should be encouraged as this increases urine excretion.

The nurse understands that neurological assessments are also imperative. Assessing level of consciousness, headache (if child can verbalize), and seizure activity can be indications of severe electrolyte imbalance. Seizure precautions must be set up and implemented at the bedside.

Finally, the pediatric nurse should evaluate for fluid retention. When fluid retention is suspected, monitoring of input and output (I & O), baseline weight, and daily weight is essential. The nurse evaluates patients for edema in dependent areas and assesses the child's lungs to detect over hydration and monitor skin turgor carefully. Each of these assessments must be clearly communicated to subsequent physicians and nurses who will assume care for the child.

Educating parents about the importance of fluid balance is a significant aspect of teaching the care of a child with SIADH. The family must also be taught that a daily weight of the child is the most important indicator of fluid balance. Maintaining fluid balance and avoiding excessive fluid intake should also be emphasized. The pediatric nurse should be sure to include hidden sources of water in foods to optimize the outcomes of this child's care. Family members should be taught to measure the urine output accurately, using whatever is appropriate for the child i.e., diaper weights, urinal use, or toilet "hats." In addition to teaching all of the care aspects for the child with SIADH, the pediatric nurse should be sure to include basic information about SIADH and its causes, signs, and symptoms.

clinical alert

Hyponatremia

It is critical to remember that the hyponatremia (low serum sodium of less than 125 mEq/L) may cause seizures in the child with SIADH. Keeping the serum sodium level as near as normal is the goal of treatment. The pediatric nurse must be thorough and accurately track intake, output, and daily weights of the child.

Along with the primary care physician, an endocrinologist, often a nephrologist, a neurologist, and possibly a pediatric intensive care specialist may need to be consulted if the child manifests severe clinical, neurological symptoms.

Now Can You—Describe conditions of the anterior and posterior pituitary?

1. Describe conditions of the anterior pituitary?
2. Discuss nursing care for conditions of the anterior pituitary?
3. Describe conditions of the posterior pituitary?
4. Discuss nursing care for conditions of the posterior pituitary?

CONDITIONS OF THE THYROID

Hypothyroidism

Congenital hypothyroidism affects about one in every 4000 newborns in North America. In hypothyroidism the thyroid gland is underactive, secreting too little thyroid hormone for the body to function normally. If left untreated hypothyroidism can lead to a goiter. The thyroid gland secretes thyroid hormones, which control the speed of metabolism. Brain development, as well as the normal growth of the child, depends on normal levels of thyroid hormone. Hypothyroidism was once referred to as cretinism and was thought to be a major cause of severe mental retardation, but this view is not held today. In older children and young adults, hypothyroidism can also cause diverse symptoms including slowed heart rate, chronic tiredness, and inability to tolerate cold. The child may feel physically tired, mentally fatigued, and thus learning may be impaired. Infants can be born with congenital hypothyroidism, and hypothyroidism can develop in children of any age. Iodine is needed to produce thyroid hormones and is contained in many foods.

SIGNS AND SYMPTOMS. Hypothyroidism has varying levels of manifestations from subtle in infancy to overt as the child matures. In an infant the signs and symptoms are prolonged newborn jaundice, poor feeding and constipation, cool, mottled skin, increased sleepiness, decreased crying, larger-than-normal soft spots on the skull, umbilical hernia (a soft protrusion around the navel), and a large tongue.

As the child begins to grow and mature, hypothyroidism manifests in these ways: short stature for age and delayed eruption of baby teeth, delays in major developmental milestones, puffy facial features, severe mental retardation, protruding abdomen and umbilical hernia, dry skin and sparse hair.

The older child has the most overt symptoms, much like those found in the adult. These include slow heart rate, tiredness, inability to tolerate cold, dry, flaky skin, puffiness in the face (especially around the eyes), impaired memory and difficulty in thinking (appears as a learning disability), emotional depression, drowsiness, even after sleeping through the night, heavy or irregular menstrual periods (in girls at the age of puberty), and constipation.

DIAGNOSIS. Congenital hypothyroidism is usually detected during the routine newborn screening. Blood samples taken reveal abnormally low levels of T3 and T4.

Sometimes seen as an inborn error of thyroid hormone synthesis, the ill child's thyroid cannot produce T3 and T4 despite increasing levels of thyroid-stimulating hormone (TSH) produced by the pituitary (Cleary & Green, 2005). Further diagnosis may include a scan of the thyroid gland to check for abnormalities. Diagnosis is relatively simple, requiring one blood test once hypothyroidism is suspected.

NURSING CARE. Early diagnosis of hypothyroidism is of the utmost importance. One study suggests that the optimal care would include early diagnosis as soon after birth as possible and normalization of blood levels of thyroid hormone with low-dose levothyroxine (Synthroid) for one month (Yang et al., 2005). Daily treatment involves giving the child a prescription thyroid replacement hormone. The initial dose for an infant is between 25 and 50 mcg per day. Iodine supplementation is also appropriate in some cases. The easiest supplements are given in the diet. The goal of treatment is normal hormone levels within the infant's first 4 weeks of life. Frequent (usually weekly) visits to the treating physician for follow-up blood tests and adjustments of the dose are necessary. Once the baby's hormone levels are properly adjusted, return outpatient visits are needed every 2 to 3 months for the first 3 years of life. Thyroid hormone treatment may be needed for life, but fortunately, treatment is simple, inexpensive, and easily monitored.

Nursing Insight—Formula

Soy-based formula may cause a decrease in the absorption of levothyroxine (Synthroid). Switching an infant from a milk-based formula to a soy-based formula may increase the dose of thyroid hormone needed to maintain a euthyroid status (having a normally functioning thyroid gland) (Postellon, 2006).

Parents taught proper administration of the medication. The pills can be crushed in a spoon, dissolved with a small amount of water or other liquid immediately before administration, and administered to the child with a syringe, dropper, or nipple. Toddlers can be allowed to readily chew the tablets (Postellon, 2006).

Parents need to be informed that careful and regular monitoring of the child's growth, weight gain, and developmental milestone progression helps to validate that the dosing and medication administration are sufficiently accurate to achieve positive results. Laboratory blood tests

of T4 and TSH every 4 to 6 months during the first year of life and every 2 to 4 months afterward also keeps close track of the child's hormone levels. Parents should also be encouraged to seek early evaluation and intervention to any problems that become readily recognizable. Educating the parents completely at the very beginning regarding the diagnosis, its signs and symptoms, care, treatment, and outcomes of care ensures that they know what to watch for and are astute as to the most effective care possible.

It is essential that the nurse is aware that congenital hypothyroidism is an important cause of mental retardation and that it is definitely preventable with the earliest identification and subsequent treatment. Educating parents regarding the signs and symptoms helps to identify the condition early so treatment can be started as soon as possible. Alerting the families with infants with this condition that life-time treatment prevents mental retardation is an important component of teaching. Newborn lab results must be assessed and follow-up for any abnormal results is mandatory.

For children whose condition is not rapidly diagnosed or treated, the return of normal thyroid function may take a long time. The child may exhibit dramatic changes in behavior. Continued care by the primary physician, the endocrinologist, and a psychotherapist may be necessary. It should be brought to the teacher's attention as well as any ongoing recommendations to help the child achieve his or her optimum potential.

Graves' Disease

Graves' disease (hyperthyroidism) is the most common cause of hyperthyroidism in children (Ferry, 2006). Many researchers believe that Graves' disease is caused by an antibody that overstimulates the thyroid, causing an excess production of thyroid hormone. It is categorized as an autoimmune disorder.

Graves' disease is most common in young to middle-aged women and tends to run in families. Incidence increases with age, reaching a peak during adolescence. It is rare in children younger than 5 years of age (Ferry, 2006).

SIGNS AND SYMPTOMS. Excessive thyroid hormone affects all organ systems of the body. Symptoms of Graves' disease are identical to those of hyperthyroidism, with the addition of three other symptoms. Although these symptoms present somewhat differently in each child, they are: (1) goiter (enlarged thyroid gland which may cause a bulge in the neck and dysphagia); (2) raised, thickened skin over the shins, back of feet, back, hands, or face, and swollen, reddened; and (3) eyes that bulge (exophthalmos).

Other signs and symptoms can include fast heart rate with palpitations, high blood pressure, moist skin and increased perspiration, shakiness and tremor, nervousness and confusion, increased appetite accompanied by weight loss, difficulty sleeping, constant stare, sensitivity of eyes to light, and changes in menstrual periods.

DIAGNOSIS. As with other thyroid conditions, blood levels of thyroid hormones confirm the diagnosis. These hormones are elevated. TSH levels are decreased because the high levels of T3 and T4 inhibit the anterior pituitary's production of TSH (Amer, 2005).

medication: Accurate Administration of Hormone Tablets

Hormone tablets (or any pills) should never be mixed in a full bottle of formula. It is best to avoid ruining the taste of the infant's sole source of nutrition. Second, placing the medication in a full bottle will require the baby to drink the entire bottle to obtain the entire dose. Leaving even a small amount of formula on the bottom of the bottle could mean that the child will be under dosed. Most drug references state that hormone tablets mix very unevenly in solution and it is difficult for them to stay in suspension. It is best to crush and mix it in a small amount of fluid immediately before administration. The solution is then drawn up into an oral syringe and given before the feeding.

NURSING CARE. Physical assessment is first and foremost in the care of the child with Graves' disease. The astute nurse may identify these children when they are referred for evaluation of symptoms of attention deficit/hyperactivity disorder (ADHD). A complete history including school performance and how distracted the child has been, together with sleep patterns, will aid in the ongoing care of the child. Once the child is diagnosed, treatment regimens must be taught to the child and family and strictly followed. The nurse knows that treatment for hyperthyroidism is specifically individualized for each patient. Ultimately, the goal of treatment is to restore the thyroid gland to normal function in which the production of thyroid hormone is at normal levels.

Treatment may include:

- Antithyroid medications (PTU-propylthiouracil or MTZ—methimazole) to help lower the level of thyroid hormones by blocking the synthesis of T3 and T4. Pharmacotherapy has been used the longest, but has toxic side effects (Table 28-1).
- Radioactive iodine therapy (in the form of a pill or liquid), which damages thyroid cells (destruction can take 6 to 18 weeks) to decrease the production of thyroid hormones
- Surgery to remove the overactive nodule of the thyroid (subtotal thyroidectomy)
- Beta-blocking agents (Inderal) to block the action of thyroid hormone on the body (these drugs do not change the levels of thyroid hormone in the blood, but make the patient feel better by relieving tachycardia, restlessness, and tremors).

Children with Graves' disease are treated on an outpatient basis for the most part. The parents need to know the significance of continuing the medication regimen even after the symptoms of hyperthyroidism have resolved. Parents must also be taught to watch for medication side effects. The importance of routine blood tests must also be emphasized as well as following through with all return visits to the physician. If referrals are made, the importance of keeping these appointments must also be stressed.

Even though the child is being treated for hyperthyroidism, the signs and symptoms of hypothyroidism must also be taught to the family so that if treatments become toxic they would know what symptoms to observe in the child. Emergency numbers and referrals must be provided to the family in the event that any of the severe reactions occur.

The importance of a low-stress, low-pressure environment should also be reinforced because increased tension

could exacerbate the symptoms. The child may also exhibit sudden bursts of emotion such as crying, excitement, or irritability. The family should be taught to expect these feelings and that the ill child is not able to control them. The importance of discussing feelings with the child should be stressed in order to minimize these outbursts. Parents should be instructed to notify the child's school nurse and teacher about these feelings. The school nurse may need to be involved in the medication regime during school operational hours. In this case, a note from the child's physician is required. The teachers must also be alerted to the child's illness and the potential lack of focus in class. It may even be necessary to have the child tutored so that the child is able to catch up to the lessons.

The surgical option is used as a last resort when treatments have not resulted in permanent remission or when the parents cannot comply with the medication regimen. Although the treatment choice is a very delicate matter that should be thoroughly discussed between the physician and family, some physicians feel that total thyroidectomy is the preferred treatment for patients with Graves' disease (Lee, Grumbach, & Clark, 2007).

It is essential for the pediatric nurse to be very astute and know all of the many signs and symptoms of hyper- and hypothyroid, because when the child begins to deteriorate it happens very quickly and there is not enough time to wait for lab results. The only indication for care in the hospital as an inpatient is if the child with hyperthyroidism experiences a thyroid storm.

clinical alert

Thyroid storm

A thyroid storm is a rare and potentially fatal complication of hyperthyroidism. It typically occurs in patients who experience a precipitating event such as surgery, infection, or trauma. A thyroid storm must be recognized and treated on signs and symptoms alone, as laboratory confirmation often cannot be obtained in a timely manner. Patients typically appear markedly *hypermetabolic* with high fevers, tachycardia, nausea and vomiting, tremulousness, agitation, and psychosis if untreated. Patients may also become stuporous or comatose with hypotension.

CONDITIONS OF THE PARATHYROID

Hypoparathyroidism

Hypoparathyroidism is a rare condition in which there is inadequate production of parathyroid hormone. It can also occur when the parathyroid hormone that is produced cannot be used by the body or the kidneys and bones cannot respond to the production of parathyroid hormone. This deficiency of parathyroid hormone decreases the calcium level in the blood and increases the phosphate levels.

Hypoparathyroidism may be either inherited or acquired. It can result from a variety of causes:

- Underdeveloped parathyroid glands at birth (inherited)
- Medical treatment (radiation to thyroid gland, drug treatment, thyroid or parathyroid surgery) (acquired)
- An underlying medical condition such as cancer, neck trauma, Wilson's disease (high level of copper in tissues), an excess of iron in tissues, low levels of magnesium (acquired)

Table 28-1 Side Effects of Antithyroid Medications

Mild Effects	Severe Effects (can be <i>Fatal</i>)
Skin rash	Agranulocytosis (sore throat, high fever)
Mild leukopenia	Lupus-like syndrome
Loss of taste	Hepatitis
Arthralgia	Hepatic failure
Loss/abnormal hair pigmentation	Glomerulonephritis

The cause of hypoparathyroidism may also be idiopathic in that the parathyroid suddenly stops functioning for no known reason. It has also been associated with other conditions, especially cardiac defects, such as DiGeorge syndrome.

Nursing Insight— *DiGeorge syndrome*

DiGeorge syndrome is an example of a defect in parathyroid gland development. DiGeorge syndrome is comprised of hypoparathyroidism, T-cell abnormalities and cardiac anomalies.

SIGNS AND SYMPTOMS. The following signs and symptoms often appear in children with hypoparathyroidism: poor tooth development, vomiting, headaches, mental deficiency, seizures and uncontrollable, painful spasms of the face, hands, arms, and feet. Infants with hypoparathyroidism may be extremely irritable and have rigid muscles. They may also have abdominal distention and episodes of apnea causing irregular cyanosis.

DIAGNOSIS. A thorough history and physical including muscle spasms, twitches, or seizure activity is noted. Any vomiting with abdominal distention should be noted. Apnea episodes with or without cyanosis should be noted. Blood work including calcium (low), phosphate (high), magnesium (low), and low parathyroid hormone confirms the diagnosis. Bone or soft tissue abnormalities (increased bone density) are evaluated with radiographs and CT scans. A 12-lead EKG may reveal a prolonged QT interval.

NURSING CARE. Teaching the families about the disease, its signs and symptoms, as well as the importance of lifelong treatment optimizes the outcomes of the child's care. A lifelong regimen of dietary or supplemental calcium and vitamin D is usually required to restore calcium and mineral balance. In the acute phase of hypoparathyroidism, calcium is administered intravenously; diuretics may be prescribed in that circumstance as well to prevent over excretion of calcium in the urine and to reduce the amount of calcium and vitamin D needed. The active form of vitamin D, 1, 25-dihydroxyvitamin D, is preferred in the treatment of hypoparathyroidism.

Hypocalcemia that produces the symptoms of hypoparathyroidism, such as seizures, tetany, and laryngospasms, requires intravenous calcium. The pediatric nurse must continuously monitor the child with telemetry for cardiac arrhythmias and blood pressure for life-threatening hypotension. Seizure precautions should be maintained until calcium levels approach a normal level. Once serum calcium levels are greater than 7.5 mg/dL the intravenous calcium can be stopped.

critical nursing action Accurate Administration of Intravenous Calcium

It is important for the pediatric nurse to scrupulously check the IV site for accurate placement as infiltration of the intravenous calcium supplements cause extravasation and sloughing of the tissue around the site. Intravenous calcium supplements must be properly calculated, diluted, and administered strictly according to hospital's standards of care and protocols.

Oral calcium and vitamin D are administered as soon as possible. The nurse must monitor the success of the oral forms of calcium and vitamin D for at least 24 hours after intravenous calcium is stopped because "rebound" hypocalcemia can occur. The pediatric nurse must be alert for subtle changes in the child's status.

Nursing Insight— *Assessing for Hyperreflexia of Muscles*

The nurse can assess for hyperreflexia (increased action of the reflexes) by tapping on the facial nerve. If there is a spasm of the facial muscles, this is a positive Chvostek sign (facial muscle spasm) and confirms the fact that the child has muscle pain, cramps, and probably twitches. These muscle manifestations may progress to numbness and tingling of the hands and feet as well as stiffness. Remember infants and small children cannot express these manifestations, and therefore just cry to communicate pain.

The prognosis for hypoparathyroidism is fairly good, especially with an early diagnosis. No special diet is needed, but adequate calcium and vitamin D intake is recommended. If phosphorus levels are extremely elevated, a diet may be given that excludes high-phosphorus foods such as eggs and dairy products.

Nursing Insight— *Proper nutrition for hypoparathyroidism*

The following supplements have been used clinically and, therefore, may be valuable adjuncts in the treatment of hypoparathyroidism:

- Calcium, if dietary intake is not adequate.
- Magnesium, which aids in the absorption of calcium; also, often low levels of magnesium are present in the case of hypoparathyroidism.
- Boron, which enhances the absorption of calcium.
- Vitamin K, produced by bacteria in the intestines or obtained through the diet (e.g., dark leafy greens) is important for the uptake of calcium by cells throughout the body.
- Foods rich in calcium include almonds, legumes, dark leafy greens, blackstrap molasses, oats, sardines, tahini, prunes, apricots, and sea vegetables.
- Calcium and vitamin D are thought to be best absorbed in an acidic environment (e.g., lemon juice may be added to salad to facilitate calcium absorption).
- Limit carbonated beverages, as they are high in phosphates and may reduce calcium absorption; dairy may diminish calcium absorption for similar reasons.
- Avoid caffeine (such as in coffee, black tea, colas, and chocolate); it can lead to calcium loss through the urine (A.D.A.M., 2006).

Children with hypoparathyroidism may be asymptomatic and often report vague symptoms. Therefore, it is vital to report any new onset of seizure or movement disorder to the physician immediately. Further evaluation should include serum calcium levels being checked.

The nurse can tell the family that the primary care provider will consult with an endocrinologist but will continue to manage the care of the child. Careful monitoring

of calcium levels and doses of the medications ensures that the levels of calcium stay in the low to normal range. Close assessment helps to alleviate complications such as nephrocalcinosis. The nurse can also communicate that annual renal ultrasounds will ensure that this renal condition is not present.

Hyperparathyroidism

Hyperparathyroidism is rare in children. Primary hyperparathyroidism is more common in females and in adolescents. It is caused by overactive parathyroid glands that produce high levels of parathyroid hormone (PTH), which results in increased levels of serum calcium. The excess calcium leads to osteoporosis and osteomalacia (both bone-weakening diseases). Remember that high levels of parathyroid hormone cause the bones to demineralize, which increases the serum calcium levels. PTH also acts on the kidney to conserve calcium and excrete phosphate. Another result of the increased serum calcium is the development of kidney stones. Kidney stones form because of the high levels of calcium excreted into the urine by the kidneys. Primary hyperparathyroidism may develop as a result of one of the following conditions:

- Single or multiple benign tumors in the parathyroid glands
- Parathyroid hyperplasia (excessive growth of normal parathyroid cells)
- Parathyroid malignancies (rare)
- Certain endocrine disorders, such as type I and II multiple endocrine neoplasia (MEN) syndromes

SIGNS AND SYMPTOMS. At least 50% of patients with primary hyperparathyroidism have no symptoms, and approximately 1% of cases go undiagnosed. When symptoms do occur, they are generally attributed to persistently high levels of calcium. Symptoms include bone and joint pain, bone loss leading to osteoporosis with possible bone fractures, muscle weakness, abdominal discomfort due to pancreatitis heartburn, nausea, and vomiting, constipation, lack of appetite, peptic ulcers, kidney stones, excessive thirst, excessive urination, depression, anxiety, memory loss, and excessive drowsiness or fatigue.

DIAGNOSIS. Although this diagnosis is frequently delayed in children, it is usually diagnosed when the child becomes symptomatic. Evaluation of elevated blood calcium and parathyroid hormone levels is diagnostic in 100% of the children (Kollars et al., 2005). If radiographs are performed, the child's bones may show signs of rickets (Fig. 28-2).

NURSING CARE. Parathyroidectomy is effective and restores the normal blood calcium levels. This surgery has few complications and is the treatment of choice in children with primary hyperparathyroidism (Kollars et al., 2005). Unfortunately, if diagnosis is late, this surgical procedure cannot reverse the late effects of hyperparathyroidism on other organs, like the kidneys.

Postoperative care of the child after removal of the parathyroid is focused on airway management and frequent assessments for respiratory distress or airway obstruction due to edema at the surgical site. As with all surgical procedures, continual monitoring for signs of infection and hematoma should be done. Additional nursing care should focus on fluid management and

Figure 28-2 A radiograph taken to diagnose rickets.

consistent monitoring of the child's intake, output, and electrolyte balance.

The child and her family must be taught to consistently observe for signs and symptoms of hypocalcemia. Learning to administer calcium supplements is invaluable in that this treatment may need to be done for life.

Family members should also be taught to realize that frequent blood draws may be necessary initially to monitor calcium and phosphorus levels. The nurse can explain to the family that eventually, the lab work can be done less frequently, but it needs to be stressed that these blood tests are an important part of the continued health care of the child. The primary health care provider may recommend that the child take particular nutritional supplements because a child with primary hyperparathyroidism may develop deficiencies. Vitamins C and K as well as manganese are necessary for normal bone formation.

CONDITIONS OF THE ADRENALS

Acute Adrenocortical Insufficiency

Nursing Insight— An adrenal crisis is a life-threatening condition

Adrenal crisis is a life-threatening condition in which the anterior pituitary gland does not make enough adrenocorticotropic hormone (ACTH). ACTH is responsible for regulating the adrenal gland (a gland near the kidneys that makes hormones that regulate bodily functions). Adrenal crisis is very serious, and children with adrenal crisis require *immediate* treatment. Parents need to seek emergency medical care immediately if they suspect an adrenal crisis.

Adrenal crisis may be caused by any of the following: rapid withdrawal from steroid therapy, sepsis, surgical stress, bleeding into the adrenal glands, pituitary necrosis, or thyroid hormone replacement in someone with adrenal insufficiency. The following factors increase the chance of developing adrenal crisis: septic shock, adrenal

insufficiency, or use of steroid medications. If the child has any of these risk factors, the physician must be notified.

critical nursing action Steroid Administration

Steroid administration is never stopped abruptly. Steroids must be slowly weaned according to the physician's orders. An abrupt withdrawal can cause an adrenal crisis.

SIGNS AND SYMPTOMS. The child in adrenal crisis may exhibit any of these symptoms. Yet, it is important for the pediatric nurse to remember that these symptoms may also be caused by other, less serious health conditions. However, it is vital to report any of the following signs and symptoms to the physician: weakness, feeling tired all the time, nausea, vomiting, loss of appetite, weight loss, low blood pressure, abdominal pain, fever, confusion or coma, diarrhea, cyanosis, and dehydration.

DIAGNOSIS. Tests to diagnose adrenal crisis may include chest radiograph, computed tomography (CT) scan of the abdomen, and blood tests that detect ACTH and electrolytes levels, red blood cells, and other autoimmune or endocrine disorders.

NURSING CARE. Initially, steroid IV hydrocortisone (A-Hydrocort) and antibiotic drugs are needed to treat an adrenal crisis. If the child is vomiting or unconscious, the nurse gives these medications by injection or intravenously (IV). Owing to fluid loss, the child is given IV fluids to reverse dehydration, electrolyte imbalances, and hypovolemia. Whole blood may be given if the child has hemorrhaged. If the child is in severe crisis and has a decreased blood pressure, vasopressor may be used to raise the child's blood pressure quickly by vasoconstriction.

When all of these conditions are corrected and the child is stable, the cortisone medications and sodium chloride (NaCl) may be given orally. Retention of sodium is maintained by replacing aldosterone with synthetic steroids that retain salt.

The pediatric nurse must be cognizant of the fact that this crisis can be fatal and may quickly appear. The nurse must use constant assessment, and recognition of the signs and symptoms is essential. It may be necessary to take the child's vital signs every 15 minutes, always carefully watching for the most subtle signs of the onset of shock. These subtle signs of shock can include a slight cooling of the hands and feet along with a decrease in skin color. For instance, infant's periphery go from pink to extreme pallor.

Ethnocultural Considerations— Shock in dark-complexioned children

When assessing for shock in children with a dark complexion remember to look at the palms of the hands, soles of the feet and lips to ascertain color changes.

The nurse recognizes that fluid shifts may also occur quickly, so lab values must be reviewed often. Cortisone and sodium chloride treatments are often given rapidly to

Labs: Potassium Depletion

Since treatments for adrenal crisis cause potassium depletion, it is crucial to keep a close watch on the child's lab values. Nursing assessments should always be mindful of the warning signs of hyperkalemia and hypokalemia (apnea, cardiac arrhythmias, paralysis, poor muscle control, and weakness).

rectify ominous situations. A consequence of this rapid treatment is an abnormally low potassium level such that the child can now be at risk for flaccid paralysis or seizures. It is good practice to keep the child in constant observation and to perform frequent assessments.

The nurse must monitor IV fluid rates and remain in constant communication with the physician so that responses to the treatments are known and counteracted if necessary. The pediatric nurse should be prepared to act quickly.

Medication administration is also a significant part of nursing care. Medications and doses should be given as prescribed by physician. Once the child has stabilized, clear, oral fluids can be initiated slowly. It would defeat the purpose if, in the child's eagerness to drink, he or she began to vomit again. For this reason, encourage the child to drink slowly. If the child refuses to drink, other forms of liquid such as ice pops, frozen ice, gelatin, or broth may give the child incentive to take fluids orally.

In this situation, parents are often in a state of confusion and shock because the treatments and changes in their child's condition occur so rapidly. The nurse should calmly explain the treatment and the child's response often. To decrease the parents' fear, noting slight improvements in the child's status helps them remain positive. Since neurological symptoms can be so devastating, remind the parents that these are only temporary and that paralysis will be reversed once the child is stabilized.

Discharge preparation should be started as soon after the crisis as possible. Keep in mind the readiness of the parents to learn. Be sure that the parents are ready to listen and learn about the care of the child at home. In some cases, it may be necessary to wait a day until the parents feel secure about the fact that their child will be going home under their care.

Parents need to know that some teens do not take prescribed medication doses because of the side effects. The nurse can reassure parents that this may happen and to call the primary pediatrician if it does.

Chronic Adrenocortical Insufficiency

Chronic adrenocortical insufficiency, or Addison's disease, is the result of an underactive adrenal gland. An underactive adrenal gland produces insufficient amounts of cortisol and aldosterone.

Nursing Insight— Cortisol and aldosterone

Cortisol is a steroid hormone that helps to control the body's metabolism of fats, proteins, and carbohydrates; suppresses inflammatory reactions in the body; and affects immune system functions.

Aldosterone is a steroid hormone that controls sodium and potassium in the blood.

The onset of this disease may occur at any age. Most of the time, the cause of the disease is unknown. About one-third of Addison's disease cases are caused by the actual destruction of the adrenal glands through cancer, infection, an autoimmune process, or other diseases. Other causes may include the following:

- Use of corticosteroids as a treatment (such as prednisone) may cause a slow down in production of natural corticosteroids by the adrenal glands and mimic Addison's disease.
- Certain medications used to treat fungal infections may block production of corticosteroids in the adrenal glands, causing signs and symptoms similar to those of Addison's disease.
- Rarely, Addison's disease is inherited as an X-linked, recessive trait, where the gene responsible for the condition is located on the X chromosome and passed down from a healthy female carrier to her sons who are affected. In this form, symptoms typically begin in childhood or adolescence.

Failure to produce adequate levels of cortisol can occur for different reasons. Corticosteroids play an important role in helping the body fight infection and promote health during physical stress. The problem may be due to a disorder of the adrenal glands themselves or to inadequate secretion of ACTH by the pituitary gland. The lack of adrenal hormones may cause:

- Elevated levels of potassium.
- Extreme sensitivity to the hormone insulin, which normally is present in the bloodstream. This sensitivity may lead to low blood sugar levels.
- Increased risk during stressful periods, such as surgery, infection, or injury.

PRIMARY ADRENAL INSUFFICIENCY. Most cases of primary adrenal insufficiency are caused by the gradual destruction of the adrenal cortex, the outer layer of the adrenal glands, by the body's own immune system. About 70% of reported cases of Addison's disease are caused by autoimmune disorders, in which the immune system makes antibodies that attack the body's own tissues or organs and slowly destroy them. Adrenal insufficiency occurs when at least 90% of the adrenal cortex has been destroyed. As a result, often both glucocorticoid (cortisol) and mineralocorticoid (aldosterone) hormones are lacking. Sometimes only the adrenal gland is affected, as in idiopathic adrenal insufficiency. In other cases, additional endocrine glands are also affected, as in the polyendocrine deficiency syndrome.

POLYENDOCRINE DEFICIENCY SYNDROME. The polyendocrine deficiency syndrome is classified into two separate forms:

- Type I occurs in children, and adrenal insufficiency may be accompanied by underactive parathyroid glands, slow sexual development, pernicious anemia, chronic *Candida* infections, chronic active hepatitis, and hair loss.
- Type II, often called *Schmidt's syndrome*, usually affects young adults. Features of type II may include an underactive thyroid gland, slow sexual development, diabetes, vitiligo, and loss of pigment on areas of the skin.

Scientists think that the polyendocrine deficiency syndrome is inherited because frequently more than one family member tends to have one or more endocrine deficiencies.

SIGNS AND SYMPTOMS. It is important to note that mild symptoms of Addison's disease may manifest only when the child is under physical stress. The most common symptoms of Addison's disease may often be seen individually or in any combination. Remember that each child experiences symptoms very differently. The astute pediatric nurse consistently observes for any of the following symptoms: weakness; fatigue; dizziness; rapid pulse; dark skin that is first noted on hands and face; black freckles; bluish-black discoloration around the nipples, mouth, rectum, scrotum, or vagina; weight loss; dehydration; loss of appetite; intense salt craving; muscle aches; nausea; vomiting; diarrhea; and an intolerance to the cold.

If left untreated, Addison's disease can lead to severe abdominal pain, extreme weakness, low blood pressure, kidney failure, and shock, especially when the child experiences physical stress. Although the symptoms of Addison's disease may resemble other problems or medical conditions, it is best for the pediatric nurse to encourage the parents to always consult the child's physician for a diagnosis confirmation.

The symptoms progress slowly and are usually ignored until a stressful event such as an illness or an accident causes the child's condition to worsen. This is called an Addisonian crisis, or acute adrenal insufficiency. In most cases, symptoms are severe enough that patients seek medical treatment before a crisis occurs. However, in a few children, symptoms first become readily apparent during an Addisonian crisis.

clinical alert

Symptoms of an Addisonian crisis

Symptoms of an Addisonian crisis include sudden penetrating pain in the lower back, abdomen, or legs, severe vomiting and diarrhea, dehydration, low blood pressure, and a loss of consciousness. If left untreated, a child with Addison's disease in crisis can die (NIH Publication No. 04-3054 June 2004).

DIAGNOSIS. Aside from the clinical symptoms and the signs found on physical examination, including low blood pressure, a diagnosis of Addison's disease is usually confirmed by laboratory tests. Typically, a patient has low blood sodium, high potassium, and low blood sugar. The initial test for adrenal insufficiency is the measurement of serum cortisol levels. The serum cortisol level is drawn in the morning between 6:00 A.M. and 8:00 A.M. because the levels are the highest at this time owing to circadian rhythm. Cortisol levels greater than 19 mg/dL are considered normal, whereas levels less than 3 mg/dL are diagnostic of Addison's disease (Liotta, 2007). Levels between 3 and 19 mg/dL are considered indeterminate and further testing is necessary.

NURSING CARE. Addison's disease is treatable with oral forms of the missing hormones. Cortisol (Solu-Cortef) is available in tablet form, and it is given two to three times

a day. This medication helps maintain the child's blood glucose levels (Children's Hospital and Clinics of Minnesota, 2006).

If the patient has an illness that is accompanied by vomiting, an intramuscular injection of cortisol (Solu-Cortef) must be given at home. Then the patient must be taken to an emergency room for further treatment. All patients or their parents must have a dose of Cortisol (Solu-Cortef) available at home and be instructed on the proper technique to administer it during a crisis.

When a child is hospitalized in an adrenal crisis, the focus of nursing care is on fluid and electrolyte replacement. The pediatric nurse must monitor closely for signs of hypovolemic shock. The nurse understands that peripheral circulation must be checked often. Frequently, hourly assessments help the nurse detect subtle changes that can be the earliest indicators of potential imbalances not yet detected by laboratory tests.

Optimizing Outcomes—Hormone treatment

The best outcome of care for the child is optimized with adequate hormonal treatment. Hormone treatment helps maintain a normal growth pattern. Even though a child with Addison's disease rarely grows beyond the fifth percentile, development during puberty is normal (Liotta, 2007).

Parents need to be aware of the diligent commitment that is necessary to giving the child medications routinely and regularly. They must plan medication delivery into their day so that it is never forgotten. The morning rush to school, the bus, or carpool may not be the best time to plan the cortisol replacements. Parents must also know that the drug cannot be stopped suddenly and that if the child is unable to ingest it due to vomiting, the injectable hydrocortisone must be given intramuscularly. Teaching IM injections is also necessary. Another important aspect of parent teaching involves providing information on the side effects of the drug as well as the signs and symptoms of adrenal crisis. A home free of stress is the best environment for a child with Addison's disease because the body needs increased cortical hormones during times of stress and this child's body is unable to produce the hormone. During times of emotional stress or physical stress, the parents may have to give additional hormone replacements. Since dehydration and stress situations are the likely triggers of a crisis, instructing parents to keep the child well hydrated in situations such as extreme heat, exercise, or influenza. These conditions should be discussed before discharge so that the parents feel in control when at home.

One of the best recommendations to make to parents when caring for a child with Addison's disease is to purchase a medical alert bracelet or tag for the child to wear. This would ensure that the treatment of a child in crisis would not be delayed. It is also important to teach the family and the child about electrolyte loss (especially sodium) during vigorous exercise or on extremely hot days when the child would perspire. Eating more salty food and drinking more water in the hot weather helps the child maintain a mineral balance in his or her body that will ward off a crisis.

clinical alert

Cortisone insufficiency

When caring for this child, whether in the hospital or clinic, the pediatric nurse must be aware of the signs and symptoms observed before an adrenal crisis: headache, dizziness, and nausea or vomiting (stomach ache) or "wobbly knees." By the time the child exhibits extreme weakness and mental confusion the adrenal crisis is imminent.

Parents also need much support to manage the care and the medications of a child with Addison's disease. This is often very frightening for parents. A well thought through plan can help the parents be ready for any emergency.

Collaboration in Caring—The child with Addison's disease

Along with the primary care pediatrician or family physician, the endocrinologist is an important member of the team.

Including the parents as members of this team will ensure that they will feel in better control of potential crisis situations. As the child matures and becomes a teenager, it is essential to include him or her as well so that the child is educated and understands the consequences of skipping doses of medication or of stress. The child also needs to be competent to administer emergency, injectable doses of the cortisone.

Cushing's Syndrome

Cushing's syndrome is a rare disorder that seldom is seen in young people younger than 20 years of age. It is hormonal in nature and presents when a person has been exposed to increased levels of cortisone for an extended period of time. When seen in young children it is often caused by an adrenal tumor or prolonged steroid therapy.

About 10 to 15 million new cases are diagnosed annually. It is estimated that only 10% of all individuals affected in a year are children (Keil, 2007). Although the true etiology of Cushing's syndrome is not clear, it can be due to several causes including the oversecretion of the pituitary, causing an excessive amount of serum ACTH and of the adrenal gland, causing an overload of glucocorticoids, usually tumor related. Long-term administration or large amounts of corticosteroids are also known to cause a child to present with Cushing's syndrome. If a child's adrenal glands are insensitive to normal levels of cortisone then levels can become dramatically abnormal (Keil, Batista, & Stratakis, 2003).

SIGNS AND SYMPTOMS. The signs and symptoms of Cushing's syndrome develop gradually, so insidiously in fact that it may be years before the child shows clearly visible signs of Cushing's syndrome. Often children are hypokalemic, causing alkalosis due to potassium excretion and hypercalcemic due to excessive amount of urinary calcium.

Nursing Insight—Signs and symptoms of Cushing's syndrome

Common signs and symptoms of Cushing's syndrome include weight gain, especially pendulous abdomen; fatigue; muscle wasting and weakness, thin extremities; round "moon"

face; facial flushing; fatty pad between shoulders (buffalo hump); pink or purple stretch marks (striae) on abdominal skin, thighs, breasts, and arms.

The child's skin is also thin and fragile with little subcutaneous tissue causing easy bruising; slow healing of cuts. There may also be insect bites, and infections due to a lessened inflammatory response.

The child may exhibit depression; anxiety and irritability; euphoria and frank psychoses; irregular or absent menstrual periods in females erectile dysfunction in males.

Hyperglycemia may eventually lead to latent or overt diabetes, high blood pressure, or arteriosclerosis.

Owing to the excess production of androgens, signs and symptoms related to secondary sexual characteristics can also be seen.

DIAGNOSIS. Children who are being evaluated for Cushing's syndrome must be seen by a pediatric endocrinologist because test result adjustments must be considered before the diagnosis is confirmed. Levels of cortisone are recorded so that escalating levels are clearly seen.

A 24-hour urine collection is a valuable tool to determine if the child's urine is clear of free cortisol. Because 24-hour urine collections can be very difficult to obtain in an infant and child, sometimes the test must be duplicated to obtain reliable results. It is important to remember that in order to correctly interpret the results of the 24-hour urinary free cortisol (UFC), the result must be "corrected" for the child's body surface area. Since cortisone is released by the child's body in response to stress, several other conditions could cause high UFC levels, for instance, physical stress, such as overexertion, or obesity, and emotional stress such as depression.

Cortisol levels can also be measured in a child's saliva by taking both a midnight and morning sample. Levels are usually at the lowest point at midnight and the highest in the morning. This normal pattern is lost in children with Cushing's syndrome and the midnight levels are not very different from the morning levels.

Diagnosis is based on the results of not only urine and saliva screening but also on serum blood levels, including fasting blood glucose, and electrolyte levels as well as a bone scan for osteoporosis and a radiograph of the skull for an enlarged sella turcica. An MRI of the pituitary as well as a CT scan of the child's adrenal glands may also be performed. The medical history of the child may also hold the key to the diagnosis. A complete physical exam including the review of several growth charts may indicate that there is a decline in linear growth with a simultaneous dramatic increase in weight gain. Testing does not stop with a diagnosis confirmation. Additional results need to be investigated to determine the cause of the syndrome.

NURSING CARE. As with many diseases, the best treatment is based on the exact cause. Tumors in either the pituitary or in the adrenal glands must often be excised. Referrals to a neurosurgeon are necessary. If it is determined that surgery is not possible radiation therapy is used. Treatments can also include pharmaceuticals that inhibit the production of cortisol. Nursing care depends on the cause and the treatment of the illness. If the child has a surgical intervention, nursing care involves preoperative

assessments and fluid hydration as well as postoperative assessments, pain control, and medication regimens. When a child's adrenal glands have been removed, cortisol replacement is necessary. This medication is best given early in the morning or every other day to decrease the side effects. This regime closely mimics the body's normal diurnal pattern of cortisone secretion.

The nurse needs to teach the child and family about the disease, its cause, and subsequent treatments. If a surgical intervention is indicated, thorough preoperative and postoperative teaching must be done. Often the operating room is a very frightening place for children. Many pediatric hospitals perform this teaching well before the procedure and have children tour and touch equipment when they are in a relaxed state of mind, which enables the day of the procedure to go much more smoothly.

Teaching the parents how to give the medication including the injectable form that is given during an emergency situation helps gain the confidence necessary to manage a child recovering from Cushing's syndrome. It is important to inform the parents that the "Cushing-like" appearance will decrease as the child recovers.

Finally, it is very important to alert the parents to watch for signs of adrenal insufficiency. If corticosteroid treatments are stopped, the child will exhibit signs of adrenal insufficiency. Encourage the family to have the child wear medical alert identification at all times.

Congenital Adrenal Hyperplasia

Children born with congenital adrenal hyperplasia (CAH) lack the ability to produce cortisol. The condition begins early during the fetal gestational period and the infant is born with the disease. With this deficiency, or lack of cortisol, the negative feedback system fails, causing an excessive amount of corticosteroid-releasing hormone to be secreted from the hypothalamus as well as ACTH from the anterior pituitary. Overproduction of ACTH in turn causes the adrenal glands to become hyperplastic, causing an excessive amount of androgens to be secreted.

The most common cause of CAH is due to a deficiency of 21-hydroxylase (an enzyme, steroid), which is seen in about 1 out of every 15,000 live births (Glatt, Garzon, & Popovic, 2005). This deficiency leads to two major problems: deficient production of both cortisol and aldosterone as well as shunting of steroid precursors that form androgens (Bowen, 2003). The abnormal production of androgens causes an abnormal development of sexual organs in male infants and virilization in females. It results in the masculinization of females that make the sex of the baby unclear, ambiguous genitalia (*pseudohermaphroditism*), or more male-like features.

SIGNS AND SYMPTOMS. Generally, the male infant has no physical differences until later in childhood when the early development of pubic hair, penial enlargement, or both are accompanied by accelerated linear growth and advancement of skeletal maturation (Wilson, 2006c). At birth, it is the female who has malformed external genitalia. The clitoris is enlarged and there can be a fusion of the labial folds; this can give the female a male appearance externally. Internally, the uterus, fallopian tubes, and ovaries are normal.

DIAGNOSIS. Despite the fact that prenatal screening is used to diagnosis CAH as early as possible, false positives

indicate that the physician needs to be cognizant of the clinical signs and symptoms postnatally, because milder cases may be missed by the newborn screening programs (Kaye, 2006). Elevated serum levels of 17-hydroxyprogesterone (17-OHP) may indicate the disease. It is important to note that these levels are highest in preterm infants. The levels decrease as infants mature, except in an infant with CAH, in whom the levels continue to escalate.

Although considered a “social emergency,” care must be taken to determine the actual diagnosis of the child with ambiguous genitalia. Chromosomes can be studied microscopically to determine the child’s gender.

NURSING CARE. Health care professionals must maintain a positive atmosphere from the moment the baby is born. In the delivery room, a positive emotional tone has a lasting effect on the parents’ understanding of this disease.

Nearly all children diagnosed with CAH are treated with replacement of glucocorticoids. By alleviating the deficiency of cortisol, the negative feedback loop suppresses ACTH secretion and thus prevents adrenal stimulation.

The mineralocorticoid fludrocortisone (Florinef) or hydrocortisone (A-Hydrocort) is also given. Neither of these drugs has significant side effects at replacement doses. Side effects are seen only when doses exceed those necessary for replacement. If the levels are above normal, the child can acquire acne, an elevated blood pressure, or even growth retardation.

Since these medications need to be given throughout the child’s life, parents need to be instructed to give the medication regularly. Often, making the administration part of the family’s routine will ensure that the medication is not forgotten. The alternative route to the oral medication, namely the intramuscular medication, must also be taught in the event that the child has an illness in which oral doses are contraindicated. Emergency procedures, including IM injection of hydrocortisone, must be taught to the parents. It is essential for the family to know that if the medication cannot be given at all, the child must be taken to the emergency department of the closest hospital for treatment. It is always good advice to recommend that the child wear a medical alert tag.

Since all females with CAH are fertile, surgical repair can be performed once the replacement of hormones has begun. Usually it is done before the girl’s first birthday, and if necessary, may be further corrected before menarche.

Nursing Insight— Congenital adrenal hyperplasia

It is important to address congenital adrenal hyperplasia (CAH) and the decision about whether to wait to perform surgical correction until the child can participate in the discussions. Questions to consider include: Since the surgery is usually cosmetic in nature, what harm would there be to wait? What are the consequences of early surgical repair? Will the nerve endings to the female’s clitoris be damaged? What impact will the early surgery have on the child’s sexuality in later life and on the sexual identity of the child? Obviously, the decision is very complex and requires careful thought. The nurse can also examine personal thoughts about what makes up a child’s sexuality.

Family Teaching Guidelines... Parent Teaching for Hydrocortisone (A-Hydrocort) Administration

ESSENTIAL INFORMATION

- ◆ Medication must be used as prescribed.
- ◆ Parents must know to always have the injectable hydrocortisone available at home, school and wherever the child travels.
- ◆ An emergency kit should be on hand at all times with a cortisol supply to administer to the child during acute illness, vomiting, diarrhea or during stressful circumstances. When oral doses cannot be tolerated, the injectable dose should be readily available.
- ◆ Administer the medication *on time* because this follows the child’s body’s normal cortisol release patterns (Wilson, 2006c).

Much parental teaching is needed not only regarding the medication and its various route/administration methods, but also about this chronic illness and its treatment, as well as pre- and postoperative teaching if genital reconstruction will be done. Emotional support of the parents is also essential for this lengthy process.

Family education, including siblings and grandparents, must be provided and the pediatric nurse can best help the parents address these family members. Referring to the infant as a “beautiful baby” will help the parents accept the baby as early as possible.

As with any lifelong illness, it is important for the parents to acknowledge the importance of regular check-ups. The primary pediatrician, as well as the endocrinologist, pharmacist, dietician, and nurse, should work together to support the entire family to reach their maximum potential.

nursing diagnoses Congenital Adrenal Hyperplasia

- Risk for Deficit Fluid Volume related to the excess salt excretion of the kidneys and the failure of the negative feedback system.
- Risk for Disproportionate Growth related to initial accelerated growth and early fusion of the epiphyseal plates of the long bone.
- Risk for Impaired Parenting related to the fact that the sex of the child will be uncertain until the karyotype result is determined.
- Caregiver Role Strain related to a chronic, life-threatening illness that can cause strain on the entire family.

Hyperaldosteronism

Hyperaldosteronism produces excessive secretion of aldosterone, which may be caused by an adrenal tumor or syndrome that is due to an enzyme deficiency. Similar to other endocrine disorders, hyperaldosteronism becomes symptomatic with excessive sodium levels and deficient potassium levels as well as fluid retention. (A.D.A.M., 2004).

SIGNS AND SYMPTOMS. With fluid retention, the child becomes hypervolemic and presents with a headache and hypertension. The hypokalemia causes the child to have muscle weakness, paresthesia, and may cause episodic

paralysis and tetany. The low potassium levels can lead to polydipsia and polyuria.

DIAGNOSIS. When a young child presents with hypertension, the physician must rule out adrenal tumors. In addition to the hypertension, the child presents with hypokalemia and polyuria; if these conditions fail to respond to ADH administration, the clinical diagnosis of hyperaldosteronism is suspected.

NURSING CARE. Nursing care and treatment are similar to those for chronic adrenocortical insufficiency. Initially, the potassium depletion is replaced and the diuretic spironolactone (Aldactone) causes diuresis and thus blocks the aldosterone effects by preserving potassium and promoting sodium and water excretion.

Surgical excision of the affected adrenal gland or tumor is always recommended. Once the gland or tumor is excised, it is common for the child to experience hyperaldosteronism postoperatively. Hyperkalemia is also seen in this period due to the potassium replacements. Children may need mineralocorticoid supplementation for several months after the removal of the adrenal gland or tumor. Although postoperatively the blood pressure declines, it may not be sustained and may also need to be controlled with sodium restriction diet, or antihypertensive medications.

Any child admitted with hypertension should be observed closely for the signs and symptoms of hyponatremia and hyperkalemia. Excessive thirst, bed wetting or unexplained weakness should begin to raise suspicions in the nurse that the child has a serious illness. When vital sign assessments do reveal hypertension, it is important to notify the physician immediately and to continue frequent vital signs until a physician performs a thorough physical.

Once the diagnosis is confirmed, the nursing care focuses on preoperative care and teaching. The treatment plan must be followed, but more importantly taught to the family because often the child will need medication that must be adjusted for growth for the duration of the condition.

Postoperative care again focuses on the child's immediate status and care on continual assessments of fluid balance, incision site, as well as adherence to the medication regime. If diuretics are ordered, it is best to administer as early in the day as possible to avoid bed wetting at night. Since the potassium supplements can be difficult to swallow mixing with strong flavored juice helps make the medication more palatable.

The medication regimens are the focus of parent teaching (i.e., give diuretics early in the day). Alerting the parents to subtle signs of electrolyte imbalances is the best weapon against serious consequences. Parents should know the signs and symptoms of hypo- and hyperkalemia. The parents can also meet with a dietician to discuss foods that are high in potassium so that they can be included in the child's diet. Being open and available to answer questions

or to help the parents in any way is the best support that can be given to the family.

Pheochromocytoma

Pheochromocytoma is a condition in which there is an adrenal gland tumor. Unlike other tumors, it may not be physically connected to the adrenal gland. In this case, it is called *extra-adrenal*. The tumor intermittently releases excessive catecholamines (i.e., epinephrine and norepinephrine), making the child hypertensive at times.

Although pheochromocytoma is rare in childhood, it generally occurs between 6 and 14 years of age (Baykan et al., 2005). Children have a higher incidence of bilateral tumors than adults do and a lower incidence of malignancy (Vuguin, 2007).

SIGNS AND SYMPTOMS. Hypertension is the most common symptom of pheochromocytoma. It is sometimes very extreme, with the systolic reading reaching as high as 250 mm Hg. Each child may experience symptoms differently. Typical symptoms are tachycardia, arrhythmias, heart palpitations, headache, dizziness, poor weight gain, and growth failure, nausea, vomiting, abdominal pain, pale skin, clammy skin, profuse sweating, cool extremities, polydipsia, and polyuria. Pheochromocytoma can mimic the signs and symptoms of diseases such as hyperthyroidism or diabetes mellitus.

DIAGNOSIS. Thorough assessments begin with a complete medical history and physical examination. Additional studies to diagnosis pheochromocytoma may include blood chemistry and urinalysis to measure hormone levels, CT scan to locate tumor, and an MRI scan to create an image of the functioning adrenal gland.

NURSING CARE. Nursing management includes caring for the child undergoing surgery to remove the tumor. If the tumor is bilateral and both adrenal glands must be removed, the child will be placed on lifelong treatment with mineralocorticoids and glucocorticoids. Tumor removal causes an excessive release of catecholamines, causing severe hypertension and tachyarrhythmias. Other complications include hypovolemic shock, and catecholamine withdrawal can cause a dramatic shift in blood pressure now, leading to hypotension.

To avoid these challenging and life-threatening surgical complications, preoperative treatment with medication to inhibit the effects of the catecholamines is begun 1 to 3 weeks before surgery. The drug used most often is an α -adrenergic blocking agent, phenoxybenzamine (Dibenzylin). This medication is long acting, can be given by mouth every 12 hours, and is suitable for long-term use. This blocking agent may be combined with β -adrenergic blocking agents to increase the efficacy of the treatment.

Treatment is continued to keep blood pressure within a normal range and to decrease or eliminate hypertensive attacks that include facial flushing, headaches, tachycardia, nausea and vomiting, as well as hyperglycemia.

As with any of these disorders, it is imperative that the pediatric nurse be alert during assessments for the most subtle signs of the impending disorder. Hypertension or hypertensive attacks are sometimes the first sign that should be acted upon. The nurse must thoroughly document history of the symptoms and precipitating factors.

Labs: Hyperaldosteronism

Lab results indicate decreased potassium level, increased aldosterone level, and decreased renin activity. Urinalysis reveals an elevated aldosterone level. A CAT scan of the child's abdomen reveals an adrenal mass and an EKG shows abnormalities that can occur with low potassium levels.

Frequent assessment of vital signs is essential preoperatively. The preoperative nurse should note any hypertensive states or signs of congestive heart failure (CHF). Blood glucose levels should also be taken at least daily. Prompt reporting of any hyperglycemic readings is important.

Postoperatively, the nurse should continue close observation and assess for signs and symptoms of shock that could be caused from the removal of excess catecholamines. Just as preoperatively, the hospital environment should be calm. Undue physical or emotional stress should be avoided for the child's best possible recovery. Since normal visiting hours can cause stress, parents should be allowed to room in and stay with the child. This helps to alleviate the stress that leaving the child can cause. Distractive play should be encouraged as long as it does not exceed the child's energy level.

Parent teaching about the diagnosis should focus on the signs and symptoms of the condition. Careful observation of the precipitating factors that cause stress can be helpful to keep the child's metabolic needs at a minimum. Anxiety can cause stress, exaggerate the symptoms, and increase metabolism, which causes more catecholamines to be secreted and stimulates a severe hypertensive crisis with possible tachyarrhythmias as well. The parents need to know that touching or palpating the mass can further harm the child in the same manner as stress.

critical nursing action Pheochromocytoma

The child with pheochromocytoma can potentially be very ill. The nurse should remember to perform assessments frequently. Since the adrenal tumor may sometimes be visible abdominally, it is critical to remember *not* to touch or manipulate it in any way. Palpation can cause a further release of catecholamines increasing the likelihood of a severe hypertensive crisis that could cause potentially harmful tachyarrhythmias.

Metabolic Conditions

Metabolic conditions of the pancreas most often involve the destruction of the islets of Langerhans (beta [β] cells), which causes a failure to produce and secrete enough insulin to digest the carbohydrates, proteins, and fats eaten by the child. Most commonly called "diabetes," it is one of the leading causes of chronic illness in the United States. As American society unknowingly increases carbohydrate intake the incidence of diabetes is on the rise. It is important to note that previously, diabetes was merely classified as child (type 1—insulin dependent) or adult (type 2—non-insulin dependent) depending at the time of onset and insulin dependency. Today classification is much more complex because either type can affect a person of any age and can be either insulin dependent or non-insulin-dependent.

- Type 1 diabetes mellitus: due to β -cell destruction resulting in definite insulin dependency
- Type 2 diabetes mellitus: due to insulin resistance in which the body fails to recognize and use insulin properly

DIABETES MELLITUS TYPE 1

Type 1 diabetes is an autoimmune disease that arises when a child with a particular genetic makeup is exposed to any precipitating event, such as infection, particularly a virus or other environmental factors such as diet. This is the most common form of diabetes in persons younger than 40 years of age. Children with type 1 diabetes make up about 10% to 15% of all people with diabetes. In the United States it is about 127,000 cases (ADA, 2007b).

SIGNS AND SYMPTOMS. Even though the production of insulin decreases very gradually over many years, the manifestations of type 1 diabetes seem to appear abruptly, and the pancreatic cells can no longer make insulin. There are several signs and symptoms a child could exhibit. There may be excessive urination, in volume and frequency (polyuria), and loss of bladder control in children after they had already been trained, especially at night. Excessive intake of water and/or food (polydipsia and/or polyphagia), unintended weight loss over several days and tendency to be thin is common. Glucose levels in the blood and urine (hyperglycemia and glycosuria) are high. Nausea and vomiting, abdominal pain or discomfort; weakness and excessive fatigue; increased susceptibility to infection, especially urinary tract, respiratory, and skin infections; dehydration; blurred vision; irritability; restlessness; and/or apathy are also common.

DIAGNOSIS. Primarily, elevated blood glucose levels (usually in excess of 200 mg/dL) and elevated hemoglobin (A1C) (greater than 7.0) level are indicative of diabetes mellitus. There are also changes in the child's urine where both sugar and ketones may also be increased. The child usually presents with the complaint of the usual triad of symptoms (polyuria, polydipsia, and polyphagia). Repeat fasting blood glucose and at least two random elevated blood glucose studies make the final determination of the diagnosis.

NURSING CARE. Type 1 diabetes affects mostly children. There are five major components of management and care: insulin types, diet and nutrition, exercise, stress management, and blood glucose and ketone monitoring. Long-term treatments focus on reducing symptoms and preventing complications. Each of these therapies is a vital part of effective metabolic control. Although children and

where research and practice meet: Type 1 Diabetes is not Purely Genetic

Most recently published from the University of Philadelphia and McGill University in Montreal, a fifth gene variant has been identified that increases a child's risk for type 1 diabetes. With hopes to isolate the genes and determine their function researchers will be better able to treat type 1 diabetes early, perhaps even before the child's entire islet cells are destroyed (*Science Daily*, 2007). Research has indicated that the cause of type 1 diabetes is not purely genetic. Studies of identical twins have shown that identical twins do not always both acquire the disease. This indicates that environmental factors may place a significant role as well. Environmental factors include viral infections, congenital rubella, excessive nitrates in foods, and early cow's milk introduction into the child's diet, although there is no conclusive evidence at this time (Chase & Eisenbarth, 2005).

adolescents can be taught to perform the components, family management has proven to afford the diabetic child an improved glycemic control (Wysocki, Buckloh, Lochrie, & Antal, 2005).

Because high glucose levels and ketoacidosis are critical situations, a child initially diagnosed with type 1 diabetes usually is hospitalized to control the blood glucose level and to determine what type, dose, and frequency of insulin works best for the child.

Insulin Types. Many factors influence the child's insulin requirements. Insulin needs are affected by the child's nutritional intake and physical energy expended, as well as the child's emotional and stress level that accompany normal activities like growth spurts, puberty, and illness. Despite these variables that make insulin regulation extremely difficult, it is the foundation of treatment for a child with type 1 diabetes.

Many types of insulin are available today. Generally, the type of insulin used for each individual patient is based on the child's blood glucose levels and the child's lifestyle (Children With Diabetes, 2006). Combinations of long-, intermediate-, and short-acting insulin ("insulin cocktails") are given subcutaneously throughout the day in an attempt to simulate the body's natural release of the hormone (Tables 28-2 and 28-3).

- Humalog/NovoLog insulin is clear and usually taken immediately before meals. This regular insulin works so quickly that it can even be taken after meals. It is usually used for children who are picky eaters or

toddlers who do not always eat the same amount of food and thus can take the insulin right after they eat.

- Regular insulin is also clear and begins to act quickly; it merely takes slightly longer to reach its peak than Humalog or NovoLog.
- NPH insulin is cloudy and absorbs more slowly. It is made with a protein enabling its slow release. Even though the peak and the duration can vary from child to child, generally when this insulin is taken in the morning it does not take effect until the afternoon.
- Ultralente insulin peaks somewhat more slowly than the previous NPH. It can be given at dinner and its effects can help maintain a normal blood glucose level until morning.
- Lantus insulin is a clear insulin that last 24 hours with steady levels giving it nearly no peaking action. It is like NPH in that it is consistent and predictable in its action, but can vary within the same child in the time it takes to peak from one day to the next. Lantus, like all types of insulin, is given subcutaneously but since it cannot be mixed with any other insulin, it must be given as a separate injection.
- Lente, 70/30, and 75/25 "cocktail" insulin is premixed to allow the child the benefit of several types of insulin with the benefit of one injection. As many as three types of insulin can be mixed together. The premixed varieties are usually used by families who do not want to have to draw from several bottles.

Insulin must be given by subcutaneous injection. Parents should be lead to expect that their child may need one to four injections per day and that generally the more injections, the greater the blood glucose control. Children are very fearful of injections. Parents need time, patience, and encouragement. Help them practice giving injections away from the child to alleviate the child's fears and to boost their confidence. Audio and visual injection techniques can be viewed on the BD Diabetes Web site: <http://www.bddiabetes.com/us/main.aspx?cat=1&id=258> (see Procedure 28-1).

With some children and adolescents, the use of the insulin pump is increasing because the delivery of insulin is steady throughout the day, which most closely resembles the body's natural response. Recent research has shown that with proper training and follow-up, insulin pump therapy provides a lasting and effective treatment modality (Joslin Diabetes Center, 2006). Since pumps can be easily mistaken for a cell phone, pager, or I-Pod, communication with school teachers regarding the use, and occasional beep is essential (Fig. 28-3).

Table 28-2 Insulin Types and Peak Affects

Insulin Name	Insulin Type	Begins to Work	Peak Effect	Used Up
Humalog/NovoLog	Short-acting	10–15 minutes	30–90 minutes	4 hours
Regular	Short-acting	30–60 minutes	2–4 hours	6–9 hours
NPH	Intermediate acting	1–2 hours	3–8 hours	12–15 hours
Ultralente	Intermediate acting	2–4 hours	6–14 hours	18–20 hours
Lantus	Long-acting	1–2 hours	2–22 hours	24 hours

Table 28-3 Insulin "Cocktails"

Insulin Name	Insulin Type	Begins to Work	Peak Effect	Used Up
Lente	Premixed	1–2 hours	3–14 hours	18–20 hours
70/30 NPH/Regular	Pre-mixed	30–60 minutes	3–8 hours	12–15 hours
75/25 NPH/Humalog	Pre-mixed	10–15 minutes	30 minutes–8 hours	12–15 hours

medication: Insulin Dosage and Frequency

Although the dosage of insulin is based on the individual needs of the child or adolescent, the precise dose needed for each individual child cannot be predicted. Common insulin dosage for a child is generally 0.75–1.0 unit per kilogram per day.

Common insulin dosage for an adolescent is usually 1.0–1.7 units per kilogram per day. If two doses of insulin are the goal of treatment, then usually 60%–75% of the insulin is given before breakfast, with the remainder given with the dinner meal.

Procedure 28-1 Teaching Parents How to Inject Insulin

Purpose

To teach parents how to inject insulin

Equipment

- Insulin bottle from refrigerator (remove up to 1 hour before injection to allow it to warm to room temperature),
- Appropriate syringe (U-30, U-50, or U-100)
- Alcohol wipes
- Container for the dirty, used syringe

Steps

1. Check the expiration date on the insulin bottle.
RATIONALE: Ensures that the insulin has not expired.
2. Wash hands.
RATIONALE: Prevents the spread of bacteria.
3. Clean rubber stopper on insulin bottle with alcohol wipe.
RATIONALE: Promotes asepsis.
4. Remove syringe cap and pull air into the syringe line up the end of the black plunger to the exact amount the insulin dose will be.
RATIONALE: Ensures accurate dosage of insulin to be drawn-up.
5. Put the syringe needle through the bottle rubber top and push syringe plunger so that all the air goes from the syringe into the bottle.
6. Turn the insulin bottle upside down and pull the syringe plunger so that the insulin enters the syringe until the top of the black plunger exactly lines up with the dose of insulin to be given.
7. Remove every air bubble, always checking that the dose is exact.
RATIONALE: Exact dosing is essential in managing the child's condition.
8. Choose (or let the child choose) the site of the injection.
RATIONALE: Allowing the child to participate may help them feel more in control of his condition.
9. Clean the injection site with an alcohol swab.
RATIONALE: Alcohol will decrease the presence of microorganisms.
10. Pinch up the skin slightly and gently, with the syringe at a 90-degree (perpendicular) to the skin, with a dart-like motion, insert the needle into the skin, release the skin.
RATIONALE: Ensures proper medication administration.
11. Slowly inject the dose of insulin.
12. Discard the used syringe in a hard, rigid container with a tight-fitting lid.

Clinical Alert The nurse teaches the parents to evaluate the child for the signs and symptoms of either hypo- or hyperglycemia. In understandable terms, explain these signs and symptoms to the parents so they can watch for them at home.

Hypoglycemia (LOW Blood Sugar)

Cold, pale skin
(cold sweat)

Shakiness/hand tremors
Sudden hunger (crave salt/sweet)
Emotional outbursts
(personality changes)
Drowsiness/extremely tired
Pounding heartbeat/palpitations
Nervousness/dizziness
Anxiety/irritability
Headache, mental confusion,
difficulty concentrating
Numbness or tingling of lips/mouth
Poor coordination/staggering
unable to walk
Slurred or slow speech
Dilated, enlarged pupils
Fainting (needs emergency
treatment NOW)

Hyperglycemia (HIGH Blood Sugar)

Increased thirst, even if
consuming a large amount
of liquids
Loss of appetite, nausea/vomiting
Weakness, stomach pains/aches
Heavy, labored breathing

Fatigue, tired often sleepy
Large amounts of sugar in urine
Ketones in urine
Frequent urination
Blurred/double vision

Teach Parents

If the child expresses that the injection is painful, the following measures can be taken to decrease the pain:

- Inject room temperature insulin.
- Clear even the tiniest air bubbles from the syringe.
- Let the alcohol dry completely before injection.
- Tell the child to relax muscles in area of injection (the more tense the muscles during injection, the more painful the procedure).
- Use syringelike dart to pierce skin quickly.
- Do not change the needle direction during insertion or withdrawal.
- Never reuse syringes.
- Rotate sites with each injection (giving the insulin in the same place twice in one day can cause unnecessary discomfort for the child and undue stress on the tissue).

- Document exactly where each injection was given so as to avoid the same place more than once a day.
- Create and keep a Diabetes Management Notebook with the plan and a place to record daily blood sugar values as well as doses of insulin administered including injection site.

Procedure 28-1 Teaching Parents How to Inject Insulin—cont'd

For example:

Date	Blood Glucose AM	Blood Glucose PM	Insulin Dose Given and Time	Injection Site	Given by
8/9/07	124		4 units Regular at 0700	right mid-arm	Mom
8/9/07		144	4 units Regular 4 units NPH 1230	left mid-thigh	Dad

Documentation

Mother gave 4 units of Regular at 0700 in right mid-arm, noted by R. Such, RN
 Father gave 4 units of Regular and 4 units NPH at 1230 in left mid-thigh, noted by R. Such, RN

Diet and Nutrition

According to the American Diabetes Association, Medical Nutrition Therapy (MNT) is important in preventing and managing diabetes as well as preventing the development of diabetic complications. These nutritional recommendations and interventions for diabetes are intended to help those with diabetes and their health care providers (ADA, 2007a). Contrary to past belief, there are no forbidden foods in the diabetic child's diet. This is considered a unique time in the life cycle and even though some foods are more nutritious than others, no food is automatically eliminated. The goal for a dietary plan should balance various foods and include the caloric intake from:

- Carbohydrates (50–60%), milk, fruits, vegetables, grains (wheat, rice, corn, oats, barley)
- Fats (20–30%), mayonnaise, butter, margarine, oils (corn, olive, canola, peanut, etc.)
- Proteins (10–20%) meats, eggs, cheese, beans, legumes (lentils)

Figure 28-3 Wearing an insulin pump is a good way for children to regulate glucose levels.

It is also recommended that diet plans be revised at least annually. The goal of treatment for children with type 1 diabetes is that the blood glucose levels are maintained at a relatively normal level or as close to normal as possible. A1C levels are indicative of the average blood glucose levels over the past several (2 to 3) months (Table 28-4).

Table 28-4 Equivalent of A1C Level and Blood Glucose Level

Hemoglobin A1C Levels (mean %)	Mean Blood Glucose Level (mg/dL)	
Normal	4	60
	4.5	
	5	90
	5.5	
Slightly Elevated	6	120
	6.5	
	7	150

Nursing Insight— Equivalent of A1C level and blood glucose level

Although a child with type 1 diabetes does not need any special foods, it is imperative that his or her food intake is coordinated with the peak action of the insulin injected subcutaneously. Normally, the child with type 1 diabetes needs as many calories and variety of foods that are necessary for the normal growth and development of any child. Timing is the key to success. Specific parameters have been set by the ADA regarding the type 1 diabetes A1C goals for each specific age group (Table 28-5).

Exercise

Exercise and extracurricular activities should never be restricted unless the child with type 1 diabetes has health that warrant activity restriction. Children are much more likely to have a hypoglycemic crisis and must be reminded that calorie intake and insulin dosage may need adjustment with increased activity. Exercise is an excellent way to increase the cells' sensitivity to insulin and actually helps insulin to be better utilized by the body.

The spontaneity of childhood activity does not leave much time for parents to plan appropriate meals and snacks. Often it is difficult to encourage snacks before the activity. Remind parents that snacking during an activity may ward off a hypoglycemic crisis later.

Stress Management

Normal childhood milestones create varying times of stress in a child's life. From report cards to college preparation, growing young people experience anxiety, adjustments, and depression. It has been found that A1C levels increase with depression. It is important to consult with mental health professionals for patient screening and also to become a part of the team in order to create a network of referrals for each particular family.

Blood Glucose and Ketone Monitoring

The ADA has recommended that the health care provider weigh the benefits of lowering the child's blood glucose levels against the unique risk of hypoglycemia. Children

Figure 28-4 Home monitoring requires parents to perform glucose checks on the child with diabetes.

with type 1 diabetes may lack the capacity to recognize and respond to hypoglycemic symptoms. Hypoglycemic unawareness is a unique challenge for all pediatric health care professionals and parents. Home glucose monitoring occurs 3 to 6 times per day (Fig. 28-4). With home testing, glucose control is more exact than in the past. The importance of home monitoring is a vital aspect of care. Parents can be reassured that the glucose monitor is generally covered under most insurance plans.

Urine testing for ketones should be performed at least every 3 hours during a child's illness. It should also be checked whenever blood glucose readings exceed 240 mg/dL or when the child experiences unexplained weight loss even if he or she is well. Ketones in the urine are indicative of insulin deficiency.

Long-term Treatments

Long-term treatments focus on reducing symptoms and preventing complications such as blindness, kidney-failure, and limb amputation. The goal of care is to prolong life while enabling the child to grow into adulthood.

The focus of nursing care for a child with type 1 diabetes should be based on the cornerstones of nursing care

Table 28-5 Plasma Blood Glucose and A1C Goals for Type 1 Diabetes by Age Group

Age Group (years)	Plasma Blood Glucose Goal Range (mg/dL)		Hemoglobin A1C %	Rationale
	MORNING BEFORE MEALS	BEDTIME/OVERNIGHT		
Toddlers and preschoolers (0–6 years)	100–180	110–200	<8.5% (but >7.5%)	High risk/vulnerability to hypoglycemia
School age (6–12 years)	90–180	100–180	<8%	Risk of hypoglycemia and low risk of complications prior to puberty
Adolescents and young adults (13–19 years)	90–130	90–150	<7.5%	<ul style="list-style-type: none"> • Risk for severe hypoglycemia • Developmental and psychological issues <p>Lower goal < 7.0% is reasonable if it can be achieved without excessive hypoglycemia</p>

Modified from the American Diabetes Association (2007). Standards of medical care in diabetes – 2007. *Diabetes Care* 30 (Supplement), S4–S41.

with great emphasis placed on teaching the child and family about the chronic illness and its management. The nurse must continually assess the child's blood glucose, as well as observe for signs of complications or complex management issues. Most importantly, the nurse must assess the child and family's readiness to learn. Once the family is ready, the nurse must take every opportunity to teach the family about the illness or the child's care. By expanding the understanding and knowledge of the child and his or her caregivers, the nurse is creating the skills necessary for the home management of this chronic illness.

nursing diagnoses The Child with Type 1 Diabetes

- Risk for injury related to hypoglycemia or hyperglycemia
- Knowledge deficit related to management of type 1 diabetes
- Interrupted family processes related to management of the chronic illness
- Disturbed body image related to management of type 1 diabetes

Once the plan is complete, the nurse may begin to implement it. Education of the child and family can begin once the child is stable and ready to learn. It is an ongoing process and continues whether the child is in the hospital, or at home, just going for an outpatient visit. Outcomes can then be evaluated to determine if the child's glucose levels are normalized, if there are adequate insulin levels, and to determine if the child has a positive body image and is capable of managing the diabetes in the home with the support and guidance of others. Finally, the nurse evaluates that the child does not manifest the signs and symptoms of either hypo- or hyperglycemia.

Patient/Family Teaching that Optimizes Outcomes

Higher caregiver knowledge was associated with better glucose control/outcomes in young children with diabetes (Stallwood, 2006). Education is the main route by which a family achieves the best glucose control for the child with type 1 diabetes. The better the blood glucose is controlled, the less frequent the child experiences complications. Education must focus on insulin types; use; administration and schedule; meal planning including the balance of carbohydrates, proteins, and fats; physical exercise; blood glucose monitoring; and extremity care.

Children with diabetes could use alternative therapies to help manage blood glucose levels and to prevent any of the complication associated with the condition:

- Lifestyle changes, particularly diet and exercise
- Medications, namely insulin for individuals with type 1 diabetes
- Stress reduction and relaxation techniques
- Acupuncture for pain from nerve damage

Stressful life events can worsen diabetes in several ways. For example, stress stimulates the nervous and endocrine systems in ways that increase blood glucose levels and disrupt healthy behaviors (eating habits, etc.). Stress management is an integral part of the treatment of diabetes. Studies have shown that diabetics who participate in biofeedback sessions are more likely to reach normal blood glucose levels. Although other studies have produced results that contradict this, researchers and clinicians generally agree that long-term stress is likely to worsen diabetes and that biofeedback, tai chi, yoga, and

Family Teaching Guidelines... Dealing with a Hypoglycemic Crisis

How To: Recognize the signs of hypoglycemia (child is pale, sweaty, dizzy, “shaky” [tremors], confused, irritable, numb on lips or mouth and can have an altered mental status)

ESSENTIAL INFORMATION

- ◆ Check blood glucose level
- ◆ If blood glucose is below 70 mg/dL, rapidly give one of the following sources of carbohydrates (about 10–15 grams each), the right amount to treat hypoglycemia:
 - 1/2 to 3/4 cup of orange or grape juice (a juice box is good when one is away from home)
 - 2 glucose tablets or 2 doses of glucose gel
 - 2–4 pieces of hard candy
 - 5 gumdrops
 - 1–2 tablespoons of honey
 - 1 small box of raisins
 - 6 oz. regular (not diet) soda (about half a can)
 - 2 tablespoons of cake icing
- ◆ Recheck blood glucose in 15 minutes, if reading is still below 70 mg/dL, then
- ◆ Give another glass of juice, etc.
- ◆ Recheck blood glucose again after another 15 minutes.
- ◆ When blood glucose returns to at least 80 mg/dL a more substantial snack (nonconcentrated sugar) may be given, i.e., cheese and crackers, bread and peanut butter, etc. if the next meal is more than 30 minutes away or if a physical activity/exercise is planned.
- ◆ If the child is unconscious, glucagon should be given either subcutaneously or intramuscularly (ADA, 2007a).

other forms of relaxation may help motivate people with diabetes to change their habits in order to manage their condition.

Nursing Insight— Differentiation between hypo- and hyperglycemia

The nurse can help the family understand the differentiation between hypo- and hyperglycemia is critical for the nurse to be able to easily recognize (Table 28-6).

Across Care Settings: A team approach

The care of a child with type 1 diabetes is very complex. A team approach with the family at the core of the team is paramount. The child should be included in the plan and the care as much as possible (whenever appropriate). The most effective team consists of several members across the specialties within the hospital, including primary pediatrician, pediatric endocrinologist, diabetes nutritionist and nurse educator, exercise physiologist, as well as mental health professionals for psychological support as needed.

Nursing Care Plan The Child with Type 1 Diabetes

Nursing Diagnosis: Imbalanced Nutrition: Less than Body Requirements related to inability to metabolize carbohydrates

Measurable Short-term Goal: The child will exhibit blood glucose levels between (specify range for age).

Measurable Long-term Goal: The child will not experience hypoglycemia or diabetic ketoacidosis

NOC Outcomes:

- Nutritional Status: Biochemical Measures (1005)
Body fluid components and chemical indices of nutritional status
- Nutritional Status: Food and Fluid Intake (1008)
Amount of food and fluid taken into the body over a 24-hour period

NIC Interventions:

- Hyperglycemia Management (2120)
- Hypoglycemia Management (2130)
- Teaching: Prescribed Diet (5614)

Interventions:

1. Identify when the child and family are ready and motivated to learn all aspects of diabetic care.
RATIONALE: Children and families need time to accept this chronic illness and will not be able to learn until ready.
2. Explain clearly signs and symptoms of hypoglycemia, hyperglycemia, and diabetic ketoacidosis with appropriate treatment options.
RATIONALE: Children are highly susceptible to hypoglycemia and cannot always verbalize exactly how they feel.
3. Provide multiple opportunities to practice blood glucose testing and insulin preparation and administration.
RATIONALE: Children and families learn best with multiple demonstrations and return demonstrations. Various scenarios will enhance their problem-solving and critical thinking skills.
4. Include the parents and child in the development of the diabetic management plan including diet and exercise.
RATIONALE: Plans that include the input from the child and the family are more likely to be successful.

Lines of communication must be kept open to best serve the family and the child. It is also vital to include other significant adults (living in the home) into the diabetic child's plan of care.

The glucose balance of a child with type 1 diabetes is daunting. Because glucose control highly depends on monitoring and regulating the child's diet, exercise, and insulin dose and administration, those significant people in the child's daily life must know the plan. That is, the child's teachers, coach, school nurse, counselor, principal, or assistant and even the "lunch mom" must know those appropriate parts of the plan in order to help actualize it. A child should not be left unsupported at any time. Whether in Sunday school or at the school play, those responsible adults must know the appropriate care of the diabetic child.

DIABETES MELLITUS TYPE 2

Unlike type 1 diabetes, type 2 diabetes is caused by the body's resistance to recognize and utilize insulin rather than a deficient production of insulin as in type 1. For years, type 2 diabetes was labeled as "adult-onset," but in the past several decades there has been an alarming increase in type 2 diabetes in young people.

It is estimated that over one-third of all people with type 2 diabetes are undiagnosed. The increase of type 2 diabetes in the adolescent population has been dramatic over the past decade (ADA, 2007b). It is estimated that more than 2.7 million teens in the United States have impaired fasting blood glucose levels (Duncan, 2006).

where research and practice meet: Alternatives to Injectable Insulin

Alternatives to injectable insulin are in development. Several variant routes are being studied in an attempt to change the method of delivery of insulin doses. Currently the inhaled method is approved only for use with adults, but with more research, it will be seen in the pediatric population soon. Other methods of delivery under investigation include transdermal, buccal (sprayed into the back of the mouth to be absorbed by the oral mucosa), and oral methods. As with any new technology, stringent criteria must be met in order to be prescribed the alternate medication. Children need to reap the benefits of these advanced scientific/medical breakthroughs). Islet cell transplants or pancreatic transplantation may offer a cure to patients in the future (Juvenile Diabetes Research Foundation International, 2006).

Ethnocultural Considerations— People from some ethnic backgrounds are more prone to type 2 diabetes

Type 2 diabetes in children is often associated with ethnic background (African American, Hispanic, Asian, or American Indian), obesity (85% at diagnosis), and a family history of type 2 diabetes (74–100%) as well as with insulin resistance.

Insulin resistance is when the individual cells do not recognize the insulin molecule and resist its influence. The

Table 28-6 Clinical Comparison of Hypoglycemia and Hyperglycemia

Clinical Condition	Manifestations	Critical Nursing Actions
Hypoglycemia		
Too much insulin for amount of food eaten	Rapid onset	<ul style="list-style-type: none"> • Give 15 grams of carbohydrates (½ glass orange juice)
	Irritable	
	Nervous	
Injected insulin into muscle	Shaky feeling, tremors	<ul style="list-style-type: none"> • Recheck blood glucose in 15 minutes
Too much activity for insulin dose	Difficult to concentrate	<ul style="list-style-type: none"> • If blood glucose is <70 mg/dl give another 15 grams of carbohydrates
	Difficult to speak	
Too much time between meals	Behavior change	<ul style="list-style-type: none"> • Recheck again in another 15 minutes
	Confused	
	Repeats over and over	
Too few carbohydrates eaten	Unconscious	<ul style="list-style-type: none"> • If unconscious, give IM glucagon
	Seizure	
Illness or stress	Tachycardia	
	Shallow breathing	
	Pale, sweaty	
	Hungry	
	Headache	
	Dizzy	
	Vision blurry or double	
	Photophobic	
	Numbness of mouth or lips	
Hyperglycemia		
Too little insulin for the food eaten	Gradual onset	<ul style="list-style-type: none"> • Give additional insulin at usual injection time
	Lethargic	
	Sleepy	
Illness or stress	Slow response	<ul style="list-style-type: none"> • Use sliding scale doses for specific level of blood glucose
	Confused	
Too many carbohydrates eaten	Breaths deeply and rapidly	<ul style="list-style-type: none"> • Increase fluids
	Skin flushed and dry	
Meals too close together	Mucous membranes dry	<ul style="list-style-type: none"> • If ketones are elevated, • Give an extra insulin injection
Too many snacks	Thirsty, hungry, dehydrated	
Insulin given just under skin	Weak, tired, headache	
Too little activity	Abdomen hurts	
	Nausea and vomiting	
	Vision blurry	
	Shock	

cell membrane does not allow the insulin to initiate the normal enzymatic reactions that cause metabolism. The glucose cannot be utilized by the cells, the cells begin to be “starved,” and the blood glucose levels slowly but steadily rise.

SIGNS AND SYMPTOMS. Children with type 2 diabetes often have no symptoms, and their condition is detected only when a routine exam reveals high blood glucose levels or complications appear. Occasionally, a child with type 2 diabetes may experience some of the following

symptoms which tend to appear gradually over time: numbness or burning sensation of the feet, ankles, and legs, blurred or poor vision, impotence, fatigue, and poor wound healing. In some cases, symptoms may mimic type 1 diabetes and appear more abruptly. These symptoms include excessive urination and thirst, yeast infections, whole body itching, and even coma.

DIAGNOSIS. In the 2007 ADA position statement, specific criteria were established for type 2 diabetes testing in children:

- Overweight defined as a BMI greater than 85th percentile for age, and sex, weight greater than 85th percentile for height, or weight greater than 120% of ideal weight for height

Plus two of the following risk factors:

- Family history of type 2 diabetes in a first- or second-degree relative
- Race/ethnicity (Native American, African American, Latino, Asian American, Pacific Islander)
- Signs of insulin resistance or a condition associated with insulin resistance such as acanthosis nigricans (black-brown velvety skin condition on the back of the neck, axilla, arms, caused by too much insulin in the blood), hypertension, dyslipidemia, or polycystic ovary syndrome (PCOS)
- Maternal history of diabetes or gestational diabetes mellitus (GDM)

Blood glucose testing should begin at age 10 years or at the onset of puberty if younger. The frequency of this testing should be every 2 years. The preferred test is the fasting blood glucose level (ADA, 2007b). Diagnosis is confirmed with two fasting blood glucose results that exceed 125 mg/dL or two random blood glucose readings over 200 mg/dL.

NURSING CARE. The management of type 2 diabetes can vary depending on the severity of the disease. With normal or near normal A1C levels, nutritional teaching such as decreasing calories, and behavioral changes, especially increasing activity is pivotal to successful therapy. Teaching lifestyle modification must include the entire family to ensure compliance (McKnight-Menci, Sababu, & Kelly, 2005).

With a mildly elevated A1C level (6.2% to 9.0%) an oral hypoglycemic agent such as metformin (Actoplus MET) may be given (Ibanez et al., 2006). The medication, in combination with lifestyle modification usually successfully lowers the blood glucose level. With severe presentation (>9.0%) treatment is similar to that of type 1 diabetes. Insulin is given either intravenously or subcutaneously until the child is stabilized. Oral hypoglycemic agents can be given, particularly if the child has lost weight (Chase & Eisenbarth, 2005).

Increased awareness of the escalating type 2 diabetes crisis in the pediatric population can give the nurse the necessary tools to begin to fight this problem. Nurses, no matter what their care setting or work environment, should teach the public about the value of weight control, active lifestyles, and role model a healthy example for teachers, families, and most importantly the children.

Teaching the child, parents, teachers, counselors, coaches, and clergy should be his primary focus of care. Healthy eating habits and increasing activity in a sedentary

lifestyle are very difficult. All of this must be done without compromising normal growth and development while improving the quality of life.

The nurse must provide diabetes education for the entire household (Table 28-7). For instance, if a grandmother resides in the patient's home, but was not included in the teaching, she may unknowingly sabotage the efforts to change eating habits and lifestyle. The pediatric nurse must be cognizant of any factors that may make compliance difficult and talk to the parents and the child about home routines, especially those around mealtime and activities.

Consistent monitoring for complications of diabetes is a critical component of the care of a diabetic child. The pediatric nurse must be alert to the sign and symptoms of eminent complications. The signs of acute complications include hypoglycemia, weight loss, and diabetic ketoacidosis. Long-term complications involve the degradation of vital bodily systems, including, cardiopathy, nephropathy, neuropathy, and retinopathy. Many complications can have devastating effects including, growth failure, delayed puberty, menstrual disturbances, emotional disturbances, cataracts, impaired cognitive function, hyperlipidemia and breakdown or buildup of subcutaneous tissue at injection sites.

The nurse must communicate not only with the primary pediatrician but with the endocrinologist, the nutritionist, the diabetic nurse educator, the pharmacist, the social worker, the school nurse, and the home health nurse, so that everyone is knowledgeable about the individual needs of each particular child and his family.

DIABETIC KETOACIDOSIS

Diabetic ketoacidosis (DKA) is the presenting complaint in nearly one fourth of all newly diagnosed pediatric patients with type 1 diabetes mellitus (Young, 2007). It is a very complex combination of hyperglycemia, ketosis, and acidosis resulting from severely deficient insulin in either type 1 or type 2 diabetes. The abnormal metabolism of carbohydrates, protein, and fat that leads to very high glucose levels that causes DKA. It is important to know that DKA is the leading cause of death in children with type 1 diabetes.

Although the exact incidence is unknown, it is estimated that about 4 to 8 children per 1000 present with DKA at the time of diagnosis. In many cases, this is a common occurrence with young children who have difficulty verbalizing the classic signs and symptoms.

SIGNS AND SYMPTOMS. It is important to note that in the toddler age group, the classic manifestations of DKA are often absent. Many times the child is not known to be diabetic because the onset can be often insidious, but if it is known, a complete history, especially noting the compliance with insulin regimens and the name of the endocrinologist, is essential.

Some of the following signs and symptoms may be difficult for the young child to verbalize: fatigue and malaise, nausea/vomiting, abdominal pain, polydipsia, polyuria, polyphagia, weight loss, and fever.

The physical manifestations include altered mental status (may be alert or in a coma), tachycardia, tachypnea or hyperventilation (Kussmaul respirations), normal or low blood pressure, increased capillary refill time, poor perfusion, lethargy and weakness, fever, and acetone (fruity) odor of breath, indicates metabolic acidosis.

Table 28-7 Educating Different Groups on Diabetes

Content Topics	Parent	Child	Adolescent
Disease Process	<ul style="list-style-type: none"> • Include type of diabetes. • Treatment options • Benefits of healthy lifestyle 	<ul style="list-style-type: none"> • Explain disease simply. • Begin to teach self-care. • Include in treatment plan 	<ul style="list-style-type: none"> • Talk to as an adult. • Expect self-care, but also expect limitations.

Psychosocial Adjustments	<ul style="list-style-type: none"> • Avoid giving too much responsibility too soon. • Identify friends where child could spend the night (friends know child's care routine). • Notify teachers and principal of child's health needs. • Adaptation of family life to incorporate care without stress • Stress reduction • Parental relief (who could stay overnight with family so parents can "get away")? 	<ul style="list-style-type: none"> • Blood glucose testing before meals at friends, in restaurant, at school (in public) • Learn weight control • Manage overnight stays. • Healthy habits amidst unhealthy environments 	<ul style="list-style-type: none"> • Body image and weight concerns • Puberty and effect of hormonal changes • Learn to prevent complications. • Prevent DKA. • Modify high-risk behaviors. • Diabetes and dating, sex and conception • Peer pressure • Alcohol, tobacco, drugs

Source: Atkinson, A., & Radjenovic, D. (2006). Meeting quality standards for self-management education in pediatric type 2 diabetes. *Diabetes Care*, 40–46.

DIAGNOSIS. Diagnosis is confirmed with a blood glucose of greater than 200 mg/dL, ketonuria, or ketonemia with a serum bicarbonate level of less than 15 mEq/L. The pH of the blood will indicate the degree of the acidosis, that is,

- Mild DKA—venous blood pH equals 7.2 to 7.3
- Moderate DKA—venous blood pH equals 7.10 to 7.19
- Severe DKA—venous blood pH below 7.10

clinical alert

Diabetic ketoacidosis

Infection is the most frequent cause of DKA, particularly in known diabetics. Aggressive evaluation for infection always is necessary. Antibiotic therapy should strongly be considered until the culture results are known. The following patient-related issues can also be considered:

- Patient has poor compliance with existing insulin regimens.
- Patient exhibits underlying endocrine changes of adolescence.
- Thelarche—before puberty, just at the beginning of rapid growth.
- Adrenarche—activity of the adrenal cortex intensifies and hormones increase (at about 8 years of age).
- Menarche—the first menstruation usually occurs between 9 and 17 years of age.
- The caregiver's lack of competence.
- Insulin pump failure may occur.

NURSING CARE. Care of the patient with DKA is based on four essential physiologic principles (Chase & Eisenbarth, 2005):

- Restore fluid volume.
- Return child to a glucose utilization state by inhibiting lipolysis.
- Replace the child's body electrolytes.
- Correct acidosis, restore acid–base balance.

Children in DKA are unstable. Fluids and electrolytes can shift rapidly. The acid–base balance can fluctuate.

Therefore, do not expect exact treatment protocols with precise steps to follow because treatment ensues based on the signs and symptoms presented by the child and by the lab results. The nurse can expect to rapidly change intravenous solutions and to adjust the plan before one therapy is completed. The outcome of care is to restore hemodynamic and acid–base balance slowly, reducing the acidosis and restoring the child to a normal stabilized state.

The diabetic child in DKA is usually in the intensive care unit. The pediatric intensive care unit nurse must assess the child rapidly, frequently, and thoroughly. The focus of nursing care is to replenish the intravascular volume. Fluid status can be determined by the child's weight, skin turgor, pulse rate, level of consciousness, and blood pressure. As fluid and electrolyte deficits are replaced carefully and the child slowly returns to an acid–base balance status. Ongoing maintenance fluids are then given.

Nursing assessment of acidosis can be ascertained by the presence of Kussmaul breathing, flushed cheeks, acetone (fruity) breath, and complaints of back and abdominal pain. The bedside nurse is responsible to observe and document the child's response to each of the interventions. This requires a skilled nurse who understands and is comfortable with the care of a child in DKA.

With a child in DKA possibly comatose and in the intensive care unit, stress levels of the parents and caregivers are increased. The nurse must stay calm and think clearly. Performing assessments every 15 minutes is not too often. One aspect of assessment that is essential to know is the sound of Kussmaul breathing. **Kussmaul breaths** are very deep and laborious. In an attempt to correct the metabolic acidosis, the respiratory system works hard to "blow off" excess carbon dioxide. When a child breathes this way, some say it sounds like a locomotive.

Blood glucose is monitored every hour with the blood glucose goal results at approximately 100 to 180 mg/dL. When the child's blood glucose returns to a value below 300 mg/dL, 5% dextrose may be added back to the maintenance IV. Some physicians prefer a two-bag system hanging at the bedside, one IV bag with and one without glucose. Given through a Y-port, the nurse is able to infuse either one fluid or the other or both if the child needs them.

Serum potassium levels must also be checked regularly. Initially the DKA causes the child to be hyperkalemic. As the acidosis improves, and insulin and glucose are given, the child becomes hypokalemic. When the child's urinary output is adequate, potassium may be added to the IV fluids. With normal potassium levels, the child in DKA may need potassium. With abnormally low potassium levels, the ill child may need as much as 40 to 80 mEq/L. Placing the child on telemetry and obtaining an EKG may be needed to monitor for lethal arrhythmias.

Insulin infusions are begun at 0.1U/kg per hour. As the hyperglycemia and acidosis are corrected, the insulin rate is decreased. The insulin infusion is continued until the pH and the acidosis are corrected.

The child's electrolytes are carefully monitored and the acid-base balance is checked and documented every 2 to 4 hours. As the DKA is resolved, usually in 24 to 48 hours, and the child tolerates oral fluids, the insulin administration is switched to a subcutaneous regimen.

case study A 3-Year-Old Child with Type 1 Diabetes Who is Vomiting

It is the middle of December and this young family is busy with holiday preparations, the children only have a week left of school before the holiday break, and Johnny, the first-grader, has had "a runny nose." It is craft day and the children are excited. The 3-year-old sister begins to cry. She is flushed and seems feverish and will not drink her favorite juice. The mother calls the clinic and states, "My daughter has vomited twice and is a newly diagnosed type 1 diabetic, I cannot get her to drink, what should I do, I think she may have the flu?"

critical thinking questions

1. What is the most important concept to relay to this mother?
2. How can she get the child to drink?
3. What should she do for the fever?
4. Should the mother call 911 or take the child to the Emergency Department?

◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

With the diabetic child in the intensive care unit, there are many members of the health care working together in collaboration to prevent future episodes. In some cases, it was unknown that the child had diabetes and the DKA is the first time the parents realize that their child is ill. Whatever the scenario, working together, keeping lines of communication open, and realizing that the plan is ever-evolving keeps everyone focused on the best possible outcomes for each child.

To prevent DKA, families must be taught to check and recheck blood glucose levels or urine ketone levels any time the child is sick (vomiting) or if a blood glucose result is greater than 240 mg/dL. Ideally, the parents should be taught and become comfortable with the child's management plan before discharge. Meals and insulin administration should be planned to give the child the most normal blood glucose level on average

(A1C). Parents need to know that long-term complications occur when blood glucose is abnormally high and that keeping the blood glucose at as normal a level as possible will be the best protection their child can receive.

Now Can You— Discuss Diabetes Mellitus?

1. Examine the difference between type 1 diabetes mellitus and type 2 diabetes mellitus?
2. Discuss the nursing care for the child with type 1 diabetes?
3. Discuss the nursing care for the child with type 2 diabetes?
4. Discuss the nursing care for the child with diabetic ketoacidosis (DKA)?

summary points

- ◆ The endocrine system controls a child's growth and development.
- ◆ Hormones regulate a child's response to stress and physical trauma.
- ◆ The nurse must document consistent, accurate record-keeping of child's growth rate because while he or she is on most treatments, these measurements are essential parameters of goal attainment.
- ◆ Complementary care could be significant in treating the common childhood illnesses but should be verified with a physician before all treatments.
- ◆ Dehydration is a severe problem, causing the infant/child to be irritable with many other manifestations, including dry mucous membranes, decreased skin turgor (tenting of abdominal skin in infant), decreased tears when crying, sunken fontanel, and tachycardia. The nurse must act quickly to avoid serious consequences of hypotension and shock.
- ◆ Pharmaceutical treatments are successful only with proper administration, the nurse must ensure that the medications are given accurately and that parents are taught techniques correctly.
- ◆ The nurse must educate parents regarding the signs and symptoms of endocrine conditions for the condition to be recognized early and treated as soon as possible.
- ◆ Insufficient amounts of cortisol and aldosterone cause Addison's disease.
- ◆ Children with aldosterone deficiencies may also present with hyponatremia, dehydration, and hyperkalemia. If not diagnosed early after birth, this salt wasting may become life-threatening with the infant in adrenal crisis.
- ◆ Diabetes is one of the leading causes of chronic illness in the United States.
- ◆ Type 2 diabetes is caused by the body's inability to recognize and utilize insulin rather than a deficient production of insulin as in type 1 diabetes and has become an epidemic in the pediatric population.
- ◆ Diabetic ketoacidosis (DKA) is a potentially fatal condition marked by an accumulation of ketones and increased acidity of the blood.

review questions

Multiple Choice

1. A parent of a child with growth hormone deficiency is interviewed in the public health clinic. Which of the following signs and symptoms must be included in the discussion? (*Select all that apply.*)
 - A. Short stature below the 3rd or 5th percentile
 - B. Early closure of the anterior fontanel
 - C. Delayed dental eruption
 - D. High-pitched voice
2. The mother of a 7-year-old African American girl brings her daughter to the pediatrician's office for an annual examination. On assessment, the pediatric nurse notes which of the following signs or symptoms, which may suggest a diagnosis of precocious puberty? (*Select all that apply.*)
 - A. Breast development
 - B. Some pubic hair
 - C. Brittle hair
 - D. Beginning of menstruation
3. The pediatric nurse is providing discharge teaching to the family of a child who has been newly diagnosed with acromegaly. Included in the teaching should be the discussion of possible signs and symptoms that may occur. Which of the following sign and symptom should be included?
 - A. Hypotension
 - B. Arthralgia
 - C. Early onset of menarche
 - D. Small fingers and toes
4. A 9-year-old who has recently had surgery that involved the pituitary gland is now exhibiting signs and symptoms of diabetes insipidus. Which of the following signs and symptoms help confirm the nurse's suspicions? (*Select all that apply.*)
 - A. Vomiting
 - B. Enuresis
 - C. Polyuria
 - D. Polydipsia

True or False

5. If the child receiving human recombinant growth hormone therapy begins complaining of a headache, the pediatric nurse should suspect that this symptom may be indicative of increasing intracranial pressure.
6. The child who is on strict intake and output must be evaluated for fluid retention. As a component of the nursing assessment, the pediatric nurse should auscultate the child's lung sounds to detect overhydration.
7. To ensure that the infant receives the full dosage of the ordered hormone tablet, the prudent pediatric nurse should dilute the medication in the infant's bottle of formula.
8. The pediatric nurse would not be surprised to see a child with acromegaly exhibit a rapid increase in skeletal growth each time the child's height and weight is plotted on the growth chart.

Fill-in-the-Blank

9. The child with growth hormone deficiency will have studies done to evaluate his/her bone age. It would not be unrealistic to expect to find the child's _____, _____, or _____ size to be less than the child's chronological age.
10. It is important to note that in the _____ age group, the classic manifestations of DKA are often absent.

See Answers to End of Chapter Review Questions on the Electronic Study Guide or DavisPlus.

CONCEPT MAP

Caring for the Child with a Neurological or Sensory Condition

"The brain is wider than the sky,
For, put them side by side,
The one the other will include
With ease, and you beside.
The brain is deeper than the sea,
For, behold them, blue to blue
The one the other will absorb
As sponges, buckets do."

—Emily Dickinson

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Discuss the physiology and normal function of the nervous system.
- ◆ Discuss the neurological assessment of a pediatric patient.
- ◆ Examine the altered states of consciousness along with the nursing care for a pediatric patient.
- ◆ Explore increased intracranial pressure (ICP) and the impact on the child's life.
- ◆ Identify conditions that cause a dysfunction of the nervous system.
- ◆ Recognize signs and symptoms of life-threatening complications of neurological disorders and sensory disorders.
- ◆ Discuss nursing care for various conditions affecting a child's nervous system and senses.
- ◆ Identify agencies and organizations available to provide support for a child and his or her family.
- ◆ Formulate a plan of care for a child with a neurological and/or sensory disorder.
- ◆ Prioritize nursing interventions when planning care for a patient with an alteration in neurological or sensory function.

moving toward evidence-based practice Connection Between Epilepsy and Migraine Headache

Stevenson, S.B. (2006). Epilepsy and migraine headache: Is there a connection? *Journal of Pediatric Nursing Care*, 20(3), 167–171.

The purpose of this study was to investigate the prevalence of migraine headache in children with epilepsy and the presence of both migraine and epilepsy in the family history.

A sample of 470 pediatric participants was selected from a retrospective chart review of children with a primary diagnosis of epilepsy that were evaluated for follow-up in a neurology clinic between January 2003 and June 2004.

- The diagnosis of epilepsy was based on the International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) epilepsy codes.

- The definition for migraine headache included one or more of the following: phonophobia, photophobia, or other visual changes, and headache with nausea and/or vomiting.
- Descriptions for migraine headache or symptoms in participants too young to describe specific symptoms were based on parental reports. Information about family history included reports about close relatives with complaints of migraine headache, other types of headaches, epilepsy, or both (any type of headache and epilepsy).

(continued)

moving toward evidence-based practice (continued)

Data from the participants' charts was obtained through interviews conducted by physicians, residents, nurses, and medical students. Analysis of demographic data revealed that:

- The participants' mean age was 10.6 years: 29% were ages 1–7 years; 62% were ages 8–17 years; and 9% were age 18 years or older.
- Fifty-five percent were males.
- Headaches (any type of headache) were reported by 22.1% of females and 18.3% of males.
 - Participants younger than 7 years of age reported headaches 10% of the time.
 - Participants between 8 and 17 years of age reported headaches 23.5% of the time.
 - Participants between the ages of 18 and 26 years of age reported headaches 24% of the time.
- Sixty-nine participants reported both epilepsy and migraine headaches.
- Fourteen participants reported a family history of migraine, 97 had a positive family history of epilepsy,

and 11 reported a family history of both migraine headache and epilepsy.

Twenty percent of the participants reported headaches. This figure is consistent with headache incidence reported in other national studies. Occurrence of migraine headache in the general pediatric population ranges from 2.7% to 11%.

The increased presence of a family history of epilepsy and the prevalence of comorbid conditions, i.e., epilepsy and migraine, was also supported in the literature.

The researcher concluded that a higher incidence of migraine headaches occurs among the pediatric population diagnosed with epilepsy than in the general population.

1. What might be considered as limitations to this study?
2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

The nervous system is a complex system of structures that initiate, coordinate, and control all major functions of the body. A dysfunction of the nervous system resulting from internal and/or external factors may occur throughout the lifespan. The nervous system of a fetus is fragile. Injury to the nervous system may result in a life-altering or life-threatening disorder. In addition to congenital disorders, infants and children may be exposed to microbes that result in illnesses with short- and/or long-term effects. Traumatic events such as near drowning and head trauma sometimes have devastating neurological consequences. Congenital disorders, illnesses, and accidents affect not only the infant or child, but also the entire family. This chapter provides a review of the alterations related to congenital anomalies, illness, traumatic events, and sensory disorders.

A & P review The Nervous System

The nervous system is made up of the central nervous system (CNS) that consists of the brain and spinal cord and the peripheral nervous system. The peripheral nervous system (PNS) consists of the cranial nerves, the spinal nerves, and peripheral nerves. The peripheral nervous system is subdivided into the sensory-somatic nervous system and the autonomic nervous system. The brain is a network of nerve cells called neurons consisting of consist of axons and dendrites. Axons take information away from the cell body and dendrites bring information to the cell body. Brain tissue may be white or gray. White matter consists of axons that are coated with myelin which allow nerve impulses to travel rapidly and gray matter is made of neuronal cell bodies and surrounds the cerebral hemispheres, thus forming the cerebral cortex. Areas of gray matter are also found deep in the brain and include the

basal ganglia (affects movement), the hypothalamus (maintains homeostasis and regulates blood pressure, heart rate, and temperature), and the thalamus (processes sensory impulses and sends them to the cerebral cortex). Another important structure of the nervous system is the spinal cord.

The spinal cord is a mass of nerve tissue encased in a vertebral column, and the cord contains sensory and motor pathways. The spinal cord does not extend the length of the vertebral canal. A disruption in the pathway from the brain to the peripheral nervous system and spinal cord results in altered neurological function (Bickley & Szilagyi, 2003). ♦

Altered States of Consciousness

A child who is fully conscious is aware of the environment and self. The child is able to react to internal and external stimuli in an appropriate manner. A decrease in this awareness may result in a decrease or alteration in consciousness. Consciousness comprises two components: arousal and thought content. Arousal or level of consciousness (awareness of the environment) is a child's level of alertness or responsiveness to stimuli. Level of consciousness is controlled by the reticular activating system and the cerebral hemispheres of the brain. Cognitive cerebral function cannot occur without an active reticular activating system.

Content of thought includes all cognitive functions that ensure awareness of affective states, self, and environment. Content of thought is controlled by language and attention, concept and reasoning, memory, and the executive system (the cognitive processes involving logic, planning, analysis, and reasoning). An alteration in content of thought may be caused by internal or external factors

including structural, metabolic, and psychogenic. Structural factors are abnormalities of the anatomy of the brain. Metabolic factors include infections, trauma, congenital anomalies, vascular anomalies, and toxins (McCance & Huether, 2002). Psychogenic factors are influenced by psychological disturbances within a child.

When determining the etiology of an altered state of consciousness, organic and functional causes must be evaluated. Whatever the etiology of the alteration, there are degrees of consciousness. Abnormal responses and nursing actions to assess the state of consciousness are identified in Table 29-1.

THE UNCONSCIOUS CHILD

Unconsciousness is a state in which a child's cerebral function is depressed. Unconsciousness ranges from a stupor (aroused only with vigorous or unpleasant stimulation) to a coma (state of unconsciousness when the child cannot be aroused) (Venes, 2009). A child may be in an unconscious state for many reasons. The more common etiologies for unconsciousness in a pediatric patient are infection, trauma, and hypoxemia. The unconscious child requires astute and continuous monitoring by the nurse. The nurse carefully monitors vital signs, level of consciousness, reflexes, and pupil reaction. The nurse carefully and meticulously documents the objective data obtained to determine any deterioration that may alter therapy. The cause of the patient's unconscious state guides the nursing care and medical management. Unconsciousness caused by trauma requires a different plan of care than unconsciousness caused by an infection. The child may be in this state for a short time or for an extended time depending on the etiology, the effectiveness of treatment, and the ability to return to a normal

state of consciousness. The nurse also assesses the child for any seizure activity that may occur as a result of cerebral ischemia and edema.

Caring for the Unconscious Child

EVALUATING NEUROLOGICAL STATUS. The nurse carefully monitors the child's neurological status by assessing his or her level of consciousness (LOC) with the use of a pediatric Glasgow Coma Scale (GCS). The pediatric Glasgow Coma Scale consists of three components of assessment: eye opening, verbal response, and motor response (Fig. 29-1).

Nursing Insight— Assigning a numeric value for level of response

When performing an assessment using the Pediatric Glasgow Coma Scale, the nurse assigns a numeric value to each of the levels of response (1–15).

- Score of 9–15 (unaltered state of consciousness)
- Score of 8–4 (state of coma)
- Score of 3 or below (deep coma)

Coma scale scores may fluctuate if a change in neurological state occurs, including cerebral ischemia, the administration of medications, including paralytics and sedatives, and a regaining of consciousness.

Table 29-1 States of Consciousness Technique and Patient Response

State	Technique	Abnormal Response
Alertness	Speak in a normal tone of voice	An alert patient answers appropriately while opening his eyes and responding fully
Lethargy	Speak in a loud voice	A lethargic patient opens his eyes but appears drowsy; answers questions appropriately but falls asleep easily
Obtundation	Shake gently to arouse	An obtunded patient opens his eyes and looks at the stimuli; appears slightly confused; alertness and interest in surroundings are decreased
Stupor	Use a painful stimuli	A stuporous patient only responds to painful stimuli; verbal responses are absent or slow; responsiveness to a painful stimuli ceases
Coma	Apply repeated painful stimuli	A comatose patient does not respond to internal or external stimuli; he remains in an un-arousal state with eyes closed

Pupil scale (mm)

Figure 29-1 The pediatric Glasgow Coma Scale.

MONITORING VITAL SIGNS. The nurse carefully monitors, measures, and documents vital signs, level of consciousness, reflexes, and pupil reaction as prescribed by the healthcare provider or as dictated by facility policy. The frequency of vital sign measurement is dependent on the etiology, neurological status, and cerebral involvement. Any change in vital signs needs to be evaluated because the child's condition can deteriorate rapidly. The child's vital signs may need to be assessed every 15 minutes or more often if the neurological state or physical state is unstable. If the child's condition is stable, vital signs may be measured every 2 hours.

Cerebral infections can cause elevated temperatures, so the child's temperature must be measured every 2 to 4 hours. Intracranial bleeding may cause hyperthermia (body temperature elevated above the normal range). Administering antipyretics, applying a hypothermic blanket, providing a tepid bath, and maintaining a cool environment are used to decrease temperature.

MANAGING THE AIRWAY. A priority for any unconscious child is obtaining and maintaining a patent airway. Cardiopulmonary resuscitation may be the initial treatment. If a child is unconscious because of trauma or a neck injury, the respiratory structures may be damaged. If the structures are damaged or if edema is present, the airway may be compromised. A child with a fractured cervical spine injury may also be unable to breathe independently. The nurse needs to maintain adequate positioning and deliver oxygen by using various devices or mechanical assistance to maintain adequate respiratory function.

When caring for an unconscious child, the nurse meticulously monitors respiratory status including respiratory rate and rhythm, use of accessory muscles, apnea, level of consciousness, breath sounds, and level of oxygenation. A child in a light coma still may be able to cough and swallow and maintain adequate respiratory function. A child in a deep coma may be unable to swallow and adequately handle oral secretions. It is important to note that the gag reflex of an unconscious child may be impaired. The nurse suction the airway to remove secretions that may obstruct the airway or be aspirated. The nurse must be careful when suctioning the child's airway because intracranial pressure may increase.

A child who cannot maintain respiratory function needs to be mechanically ventilated. The child may need ventilator assistance for only a short time or may be dependent on the ventilator indefinitely. When caring for a mechanically ventilated child, the nurse monitors the arterial blood gases. The nurse may administer medications to sedate or relax the child to prevent injury related to manipulation of the endotracheal tube or accidental extubation.

The unconscious child who is intubated for an extended period of time requires a tracheostomy. The nurse performs tracheostomy care for these patients. The nurse changes the child's position at least every 2 hours and performs chest physiotherapy to prevent respiratory complications of atelectasis and pneumonia.

MANAGING BLADDER AND BOWEL ELIMINATION. A child who has been continent may become incontinent during an unconscious state. The child may also experience urinary retention (incomplete emptying of the bladder) or a bladder infection. An indwelling catheter may be necessary

if urinary function is lost and accurate output measurement is required.

Meticulous catheter care is imperative to prevent a urinary tract infection, which may further compromise the child's condition. If the child is in an extended state of unconsciousness, the indwelling catheter may be removed and the nurse may perform intermittent catheterizations. If the child regains consciousness and has no physical dysfunctions preventing bladder control, the nurse initiates bladder retraining. If a catheter is not inserted, a diaper may be used, and the nurse weighs the diaper to obtain accurate urine output measurement.

Bowel elimination in an unconscious child may also be affected. The child may experience constipation because of immobility. The child may also lack dietary fiber and experience medication side effects that can alter bowel elimination. The nurse monitors the child's bowel habits to assess for constipation and impactions. Stool softeners, suppositories, or enemas may be necessary to promote bowel elimination.

MAINTAINING HYDRATION AND NUTRITION. The hydration and nutritional needs of an unconscious child must be met based on the specific condition and progress of the child. The fluid needs of the child are based on weight, age, and illness or injury. The nurse administers intravenous fluids to promote fluid and electrolyte balance, prevent dehydration, and maintain urine output. The nurse carefully monitors intravenous fluid therapy and assesses for fluid overload.

If the child remains in an unconscious state, fluid and enteral feedings administered through a nasogastric or gastrostomy tube. Feedings may be continuous or bolus. Before administering fluid or feeding, the nurse verifies placement of the tube in order to prevent aspiration. Gastric residuals must be measured before feedings are administered. If the residual is excessive (determined by the physician), the nurse replaces the gastric contents and delays the feeding as prescribed by the physician. If the residuals are consistently too great, the composition, frequency, and amount of enteral formula may need to be changed. When enteral feedings are first initiated, the child may experience diarrhea. The nurse must assess the child frequently for diarrheal stools. Also, in order to prevent dehydration, constipation, and renal complications, the nurse administers water through the nasogastric or gastrostomy tube.

PROVIDING PROPER HYGIENE. Skin care is imperative when caring for an unconscious child. The child's skin is fragile and prone to breakdown. The nurse can bathe the child every other day or as needed. The perineal area is cleansed often, sometimes several times a day. The child who is unable to move may develop pressure ulcers. The nurse assesses areas on the child's body that are prone to breakdown such as the shoulder, ankle, elbow, and trochanter. The child's position is changed every 2 hours, and pressure-relieving devices are used to prevent pressure ulcer formation. The nurse assesses skin folds for maceration due to moisture and keeps the child's skin dry and clean of body secretions and excretions.

Providing mouth care is an important nursing action because the child may have dry mucous membranes. The nurse cleans and moistens the child's mouth at least twice

daily and assesses for any mouth ulcers or irritation, and lip emollients are applied to the mouth to prevent dryness (Fig. 29-2).

An unconscious child may not close his or her eyes or may keep the eyes open for long periods of time, and corneal irritation may develop. The nurse assesses the child's eyes for irritation and inflammation and may administer artificial tears at least every 2 hours to lubricate the eyes.

POSITIONING AND EXERCISE. The unconscious child is placed in a position that prevents aspiration and is anatomically correct. The nurse elevates the head of the bed 30 degrees and maintains the child's head in a midline position to prevent jugular compression and facilitate venous drainage. This position prevents increased intracranial pressure (ICP) due to jugular vein compression. The nurse performs passive range-of-motion exercises at least every 2 hours to prevent the development of contractures.

Complementary Care: The benefits of massage

The oldest and simplest form of nursing care may be massage. Massage was used in ancient Egypt, China, and India to treat disease and injuries. Therapeutic massage has been performed to promote a sense of well-being and enhance self-esteem while benefiting the immune and circulatory systems. The resulting sense of well-being has been found to decrease the amount of circulating stress hormones cortisol and norepinephrine that may weaken the immune system. The decreased anxiety and tension allows people to feel more serene and enhances their ability to cope with life stressors. As a result of the many benefits of massage, different massage techniques have been integrated into various complementary therapies.

All forms of touch are perceived through the body's largest organ, the skin. Thousands of specialized receptors found in the dermis react to external stimuli, including touch, by

sending messages to the brain through the nervous system. Gentle massage or stroking releases endorphins (the body's natural pain killers) and a feeling of comfort is experienced. Stronger, more vigorous massage helps to stretch tense and uncomfortable muscles, leading to improved mobility and flexibility. Also, massage aids in relaxation by affecting the body system that controls blood pressure, digestion, and respiration. The stimulation of circulation improves the supply of oxygen and nutrients to the body's tissues and enhances skin tone. Stimulation of the lymphatic system improves the body's ability to eliminate lactic acid and other chemical wastes that cause muscle stiffness and pain (Woodham & Peters, 2006).

When caring for an unconscious child, the nurse can incorporate therapeutic massage. The child may benefit from the many positive results of massage (e.g., decreased blood pressure, increased circulation, increased skin tone, improved peristalsis). Benefits of massage may also include decreased anxiety, decreased skin breakdown, and decreased constipation.

PERSISTENT VEGETATIVE STATE

A persistent vegetative state is a complete unawareness of the environment accompanied by sleep–wake cycles. The diagnosis of this condition is established if it is present for 1 month after acute or nontraumatic brain injury or has lasted for 1 month in children with degenerative or metabolic disorders or developmental malformations (Venes, 2009).

The primary causes of a persistent vegetative state are developmental malformations, metabolic and degenerative disorders affecting the nervous system, and acute traumatic and nontraumatic brain injuries. The most common cause of acute brain injury associated with a persistent vegetative state is a hypoxic–ischemic **encephalopathy** (generalized brain dysfunction marked by varying degrees of impairment of speech, cognition, orientation, and arousal) and trauma (Venes, 2009).

A child in a persistent vegetative state remains unconscious but has irregular episodes of wakefulness alternating with sleeping. The child exhibits nonpurposeful movements and sounds. Most children in this state have adequate respiratory function although they may have previously required a tracheotomy or mechanical ventilation. A child's persistent vegetative state may be for a short period of time or lifelong. A child's recovery from a persistent vegetative state is dependent on the etiology. A child who is in a persistent vegetative state because of trauma may recover some function even though complete recovery of function is rare. If a metabolic or degenerative disorder is the cause of the persistent vegetative state, the child does not recover any function because of the progressive nature of the disease. A child with a congenital malformation severe enough to cause a persistent vegetative state does not acquire any awareness of self or environment. The life expectancy of a child in a persistent vegetative state is shortened due to respiratory complications (Ashwal, 2004). The nursing care provided for a pediatric patient in a persistent vegetative state is similar to care provided for an unconscious child.

Figure 29-2 The nurse cleans and moistens the child's mouth at least twice daily.

nursing diagnoses The Unconscious Child

- Impaired Mobility related to altered neurological functioning
- Impaired Gas Exchange related to increased intracranial pressure
- Risk for Impaired Skin Integrity related to decreased mobility and incontinence
- Risk for Infection related to invasive hospital procedures
- Risk for Aspiration related to enteral feeding
- Risk for Altered Bowel Elimination related to decreased peristalsis

Family Support

The outcome for a child in a state of unconsciousness is uncertain. The family of a child who is in a persistent vegetative state experiences many emotions including fear, guilt, anxiety, anger, and depression. The nurse helps them cope with this difficult situation and plays a major role in providing support to the family members.

The intensive care unit can be a frightening environment because of the equipment, monitors, procedures, and invasive lines. The nurse helps the parents face this new environment and difficult experiences by being supportive and honest. The nurse facilitates family members' acceptance and healing by allowing them to express their feelings and to participate in the child's care. The nurse encourages the family to touch and talk to the child, which offers comfort and stimulation. Parents are asked to bring familiar toys. After the child's condition has stabilized, parents may decide to care for the child in the home or place the child in an extended care facility. Sometimes parents must make the difficult decision to end measures that are sustaining the child's life.

“What to say” — Parental education

The nurse must provide the family with specific instructions if the child is going to be cared for at home. Skills required to care for the child at home are determined by the condition of the child. The nurse communicates information about bathing, feeding, medical equipment, tracheostomy suctioning, gastrostomy tubes, urinary catheterization, positioning, and range-of-motion exercises. The importance of performing these procedures correctly is also stressed. To validate parental understanding, the nurse asks the parents to demonstrate the tasks. Parents may appear reluctant and fearful. The nurse must remain supportive and patient as parents learn new skills.

The nurse also discusses signs and symptoms of complications with the parents that may need further medical evaluation. The parents must also be able to identify non-verbal indicators of illness or distress because the child is unable to communicate pain or discomfort. The nurse may suggest that the parents ask family and friends to care for the child occasionally. Some communities have respite care centers for parents with medically fragile children.

The community health nurse can assist the parents with the child's care and be a resource to answer questions, address concerns, and find other community resources.

INCREASED INTRACRANIAL PRESSURE

A delicate balance exists between the volume of the intracranial vault and the contents including the brain, blood, and cerebrospinal fluid (CSF). The CSF is the fluid of the brain and spinal cord that supplies nutrients and removes waste products and also serves as a watery cushion that absorbs shock to the central nervous system (Venes, 2009). The **intracranial pressure (ICP)** is the pressure of the CSF in the subarachnoid space between the skull and the brain.

clinical alert

Monroe-Kellie hypothesis

The pressure–volume relationship among the blood, intracranial pressure (ICP), volume of cerebrospinal fluid (CSF), and brain tissue and cerebral perfusion pressure is known as the Monroe-Kellie hypothesis or Monroe-Kellie Doctrine. The hypothesis states that if one of the components increases, the other components must compress (LeJune & Howard-Fain, 2002). The body tries to compensate by an increase in CSF absorption, a decrease in CSF production, a reduction in blood volume, or a decrease in brain mass. When compression is exhausted, the ICP rises. As a result of increased ICP, blood flow and oxygen delivery may be compromised. When blood flow and oxygen decrease, secondary brain injury occurs (Marcoux, 2005).

Nursing Insight— Increased intracranial pressure

Increased intracranial pressure (ICP) can have devastating and long-term consequences for the child and family. Infants and children whose fontanels have not closed are able to compensate for increased ICP for a short time. The child's fontanels bulge and skull sutures may separate to accommodate the increased volume.

A child can have increased ICP as a result of many internal or external factors. If the child has suffered a primary brain injury, the child is at risk for developing increased ICP and secondary brain injuries. Primary brain injury is irreversible, immediate, and can result from traumatic injuries (e.g., a blow to the head) or nontraumatic injuries (a tumor or infection). Secondary brain injuries include hypoxia, hypercapnia (increased serum CO₂), hypotension, acidosis, and reduced oxygen delivery (LeJune & Howard-Fain, 2002). The etiologies of increased ICP can be classified by the mechanism through which the ICP is increased. Many disorders increase brain mass or volume, including contusions (bruises), a brain tumor, a subdural or epidural hematoma (swelling composed of blood), or an abscess (a collection of pus).

Generalized brain swelling can be caused by ischemic–anoxic states, hypertensive encephalopathy, acute liver failure, hypercapnia, or Reye syndrome that may result in a decrease in cerebral perfusion with minimal brain shifts. An increase in venous pressure can result from venous sinus thrombosis, obstruction of superior mediastinal or jugular veins, or cardiac failure. If an obstruction to CSF flow or absorption is present, ICP increases. Some disorders in which CSF is obstructed are hydrocephalus,

extensive meningeal disease, or obstruction in superior sagittal sinus and cerebral convexities. Meningitis, choroid plexus tumor, and subarachnoid hemorrhage can increase CSF production, resulting in increased ICP (Dennis & Mayer, 2001).

The cranium and vertebral body form a rigid container, and if any of its contents increase, an increase in ICP occurs. Small increases in brain volume do not result in an immediate increase in ICP because the CSF is able to be displaced into the spinal cord. The tentorium between the hemispheres and cerebellum and the falx cerebri between the hemispheres are slightly flexible, allowing for some stretching. An infant's normal ICP values are 2 to 6 mm Hg, young children's values are 3 to 7 mm Hg, and older children's values are 0 to 10 mm Hg. Once the ICP reaches approximately 20 mm Hg, small increases in blood volume can result in extreme elevations in ICP.

Nursing Insight— Cerebral perfusion pressure (CPP)

The difference between the mean arterial pressure within the cerebral vessels and ICP is termed cerebral perfusion pressure (CPP). The CPP is calculated by subtracting the ICP from the mean arterial pressure: (CPP = MAP – ICP).

One of the primary dangers of increased ICP is that decreasing cerebral perfusion can cause ischemia (Dennis & Mayer, 2001). As the ICP nears the level of the mean systemic pressure, it is more difficult for blood to enter the intracranial space. The body's natural response to a decrease in CPP is to increase blood pressure and dilate the blood vessels in the brain. The vasodilation results in increased cerebral blood volume that increases ICP and lowers CPP further. This vicious cycle results in widespread reduction in cerebral blood flow and perfusion leading to ischemia and brain infarction. CPP should be maintained greater than 50 to 70 mm Hg with increased ICP because a lower level may result in secondary hypoxic–ischemic injury (Marcoux, 2005). An increase in blood pressure may also make intracranial hemorrhages bleed more quickly, which increases ICP. If brainstem compression is involved, the respiratory center is affected and respiratory depression and arrest may occur.

SIGNS AND SYMPTOMS. The signs and symptoms of a child with increased ICP demonstrate are related to cerebral edema and ischemia (Table 29-2).

Nursing Insight— Cushing's triad

A child with significantly increased intracranial pressure may exhibit Cushing's triad. Symptoms of Cushing's triad are hypertension (with widening pulse pressure), bradycardia, and an irregular respiratory pattern. Cushing's triad is usually indicative of impending herniation (the displacement of the foramen magnum; Venes, 2009).

DIAGNOSIS. The diagnosis of increased ICP is based on signs and symptoms exhibited by the child and diagnostic tests results. **Papilledema** (a mass of blown-out

Table 29-2 Signs and Symptoms of Increased Intracranial Pressure in Infants

Early Signs and Symptoms	Late Signs and Symptoms
Headache	Further decrease in LOC
Emesis	Bulging fontanel (infant)
Change in LOC	Decreasing spontaneous movements
Decrease in GCS score	Posturing
Irritability	Papilledema
Sunsetting eyes	Pupil dilation with decreased or no response to light
Decreased eye contact (infant)	Increased blood pressure
Pupil dysfunction	Irregular respirations
Cranial nerve dysfunction	Cushing's triad (late, ominous sign)
Seizures	

Adapted from Marcoux, K. (2005). Management of increased intracranial pressure in the ill child with an acute neurological injury. *AACN Advanced Critical Care*, 16(2), 212-231.

blood vessels located around the optic nerve) is an important sign of increased ICP. This finding can be observed when the nurse assesses the child's eyes with an ophthalmoscope.

Diagnostic Tools Determining Increased Intracranial Pressure (ICP)

Magnetic resonance imaging (MRI) or computed tomography (CT) is used to determine the etiology and severity of increased ICP. As a rule, CT contrast should be avoided in the presence of intracranial bleeding. The child's ICP can also be monitored by inserting an intracranial catheter.

NURSING CARE. The nurse closely monitors the pediatric patient with increased ICP because changes in the neurological status can occur very quickly and may have life-threatening consequences. The nurse's initial assessment provides a baseline by which the child's progress is evaluated. The goals of the child's care are to provide general supportive care and prevent secondary injury.

A priority nursing intervention is maintenance of a patent airway. Inadequate oxygenation or excess carbon dioxide causes cerebral blood vessels to dilate, resulting in an increase in ICP. The child should be intubated if the Glasgow Coma Score is less than 8 (Marcoux, 2005). If the child is intubated, the nurse monitors the ventilator equipment too. It is important to maintain normal ventilation with a PO_2 of 120 to 140 mm Hg and a PCO_2 of 30 to 35 mm Hg. Sometimes positive end expiratory pressure (PEEP) is necessary to maintain oxygenation saturations above 95%.

If the child's condition deteriorates, hyperventilation, with an Ambu-bag, may be performed until the ICP decreases. Hyperventilation is aimed at keeping a low level of serum PCO_2 so that cerebral blood flow decreases and reduces cerebral blood volume, thereby reducing ICP. Prolonged hyperventilation is avoided because it may

cause hypotension due to decreased venous return (Marcoux, 2005). Mild hyperventilation may be prescribed by some healthcare providers. If the child is not intubated, supplemental oxygenation will be necessary. If possible, the nurse positions the child on the side in order to decrease possible airway obstruction.

The child's vital signs are monitored very closely. Intracranial bleeding is often accompanied by an increase in body temperature which is usually resistant to antipyretic agents. Hyperthermia is to be avoided because brain metabolic needs will be greatly increased. The nurse may use a hypothermic blanket if the child's temperature is higher 102°F (39°C).

critical nursing action Assessing for Hypothermia

When using a hypothermic blanket, the nurse must monitor the patient's temperature continuously to prevent hypothermia (a body temperature below 95°F [35°C]). Hypothermia causes shivering and an increase in ICP.

Acetaminophen (Children's Tylenol) or ibuprofen (Children's Advil) may be administered by the nurse to lower the child's temperature. Cooling the environment may help as well.

The head of the bed can be elevated 15 to 30 degrees to promote venous blood return, but a side effect of elevating the head is that the pressure of blood being delivered to the brain decreases, resulting in inadequate blood supply and perfusion. Another simple way to decrease ICP (particularly in trauma patients) is to loosen clothing around the neck.

clinical alert

Patient safety

Never place the patient's head lower than the body. This position significantly increases the patient's ICP.

Administer intravenous fluid cautiously because hypertonic IV solutions have an osmotic effect. Normal saline, lactated Ringer's solution, and albumin are primarily used.

Nursing Insight— Intravenous fluids

Hypotonic intravenous fluids (a combination of dextrose [5% or 10%] and sodium chloride [0.22% or 0.3%]) are avoided because they cross the blood–brain barrier resulting in increased cerebral edema and ICP.

If a child has increased ICP and has inadequate circulation, fluid administration takes priority over concern about cerebral edema. Fluid restriction is contraindicated in children who are poorly perfused with brain pathology or hypovolemic (an insufficient amount of fluid in the circulatory system) because hypovolemia results in decreased cerebral perfusion. To closely monitor fluid balance, the nurse accurately measures and records intake and output.

Another responsibility of the nurse is to protect the child from injury. The child with increased ICP may be predis-

posed to seizures. The nurse administers antiseizure medications as prescribed. Phenytoin (Dilantin) or a similar medication may be used. The nurse also places the child under seizure precautions. The nurse monitors seizures for such factors as frequency, severity, and type of seizure.

clinical alert

Seizure precautions

- Maintain airway patency—Ensure nothing is placed in the child's mouth during a seizure. A loose tooth may be aspirated or knocked out.
- Monitor oxygenation—The child's color should remain pink. The pulse oximeter should read 95% or greater and the heart rate should be normal or slightly raised.
- Administering medications—When administering intravenous medications during a seizure, give the medication slowly to reduce the risk of side effects such as respiratory or circulatory failure.
- Raise and pad the side rails when the child is in bed or crib—The child needs to be protected from self harm (Fig. 29-3).
- Helmet—If the child has frequent seizures, a helmet can be worn to protect his head in case of a fall.
- Medical alert bracelet—The child who has seizures should wear a medical identification bracelet at all times.

The nurse must provide emotional support to the child and family. The nurse allows the child and family to express their feelings, can offer a support group, and reminds the family to treat the child as normally as possible.

Nursing Insight— Phenytoin (Dilantin)

Phenytoin (Dilantin) may cause gingival hyperplasia. The nurse observes for swelling and bleeding of the child's gums and provides good dental hygiene. Parents need to be taught the necessity of performing proper hygiene.

Figure 29-3 An important care measure is padding the side rails.

medication: Mannitol (Osmitol)
Mannitol (**man**-i-to)**Classifications:** Osmotic diuretic, diagnostic agent**Indications:** Reduction of intracranial pressure and treatment of cerebral edema**Action:** Increases the osmolarity of the glomerular filtrate, preventing the reabsorption of water and resulting in a loss of sodium chloride and water.**Contraindications:** Use cautiously with hypersensitivity, anuria, and active intracranial bleeding.**Incompatibilities:** Do not add to blood products.**Adverse Reactions and Side Effects:** Confusion, headache, blurred vision, rhinitis, chest pain, pulmonary edema, tachycardia, nausea, thirst, vomiting, renal failure, urinary retention, dehydration, hyperkalemia, hypernatremia, hypokalemia, hyponatremia and phlebitis at the IV site.**Route and Dosage:** Reduction of intracranial/intraocular pressure: 1–2 g/kg as a 15–20% solution over 30–60 minutes**Nursing Implications:**

1. Do not administer electrolyte-free mannitol with blood products. If blood is administered, add at least 20 mEq of NaCl to each liter of mannitol
2. Confer with physician regarding placement of an indwelling Foley catheter (except when used to decrease intraocular pressure).
3. Administer by IV infusion undiluted.

Evaluation/Desired Outcomes:

1. Urine output of at least 30–50 mL/hr or an increase in urine output in accordance with patient parameters set by physician
2. Reduction in intracranial pressure
3. Reduction in intraocular pressure
4. Excretion of certain toxic substances

Data from Deglin, J.H., & Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

The nurse may also administer medications to decrease cerebral edema. A drug frequently prescribed is mannitol (Osmitol).

Barbiturates may be administered to reduce ICP. Barbiturates cause the blood vessels in the brain to constrict but the blood vessels in the rest of the body to dilate. The nurse must carefully monitor volume status and blood pressure. The use of steroids with increased ICP is controversial. Corticosteroids reduce vasogenic edema surrounding brain abscesses and tumors and after neurosurgical manipulation such as with tumor resection. Corticosteroids have no effect on cytotoxic brain edema resulting from metabolic, infectious, or hypoxic–ischemic disorders (Dennis & Mayer, 2001).

The child with increased ICP may require analgesia and sedation. The child who is hospitalized for increased ICP is usually in an intensive care unit or in an area where he or she is closely monitored. Overstimulation from the child's environment, in addition to fear and pain, may increase the ICP. Pain and agitation should be treated aggressively if increased ICP is present. Nursing actions that may increase ICP include endotracheal suctioning, bathing, and positioning. If the child's ICP becomes dangerously high, the child should be sedated and, if necessary, paralyzed. Narcotics such as morphine (Astramorph) or fentanyl (Sublimaze) and benzodiazepines such as lorazepam (Ativan) are titrated to the desired effect.

Optimizing Outcomes— Intracranial pressure monitoring

A pressure line may be inserted to accurately monitor ICP. Several types of monitoring devices are available, including intracranial bolts, intraventricular catheters, and intraparenchymal fiberoptic catheters. Intracranial pressure monitoring is indicated for the child who has a GCS score <8, exhibits signs of increasing ICP, who is post major neurosurgical procedures, or has a high probability of having increased ICP. The best outcome for ICP monitoring is to maintain cerebral perfusion pressure between 50 and 70 mm Hg, maintain ICP <20, and detect occurrences such as herniation or bleeding (Marcoux, 2005).

A craniotomy (an incision through the cranium) is recommended only when all other measures have been unsuccessful. A complication of a craniotomy is herniation of the brain through the defect, leading to further edema and increase in ICP. After a craniotomy, the nurse assesses the child for signs and symptoms of infection and increased ICP postoperatively.

SEIZURE DISORDERS

A seizure is an electrical disturbance within the brain, resulting in changes of motor function, sensation, or cognitive ability. Seizure activity is classified according to the area of the brain experiencing the abnormal electrical activity and the neuromuscular sensory and psychogenic alteration from the electrical conduction disturbance. The incidence and onset of seizure disorders varies by age and underlying physical or pathological condition. Seizures may be genetically linked in susceptible children or the etiology may be unknown. Seizures can result from a traumatic brain injury, an infection in the central nervous system, toxic ingestion, endocrine dysfunction, atrial–venous malformation, or an anoxic episode. Neonates may develop seizures due to intrapartum or postpartum anoxic episodes, maternal ingestions or exposure to teratogens, and prenatal infections. Hypoglycemia and congenital malformations can also cause neonatal seizures in the first month of life. The prevalence of seizures is approximately 4 to 6 cases per 1000 children but the type of seizure incidence varies according to genetic predispositions in families (Richardson, 2006).

Nursing Insight— Febrile seizures

Febrile seizures occur in less than 5% of the population and typically are seen in children younger than 3 years of age. Children may experience a febrile seizure between the ages of 6 months to 5 years but the most common occurrence is in the first 1 to 2 years of life. The exact etiology of febrile seizures has not been clearly identified. There may be a family history of seizure activity or febrile seizures. The child has a normal EEG without epileptiform (having the appearance of epilepsy) activity. In the emergency room, the nurse notes that the child with a febrile illness has a generalized tonic–clonic seizure lasting less than 15 minutes with a loss of consciousness. This pathological process can be controlled with antipyretics and anticonvulsant therapy, but this treatment is controversial and prescribed mainly in the case of anxious parents and/or

prolonged febrile seizures (O'Dell et al., 2005; Robertson and Shilkofski, 2005). There is no preceding aura and the child may be postictal (confused) for a short time after the seizure is over. There is a slight increased incidence of epilepsy in children with febrile seizures over the general population, especially if other types of seizures or abnormal CNS development are present in the child or the family (Robertson & Shilkofski, 2005).

SIGNS AND SYMPTOMS. Although seizures in children may be a direct result of a known disease process or injury, most seizures have unknown causes. Head injuries, infection, brain tumors, anoxic or hypoxic events such as a near drowning or intrauterine fetal compromise, or metabolic imbalance events can precipitate seizures in infants and children. Because seizures can indicate a disease process rather than be a disease entity alone, all pediatric seizures are thoroughly investigated (Table 29-3).

DIAGNOSIS. Seizures are diagnosed clinically with the use of neurological testing. Neurological testing procedures are used to determine the etiological epileptic focal center in the brain causing the abnormal electrical activity. In-depth testing of the neurological system helps to classify the type of seizure and determine appropriate anticonvulsant therapy. The neurological exam consists of a cranial nerve assessment, deep tendon reflex, sensory and motor response, level of consciousness, and hearing

and pupil checks. A computed tomography (CT) scan or an MRI may be performed to look for CNS malformation, lesions, neoplasms, hemorrhage, trauma, foreign body, or edema. An angiography is done to assess for arteriovenous malformations that may be hereditary. New-onset seizures may suggest malignant neoplasms and warrant emergent neuroimaging.

Electroencephalogram (EEG) is the accepted standard test for diagnosing a seizure disorder. The EEG evaluates the electrical activity of the brain while the brain is in a sleepy or drowsy state and also when stimulated (Fig. 29-4). Loud noises, bright lights, and rapid flashing images are presented during the procedure and the resulting electrical brain wave response is graphed. This information is useful to the neurologist in diagnosing the type of seizure activity, especially if the history and exam do not support a clear diagnosis. Video EEG can also be done if the EEG is inconclusive or if the child experiences sleep and waking onset seizures. Positron emission tomography (PET) is performed if brain structures require outlining or mapping before a surgical procedure, but is not routinely indicated for seizure evaluations.

NURSING CARE. Seizure management is a collaborative effort among the nurse, the medical team, the primary care provider, and the family. Specific nursing care for a child with seizures is determined by the type of seizure. If the etiologic agent for the seizure is pathological in origin, seizures are managed medically until the cause can be resolved. If the cause is a brain tumor, the mass is excised.

Table 29-3 Types of Seizures and Signs and Symptoms

Type of Seizures	Brain Location/Cause	Signs and Symptoms
Partial (Focal)	Localized to one area	One area affected: hands, lips, wrist, arms face. Impaired loss of consciousness at onset.
Partial complex (psychomotor)	Temporal lobe	Loss of consciousness and loss of awareness or surrounding. Change in behavior: lip smacking, picking, inappropriate mannerisms, confusion follows the seizure.
Partial simple		Lasts 5 minutes, child only remembers the aura. Automatisms are noted. No loss of consciousness or awareness. Motor signs are isolated to one area of the body and then spread to the rest of the body. May experience senses such as buzzing sounds, tingling, flashing lights, anxiety, fear or anger.
Generalized		
Tonic clonic	Genetic predisposition or brain injury secondary to anoxia.	Partial simple and complex seizures evolve to generalized seizures. Aura is experienced followed by loss of consciousness and tone. Patient falls to the floor with tonic clonic muscle contractions. Patient is postictal and confused after the seizure is over. Loss of urine may occur.
Atonic: loss of muscle tone, drop attacks. Absence (petit mal)		Sudden drop to the floor due to loss of motor muscle tone. Seen in children 2–4 years of age.
		No loss of consciousness but experiences loss of awareness. Non-convulsive. Periods of staring or minor movements lasting seconds. May occur several times a day, interferes with learning and school work.
Tonic		Stiffening of the body that is sustained, involving all four extremities.
Myoclonic	Metabolic etiology	Single or multiple jerks or flexion of limbs.
Clonic		Intermittent rhythmic jerking, 1-3 per second, may start in one body location and move or migrate to another location.
Myoclonic and Akinetic		Complete or total lack of movement

Source: Fox, J.A. (2002). *Primary health care of infants, children and adolescents*. St. Louis, MO: C.V. Mosby.

Figure 29-4 The EEG evaluates the electrical activity of the brain while the brain is in a sleepy or drowsy state and when stimulated.

If the cause is endocrine dysfunction, it is resolved. If infection is present, appropriate antibiotic therapy is initiated. If the cause of the seizure is unknown and a structural abnormality is not present, the child is placed on an anticonvulsant therapy specific for the type of seizures being experienced.

The nurse completes a detailed history of the seizure event, an in-depth review of the child's prenatal and postnatal history, and review of systems. The event history must include antecedent events that may have precipitated the seizure such as dehydration, video gaming, exercise, or any ingestion of substances that may cause seizures. Information regarding the type of activity during the seizure, any loss of consciousness, loss of urine, noises made, cyanosis, and history of present illness is also retrieved from the persons who witnessed the event. Due to the genetic predisposition of some types of seizures, a family history of and type of seizure activity must be obtained. The neurological exam is completed by the physician or a neurological specialist. Pseudoseizures (false) seizures are evaluated as neurological episodes until determined to be psychological or not pathological in nature and etiology.

critical nursing action Nursing Care for the Child Having a Seizure

1. Call for help. In a hospital, use the designated emergency number. In the community setting call 911.
2. Maintain a patent airway. If the airway is occluded, open the airway with a jaw thrust maneuver. Administer oxygen if needed and available. Do not put anything in the mouth. If the situation warrants emergency medical care, qualified health care personnel can insert an appropriate sized oral airway.
3. Loosen restrictive clothing to ensure adequate circulation to essential body organs.
4. Administer medications such as diazepam (Valium), lorazepam (Ativan), or fosphenytoin (Cerebyx) as ordered by the physician.
Do not do this with a neonate. These medications become toxic due to immature liver function.

5. Monitor respiratory status and circulatory status throughout the seizure.
6. If the child has a seizure (convulsion), the nurse positions the child in a lateral position to prevent aspiration (entry of secretions into tracheobronchial passages) (Fig. 29-5).
7. Inform the child that they have just had a seizure. Tell the family that the child may still be confused and disoriented for a short time.
8. Stay with the child. Support is essential because a seizure is frightening to both the child and family.
9. Document all important details about the seizure, care provided, and notification to physician, and condition of child after the seizure.

Airway management is the priority nursing intervention for the child experiencing a seizure. Oxygenation, supportive ventilation and removal of obstructing secretions or foreign bodies with proper body positioning to prevent injury are required for a successful outcome. The child who has experienced a seizure needs continuous monitoring of respiratory status because seizure medications that are administered intravenously during a seizure can cause a decreased level of consciousness, apnea, and hypotension. The seizure either arrests independently or after medication administration.

Anticonvulsant therapy is the mainstay for seizure management in children. Many medications are available and have varying therapeutic effects on the brain (Table 29-4). The correct medication must be selected to treat the specific electrical abnormality or clinical symptomatology. The child who has seizures may require daily medication such as fosphenytoin (Cerebyx) or phenytoin (Dilantin) to control the seizure activity and to prevent further seizures. During a seizure, intravenous medications such as diazepam (Valium) or lorazepam (Ativan) are administered to stop the seizure activity and to prevent respiratory compromise.

Phenobarbital (luminal sodium) may be given intravenously (usually a loading dose of 20 to 40 mg/kg given one time is ordered to treat status epilepticus followed by

Figure 29-5 When the seizure is over, place the child in the recovery position on the left lateral recumbent position.

Table 29-4 Seizure Medications

Type of Seizure	Medication	Dose Range	Adverse Reactions	Nursing Care
Partial Complex (Psychomotor)	Carbamazepine (Tegretol)	10–30 mg/kg per day in divided doses. Increase until best response is achieved.	Drowsiness, nausea, liver changes, increased appetite.	Give with food but not with milk.
	Valproic acid (Depakene)	0.1–0.2 mg/kg/day in two or three divided doses per day.	Confusion, ataxia, nystagmus, nausea, gingival hyperplasia, bleeding disorders.	Always give with food and monitor serum drug levels. Teach parents about oral hygiene and wear a medical alert tag. Teach parents to watch for adverse effects indicating toxicity.
	Phenytoin (Dilantin)	5 mg/kg per day in two to three divided doses.	May cause dizziness, drowsiness, or physical incoordination. Avoid abrupt discontinuation of use. Daily multivitamin is recommended while on this medication.	Give with water, juice or milk.
	Phenobarbital (Luminal)	Infants 5–6 mg/kg per day in one or two divided doses		
	Fosphenytoin (Cerebyx)	Children 1–6 years, 6–8 mg/kg per day in one or two divided doses. Loading dose of 10–20 mg/kg. Then 4–6 mg/kg per day.		
Generalized Tonic clonic	Valproic acid (Depakene) and carbamazepine (Tegretol). Phenytoin (Dilantin). Phenobarbital	May be an inexpensive medication.	Monitor for sleepiness, hyperactivity, drowsiness and school performance changes.	
	Ketogenic diet high in fat and low in protein and carbohydrates.	Causes a high level of ketones which decrease myoclonic or tonic-clonic seizure activity.	Nausea, vomiting, headache, drowsiness, dizziness	This diet is hard to maintain for a long period of time due to the lack of food variety and difficulty of food preparation and parental involvement.
Absence (Petit Mal)	Ethosuximide (Zarontin) or Valproic Acid	3–8 mg/kg per day		Avoid antacids.
Partial Simple	Topiramate (Topamax)	1–3 mg/kg per day	Weight loss, dizziness, diarrhea, cognitive dysfunction.	Avoid antidepressants and antacids.

a maintenance dosing regimen). However, the onset is less rapid and there may be cardiac arrhythmias associated with this medication

Many anticonvulsant medications can become toxic when taken on a daily basis. Baseline liver function, renal function, and hematological values should be assessed before initiation of pharmacotherapy and retained for future reference. Anticonvulsant drug serum levels are also monitored to maintain therapeutic levels. Children outgrow the dosage and begin having seizures due to lowered serum levels. Drug serum levels should be assessed every 3 to 6 months.

Nursing care also includes seizure precautions according to hospital protocol, which includes padded side rails or bed rails, oxygen, and suction equipment readily available, IV access, and anticonvulsant medications at the bedside according to physician prescription.

The hospitalized child should receive continuous cardiac, respiratory, and oxygen monitoring. Centrally located monitoring on the nursing unit for ease of observation in case of seizure activity is necessary. Baseline seizure activity for some children may be several seizures a day without compromise. The child must be continually monitored while an inpatient. Do not allow the child to bathe independently until the seizures have been arrested and controlled.

All caregivers of children with seizures should be instructed in CPR techniques. Medication information such as type of medication, dose, route, and frequency of dosing must be explained to the parents. The regimen must also be adhered to in the day care setting. The child should not be left alone until the seizures have been controlled and he or she is seizure free for several months. Adolescents may drive (depending on State Laws) and

participate in sports with therapeutic serum anticonvulsant drug levels and a seizure-free duration of at least 6 months.

School nurses and teachers should be informed about the child's seizure condition and follow institutional procedures if the child experiences a seizure in school or day care. Medical alert identification bracelets should be worn by younger children and may be worn by older children and adolescents.

Now Can You— Discuss seizures and related nursing care?

1. Identify the difference between tonic and clonic seizures.
2. Identify absence seizures from complex or partial seizures.
3. Identify the medications for the different types of seizures.
4. Identify the nursing care for a patient experiencing a seizure.

Inflammatory Neurological Conditions

MENINGITIS

Meningitis is an inflammation of the structures in the central nervous system caused by an infectious process. The meninges are composed of three membranes that cover the brain, protecting it from injury and infection: the dura mater, arachnoid mater, and pia mater. These structures house arterioles, venules, and cerebrospinal fluid to protect, bathe, and provide chemical functional support for the brain and its contents. Meningitis is either septic or aseptic. Septic or pyogenic meningitis is caused by a bacterial pathogen such as *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Escherichia coli*, or *Haemophilus influenzae* type B. Aseptic meningitis is caused by a known or unknown viral agent typically presenting at peak seasonal viral illness intervals in the fall and winter.

Meningitis can develop at any time during childhood. During the neonatal period, meningitis results from a pathogen transmitted during the labor and delivery process or while in utero. The most common types of neonatal meningococcal infections are caused by herpes simplex, Group B beta-hemolytic *Streptococcus*, and *E. coli*. In older infants and children, a peak incidence of *Streptococcus pneumoniae* is noted in the winter months. In summer months, bacterial organisms such as *Neisseria meningitidis* and non-bacterial agents such as rhinoviruses and adenoviruses are more prevalent. *Haemophilus influenzae* type B, once a deadly pathogen, has almost been eradicated now with scheduled routine childhood immunizations (Centers for Disease Control and Prevention [CDC], 2007).

Bacterial meningitis is the result of bacterial dissemination from a nasopharyngeal or a hematological inoculation. The pathogen migrates into the cerebrospinal fluid and imbeds in the subarachnoid space. The body reacts to the infiltration with a severe inflammatory response and white blood cell proliferation. Systemic septicemia, surgical procedures involving the central nervous system, a penetrating wound, otitis media, sinusitis, cellulitis of the scalp or facial structure, dental caries, pharyngitis, and orthopedic diseases and procedures are also antecedent events leading to bacterial meningitis.

SIGNS AND SYMPTOMS. A child with meningitis may initially appear to be mildly ill with general vague or

subtle symptoms such as lethargy, malaise, irritability, vomiting, fever, and diarrhea. If left unrecognized and untreated, meningitis may progress rapidly to a critical state depending on the age of the patient and the etiological pathogen. Younger infants and children succumb rapidly to meningitis and children with meningococemia, *H. influenzae* type B, and *E. coli* become quite toxic and deteriorate quickly if untreated.

Infants generally present with nuchal rigidity, a bulging fontanel, fever, and poor feeding. Other symptoms may include seizures, photophobia, anorexia, and emesis.

assessment tools Kernig's or Brudzinski Sign

Classic finding on examination for a child suspected of meningitis include a positive Kernig's or Brudzinski sign (Behrman, Kleigman, & Jenson, 2004). These exams indicate meningeal irritation resulting in hyperreactive reflexes (Fig. 29-6A). The test for Kernig's sign is conducted with the child lying supine with the hips flexed. As the nurse raises the lower leg to straighten the leg the child either cries out or resists the leg extension. If the child experiences pain behind the knee as the knee is fully extended, this is an abnormal finding. Bilateral increased resistance and pain upon extension of the knee is a positive Kernig sign and may indicate meningeal irritation.

Brudzinski's sign (Fig. 29-6B) is conducted with the child lying flat. The nurse attempts to raise the head toward the child's chest and place the chin on the chest. If there is pain or resistance, the child immediately flexes the hip and knee. If the child exhibits flexion of the hips and knees when the nurse performs the maneuver, meningeal inflammation may be present (Bickley & Szilagyi, 2003).

Nursing Insight— Viral or aseptic meningitis

The etiological pathogen in viral or aseptic meningitis is a viral agent. The most common pathogens are herpes and adenovirus; in most cases the etiologic agent is unknown. Some cases are the result of partially treated bacterial meningitis (Behrman et al., 2004). Clinically the child with viral meningitis presents with the same vague or subtle symptoms; however, the child does not become toxic or as acutely ill as the

Figure 29-6 Classic finding on examination for a child suspected of meningitis include a positive Kernig's or Brudzinski sign.

patient with bacterial meningitis. Diagnosis is based on CSF analysis, CSF gram stain, and culture; results are typically negative unless a viral agent is identified.

DIAGNOSIS. The nurse conducts a review of the current illness with specific information obtained regarding duration of symptoms, ill contacts in the family or school settings, seizures, loss of sleep or weight, anorexia, emesis, behavioral changes and immunization status. A complete blood count (CBC) reveals an elevated white blood cell (WBC) count and any clotting deficiencies. A disseminated intravascular coagulation (DIC) panel is collected to rule out a coagulation disorder when the child presents with petechial hemorrhage, shock, and meningococemia. Blood cultures are obtained to identify the potential hematological origin. A lumbar puncture is also performed for CSF analysis including chemistry and cell counts as well as culture and gram stain for bacterial or viral diagnosis. Meningitis is diagnosed based on the results of the lumbar puncture.

NURSING CARE. Essential nursing care includes assessing neurological status at least every 2 to 4 hours. The child's level of consciousness and the use of a pediatric Glasgow coma scale, pupil response, and overall activity provide clues to the child's neurological status (e.g., increase in ICP or response to antibiotic and fluid therapy). In small infants ICP can be subjectively monitored by palpating the anterior fontanel while the patient is lying supine. If the fontanel is tense and bulging, this may suggest increased ICP, particularly when combined with photophobia, irritability, a high-pitched cry, anorexia, and emesis. Infants with open fontanels and an enlarging head circumference during or post meningitis infection may indicate hydrocephalus and monitored. The child with an increasing head size and symptoms of increased ICP requires radiological evaluation such as a CT scan or MRI (Fig. 29-7). To prevent additional increased ICP the

Figure 29-7 The child with an increasing head size and symptoms of increased ICP requires radiological evaluation such as a CT scan.

child's room is kept quiet, dim, and without loud or noxious visual, auditory, or olfactory stimuli.

The onset of seizure activity associated with meningitis is managed medically and seizure precautions are maintained at all times. The child with meningitis may develop new-onset seizures and is treated with anticonvulsant therapy. The child is also kept NPO until nausea and vomiting has been resolved.

Comfort care includes a dim room, antipyretic therapy for fever management, nutrition as tolerated, and emotional and social support. Care for malaise with massage, nonsteroidal anti-inflammatory drugs (NSAIDs), warm baths, and rest.

Infections of the central nervous system can upset the family. The nurse can educate the family and the child about the disease and treatment options. The nurse also explains that long-term parenteral access may be maintained with a peripherally inserted central catheter (PICC) and intravenous antibiotics can be continued at home with the assistance of a home health nurse.

ENCEPHALITIS

Encephalitis is usually viral in origin and occurs with an acute febrile illness that is characterized by cerebral edema and infection of surrounding meninges. Less common etiologies are fungal, bacterial, and parasitic infections, exposure to toxins or drugs, and cancer (Wisniewski, 2003). The most common types of viral encephalitis are caused by arthropod-borne viruses (mosquito-borne), and the herpes simplex type I. Systemic viral illnesses such as rabies, mononucleosis, and poliomyelitis may also result in encephalitis. When obtaining a history and physical, the nurse must ask the parent about exposure to possible sources of encephalitis (McCance & Huether, 2002).

All types of encephalitides cause meningeal involvement. Widespread nerve cell degeneration is caused by arthropod-borne viral encephalitides. Acute viral encephalitis is the result of direct viral infection of the neural cells accompanied by associated perivascular inflammation and destruction of brain gray matter.

SIGNS AND SYMPTOMS. The symptoms experienced by children vary from mild to life-threatening. The severity of the illness depends on the child's age, immune system stability, underlying cause, and duration of illness. The child who has a compromised immune system is at greater risk. Primary encephalitis occurs when a toxin or pathogen directly attacks the spinal cord and brain. The most common causes of primary encephalitis are mosquito-borne viruses and herpes simplex. Secondary encephalitis is the result of an immune response to a foreign object or toxin within the body or an infection in another part of the body. Depending on the source of the encephalitis and the severity of the illness, signs and symptoms of the virus develop within hours to weeks after exposure. Encephalitis caused by bacteria usually results in a more serious illness state.

Signs and symptoms of encephalitis include disorientation, confusion, headache, high fever, photophobia, lethargy, aphasia, hallucinations, seizures, nuchal rigidity, and coma (Wisniewski, 2003).

Nursing Care Plan The Child with Meningitis

Nursing Diagnosis: Decreased Intracranial Adaptive Capacity related to inflammatory process secondary to microbial invasion of the central nervous system

Measurable Short-term Goal: The child will not experience complications from increased intracranial pressure (ICP).

Measurable Long-term Goal: The child will recover completely with no residual neurological deficits.

NOC Outcomes:

- Neurological Status: Autonomic (0910) Ability of the autonomic nervous system to coordinate visceral and homeostatic function
- Tissue Perfusion: Cerebral (0406) Adequacy of blood flow through the cerebral vasculature to maintain brain function

NIC Interventions:

- Intravenous Therapy (4200)
- Neurologic Monitoring (2620)
- Cerebral Edema Management (2540)
- Seizure Precautions (2690)

Nursing Interventions:

1. Implement universal precautions. Initiate respiratory isolation for first 24 hours of antibiotic administration for bacterial meningitis (specify). Instruct family in correct procedures.

RATIONALE: Universal precautions help prevent transmission of infection. Respiratory isolation prevents droplet transmission of bacteria to family and caregivers until the prescribed antibiotic has been implemented for 24 hours.

2. Initiate and maintain intravenous access (specify fluids and rate) as ordered. Monitor hourly intake and output, notifying the caregiver if urine output is less than 0.5–1 mL/kg per hour.

RATIONALE: Intravenous access is required for optimal medication administration; fluids promote adequate hydration; decreased output may signal impending syndrome of inappropriate antidiuretic hormone (SIADH).

3. Administer prescribed IV antibiotic, antiviral, steroid, and antipyretic medications as prescribed (specify drug, dose, route, and times).

RATIONALE: Antimicrobial medications should be administered as soon as possible. Drugs that are specific for the cultured microorganism will be most effective in combating infection. Steroids reduce cerebral edema, decreasing meningeal irritation to help prevent complications such as hearing loss, hydrocephalus, and learning disorders.

4. Monitor vital signs every 1–4 hours (specify, depending on severity of symptoms). Place on cardiac monitor as indicated (specify).

RATIONALE: Changes in vital signs such as tachycardia, tachypnea, and hypotension signal increasing intracranial pressure and possible septicemia.

5. Monitor neurological status and symptoms closely; compare with baseline for child.

RATIONALE: Decreased consciousness and changes in reflexes may signal increasing ICP.

6. Maintain the child in a quiet darkened environment with padded side rails up when in bed.

RATIONALE: Promotes comfort by reducing noise, light, and activity. Padded side rails may help prevent injury in the event of seizure activity.

DIAGNOSIS. The clinical symptoms of encephalitis mimic those of other neurological disorders. When obtaining a history and physical, the nurse assesses the child's skin for any lesions that might be vector bites. The nurse asks the child and family about possible exposure to mosquitoes, bats, or other sources of encephalitis. The family needs to be questioned about outdoor play, camping trips, unvaccinated pets, wild animals, medication, and recent illnesses. MRI or CT may be used to determine any cerebral edema, shifts within the brain, or focal lesions. The healthcare provider may also order cerebral fluid analysis, an electroencephalogram, and lab work. Brain biopsy is the test for a definitive diagnosis (Wisniewski, 2003).

Across Care Settings: Complications from encephalitis

The complications resulting from encephalitis may include motor or cognitive deficits, seizure disorders, hearing or vision loss, memory loss, and paralysis (Wisniewski, 2003). If a child has permanent or lingering problems, the treatment plan for them may be multidisciplinary. This multidisciplinary approach optimizes the child's recovery and maximizes skills necessary for life.

NURSING CARE. Treatment for encephalitis is determined by the etiology. Viral encephalitis is treated with an antiviral medication such as acyclovir (Zovirax) (McCance & Huether, 2002). Encephalitis of a bacterial origin is treated with a narrow-spectrum antibiotic. Other medications that may be prescribed are antipyretics, anticonvulsants, analgesics, and anti-inflammatory agents (Wisniewski, 2003).

The nurse must be astute when caring for a child with encephalitis because of the rapid neurological changes that may occur with the illness. The nurse provides care and support for the child and the family during the acute and convalescent phases of the disease process. During the acute phase of the disease, the nurse administers intravenous fluids, medications, and nutrition. Seizure precautions must be initiated because of cerebral edema and increased ICP. To decrease ICP, the nurse performs interventions such as ongoing neurological assessments, ensuring the child is afebrile and seizure free, maintaining homodynamic stability, and positioning the child to avoid neck vein compression. The nurse also carefully monitors the child's fluid and electrolyte balance and watches for syndrome of inappropriate antidiuretic hormone (SIADH) (Wisniewski, 2003). Suctioning and percussion are not recommended unless the child has a current respiratory condition.

Across Care Settings: Community education about DEET (N, N-diethyl-m-toluamide)

The nurse can educate others in the community about DEET. "Insect repellents containing DEET (*N,N*-diethyl-*m*-toluamide, also known as *N,N*-diethyl-3-methylbenzamide) with a concentration of 10% appear to be as safe as products with a concentration of 30% when used according to the directions on the product labels." The American Academy of Pediatrics recommends that repellents with DEET should not be used on infants younger than 2 months old. (American Academy of Pediatrics: http://www.bt.cdc.gov/cdclinkdisclaimer.asp?a_gotolink=http://www.aap.org/family/wnv-jun03.htm)

BRAIN ABSCESS

A brain abscess is an uncommon but life-threatening infection that occurs when infectious material collects in brain tissue. Brain abscesses affect more males in the first 2 decades of life and comprise approximately 1% of all space-occupying lesions in the United States (Bader & Littlejohns, 2004). Brain abscess may result from an infection of contiguous structures (e.g., otitis media, dental infection, mastoiditis, and sinusitis), after penetrating head trauma or surgery, hematogenous spread from a distal location (endoscopy, lung infections), and after meningitis. The child with congenital cyanotic heart disease is more predisposed to developing a brain abscess because he or she has frequent and recurrent episodes of otitis media and sinusitis (Brook, 2004).

The infection can enter the brain by several routes, such as necrotic areas of bone, if sinusitis is present. If a child has otitis media, the infection can enter directly through the ear. Trauma causing an open fracture of the skull may also result in an abscess. Infection in another

Labs: Brain Abscess

Serum laboratory studies, including complete blood count, blood cultures, and C-reactive protein, may be ordered. With a brain abscess, the child usually demonstrates moderate leukocytosis, and an elevated erythrocyte rate and C-reactive protein level. If the abscess is aspirated, the specimen should be cultured to identify the causative microorganism (Brook, 2004).

part of the body can travel through the vascular system to the brain and result in an abscess (Brook, 2004).

SIGNS AND SYMPTOMS. The signs and symptoms exhibited by a child with a brain abscess may be minor or life-threatening. Symptoms may occur for up to 2 weeks before a definitive diagnosis is made. The signs and symptoms include a localized headache, fever, drowsiness, stupor, confusion, general or focal seizures, focal motor or sensory impairments, ataxia, nausea and vomiting, papilledema, and hemiparesis. General seizures and mental changes can also occur. A brain abscess may present as encephalitis accompanied by symptoms of increased ICP. If a brain abscess ruptures, meningitis can occur (Brook, 2004). Residual deficits including hydrocephalus may exist after a rupture.

DIAGNOSIS. Diagnosis is made based on the clinical presentation and MRI or CT. The MRI differentiates between an abscess, tumor, and stroke.

NURSING CARE. Nursing care focuses on assessment of the neurological status, response to treatment, medication administration, and supportive care. The nurse continually monitors the neurological status to identify any changes in ICP that may require more aggressive intervention and documents the child's condition.

The nurse monitors serum labs, especially blood glucose and potassium levels, because of the effects that corticosteroid therapy has on body systems. Based on the laboratory results, the nurse may need to administer insulin or electrolytes (Smeltzer, 2008). The course of the medical treatment may be short or long, depending on the causative agent, area of brain affected, and size of the abscess. Most brain abscesses require a lengthy course of antimicrobial therapy (4 to 8 weeks) because the brain tissue takes time to heal (Brook, 2004) (Table 29-5).

If the child does not respond to antimicrobial therapy or does not meet the criteria for medical therapy alone, surgery may be required. The abscess can either be aspirated or excised (Brook, 2004). If surgery is performed, the nurse must assess the child postoperatively for possible neurological complications such as meningitis or cerebral edema. The child's safety becomes a priority so the nurse must implement fall and seizure precautions (Smeltzer, Bare, Hinkle, & Cheever, 2008).

REYE SYNDROME

For many years, childhood illnesses and discomforts were managed with the administration of aspirin (acetylsalicylic acid). Acetylsalicylic acid is a component found in many over-the-counter medications to relieve fever, muscle aches, and nausea (Table 29-6). Reye syndrome was first identified in 1963 and reached a peak in the 1970s

Table 29-5 Antimicrobial Therapy Used in Brain Abscesses

Cause of Brain Abscess	Therapy
Meningitis	Neonates: Cefotaxime + ampicillin Infants and children: Ceftriaxone or cefotaxime + vancomycin
Cyanotic congenital heart disease	Ampicillin + chloramphenicol, or ceftriaxone + metronidazole, or ampicillin-sulbactam
Otitis or sinusitis	Ampicillin + chloramphenicol, or ceftriaxone + metronidazole, or ampicillin-sulbactam
Ventriculoperitoneal shunt or trauma	Vancomycin + antipseudomonal

and early 1980s. The syndrome can affect persons of all ages but it usually affects children. Reye syndrome is primarily associated with the administration of aspirin during viral illnesses (Bhutta, Savell, & Schexnayder, 2003). A decline in the incidence of Reye syndrome has been evident in the recent past, primarily due to the decreased administration of acetylsalicylic acid and parental education about the disease.

Reye syndrome affects all organs of a child's body but causes the most damage to the brain and liver. The brain is affected by an increase in ICP and other organs are affected by an accumulation of fat. The disorder is considered to be a two-phase illness because it usually occurs in conjunction with a viral infection, especially varicella (chickenpox) or influenza (flu). The child develops the disorder during the recovery phase of the viral infection. Reye syndrome may be misdiagnosed because the symptoms mimic those of other neurological illnesses such as meningitis, encephalitis, diabetes, poisoning, drug overdose, and sudden infant death syndrome.

SIGNS AND SYMPTOMS. The signs and symptoms of the illness are a result of hyperammonemia, hypoglycemia

Table 29-6 Medications Containing Acetylsalicylic Acid

Nonprescription Products	Prescription Products
Alka-Seltzer	Darvon
Excedrin	Norgesic
Pepto-Bismol	Robaxisal
Anacin	Talwin
Kaopectate	Butalbital
BC	Percodan
Pamprin	Roxiprin
	Lortab
	Propoxyphene
	Soma

and an increase in short-chain fatty acids found in the serum after the liver becomes involved. The liver has diffuse deposits of lipids with an absence of necrosis or inflammatory reaction. Azotemia also (excess urea in the serum) occurs as a result of fatty degeneration of the kidneys (McCance & Huether, 2002).

There are several stages of Reye syndrome. The child may progress through all of the stages or stop at any stage if treatment is effective (McCance & Huether, 2002).

Nursing Insight— The stages of Reye syndrome

- Stage I: Lethargy, vomiting, drowsiness, liver dysfunction
- Stage II: Disorientation, combativeness, aggressiveness, delirium, hyperactive reflexes, hyperventilation, shallow breathing, stupor, liver dysfunction
- Stage III: Obtundation, coma, decorticate posturing, hyperventilation
- Stage IV: Deepening coma, large fixed pupils, decerebrate posturing, loss of ocular reflexes, liver dysfunction
- Stage V: Loss of deep tendon reflexes, seizures, flaccidity, respiratory arrest, usually no liver dysfunction

DIAGNOSIS. Because a number of inherited metabolic diseases present with many of the same symptoms as Reye syndrome, these illnesses need to be excluded before a diagnosis of Reye syndrome can be made. When obtaining a history and physical, the nurse must ask about recent viral illnesses and the use of any medications containing acetylsalicylic acid. The nurse performs a complete neurological assessment. A definitive diagnosis of this syndrome is established with a liver biopsy obtained during the illness or at autopsy. Other diagnostic tests that may be ordered are serum tests including liver enzymes, blood glucose, ammonia level, coagulation studies, and others to exclude metabolic inherited disorders. The child may have a lumbar puncture to rule out infections, including meningitis and encephalitis.

If a liver biopsy is to be performed, the nurse prepares the child and family by explaining that the child may be given a sedative to help calm him or her. If the child is old enough, the nurse can allow the child to practice the position that is needed for the procedure (lying on the back with the right hand under the head). The nurse tells the family that during the procedure an ultrasound is used to guide the needle. The child will have a small incision where the biopsy needle was inserted and a bandage over the insertion site.

critical nursing action Liver Biopsy

After a liver biopsy, the nurse must monitor for bleeding. The child is predisposed to bleeding after the procedure because the liver is highly vascular and Reye syndrome causes hepatomegaly and liver dysfunction. After the biopsy, the physician places a dressing to splint the puncture site and positions the child to lie on the right side for 2 hours (Lewis, Heitkemper, Dirksen, O'Brien, & Bucher, 2007).

The anticipated results of a liver biopsy would include elevated liver enzymes (aspartate aminotransferase and

alanine aminotransferase), low blood glucose, elevated serum creatinine and blood urea nitrogen, prolonged prothrombin and partial thromboplastin times, and elevated serum ammonia.

NURSING CARE. Reye syndrome is an illness that progresses quickly and may not have a favorable outcome. The nurse performs astute neurological assessments because of the high incidence of increased ICP and brain injury. The child's level of consciousness, seizure activity, and reflex function are assessed to determine the stage of the illness. To reduce the risk of increased ICP, the nurse carefully administers intravenous fluids. The intravenous fluids may include glucose to correct hypoglycemia and potassium, chloride, and sodium to correct electrolyte imbalances. Corticosteroids may be prescribed to decrease cerebral edema and inflammation, and insulin may be administered to increase glucose metabolism. Diuretics may be prescribed to enhance fluid elimination, resulting in decreased ICP. If the child is experiencing respiratory difficulty, the nurse monitors the oxygen saturation concentration with the use of pulse oximetry. Supplemental oxygen may be administered via nasal cannula. If the child's condition worsens, the child may need intubation and mechanical ventilation. The health care provider may insert an arterial line to monitor blood pressure and obtain arterial blood gases. The nurse then assesses the insertion site for complications of infection and leaking. The nurse initiates seizure precautions if the child demonstrates signs of increased ICP. Invasive procedures are limited and handled carefully because of the risk of bleeding due to liver involvement. Emotional support is provided to the child and parents.

Across Care Settings: Reye syndrome

The child may have residual physical and psychological conditions because of brain injury. The nurse can provide information about resources available to support survivors and their caregivers. These resources include Crippled Children's Services, child developmental clinics, State Developmental Disabilities Agencies, local school systems, and health departments. Caregivers should familiarize themselves with legal acts that protect patient's rights including Equal Opportunities for Individuals with Disabilities Act, Americans with Disabilities Act of 1990, Title 42, Chapter 126, Sec. 12101-12213 (National Reye Syndrome Foundation, 2008).

“What to say” — Can I give my child aspirin?

If a parent asks, “Can I give my child aspirin?” The nurse should respond:

“No product containing acetylsalicylic acid should be given to any person younger than 19 years of age because of the risk of Reye syndrome.”

GUILLAIN-BARRÉ SYNDROME

Guillain-Barré syndrome (GBS) is a rare self-limiting disease characterized by clinical manifestations of ascending muscle weakness or paralysis. GBS is a rare and potentially

debilitating self-limiting autoimmune disease. If it is effectively and supportively managed, full recovery can be anticipated.

GBS is the most common form of acquired acute paralysis in children. Loss of function can range from fatigue and lethargy to complete paralysis of the lower limbs extending upward and affecting upper motor and sensory neuron pathways.

The incidence of GBS is about 0.5 to 1 cases per 100,000 children younger than 18 years of age. School-age children are most susceptible and more males than females are affected (Sladky, 2004). The syndrome is an acute autoimmune inflammatory response resulting in one of two subtypes: acute inflammatory demyelinating neuropathy (AIDP), causing transient ascending paralysis of both sensory and motor neuropathy (Hughes & Cornblath, 2005), or acute motor axonal neuropathy (AMAN), or a combination of the two subtypes (Lu et al., 2000). The child loses motor function and in some cases sensation in peripheral, spinal, sensory, and motor neurons. Infrequently cranial nerve function is also involved (Sladky, 2004).

The exact cause of GBS is unknown. The syndrome may follow an antecedent gastrointestinal or respiratory illness. Commonly occurring etiologic pathogens are *Mycoplasma pneumoniae*, the Epstein-Barr virus, cytomegalovirus, *Varicella*, and *Campylobacter jejuni*. Inflammatory mediators penetrate the Schwann cells in the nerve axons, causing demyelination (removal of the myelin sheath of nerve tissue) and denuding (loss of nerve covering) of the neuronal pathways, resulting in decreased conduction of sensory and motor peripheral and spinal pathways. Areas of nerve involvement are assessed and monitored as nerve function and sensation is blocked or slowed. Some cases of GBS have been linked to several vaccines such as meningococcal, influenza, swine vaccine, and rabies vaccine, but the evidence is weak and anecdotal (Aschenbrenner, 2006; Schessl, Luther, Kirshner, Mauff, & Korinthenberg, 2004).

SIGNS AND SYMPTOMS. The initial diagnosis of GBS may be missed owing to the wide variety of presenting signs and symptoms that can be attributed to other disease causes. GBS becomes clinically apparent as the child progresses through three phases. Each phase is marked by a leveling of symptoms. The acute phase is preceded by a febrile viral illness, ataxia, lethargy, motor and sensory nerve weakness, and pain in the lower extremities that continues to progress up the body starting in the lower extremities. This phase may take several days or weeks and seems to plateau at around 2 to 3 weeks. During this time, the level of functional and sensory loss may necessitate ventilatory and or oxygen support if respiratory function is compromised. The second phase is the plateau phase, which is characterized by arrested progression in the degree of involvement or loss of sensation and function. This phase has no specific duration and lasts for varying intervals. The recovery phase begins with the return of motor and sensory function. The degree of disability is assessed and rehabilitation services are begun. Physical and occupational therapy are necessary to aid the child's return to normal function; recovery occurs over time, most cases resolving in 4 to 8 weeks.

DIAGNOSIS. Diagnosis of GBS is based on clinical and laboratory procedures. The child presents with muscle

weakness, sensory disturbances, loss of deep tendon reflex responses, and muscle paralysis. Elevated CSF protein levels in the absence of infection support the clinical diagnosis. Sensory and motor nerve conduction studies such as electromyography (EMG) define the subtype classification and degree of inflammatory involvement; results will demonstrate blocked impulses or conduction slowing along the peripheral motor and sensory nerve endings (Sladky, 2004).

NURSING CARE. Supportive measures are the hallmark of care for the patient with GBS. Plasma exchange and intravenous immunoglobulin therapies shorten the disease duration, support the recovery phase, and reduce the duration of disability. Corticosteroid use may be initiated to slow the inflammatory response. The use of high-dose steroid therapy alone remains poorly established as single regimen therapy for GBS in children (Kuwabara, 2004; van Doorn, 2005).

Vigilant clinical monitoring related to the progression of motor, sensory, and functional losses, as well as the degree of respiratory compromise are the priority nursing assessments. As GBS progresses, the nurse monitors pulse oximetry, respiratory function, ease of breathing, and lung sounds for potential atelectasis leading to pneumonia. Respiratory support is provided with intermittent positive pressure breathing, cough assist, and incentive spirometry. Frequent repositioning is also required every 2 hours. To maintain urinary output it may be necessary to use an indwelling urinary catheter or intermittent clean catheterization. Parenteral or enteral nutrition is maintained if the child is unable to meet nutritional intake needs or is experiencing dysphagia.

The nurse must assess the pain level in the child. GBS is painful and requires opioid analgesia that is administered on a scheduled basis to treat the severe neuralgia. Children with GBS may underreport the pain associated with the neuritis and expect the nurse to understand their discomfort. The nurse must have a high index of suspicion and proactively manage the pain in GBS.

Immobilization and loss of function can lead to muscular contracture and loss of function after the inflammation has subsided. Passive range-of-motion exercises, frequent position changes, and hand and foot orthotics or splints may be used temporarily to preserve function and prevent contractures. Skin integrity over bony prominences or pressure areas must be monitored and managed aggressively with padding, massaging, close inspection, and frequent repositioning. Age-appropriate developmental activities are provided daily as the child is able. Offer visual and auditory stimulation frequently to meet the child's cognitive, social, and emotional needs. School work, crafts, and books provide respite from the boredom and may prevent behavioral and emotional disorders related to the debilitation and limitations of the disease.

nursing diagnoses Guillain-Barré syndrome

- Ineffective Breathing Patterns related to ascending loss of nerve function
- High Risk for Alteration in Airway Clearance related to muscle weakness and/or paralysis
- Alterations in Comfort related to neuralgia
- Social Isolation related to debilitation and limitations imposed by the child's disease
- Powerlessness related to loss of function and sensation

Developmental Neurological Conditions

SPINA BIFIDA

Neural tube defects (NTDs) are a group of birth defects in which malformations of the brain and spinal cord occur and the structures lack protection of soft tissue and bone. NTDs develop when the neural tube fails to close during fetal development. Usually, the nerves below the defect are impaired, although some sparing of nerves with subsequent partial functioning may occur (Brown, 2001).

Spina bifida is the most frequently occurring and permanently disabling birth defect in the United States. No two people affected by this disorder are alike. It accounts for approximately two-thirds of all NTDs. Spina bifida is derived from the Latin words that mean “cloven backbone.” It is a congenital spinal deformity occurring early during gestation (18 to 28 days). The etiology of the disorder can be multifaceted, including environmental and genetic risks. Environmental predisposing factors include exposure to prolonged hyperthermia, diabetes mellitus, and the consumption of seizure medications during early pregnancy. Poor nutrition is an environmental risk factor. Presumptive genetic predisposing factors include hereditary defects in not only the absorption of folic acid but also in its utilization. Usually, the nerves below the defect are impaired, although some sparing of nerves with subsequent partial functioning may occur (Brown, 2001).

SIGNS AND SYMPTOMS. The signs and symptoms demonstrated by children with spina bifida vary depending on the level of the lesion and the type of defect. Spina bifida occulta is the least severe form of spina bifida. There is a localized defect of the vertebral arch and no spinal cord or meningeal involvement. A dimple or tuft of hair may be seen on the infant's back. If the child has a **meningocele**, a protruding sac is located on the cervical, thoracic, or lumbar spine at the level of the defect and a thin layer of muscle and skin usually covers the lesion. Meninges (membranes) protrude through the defect in the spine but no involvement of neural elements is present. Neurological functioning is usually not affected.

A myelomeningocele is the most severe form of spina bifida and is evident on delivery. The meninges protrude through the defect and the meninges contain spinal cord elements. It appears as a very pronounced skin defect usually covered by a transparent membrane and may even have neural tissue attached to the inner surface. The higher the defect is located on the spine, the greater the loss of spinal cord function because usually no neurological function is found below the defect. The bony prominences of the unfused neural arches can be felt at the defect's lateral border. When the child is born, the membrane covering the defect may be intact or may leak CSF. If the membrane is not intact, the risk for infection and neuronal damage is increased. Until the defect is surgically closed, CSF may accumulate, which results in further dilation and enlargement of the sac and further neuronal damage may occur. The involvement of the spinal cord has greater implications for the function of the child during childhood.

DIAGNOSIS. After 12 to 14 weeks of pregnancy, prenatal diagnosis can be made if the defect is visible through ultrasound examination. During pregnancy, maternal

serum testing of alpha-fetoprotein is performed to determine the presence of a neural tube defect. An elevated alpha-fetoprotein level may be indicative of a neural tube defect because open neural defects leak this substance into surrounding amniotic fluid, and a small portion is absorbed into the mother's blood. On delivery, the defect is usually visible, and a diagnosis is made. The defect is examined to determine the type and severity of the defect, and contents of the sac are assessed for meninges, CSF, and spinal cord. An MRI or a CT scan identifies the neurological structures contained in the sac.

NURSING CARE. On delivery, the nurse assesses the defect for the type of contents in the sac and measures the defect. A priority nursing concern is prevention of injury and infection of the sac. The nurse assesses the sac for indications of infection including redness, purulent drainage, bleeding, and necrosis. If the sac ruptures and leaks CSF, the patient is at risk of developing meningitis.

critical nursing action Preventing Injury of the Sac

As quickly as possible and using sterile technique, the nurse covers the defect with a sterile nonadherent dressing moistened with sterile saline to maintain moisture and to prevent drying. The dressing is changed every 2 to 4 hours as prescribed and when soiled.

The nurse positions the newborn in a prone position and does not place a diaper over the defect in order to prevent pressure on the sac, rupture, and infection of the sac. A laminectomy (the excision of a vertebral posterior arch, usually to remove a lesion or herniated disk) and closure of the defect is performed as soon after birth as possible to preserve the neurological function present, prevent infection or rupture, improve the appearance, and allow easier handling of the baby (Venes, 2009). Intravenous antibiotics are administered to prevent infection preoperatively and postoperatively.

The nurse evaluates the orthopedic function of the newborn. A low thoracic lesion may cause total flaccid paralysis of the lower body. A small sacral lesion may cause only patchy areas of decreased sensation in the feet. Movement or lack of movement of the extremities is assessed and documented. The child may have contractures of the hips, knees, and ankles, and the hips may be dislocated. The nurse prevents joint contractures or prevents further joint contractures by performing passive range-of-motion exercises but does not perform range-of-motion exercises of the hips because hip displacement is common. Clubfeet are a common orthopedic complication of spina bifida because the fetus cannot move the lower extremities in utero. As the child gets older, locomotion may be facilitated with the use of braces, wheelchairs, and walkers.

The bladder and bowel function of children with spina bifida may be affected to varying degrees. During the neonatal period, the nurse assesses the voiding and defecation patterns of the newborn. The newborn who constantly dribbles urine may have a neurogenic bladder and may experience urinary retention and overflow with a risk of urinary tract infections. A newborn who voids at spaced

intervals may be able to achieve some level of urinary continence later in life because there is some innervation of the bladder. Anticholinergics may be administered to improve urinary continence and antispasmodics to control bladder spasms.

Constipation and impaction are a common complaint associated with spina bifida. The child's diet needs to include fiber and fluid. If constipation occurs, stool softeners and laxatives may be administered. A child with spina bifida may not be able to feel the urge to defecate and bowel incontinence may result. The child may need to wear diapers, and as he or she gets older, psychosocial disturbances including depression, embarrassment, and shame may be experienced. If adequate innervation of the bowel exists, bowel training may be attempted.

critical nursing action Do Not Obtain a Rectal Temperature

Do not obtain a rectal temperature of a child with spina bifida because rectal irritation and rectal prolapse may occur.

Preserving skin integrity is an important nursing responsibility. Preoperatively, the nurse ensures no pressure is placed on the vulnerable defect. Postoperatively, the surgical incision is protected by not applying pressure on the area. Perineal irritation and skin breakdown may occur if incontinence is a problem. The nurse checks the perineum for stool and urine and changes the diaper as needed. The patient who is in a wheelchair for the majority of the day is prone to skin breakdown of the coccyx due to pressure. Areas where orthopedic devices apply pressure need to be padded well and assessed frequently.

The child with spina bifida is at risk for neurological complications, including meningitis because of the possibility of infection of the CSF and meninges and hydrocephalus because an obstruction to CSF absorption may occur. Early signs of infection include irritability, elevated temperature, and lethargy. Antibiotics are administered postoperatively to prevent or treat infection. The infant's vital signs and neurological function are monitored closely to identify changes that may indicate infection. The nurse performs dressing changes using sterile technique and assesses the surgical site for redness, purulent drainage, and odor. The site is assessed for CSF leakage.

Because hydrocephalus may develop after surgical repair, the nurse measures the infant's head circumference as prescribed. The nurse assesses the fontanels for bulging and cranial sutures for separation. The infant is maintained in a position that does not place pressure on the surgical site. The nurse provides postoperative pain management because when the infant cries, ICP increases. Pain management must be administered carefully so neurological impairment does not occur.

Spina bifida may be prevented by controlling environmental factors which increase the risk of a woman having a child with the disorder. It is imperative the pregnant women receive education on these risk factors. Women who are pregnant should decrease exposure to hyperther-

where research and practice meet: Latex Allergy

Research has shown that 18%–73% of people with spina bifida demonstrate sensitivity to latex. The proposed theory is that these individuals become sensitized after repeated exposure to latex early in life. Nurses caring for children with spina bifida should provide a latex-free environment.

Referrals can be made so that families can obtain information regarding latex allergy. Organizations include Spina Bifida Association of America, Allergy to Latex Education and Resource Team and Education for Latex Allergy/Support Team & Information Coalition (National Association of Neonatal Nurses, 2003).

mia (e.g., saunas, hot tubs). A pregnant patient with diabetes mellitus must be closely monitored. The patient must understand the importance of maintaining blood glucose levels within a normal range by adherence to an appropriate diet, exercise regimen, and medication therapy. Some antiseizure medications may result in spina bifida. A woman receiving these medications needs to notify the physician immediately if she becomes pregnant so the medication therapy can be altered. Every woman of childbearing age should ingest 400 mcg of folic acid per day to prevent neural tube birth defects. Sources of folic acid include green leafy vegetables, liver, legumes, orange juice, fortified breakfast cereals, and multivitamins.

HYDROCEPHALUS

Hydrocephalus occurs in approximately 1 to 2 of every 1000 live births. The term hydrocephalus is derived from the Greek, *hydor* (water) and *kephale* (head). Many functions are served by the CSF, including buffering of the brain, helping maintain normal chemical balances, and assisting in the maintenance of the very important blood-brain barrier (Chiafery, 2006).

CSF is formed and secreted by the choroid plexus (the ventricle's highly vascular lining). Newborns produce approximately 25 mL of CSF per day and children produce between 25 and 500 mL per day (Greenberg, 2001). After it is secreted, the CSF circulates through the intracranial vault and the spinal cord. With hydrocephaly, there is an increase of CSF production, an impedance to CSF absorption, or an obstruction of flow. As the fluid volume increases in the ventricles, pressure increases within the intracranial vault.

Congenital anomalies, including Chiari I and II malformations, Dandy–Walker malformation, and aqueductal stenosis, are the most common causes of hydrocephaly during the neonatal and early infancy periods. Acquired hydrocephaly occurs after birth and in infancy, usually resulting from intraventricular hemorrhage due to prematurity (Greenberg, 2001). Other causes of acquired hydrocephaly include tumors, head injury, bleeding, and infections.

There are two categories of hydrocephalus. Communicating hydrocephalus occurs when there is full communication between the subarachnoid space and ventricles. The causes of communicating hydrocephalus are defective absorption of CSF (most often), overproduction of CSF

(rarely), and venous drainage insufficiency (occasionally). Noncommunicating hydrocephalus occurs when CSF flow within the ventricular system or the ventricular outlets to the arachnoid space is prevented. Noncommunicating hydrocephalus occurs when there is obstruction of the flow of CSF (extraventricular or intraventricular) and includes tumors, anatomic malformations, or cerebral edema. Most cases of hydrocephalus are obstructive.

SIGNS AND SYMPTOMS. The signs and symptoms of hydrocephalus vary based on the child's age and cause and rate of hydrocephalus development. The child may demonstrate signs and symptoms of increased ICP, if the disorder is severe enough. On tapping of the skull, a resonant sound termed Macewen's sign or "cracked pot" sound is heard after cranial suture separation occurs. The infant may have difficulty holding the head upright. The face and cranial vault may be disproportionate and an unusually prominent forehead may be present. Dramatic head growth and enlargement, optic chiasm, and compression of optic nerves occur in untreated hydrocephalus (McCance & Huether, 2002).

DIAGNOSIS. Congenital hydrocephalus can be diagnosed with ultrasound during a prenatal examination or discovered during infancy or even early childhood. Hydrocephalus may be suggested by symptoms exhibited by the patient such as increasing head circumference inconsistent with normal growth.

diagnostic tools Hydrocephalus

The primary means of diagnosis is through imaging studies (CT, MRI, ultrasound), which usually reveal enlargement of ventricles. A cisternogram (radiographic evaluation) may be used to evaluate CSF flow dynamics in the child's brain and spinal cord. During the procedure, dye is injected into the subarachnoid area around the brain. Once the dye has circulated through the CSF path, a series of pictures is taken. The procedure is performed to reveal CSF concentration, leakage, obstruction, and pressure.

Lumbar puncture may be used to examine CSF and measure pressure. The nurse may perform transillumination to show abnormalities of the various areas of the child's head. Thinning or separation of the bones of the skull may be identified with radiographs of the skull. An ultrasound of the brain possibly may show ventricular dilation, hydrocephalus, or intraventricular bleeding.

Nursing Insight—Ventricular shunts

A shunt may be placed in a child to drain excessive intracranial CSF. Ventricular shunts have greatly improved the quality of life for children with hydrocephalus. A ventricular shunt consists of several parts including a proximal catheter that enters the lateral ventricle, a one-way valve that is set at a desired pressure to prevent CSF being drained too fast due to gravity, a small reservoir, and a distal catheter that terminates in the peritoneal cavity or alternate drainage site. The peritoneal cavity is the preferred site for placement of the distal catheter because of easy accessibility and decreased risk of complications. When the catheter is placed in the peritoneum, the shunt is called a ventriculoperitoneal shunt (Fig. 29-8).

Figure 29-8 A child may have a shunt placed to drain excessive intracranial CSF.

NURSING CARE. It is important for the nurse to understand the function of shunts and nursing care of the child with a shunt. Other sites for shunt placement other than the head are the right atrium of the heart and the pleural space of the lungs. The alternate sites pose the risks of pleural effusion, emboli, pneumothorax, respiratory distress, and endocarditis. The child with a shunt is at risk for complications related to surgery to place the shunt and the shunt itself. Complications related to shunts and shunt placement include infection, abdominal complications (i.e., bowel perforation, abscesses, and ileus), and shunt failure (Chiafery, 2006). The child may also be at risk for meningitis and encephalitis postoperatively because the shunt is placed in the ventricles of the brain and any introduction of infectious agents causes a potentially life-threatening illness. Infective complications occur in approximately 5% to 10% of shunt operations. Most shunt infections occur within the first 3 months after the surgical procedure and are more frequent in children younger than 6 months of age (Spyros, 2004). Common signs and symptoms demonstrated by a child with a shunt infection include decreased LOC, irritability, increased ICP, seizures, poor feeding, and an alteration in vital signs. Antibiotic-impregnated catheters are available and can be used for patients at high risk for infection and those who have had prior shunt infections (Chiafery, 2006).

Another complication of shunts is overdrainage. The child complains of postural headaches when sitting up, but the headache resolves when lying down. On rare occasions, a subdural hematoma develops when there is rapid decompression of the ventricles. If drainage of CSF occurs too quickly, intracranial bleeding may occur because the brain shifts into the area occupied by the ventricles (McLone, 2001).

A frequent complication is shunt malfunction (e.g., kinking, blockage, infection, and incorrect positioning due to the child's growth). A child with shunt malfunction needs surgery to replace the defective shunt. The nurse needs to make caregivers aware of the frequent rate of shunt malfunction and provide them with information regarding signs and symptoms of failure as manifested by increased ICP.

Another procedure performed to relieve increased ICP is called endoscopic third ventriculostomy. This procedure also presents complications. Children who are candidates for this procedure are those with obstructive hydrocephalus such as with a tumor or aqueductal stenosis. An endoscope is introduced and used to visualize the floor of the ventricle and a fenestration is made, which allows the CSF to flow around the obstruction (Greenberg, 2001). A child may experience life-threatening complications related to this procedure including hemorrhage, subdural hematoma, CSF leakage, bradycardia, and injury to structures located in the area of surgery. The injury to the hypothalamus may result in diabetes insipidus, loss of thirst, loss of appetite, and amenorrhea (Walker, 2004). The child needs to be monitored because the fenestration may close or narrow resulting in enlarged ventricles and increased ICP (Chiafery, 2006).

When obtaining a history and physical, the nurse must question the caregiver about predisposing factors to hydrocephalus. The nurse carefully examines the child to identify the presence of any immediate life-threatening symptoms. These symptoms exhibited by the child may be indicative of increased ICP or infection. If necessary, the nurse implements emergent measures to save the child's life. The child with hydrocephaly may need only pharmacological therapy to decrease CSF and ICP or a surgical procedure may be necessary to decrease them. The nurse performs nursing actions related to increased ICP and the proposed course of treatment. The child's head circumference is obtained and documented to identify any major changes that need to be evaluated.

assessment tools Head Circumference Measurement

Birth to 3 months Note the average head size at birth is 33–38 cm (12–14 inches)	Head circumference increases 2 cm/month (0.75 inch)
4–6 months Note the average head size at 6 months is 43 cm (17 inches)	Head circumference increases 1 cm/month (0.4 inch)
6 months to a year Note the average head size at 1 year is 46 cm (18 inches) By 1 year of age the child's head size has increased by 33% http://pediatrics.about.com/cs/weeklyquestion/a/032002_ask.htm	Head circumference increases 0.5 cm/month (0.2 inch)

Ethnocultural Considerations— Head circumference and infants of Asian heritage

The standard head circumference charts used today were developed in Denver, Colorado in the 1960s and were based on Caucasian American samples. This assessment tool does not allow for any difference in standards with reference to ethnicity. Infants of Asian heritage generally have smaller head circumferences in comparison to Caucasian infants. When Asian infants are measured using the current tool, the measurement obtained may indicate the infant is small for gestational age (SGA). However, this may not be true. The infant may be considered to be at risk for medical diseases and

Procedure 29-1 Measuring Head Circumference
Purpose

Measuring head circumference is an important component of evaluation of a child's growth as well as his or her health status.

Equipment

Flexible nonstretchable tape measure
Child's chart

Steps

1. Obtain a flexible nonstretchable tape measure (preferably one in which one end inserts into the other end).

2. Allow the parent to hold the child in his or her arms or lap.

RATIONALE: *Parents holding the child may help decrease the child's anxiety.*

3. Remove braids, barrettes, or other hair decorations.

RATIONALE: *The hair must lie flat in order to obtain an accurate measurement of head circumference.*

4. Place the tape measure over the most prominent part of the occiput (back of the head) and just above the supraorbital ridges (above the eyebrows).

RATIONALE: *The landmarks ensure accurate measurement.*

5. Pull the tape measure snugly to compress the hair and underlying tissues.

RATIONALE: *Ensures accurate measurement.*

6. Read the measurement to the nearest 0.1 cm or 1/8 inch.

7. Document the measurement on the chart.

Clinical Alert If an abnormal circumference is found based on the child's age, reposition the tape and measure the head circumference again. The new measurement should agree with the first measurement within 0.2 cm or 1/4 inch.

Teach Parents

To help ensure an accurate head circumference measurement, teach the parents how to hold the child firmly while offering verbal comfort and encouragement.

Documentation

9/10/10 1200 Head Circumference 43 cm (17 inches).

-M. Cannon, RN

complications based on data that may not be accurate. When using the current tool to obtain a head circumference measurement of an Asian infant, the nurse must recognize that the data obtained may not be accurate with regard to ethnicity. The nurse should determine if the infant exhibits other physical findings associated with SGA.

The child who is to receive a ventricular shunt receives preoperative intravenous antibiotic to help prevent development of infection. During the preoperative period, medications including acetazolamide (Diamox) and furosemide (Lasix) may be prescribed to decrease the production of CSF. These medications are sometimes used to postpone the need for shunt insertion. Preoperatively, the nurse ensures support of the child's head. The child requires frequent position changes of the head because hydrocephalus causes the skin of the scalp to thin, and prolonged pressure may result in impaired skin integrity.

Postoperatively, the child receives intravenous antibiotics and is monitored for infection. The nurse observes for redness along the shunt tract in addition to palpating for warmth to assess for infection. Other signs of shunt infection are fever, irritability, lethargy, abdominal discomfort, and apnea (Greenberg, 2001). The most common organisms that cause CSF infections in infants and children are *Staphylococcus aureus* and *Staphylococcus epidermidis*. Adolescents are more likely to experience an infection resulting from *Propionibacter acne*, which is a slow growing infection of the CSF.

**critical nursing action** Intravenous Therapy

If shunt surgery is anticipated, the nurse should not use scalp veins for intravenous therapy as the IV may be located near the surgical site.

Neurological assessment is paramount in the postoperative period after shunt insertion. Irritability, lethargy, or other alterations in neurological function may be indicative of meningitis or increased ICP. The nurse assesses and documents the child's vital signs and neurological assessments every 15 minutes or as prescribed by the surgeon. The child's head circumference is measured daily, and the fontanelles are assessed for bulging and the sutures for separation. The nurse examines the child's eyes regularly because shunt malfunction may result in pressure on the optic nerve, and if not treated promptly, irreversible damage occurs.

If peritonitis develops, the child may complain of diffuse abdominal pain and tenderness along with nausea and vomiting. When taking vital signs, the nurse pays particular attention to an elevated temperature and rapid pulse. Peritonitis results in leukocytosis (an increase in white blood cells); therefore, lab results are closely monitored. The nurse observes for signs of hypovolemia and shock resulting from loss of electrolytes and fluids into the abdominal cavity and assesses for rebound tenderness and muscle rigidity. When assessing the abdomen, the nurse auscultates for hypoactive or absent bowel sounds

to identify a paralytic ileus. The nurse obtains an abdominal circumference measurement to assess for distention. To promote accuracy, the nurse puts a mark on the abdomen so the tape measure is placed in the same spot every time. Safety precautions are implemented as pain and fever may cause the child to become disoriented.

When positioning the child, the nurse elevates the head no higher than 30 degrees in order to prevent ventricular decompression and places the child on the unoperated side to prevent pressure on the shunt. If increased CSF occurs, the physician may prescribe for the child to be elevated higher than 30 degrees. The shunt may be manually purged but only in extreme cases due to the risk of a subdural hematoma.

“What to say” — Parental education about ventricular shunts

The nurse can communicate to the parents that a child with hydrocephalus needs continuous monitoring and assessment because hydrocephalus is a lifelong disorder. Educate parents so they can recognize complications of hydrocephalus, including increased ICP and shunt malfunction (kinking, plugging within the ventricle from tissue or exudate or obstruction at the distal end from thrombosis or displacement of the tubing due to growth). Shunt infection can happen any time but most often occurs 1–3 months after placement. Instruct parents to assess for common signs and symptoms (nausea and vomiting, headache, change in customary behavior, lethargy, unresponsiveness, elevated temperature). Explain that the child will not be able to participate in contact sports because of the possibility of shunt damage. The importance of safe transport and positioning (a reclining car seat) is also emphasized.

“What to say” — Growth and development concerns

The nurse assesses the child's growth and development and compares the findings to established normal parameters so any delays and issues can be addressed and appropriate referrals made if necessary. Explain to caregivers that the child may experience delays in achieving developmental milestones. The child with hydrocephalus usually has a larger than normal head and may find it difficult to support the head. Rolling over and sitting up for the child may be delayed or difficult. The nurse informs the parents that as the child grows, the body grows more in proportion to the head size (Chiafery, 2006). Alert parents that they need to implement safety measures relevant to an enlarged head, including support while in a car seat or high chair.

CEREBRAL PALSY

Cerebral palsy (CP), the most common permanent physical disability of childhood, is characterized by physical impairment and mild to severe physical and mental dysfunction (Fig. 29-9). The United Cerebral Palsy Foundation estimated

Figure 29-9 The child with cerebral palsy has physical impairment and has mild to severe physical and mental dysfunction.

that approximately 764,000 adults and children in the United States in 2001 were diagnosed with cerebral palsy (Kriger, 2006). Cerebral palsy is a nonprogressive neurological disorder that results from brain injury occurring before cerebral development is complete. Since brain development continues for the first 2 years of life, the disorder can be a result of brain injury occurring not only during the prenatal period but also during the perinatal and postnatal periods. Prenatal risk factors include asphyxia, infections (i.e., rubella, cytomegalovirus, and toxoplasmosis), intracranial hemorrhage, blood incompatibility, and trauma. The perinatal risk factors for CP are low birth weight, birth at less than 32 weeks of gestation, and intracranial hemorrhage. Postnatal risk factors include viral encephalitis, bacterial meningitis, falls, child abuse, and motor vehicle accidents.

SIGNS AND SYMPTOMS. The signs and symptoms vary depending on the area of the brain involved and the extent of damage. Some children with CP may only have some awkwardness and can lead relatively normal lives while others are severely disabled and require extensive assistance. There are four types of CP. Spastic CP is the most common type. A child with spastic CP has stiff muscles because of increased muscle tone, and the muscles are predisposed to contracture. Children with this type of CP have poor control of posture, coordinated movement, and balance. Spastic CP is often classified according to the limbs affected (i.e., diplegia, hemiplegia, quadriplegia, monoplegia, and triplegia). Children with spastic diplegia (both legs are involved) have difficulty walking because of tight muscles in the hips and legs and may have scissoring (legs turn inward and cross at the knees) (Sankar & Mundkur, 2005).

Children with ataxic cerebral palsy have difficulties with balance and depth perception. They walk with an unsteady gait, demonstrate poor coordination, and often have fine motor control problems. Athetoid CP or dyskinetic CP is characterized by uncontrolled involuntary writhing movement of extremities. In severe cases, the facial muscles may be affected and drooling, speech difficulties, and grimacing may occur. In mixed CP, a child has two or more types of CP. Some of common symptoms of mixed CP are difficulty or inability to walk, speech difficulty, swallowing problems, breathing difficulties, bowel or bladder incontinence, seizures, vision problems, learning disabilities, hearing deficits, attention or behavioral problems, and impaired senses (Sankar & Mundkur, 2005).

case study Infant Amy Moore

Infant Amy Moore, 9 months old, has been referred to a neurologist by a pediatrician for evaluation. The neurologist questions the infant's mother about her pregnancy, the birth, and Amy's physical and psychosocial development. The mother stated Amy is her first child, and she had a complicated pregnancy. She was diagnosed with cytomegalovirus at 26 weeks of gestation and pregnancy-induced hypertension at 28 weeks. She delivered Amy at 32 weeks because of rapid progression of the hypertension. At birth, Amy weighed 2 pounds and 9 ounces, and her Apgar scores at birth were 3 and 6. Based on her initial assessment, Amy was transferred to the NICU and remained there for 65 days. Amy was mechanically ventilated for 26 days and received enteral feedings. While in the NICU, Amy had a small intraventricular hemorrhage. Amy weighed 4 pounds and 10 ounces when discharged. The mother states that she is concerned about Amy's physical and psychosocial development. Physical assessment findings are as follows: poor eye contact, anterior fontanel soft, slight drooling of oral secretions, mild head lag, few facial expressions, hypotonic extremity muscles, and right handedness noted.

critical thinking questions

1. What risk factors predisposed Amy to CP?
 2. What physical assessment findings demonstrated by Amy are indicative of CP?
- ◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

DIAGNOSIS. Diagnosis is primarily based on clinical symptoms demonstrated by the child. The child may exhibit muscular hypotonia (low tension) or hypertonia (high tension). A child with CP may demonstrate hand preference by 6 months of age instead of 12 months. An important sign of CP is persistence of some primitive infant reflexes (i.e., Moro and crossed extensor reflexes) because they reflexes normally disappear between 6 months and 12 months of age. CT, MRI, and cerebral ultrasound are tests used to diagnose CP.

NURSING CARE. The child with CP has some degree of muscular dysfunction. Splints and braces may be necessary to facilitate muscle control and improve body functioning. The nurse encourages the child to perform self-care tasks. Assistive devices may be necessary to allow the child to perform these tasks, including large handled brushes and

toothbrushes. Clothing should be easy to manipulate. To reduce muscle spasms and prevent fatigue, allow frequent rest periods.

The nurse administers medications that reduce muscle spasms. Skeletal muscle relaxants may be used for short-term control with older children and adolescents. Dantrolene (Dantrium) is administered to decrease spasticity, but the child must be monitored for hepatic impairment. The use of baclofen (Lioresal) has increased. Baclofen (Lioresal) can be administered intrathecally via an infusion pump to provide continuous and controlled relief (Kriger, 2006). Neurolytic agent nerve blocks provide a temporary decrease in spasticity. Paralysis of specific muscles can be achieved by the injection of botulinum (Botox), but the long-term effects have not been determined. Antianxiety medications such as diazepam (Valium) may be administered to older children and adolescents to reduce excessive motion and tension. Also, children with CP are predisposed to seizures. Medications including phenobarbital (Luminal) and phenytoin (Dilantin) may be administered to control seizures.

The child who does not respond to conservative management may need surgical intervention. Surgical procedures provide joint stability and balanced muscle power and may include tendon lengthening, release of spastic wrist flexor muscles, and correction of spastic hip adduction. Selective dorsal rhizotomy (severing of dorsal sensory fibers that have an abnormal response resulting in spasticity) may be performed to improve the child's ability to sit, stand, and walk.

Feeding problems may be experienced by the child due to impaired muscle control and strength. If the child can feed independently, she is encouraged to do so. Utensils with large handles may be used for easier manipulation. The child must be fed in an upright position and not hurried while eating because of the danger of aspiration. Assistance may be provided by standing behind the child and guiding the hand to the mouth. The nurse can stabilize the mandible in a child with poor facial muscle control by placing a hand on the child's mandible.

Children with CP may or may not demonstrate intellectual deficits. The degree of deficit depends on the severity of brain injury. Children with CP need intellectual stimulation. If possible, the child with CP should be enrolled in school to foster relationships, self-esteem, and normalcy. Participating in activity programs helps incorporate play into exercise. Toys are chosen based on cognitive, not chronological age. The environment needs to be safe because the child may not comprehend the concept of danger.

Neurological Injuries

NEAR DROWNING

Near drowning or submersion injuries (SIs) are a major cause of death and disability in children. Children are at risk for a SI because of the inability to swim, fatigue, inadequate muscle strength, and lack of knowledge of water safety. A child who has a SI may have only short-term complications or may have long-term life-altering disabilities. Early and aggressive medical treatment is paramount in the care of the child, and the child's prognosis depends on the treatment provided.

Near drowning involving children is usually preventable, yet more than 1500 child in the United States die every year from submersion injuries. Males are approximately four times more likely to experience a SI as females. Children younger than 3 years of age and adolescents 15 to 19 years of age are at the highest risk. SI in a child may have various causes (e.g., trauma, seizure, abuse).

A submersion injury occurs when a child who is submerged in water tries to breathe and aspirates water (wet drowning) or has a laryngospasm without aspiration (dry drowning). The most significant contributing factors to morbidity and mortality are hypoxemia with decreasing oxygen delivery to vital tissues. CNS damage may occur during the incident (primary injury) or may result from ongoing pulmonary injury, injury due to reperfusion, or multiorgan dysfunction (secondary injury). Early resuscitation is associated with an improved prognosis. Clinicians use an Orlowski scale to predict the likelihood of neurologically intact survival (Verive, 2006).

assessment tools Orlowski Scale

Clinical Application

Each item is assigned one point. If a child has a score of 2 or less, there is a 90% likelihood of a complete recovery. If a child has a score of 3 or more, there is a 5% chance of survival (Verive, 2006).

- Three years of age or older
- Submersion time greater than 5 minutes
- No resuscitation efforts for more than 10 minutes after rescue
- Comatose on admission to the emergency room
- Arterial pH <7.10

SIGNS AND SYMPTOMS. Near drowning affects many organ systems. The child may experience cerebral edema if prolonged submersion exists. Varying degrees of alterations in level of consciousness may be present. The child may have altered surfactant volume or function or both results in atelectasis and severe injury to the pulmonary capillary bed with resulting pulmonary edema. The child experiences respiratory distress with cyanosis, hypoxia, wheezing, and rales. Acute respiratory distress syndrome (ARDS) is a common complication of SI because of altered surfactant function and pulmonary edema (Verive, 2006). Pneumonia may develop if the water contains bacteria or other microbes. If the immersion occurs in water containing chemicals, such as household cleaning substances, the child may develop chemical pneumonitis. Cardiovascular complications are common.

The child may be hypovolemic due to increased capillary permeability. Vasodilation may occur if rewarming is performed and hypotension may result. The child may experience myocardial dysfunction including ventricular dysrhythmias, pulseless electrical activity (PEA), and asystole as a result of hypoxemia, acidosis, hypothermia, and electrolyte abnormalities (Verive, 2006).

DIAGNOSIS. Arterial blood gas analysis, which detects carboxyhemoglobin and methemoglobinemia, continuous pulse oximetry, and chest radiography help assess the respiratory system. CT and cervical spine imaging are used to evaluate the neurological system. The cardiovascular system is evaluated with echocardiography and electrocardiography. Laboratory tests usually include complete blood count, blood coagulation studies, liver

enzymes, renal function tests (BUN and creatinine), serum electrolytes, and serum glucose (Verive, 2006).

NURSING CARE. When caring for a patient admitted because of near drowning, a priority nursing responsibility is assessing and maintaining the airway (Orlowski & Szpilman, 2001). If respiratory or cardiac arrest occurs, life support measures are implemented. Suctioning is performed to remove debris, secretions, or emesis that may obstruct the airway (Orlowski & Szpilman, 2001). The nurse inserts a nasogastric tube to remove gastric contents and relieve abdominal distention in order to reduce the risk of vomiting and aspiration. Oxygenation is a primary concern. A nonrebreather mask may be used if the child is not intubated but oxygen saturation and respiratory status must be closely monitored in case respiratory deterioration occurs (Ross, 2005). The nurse understands that the child who is in respiratory compromise (hypoxic or apneic) or unconscious needs immediate intubation. The nurse evaluates the child for symptoms that may indicate other injuries including head or spinal trauma.

clinical alert

Cricoid pressure

To avoid vomiting during intubation, apply cricoid pressure or empty the stomach contents with a nasogastric tube (Orlowski & Szpilman, 2001).

HEAD INJURY

Traumatic brain injury (TBI) occurs when a jolt or blow to the head disrupts the normal function of the brain. The effects of a TBI may be as mild as a brief loss of consciousness or as severe as a vegetative state or death.

Each year in the United States, approximately 1.5 million people experience a TBI. 50,000 die (2685 are children), and as many as 5.3 million persons are currently living with a long-term disability. Each year many children from 0 to 14 years of age experience varying degrees of brain injury. Approximately 435,000 children are seen in emergency departments for accidents involving a head injury and 37,000 of those evaluated are hospitalized (National Center for Injury Prevention and Control, 2008). The primary causes of pediatric TBIs are motor vehicle crashes, bicycle accidents, sports trauma, violence, and falls. Any child with a TBI must be evaluated for child abuse.

A TBI can be classified as penetrating (e.g., bullet entering the brain) or nonpenetrating (e.g., fall from a tree). A TBI is further classified as primary or secondary. Primary injury occurs directly from the trauma and secondary injury is a result of complications (e.g., cerebral ischemia, hemorrhage). Children are predisposed to head injury because their heads are larger in relation to their body sizes, an unsteady gait, and thinner, softer cerebral tissue. Direct brain injury occurs when the skull vault is impended. A skull fracture may or may not be present. Indirect brain injury results when structural deformation occurs. Rotational acceleration and deceleration forces are usually present in motor vehicle accidents and they produce tearing and shearing injuries of the brain (Benham & Chavda, 2002).

SIGNS AND SYMPTOMS. The child may exhibit obvious signs including bleeding from the scalp, depression of the skull, or a visible penetrating wound. Other typical signs and symptoms are loss of consciousness, an alteration in consciousness, seizures, and combativeness. These are primarily the result of cerebral ischemia and necrosis and increased ICP.

DIAGNOSIS. A CT or an MRI identifies intracranial bleeding, compression of cerebral tissue, the presence of penetrating foreign objects, and skull fractures. An electroencephalogram (EEG) may be prescribed to determine if the child has brain activity abnormalities. ICP monitoring, cerebral blood flow, and CPP are measured if increased ICP is present. Cerebral oxygenation is monitored with the use of jugular venous bulb saturation and concentration or near infrared spectroscopy (Woodrow, 2000).

NURSING CARE. The child with a TBI needs immediate care to prevent life-threatening complications or death. Airway patency is a priority. The nurse delivers supplemental oxygen via a bag-valve-mask device until the airway is established. The child may need to be intubated and mechanically ventilated if a patent airway is not possible due to injury to the neck or pharynx, if level of consciousness is depressed, or if the neurological state is expected to deteriorate.

The nurse inserts two large-bore IV needles and administers hypertonic fluid to maintain adequate circulation. Intravenous fluids are warmed if hypothermia is a concern. If blood loss is greater than 30% of the child's total blood volume, blood products are administered (Brettler, 2004).

Assessment of the child's neurological status is imperative. The nurse uses the Pediatric Glasgow Coma scale to evaluate neurological status. The child's pupil size and reactivity are assessed and a difference or change is reported. Reflexes are assessed to determine brainstem involvement, and if the brainstem is injured, the child's prognosis is poor. The nurse palpates the skull to identify any fractures or depressions. Signs of a basal skull fracture include leakage of CSF from the ears or nose, hemotympanum (blood in the middle ear), mastoid ecchymosis (Battle's sign), and periorbital ecchymosis (raccoon eyes) (Bergsneider & Kelly, 2003). The nurse assesses the patient for increased ICP. If increased ICP is present, appropriate measures are implemented.

critical nursing action Basal skull fracture

Do not insert an NG tube if a basal skull fracture is suspected because the tube may enter the brain through the fracture. Insert an orogastric tube if needed instead (Brettler, 2004).

SHAKEN BABY SYNDROME

Shaken baby syndrome results from major rotational forces and angular deceleration encountered when an infant is shaken forcefully. The injury may be intentional or unintentional. Most victims of shaken baby syndrome are younger than 6 months of age and the source of the abuse is usually the father or a male acquaintance of the mother. The prognosis for an infant depends on the severity of the injury and response to medical therapy. Complications a

child may experience are neuromotor impairment, visual impairment, and developmental delays.

SIGNS AND SYMPTOMS. Symptoms of severe injury include seizure activity, apnea, bulging or full fontanelles, coma, hemorrhage, bradycardia, and complete cardiovascular collapse. Symptoms exhibited in less severe cases include vomiting, hypothermia, poor feeding or failure to thrive, increased sleeping, lethargy, or irritability and difficulty arousing.

DIAGNOSIS. CT scan or MRI is used to determine if a subdural or subarachnoid hemorrhage is present. Radiographs of the skull determine if any skull fractures are evident and an ocular funduscopic exam is used to assess for retinal hemorrhage, a classic sign of shaken baby syndrome.

Nursing Insight— Shaken baby syndrome

The hallmark of shaken baby syndrome is an absence of external trauma to the head, face, and neck of an infant along with massive intracranial or intraocular bleeding.

NURSING CARE. Nursing care involves initiation and maintenance of respiratory and cardiovascular support if necessary. The nurse needs to assess for increased ICP, insert a nasogastric or orogastric tube, assess for seizure activity, and implement seizure precautions, maintain adequate fluid and nutritional intake, and assess and document of any visible injuries.

The child may have either short-term or long-term impairment. Long-term impairment requires therapy consisting of gastrostomy tube feedings, a tracheostomy, pressure ulcer prevention, and other measures for children in a vegetative state. An important measure to prevent this abuse is educating parents and other caregivers (Smith, 2003).

The long-term outcome for a child with shaken baby syndrome or a TBI may be uncertain. The child's prognosis is affected by many variables including the degree of cerebral involvement, areas of the brain affected, severity of intracranial hemorrhaging, and medical management provided. The child may have minimal deficits or complications or she may experience severe and life-altering complications. The nurse must honestly address parental concerns and questions and provide information about agencies that can provide assistance and support them. The parents need to realize the child may never return to the prior level of cognitive and physical functioning.

Be sure to— Legal and ethical responsibility related to shaken baby syndrome

Nurses are legally and ethically required to report any incidences of probable abuse to the proper authorities. The health care facility should have relevant policy and procedure guideline available.

SPINAL CORD INJURY

Spinal cord injury without radiographic abnormality (SCIWORA) is a closed spinal cord injury resulting in stretching of the spinal cord without bony involvement

or radiographic abnormalities. SCIWORA occurs in more than 50% to 70% of spinal cord injuries in children. SCWORA usually occurs in children younger than 8 years of age because they are at risk for high cervical injuries because of their disproportionately larger head in relation to their body. As the child grows the spinal cord becomes less elastic but is covered by strengthened bony prominences; this added protection accounts for better resistance to injury as the child ages. The long-term outcome for children with SCIWORA is related to the etiology of the injury and the degree of functional loss.

The incidence of spinal cord injury is based on pediatric demographics, gender, and age of the child. SCIs are seen more in the summer with bike riding, swimming and diving activities, football playing, and motor vehicle collisions. Spinal cord injuries have been associated with traumatic births and child abuse in children younger than 1 year of age. SCIs are also associated with fighting with guns and knives and other forms of violence.

Spinal cord injury involves injury to the spinal cord in any or all of the following regions: cervical, thoracic, lumbar, or sacral. SCIs are due to direct or indirect force causing a contusion or bruising, compression, hemorrhage, or significant vascular damage resulting in paresthesia (loss of sensation) or paralysis (loss of function) below the level of injury. There are four types of SCIs: (1) cord resection, when the spinal cord is completely severed; (2) cord laceration caused by a blunt instrument such as a knife; (3) cord contusion caused by swelling and edema; and (4) cord injury in which there is no necrosis or obvious injury.

There are three phases of injury: acute, secondary, and chronic. The acute phase is the immediate time of injury to a few days later in which there is damage to the tissues resulting in cell necrosis. Immediately after the insult there is hemorrhage and edema combined with electrolyte and fluid shifts. The cord then experiences a spinal shock that lasts for 24 hours (Hulsebosch, 2002). The secondary phase occurs at the time of injury and continues over several weeks. The child's neurological status at this phase determines recovery outcomes. The chronic phase is marked with scarring and progression or regression of function. The nurse understands that complete resection of the spinal cord results in complete loss of motor function and sensation below the area of injury (Hulsebosch, 2002). Regardless of the mechanism of injury, the result is either temporary or permanent loss or alteration of autonomic, motor, and sensory function.

SIGNS AND SYMPTOMS. Clinically, the child has injury to the back, neck, thoracic, or lumbar area followed by numbness, tingling, or loss of function. Loss of anal tone and the ability to urinate independently combined with an abnormal neurological examination of any of the four extremities is present. There may be neck or back pain or tenderness. The child may or may not have an obvious deformity of a bony prominence.

DIAGNOSIS. The International Standards for Neurological and Functional Classification of Spinal Cord Injury identify two levels of spinal cord loss and function. Tetraplegia, currently replacing the term quadriplegia, is due to a spinal cord injury at the cervical level that involves all four

extremities. Paraplegia is the result of thoracic, lumbar, or sacral injury loss of function and sensation in the lower extremities (Dawodu, 2007).

The clinical diagnosis of SCIWORA and SCI is made both clinically and radiologically. Loss of motor function, sensation, and anal tone on exam clinically define the level of injury and degree of involvement. Radiological examination with spine series, CT scan, or MRI identifies the type of injury, the presence of hemorrhage or inflammation, and the degree of bony involvement if any.

clinical alert

Autonomic dysreflexia

Autonomic dysreflexia is a stress syndrome caused by massive amounts of stimuli overloading the autonomic system resulting in hyperactive sympathetic stimulation. This leads to a myriad of symptoms such as extreme anxiety, headache, visual and auditory sensation changes, nausea, seizures, hypertension, peripheral vascular dilation or flushing, and bradycardia. This situation is an emergent condition requiring immediate management of hypertension, cardiac, and neurological complications.

NURSING CARE. The priorities of trauma care are attention to airway management, breathing or ventilatory support, circulation support, disability identification, and exposure of known and unknown physical limitations. Immediate cervical (c-spine) immobilization is maintained continuously. Treat a SCI with full body immobilization and maintain with lumbar–thoracic–sacral orthotics (TLSOs), which are rigid body casts that maintain neuromuscular alignment until the injury is resolved.

If a child has a high cervical injury or if an open airway cannot be maintained, a temporary or permanent tracheostomy is necessary for the child to breathe. Mechanical ventilation may be a lifelong need for patients with a high C-4 injury. Cardiovascular and circulatory support is maintained with adequate fluid resuscitation, inotropic medications, and blood products to maintain circulation, cardiac output, and renal function during the immediate posttraumatic event. Large doses of steroid therapy may be used after the initial injury for up to 6 days to reduce spinal cord inflammation.

After the child is stabilized, there are several facets of ongoing care. Maintaining adequate respiratory function is necessary. The nurse works to maintain a patent airway with frequent suctioning. Tracheotomy care and proper neck and body alignment to prevent potential aspiration complications is required twice daily. Continuous mechanical ventilation or oxygen support monitoring is a priority in nursing care.

The nurse also monitors appropriate daily fluid intake and output measurements and ensures adequate daily fluid requirements are met. Renal function is evaluated with daily monitoring of serum chemistry values and urine specific gravity measurements.

A child immobilized by a spinal cord injury may have slowed peristaltic function and may require medications such as metoclopramide (Reglan), laxatives, or stool softeners to prevent constipation, gastric overdistention, and fecal

impaction. Bowel training may be a chronic issue for most children with SCI. Stool bulking with high-fiber foods may promote stool formation. Lower intestinal evacuation may be necessary with enemas, suppositories, and colonic irrigations. Exercise and abdominal massage promote peristaltic activity, and planned colonic irrigations may be used if the child experiences unplanned fecal soiling.

Nutritional support is a collaborative issue among the physician, the nurse, and the dietician. Enteral feedings may be needed until the child is able to chew and swallow without threat of aspiration. A child with altered oral pharyngeal motility or dysphagia may require an oral pharyngeal motility (OPM) study before oral feedings. Nasogastric or gastrostomy devices for enteral feedings can be implemented if the child's swallowing is impaired or if there is a threat of aspiration.

The nurse should provide emotional and social support, as the child with a spinal cord injury and his family have unique collective and individual needs. The younger child does not understand the loss of function immediately and is more concerned with parental presence and fear issues. The older child understands the loss of function and sensation and is more cooperative and eager to return to normal living as much as possible. Encourage older children and adolescents to participate in their own care as much as possible. All daily activities such as bathing, dressing, eating, grooming, and bowel and bladder care should be performed by the older child as he is able.

The adolescent presents a unique developmental challenge. The realization about the loss of friends, athletic participation, and social disruption may place the teen at risk for depression, withdrawal, isolation, and suicide. The nurse must look for these changes and recommend antidepressant medication in order to promote optimal function and return to a healthy emotional status.

The child with SCI requires lifelong care and support. This places a financial, mental, physical, and emotional strain on the family. The nurse must recognize caregiver role strain and offer or encourage respite care for the caregivers as needed.

Collaboration in Caring— Spinal Cord Injury

Nursing care of the child with spinal cord injury is an interdisciplinary approach. The child works together with the family, the medical team, physical, speech and occupational therapists, respiratory therapists, and social workers to coordinate the services needed for individualized care.

nursing diagnoses Spinal Cord Injury

- Impaired Urinary Elimination related to neuromuscular alteration.
- Constipation related to sensory and motor impairment
- Ineffective Individual Coping related to traumatic spinal cord injury and potential loss of function.
- Impaired Physical Mobility related to neuromuscular functional loss.
- Risk for Injury related to loss of sensation and motor function.
- Risk for Impaired Skin Integrity related to loss of sensation.
- Situational Alteration in Self-Esteem related to change in lifestyle.

Nontraumatic Neurological Conditions

HEADACHES

Headaches are a common occurrence in the pediatric population. Headaches are classified as primary or secondary and further classified into subtypes according to International Classification of Headache Disorders (ICHD-II) (Silberstein et al., 2005). The International Classification of Headache Disorders is a useful tool in classifying acute and chronic headaches in school-age children and adolescents but lacks sensitivity in diagnosing benign headaches in preschool and younger children (Balottin et al., 2005; Bigal, Rapoport, Tepper, Sheftell, & Lipton, 2005).

Headaches can occur in 90% of children. Most causes of a childhood headache are based on a simple etiology such as minor trauma, emotions, genetic predisposition, illness, environmental factors, or certain food and beverages (Mayoclinic.com, 2008).

SIGNS AND SYMPTOMS. Primary headaches are headaches caused by tight muscles with no etiological agent. Triggers of primary headaches have been identified as lack of sleep, stress, exercise, hunger, loud noise or persistently loud noises, weather changes, and hormonal changes due to menstrual cycles in females. Secondary headaches are associated with an organic disorder such as trauma, vascular changes, infectious processes, substance, brain neoplasms, or psychogenic issues.

Headaches are further classified into subtypes based on descriptive symptoms and frequency of disturbances. Tension headaches are common among school-age children and are associated with stress. The tension headache is located in the back of the head at the base of the skull and feels like a dull moderate pain. This pain may radiate bilaterally and may be located just above the neck and shoulders. Loss of vision, nausea, photophobia, and auditory sensitivity are not associated with tension headaches. Sleep may be affected for children with these headaches.

Migraines are another type of headache and can be present in the preschool or school-aged child. Most often, there is a family history of migraines. Migraine headache pain is located on one side of the head with a throbbing or pulsating quality that radiates. An aura may precede the migraine headache and is accompanied by nausea, vomiting, diaphoresis, pallor, photophobia, and auditory sensitivity. The aura may be sensed by a noxious smell, bright lights, or a change in vision. Migraines are not easily remedied with rest alone and typically require prophylactic and acute management.

Cluster headaches are a series of headaches over a period of weeks or months that vary in intensity and can be very debilitating. The pain is usually unilateral, behind one eye, and results in ptosis (drooping), pupil constriction, erythema, and edema of the affected eye. Rhinorrhea is also present with clear drainage in the absence of an upper respiratory illness.

DIAGNOSIS. Headache diagnoses are based on clinical symptoms according to the ICHD-II criteria. Diagnosis is based on inclusion and exclusion clinical criteria. Clinical diagnosis is difficult with a young child because of cognitive

and communication barriers. A history of headache signs are difficult to piece together as the symptoms may mimic those of other minor pediatric illnesses. Neuro-imaging studies are warranted with sudden severe onset of headaches, history of trauma, family history of brain neoplasms or vascular malformations, change in neurological function, signs of increased intracranial pressure or visual disturbances, new seizure onset, unexplained ataxia, or alterations in level of consciousness (Lewis et al., 2002).

Diagnostic assessment begins with a full neurological examination, history of present illness, family headache history, review of symptoms, and headache history including patterns, antecedent events, and symptom management. Decisions for diagnostic neuroimaging, lumbar puncture, or EEG testing are based on patient data obtained at the time of the neurological evaluation. Routine neuroimaging is not indicated in the presence of a normal neurological exam (Lewis et al., 2002).

NURSING CARE. Combined pharmacological and non-pharmacological therapies along with child and family education can successfully manage the child with primary headaches.

Prophylactic medication such as beta-blockers, calcium channel blockers, antidepressants, and anticonvulsants or a combination of these can help the child cope with primary headaches. Acute episodes are treated with acetaminophen (Children's Tylenol) and ibuprofen (Children's Advil). Intranasal sumatriptan (Imitrex) or dihydroergotamine mesylate (DHE) is administered subcutaneously.

Child and family education must target migraine prophylaxis, identification, and management of headache triggers and symptom management with analgesia. Migraine prophylaxis includes medications such as topiramate (Topamax), sumatriptan (Imitrex), ergotamine (Cafergot), NSAIDs, antiemetics, and sedative analgesics. Pharmacology therapy is titrated to individual child needs and desired function.

Intramuscular or intranasal can be also used for moderate to severe migraines in adolescents (Hamalainen, 2006; Robertson & Shilkofski, 2005; Saper & Silberstein, 2006).

The nurse educates the family on recognition of headache aura, prophylaxis strategies, and management intervention, including medication, relaxation strategies, and environmental modifications (e.g., noise reduction, dim or dark room). The nurse evaluates the effectiveness of the medication and monitors for adverse reactions. Treatment also involves rest and stress reduction strategies such as soothing baths, music, guided imagery or massage therapy.

Sensory Conditions

EYE DISORDERS

Children may experience a myriad of common eye disorders. The parent may notice an abrupt change or changes in vision function. Children are not acutely aware of changes in vision or eye disturbances and may not voice complaints of vision difficulty unless there is an injury. Common childhood eye disorders are classified as refractive disorders, astigmatism, amblyopia, strabismus, or organic diseases (Watkinson & Graham, 2005) (Table 29-7).

Nursing Insight— Vision

Vision occurs as a result of light reflection from an object passing through the cornea, aqueous humor, pupil, lenses, and vitreous humor and finally absorbed by the retina. The retina then converts the light to an electrical impulse that travels from the optic nerve to the visual cortex of the brain. The retina is composed of rods and cones that are used in night, color, daylight, and eye movement functions. The rods and cones communicate electrical energy to the retina, which then sends an impulse to the optic nerve. The majority of the blood vessels radiate from the optic nerve and the retina. The fovea centralis, which is located in the center of the macula about 2.5 disc diameters from the optic nerve, is responsible for color perception.

Refractive Disorders

The most common category of vision disorders in children is refractive errors (Simon & Kaw, 2001). Light refraction is the bending of light as it passes through a lens. As light passes through an opening in the pupil, the lens directs the light to the retina to initiate vision. In very young infants, the light rays fall behind the retina due to the shallowness of the eye. Most children are hyperopic (farsightedness). The amount of hyperopia diminishes as the child ages. In hyperopia, vision is unclear at a close range and is clearer at a far range. Young children with hyperopia may have trouble focusing on projects requiring close range visions and may lose interest. Hyperopia usually diminishes by age 5 but in some cases may persist. These children require convex lenses to correct the refractive disorder. If a child reports headaches, dizziness, or eye strain after doing school work, hyperopia is suspected and a referral is made for vision assessment (Simon & Kaw, 2001).

Some children develop myopia (nearsightedness) in the school years, particularly if there is a familial history of myopia. In myopia, light rays do not reach the retina causing blurred vision at a far range and clear vision at a close range. Children who have myopia may squint, complain of nearsightedness, and are unable to see the blackboard, television, or street signs but can clearly read a book or a computer screen at close range. About 10% of school-aged children have myopia. This condition continues to progress in severity until puberty when progression plateaus (Watkinson & Graham, 2005).

Correction of myopia includes concave lenses in eye glasses or contact lenses. Laser assisted surgery keratomileusis (LASIK) is available for the adolescents if desired. The age for LASIK surgery is controversial. If the procedure is performed before full eye growth maturity has been reached, additional surgery may be needed (U.S. Food and Drug Administration, 2007).

Astigmatism

Astigmatism is an irregular curvature or uneven contour of the eye resulting in impaired light refraction. The cause is unknown. Astigmatism may be present at birth or acquired. Light rays are unevenly distributed in the eyes, causing blurred vision at all distances. This condition is associated with birth hyperopia and myopia.

Table 29-7 Common Acute Eye Disorders

Eye Disorder	Cause/Organism	Signs and Symptoms	Treatment
Conjunctivitis	An inflammation of the conjunctiva caused by bacterial, viral or allergic agents.	Excessive tearing, erythematous, edema and with clear, watery, yellow or green drainage and eyelid crusting. Bacterial and viral agents are difficult to discriminate clinically without a culture. Viral usually seen in children older than age 6 years with a clear watery drainage. Allergic: cobble stoning and pallor of the conjunctiva, pruritus, watery clear drainage.	<p>Apply warm soaks to remove crusting, use good hand hygiene and apply cool compresses to edematous eyes.</p> <p>Antibiotic ointment or solutions are used for bacterial infections.</p> <p>Family education includes good hand hygiene before and after touching the eye, non-sharing of personal items such as pillow cases and washcloths and careful disposal of used tissues and wipes. Older children who wear contact lenses or use cosmetics should discard used materials and begin use of new materials after the infection has resolved. School attendance is permissible after the discomfort and drainage has subsided, usually after 24 hours of treatment. If symptoms are not improved in 24-48 hours the family should seek additional follow-up medical care.</p> <p>Conjunctivitis associated with herpes may be treated with oral or parenteral antiviral agents. Herpetic ophthalmicus is one of the leading causes of vision loss in children (Shaikh and Ta, 2002).</p> <p>Allergic conjunctivitis treated with allergen avoidance and antihistamines.</p>
Neonatal Conjunctivitis–Ophthalmia Neonatorum	Chemical irritation caused by maternal sexually transmitted diseases acquired at birth. <i>Chlamydia, gonorrhea, herpes.</i>	Purulent drainage either white or yellowish.	Prophylactic antibiotic ointment is used in all neonates. Lack of treatment can cause eye damage.
Stye	A localized inflammatory swelling of one or more of the glands of the eyelid. They are mildly tender, and may discharge some purulent fluid (Venes, 2009)	Painful, erythematous lesion on the lid margin. Slight edema, some lymph node tenderness or induration.	Apply warm moist compresses with an antibiotic ointment. Good hand hygiene is necessary.
Chalazion	Granuloma of the meibomian gland on the eyelid. Cause unknown.	Hard, small nodule on either eyelid may be painful.	Apply warm moist compresses and massage, antibiotic ointment, may resolve the condition spontaneously. Surgical removal or steroid injections may be used to reduce size and symptoms such as ptosis.
Blepharitis Marginalis	Staphylococcal infection of the lid margin.	Erythematous eyelid margin with crusted eye drainage.	Apply an antibiotic ointment to the lower affected eyelid. Apply warm moist compresses to remove crusting drainage.
Keratitis	Inflammation and infection of the corneal layers due to bacterial, viral, fungal or foreign body infiltration.	Very painful, excessive tearing, photophobia and erythema.	An ophthalmologist must examine the cornea to monitor or treat potential scarring and prevent loss of vision.
Periorbital Cellulitis	Inflammation of the subcutaneous tissues and skin about the eye may be bacterial or viral.	Edema, pain, erythema in the skin and orbital folds of the affected eye.	Use intravenous antibiotic therapy for 7 days.
Blocked Tear Duct	Obstruction of the nasolacrimal tear duct causing inflammation or cystitis.	Tearing, yellow drainage, crusting, small bump in the inner canthus of the affected eye. Usually unilateral, may be painful.	Apply warm compresses and gentle massage of the lacrimal sac with the forefinger milking any exudates toward the nose. This condition may require probing of the duct by an ophthalmologist if no improvement is noted in 6 months (Fox, 2002).

Corrective lenses usually solve the problem. Sometimes surgery is indicated but is not usually necessary. If a child complains of headaches, blurry vision, dizziness after doing close work or difficulty reading, he or she is referred to an ophthalmologist.

Amblyopia

Amblyopia (“lazy eye”) is one of the most common monocular eye disorders in children leading to loss of vision. Approximately 2% to 5% of children in the United States experience this condition. Strabismus and anisometropia are the most prevalent forms of amblyopia in children. **Strabismus**, or crossed eye appearance, results in malalignment of the eyes. The child attempts to compensate for this unequal vision by preferentially choosing to use one eye and not the other eye. When the child focuses on an object, one eye wanders off of the focused object while the other eye looks straight ahead. The child then experiences two separate images instead of one and develops a stronger eye. The brain eventually suppresses central vision in the unused eye causing amblyopia.

Anisometropia is a condition in which the refractive power of the eyes is unequal (Venes, 2009). If the refractive errors are significantly different in one eye the child becomes dependent on the eye that is more easily focused, leading to an irreversible loss of vision potential (Simon & Kaw, 2001). Amblyopia can also result from excessive patching, ptosis, or cataracts. Amblyopia is treated with corrective lenses for up to 6 months or until improvement plateaus, then surgery is indicated (Holmes & Llarke, 2006).

The goal of amblyopia treatment is to improve visual acuity of the weaker eye and prevent permanent loss of vision or visual impairment. Occlusion therapy or patching of the normal eye is done to restore strength and function to the lazy eye (Fig. 29-10). Duration of occlusion therapy is widely debated. No clear evidence exists. Patching for as little as 1 to 2 hours per day may be as effective as patching the entire day (Allison, 2005).

Child and parental compliance with occlusion therapy is complicated and stressful for both. Children may experience a stigma with patching at school or at home, making the treatment more debilitating than the vision loss. Children are too young to appreciate the significance of the child therapy and attempt to remove or hide the

Figure 29-10 Occlusion therapy or patching of the normal eye is done to restore strength and function to the lazy eye.

patches. Compliance is better if patching is disguised behind eyeglasses or if patching time is shortened.

Amblyopia is treatable if detected at an early age. Treatment should be initiated during the preschool years if possible (Watkinson & Graham, 2005). The success of amblyopic therapy diminishes after age 6. Correction after age 10 is very limited. It is recommended that preschoolers be screened for visual acuity using the Snellen E chart, and most schools comply.

Optimizing Outcomes— Early vision screening

Early screening for all children at risk for amblyopia and aggressive prompt treatment will result in the best outcome and prevention of visual impairment.

Strabismus

Strabismus is a condition of nonparallelism in the different fields of gaze causing visual lines to cross even when focused on the same object. Weakened or misaligned extraocular muscles pull the eyes in different directions resulting in a cross eyed appearance. Strabismus occurs in 2% to 7% of children, affecting males and females equally, and has an inherited pattern in about half of the cases.

assessment tools Strabismus

Three forms of strabismus describe the eye deviation noted on an exam:

- Esotropia: Eye turns toward the midline of the face or nose
- Exotropia: Eye turns away from the midline of the face
- Hypertropia: Eye turns toward the forehead or a downward turning

SIGNS AND SYMPTOMS. Intermittent esotropia is seen in normal children younger than 3 years of age when the child is tired, ill, or with a sudden change in light or distance. Persistent squinting, head tilting, clumsiness, or decreased visual acuity may also be assessed. Pseudostrabismus is an appearance of crossed eyes but is due to physical attributes such as prominent epicanthal folds and a flattened nasal bridge. Children outgrow this condition over time. True strabismus does not change without intervention and can lead to amblyopia and loss of vision.

DIAGNOSIS. Childhood screening is begun as early as 3 to 6 months of age. The corneal light reflex test and the cover test are performed to detect strabismus, the cover test being the most reliable. The cover test is more sensitive in that eye movement is noted in response to covering and uncovering the child’s eye while focusing on an object. This test requires the child’s cooperation. The cover test is performed by having the child focus on a toy or favorite object and covering one eye. If the uncovered eye moves, that eye was not fixated on the object and strabismus is suspected.

assessment tools Hirschberg Asymmetrical Corneal Light Reflex Test

The Hirschberg asymmetrical corneal light reflex test is performed by holding a pen light or flash light in front of the child’s face. The light reflection is noted on the cornea in both eyes. Symmetrical placement on both eyes at the same time and in the same location on each eye is a negative corneal light reflex

exam and indicates normal muscle alignment. A positive asymmetrical corneal light reflex test is when the light falls slightly medially to the center of the pupil on the iris. The presence of an asymmetrical corneal light reflex is a positive exam and is suggestive of strabismus. A cover test is then performed.

NURSING CARE. Early identification and recognition of all children suspected for strabismus is critical in order to prevent vision loss. Treatment involves ocular patching of the stronger eye in order to force the weaker eye to work independently and “exercise” to strengthen extraocular muscles. Occlusion therapy should be conducted under the care of a pediatric ophthalmologist. Patching is most successful if implemented before age 3 to 4 years. Glasses and pharmacotherapy may be used. *Oculinum botulinum* toxin (Botox) may also be used for treatment of strabismus in children. Botox can be used in conjunction or as an alternative to surgery. The toxin is injected into the extraocular muscle, causing misalignment and produces a temporary muscle shortening that results in a parallelism of vision. The Botox effects last for up to 3 months and repeat injections may be performed. Potential complications include retrobulbar hemorrhage, ocular needle penetration, and ptosis.

The nurse provides families and children with referral sources, support groups, information, and schooling. School-based screening programs are essential for early detection, identification, and initiation of treatment of strabismus-related eye disorders. The school nurse may also be involved when treatment is needed during school hours.

Color Blindness

Color blindness is an X-linked recessive inheritable color vision deficiency that causes loss of accurate color perception. Males are more affected (8%) than females (less than 0.5%). Color blindness may be selective, partial, or complete (all colors). Complete color blindness is rare and results in perception of only shades of gray. Color blindness is a deficiency of photosensitive pigments (red, green, blue, yellow) located in the cones of the retina. Color blindness is untreatable, nonprogressive, and nondebilitating.

Color blindness is detected using colored charts called the Ishihara Test plates (Fig. 29-11). Each chart is com-

Figure 29-11 Color blindness is detected using colored charts called the Ishihara Test plates.

posed of colored dots with a number located in the center of the plate in a different color, usually yellow, red, green, or brown. The child is asked to identify the number or the shape in the center of the chart. A child without a color vision deficiency sees the object clearly. A child with color blindness sees only the plate of dots without an image or the image is blurred and indistinct.

Children can learn to compensate for their color deficiency with support from family members, teachers, and friends. Some alterations in daily function may be affected but they can be compensated for with minor behavioral alterations. For instance, at a traffic signal the child will need to learn to identify the signal by order rather than by color. Assistance with clothing selection may be necessary as well as labeling the clothes. The nurse can provide reassurance to parents that color blindness does not lead to loss of vision.

Nystagmus

Nystagmus is a rapid irregular involuntary eye movement caused by a disorder of the central nervous system that may be congenital or acquired. There are many types of nystagmus. The eyes may rotate in a lateral direction, clockwise or counterclockwise direction, up and down, or any combination of these movements. Eye movement is repetitive and involuntary and in some cases can be managed by gaze redirection.

Congenital nystagmus is usually mild and nonprogressive and persists into adulthood. Brain injuries are the most common cause of acquired nystagmus. Any child who develops nystagmus early in life should be evaluated for an underlying central nervous system cause. If an identifiable cause is not clear, neuroimaging, such as an MRI, is warranted to rule out the possibility of a neoplasm. Prognosis is based on the etiologic cause. Extraocular surgery may correct some forms of congenital nystagmus. Acquired nystagmus treatments are based on the existing etiology (Watkinson & Graham, 2005).

Cataracts

A cataract is a clouding or a haziness of the corneal lens. Significant irreversible vision disorders are caused by cataracts. Cataracts can be located unilaterally in one eye or bilaterally in both eyes. Cataracts can be acquired or congenital resulting in partial or complete occlusion or both. Acquired cataracts can be caused by maternal infection acquired during pregnancy, trauma to the eye, radiation, or systemic diseases. Some cataracts are due to family inheritance patterns. Congenital cataracts are present in neonates with syndrome anomalies or mothers with TORCH (toxoplasmosis, rubella, cytomegalovirus, herpes simplex or HIV) infection during pregnancy. Congenital cataracts can be autosomal dominant in genetically linked families. However, X-linked and recessive genetic situations have been reported.

SIGNS AND SYMPTOMS. During an eye exam with an ophthalmoscope, a cataract is obvious to the examiner. The direct pupil check yields an abnormal or absent red reflex. Excessive tearing and extraocular movements may be seen. Strabismus is usually present. If a child has a cataract, the cover test is abnormal or of poor fixation quality. Photophobia is always present along with

decreased visual acuity. The infant or child may appear inattentive or have abnormal eye movements that seem random and disorganized.

DIAGNOSIS. A pediatric ophthalmologist performs a complete eye examination. Diagnosis is made when the lens appears cloudy or there is a white or dulled red reflex.

NURSING CARE. Early detection and diagnosis of a congenital cataract prevents loss of visual acuity. Referral to a pediatric ophthalmologist is indicated. In most cases, a laser procedure is performed to remove the cataract and then a small incision is made to place the lens. The child who is undergoing a cataract removal is usually admitted to the outpatient surgery unit. Postoperative nursing care for the child includes monitoring nausea, emesis, pain, hemorrhage, and signs of infection. Keep the child free from wrenching, coughing, crying, and active play that can cause increased intraocular pressure. Postoperative eye drops include a steroid preparation to reduce inflammation and prevent adhesions. Mydriatic eye drops prevent adhesions of the pupils and topical antimicrobial eye solutions prevent infection.

Follow-up care of the child is based on loss of visual acuity. Some children need glasses for correction of refraction errors. Other children may need an antiglaucoma medication to prevent intraocular pressure development. Postoperative education for the family and child includes signs and symptoms of infection, hemorrhage, increased intraocular pressure, and activity restrictions until cleared by the physician. If amblyopia is evident, the unoperated eye is patched in order to force the operative eye to “exercise,” which strengthens the extraocular muscles.

Glaucoma

Glaucoma is an increase of the intraocular pressure (IOP) in the eye due to an obstruction or impaired outflow of aqueous humor (clear fluid) that leads to retinal damage and eventual necrosis of the optic nerve. Optic nerve cupping is seen with ophthalmoscope examination. The eye enlarges due to increased IOP, causing a thinned cloudy appearing cornea. The sclera may appear bluish.

Glaucoma can be congenital or acquired. Some cases of pediatric glaucoma are due to eye trauma or from surgical procedures. Congenital or infantile glaucoma is a rare condition presenting with corneal opacification (or clouding), corneal enlargement, and eye pain. Another rare type of congenital glaucoma is when the iridocorneal (the junction of the iris and the cornea) angle of the eye at the Canal of Schlemm causes an obstruction of outflow of aqueous humor from the eye. This condition appears in the first year of life and if left untreated results in blindness.

SIGNS AND SYMPTOMS. Signs of infantile glaucoma include a triad of symptoms: buphthalmos (enlarged eye globe), epiphora (excessive tearing), and photophobia (sensitivity to light). There is also pain, excessive blinking due to the photophobia, and corneal cloudiness. Older infants experiencing light sensitivity turn away from the light, become irritable, and rub their eyes. Most infants have obvious signs of glaucoma by 4 to 5 months of age.

DIAGNOSIS. A complete eye examination is performed by a pediatric ophthalmologist. Tonometry (measurement of tension) is used to evaluate intraocular pressure. Prior

to the procedure, the child is pre-medicated with a topical anesthetic in order to obtain a reliable measure. Early surgical intervention is done to remove obstructions and allow the child flow of aqueous humor into the Canal of Schlemm. Rapid intervention reduces the risk of optic disk necrosis and retinal ischemia.

NURSING CARE. The nurse provides pre- and postoperative family-centered care and education. Prior to surgery the nurse prevents intraocular pressure increase by maintaining a quiet, calm environment with dim lighting. Anti-glaucoma medications provide temporary relief of IOP. Analgesia is given for pain as well as using anxiety reduction strategies such as distraction, massage, music, and parental presence. Favorite toys, pacifiers, and blankets are used to comfort the child. Preoperative care includes parental teaching about the condition. In the postoperative period, the nurse teaches the parents about eye dressings, medications, signs and symptoms of infection, and increased IOP, activity limitations, and follow-up care.

Retinoblastoma

Retinoblastoma is a malignant tumor of the retina seen only in children. It is a rare condition, accounting for fewer than 3% of the cases of childhood cancers. This tumor can spread to the optic nerve and invade the brain, lymph nodes, facial bones, and bone marrow.

SIGNS AND SYMPTOMS. In retinoblastoma a whitish or yellow color of the pupil called leukocoria or cat’s eye reflex is noted instead of the usual red reflex. Late manifestations include visual acuity disturbances, pain, inflammation, and hyphema (blood in the anterior chamber of the eye) (Venes, 2009).

DIAGNOSIS. Diagnosis is made when the absence or abnormality of the red reflex is noted by either the examiner.

NURSING CARE. Treatment is based on unilateral or bilateral presentation and degree of cancer infiltration. Because this tumor is a rapidly progressing cancer, early detection, laser, radiation or cryotherapy (use of ice compresses), or enucleation (removal of the eye) is necessary for survival. If the eye is saved and vision is still present but altered by the tumor, other therapies such as radiation are used to shrink the tumor. Systemic chemotherapy is used to treat metastases. Once the tumor invades other organs the success of treatment is diminished.

EYE INJURIES

Foreign Bodies

When a child has a foreign body penetrating the eye, careful history of the injury and assessment dictate immediate action. An intraocular penetration injury or laceration (tear) to the corneal or eye globe requires an immediate transport to the local hospital emergency room. An eye shield is used to prevent further trauma and all bleeding should be controlled before transport.

In foreign body penetration, vision loss is prevented by timely prompt medical treatment. The triage nurse must be able to recognize an emergent situation from a non-emergent injury. If a foreign body is visualized in the conjunctival sac, a physician can carefully remove the object using a cotton-tipped applicator or warmed normal saline irrigation. Glass particles are removed carefully using a

cotton-tipped applicator. Sand, gravel, and dirt are flushed with warm normal saline. Foreign bodies need to be removed meticulously to avoid a corneal abrasion.

Corneal abrasion is a nonpenetrating injury to the cornea. Common objects that cause an abrasion include contact lens, human fingers, animal nails, sticks, flying objects, pens, pencils, and glass. Corneal abrasions are painful. Treatment is necessary if purulent eye drainage is present. Medications include topical antibiotic solutions or ointments if infection is suspected. Administer analgesics for pain. An eye patch is placed to prevent the child from rubbing or scratching the eye causing further irritation and potential self-inoculation of bacteria. An ophthalmologist should reexamine in 1 to 2 days.

Hyphema

Hyphema is a hemorrhage into the anterior chamber of the eye. The eye requires rest and possible evacuation of the bleeding. Evacuation prevents globe rupture due to increased intraocular pressure (IOP). The child is hospitalized to monitor the IOP and to promote decreased activity. The head of bed is raised to 30 degrees and the room is kept dimly lit with minimal activity. Both eyes are patched to prevent excessive ocular movement and increased intraocular pressure.

Chemical Burns

Chemical burns to the eye are treated with rapid eye flushing for 15 to 30 minutes followed by pH analysis of the chemical agent. Eye patching and referral to an emergency room or an ophthalmologist is essential to evaluate for further treatment.

critical nursing action Chemical Burns

Nursing care of the patient with a chemical burn requires prompt assessment. The nurse assesses the injury and monitors the patient for signs of infection, hemorrhage, and increased IOP. Provide emotional and social support for the child and family. The nurse stresses the importance of follow-up care that involves evaluation of the cornea for scarring and IOP testing to determine post inflammatory response. Instruct the family that patching and eye medication may be required at home. School and normal activities are allowed after physician consultation.

HEARING LOSS

Hearing loss is diagnosed in approximately 12,000 children per year, resulting in speech and language difficulties, social and developmental delays, and slowed academic progress with psychological and occupational difficulties. Hearing loss can be caused by several factors. Approximately one third of all cases are due to genetic causes, one third of all cases are due to nongenetic influences, and one third of all cases are of unknown causes. Causes of nongenetic acquired hearing loss are seen in conditions such as meningitis and maternal TORCH infections during pregnancy, with cytomegalovirus being the most common. Prevention of hearing loss is important for all children of all ages. Hearing loss is prevented by reducing noise levels to less than 50 dB.

A middle ear infection, otitis media, is associated with allergies and causes hearing loss in children. Seventy-five

percent of children experience at least one ear infection before the age of three. Hearing loss affects approximately 17 children in 1000 under age 18 years of age. Two to three children per 1000 are born with hearing abnormalities. Of these children, 90% are born to parents who can hear (National Institute on Deafness and other Communication Disorders, 2007).

Hearing loss may be caused by conduction abnormalities associated with structural anomalies of the inner and outer ear or sensory neural hearing loss due to central nervous dysfunction. Central nervous dysfunction includes damage to the cerebral cortex, brainstem, or cranial nerve VIII. Hearing loss is also seen with severe neurological insult from trauma, anoxia, infections, or malformations.

A hearing disorder can involve a combination of both conductive and sensory-neural abnormalities. Sensory-neural hearing loss is a common sequel of bacterial meningitis affecting approximately 10% of these children with bacterial meningitis. Rapid identification and prompt treatment can prevent post meningitis hearing loss (Klutzn, Simon, Chennupati, Giannoni, & Manolidis, 2006).

SIGNS AND SYMPTOMS. Hearing loss is quantified in terms of severity and degree of functional disability and may be unilateral or bilateral (Table 29-8). Detection of hearing loss in children requires a high index of suspicion if noted developmental milestones are not observed. Any child suspicious for a hearing loss should receive a prompt referral to an audiologist. Maternal reports of infant hearing concerns should be immediately investigated and treated in order to prevent long-term consequences.

Nursing Insight— Risk factors

Critical risk factors for hearing loss in neonates also include extracorporeal membrane oxygenation (ECMO), systemically administered ototoxic medications, phototherapy, and severe hypoxic ischemic encephalopathy post resuscitation or asphyxia.

Table 29-8 Classification of Hearing Loss

Level of Hearing Loss	Range	Description
Normal	0 dB–15 dB	No impairment. Able to hear all speech sounds
Slight	16 dB–25 dB	Vowel sounds are heard clearly may miss some consonant sounds
Mild	26 dB–40 dB	Hears some speech
Moderate	41 dB–55 dB	No speech heard
Moderate/severe	56 dB–70 dB	No speech heard
Severe	70 dB–90 dB	No speech heard and no other sounds heard
Profound loss	91 + dB or more	No speech and no other sounds heard

Source: American Speech-Language-Hearing Association (2007).

DIAGNOSIS. Early detection and intervention for children with hearing loss has been recommended by the Joint Committee on Infant Hearing. Universal infant hearing screening before 1 month of age is recommended. Newborn readiness for discharge includes a hearing screening evaluation. If newborn hearing loss is suspected, a more extensive audiological evaluation is recommended by 3 months of age. Treatment for the hearing loss should begin by 6 months of age (Joint Committee on Infant Hearing, 2000; Walter et al., 2000). Hearing loss is determined by analyses of many kinds of hearing tests performed by a licensed audiologist.

diagnostic tools Audiologic Testing

Audiologic testing may include one or several procedures:

The otoacoustic emissions test (OAE) or an auditory brainstem evoked response (ABER) performed by a licensed, certified audiologist further defines the degree of hearing loss. This is a very reliable test that measures acoustic responses produced by the inner ear and cochlear function. A small probe is placed in the outer ear canal and senses sounds that are reflected or echoed back out of the ear. This bounced back sound is the otoacoustic emission that may spontaneously occur or be evoked.

The automated auditory brainstem evoked response (AABER), or the ABER, records electrical activity in response to auditory stimuli received from electrodes placed on the scalp. The electrical impulse reflects cochlear, auditory brainstem and cranial nerve VIII vibration pathways. The AABER places a series of clicking sounds through ear phones placed over the infant's or child's ears. The sounds are then converted to waveforms and detected as electrical activity by the scalp sensors. The strength of the stimulus level is in the normal voice and hearing range of 35–50 dB. The AABER is useful for screening newborns with congenital hearing loss or postneonatal intensive care therapies such as mechanical ventilation.

Audiography can be performed in children older than 3 years of age who are able to cooperate and follow directions. This test requires the child to raise his hand in response to normal hearing tones. The screening is performed under the supervision of a clinically competent audiologist, speech pathologist, or appropriately supervised personnel (American Speech-Language-Hearing Association, 2007).

A routine otoscopic examination is also performed by a healthcare provider to evaluate the presence of a middle ear effusion or otitis media (Fig. 29-12). Part of the otoscopic examination also involves the use of the pneumoscope to assess for tympanic membrane mobility.

If the hearing loss continues to be suspected, a **tympanogram** (radiographic examination of the eustachian tubes and middle ear after introduction of a contrast medium) may be completed (Venes, 2009). The tympanogram evaluates the tympanic membrane (TM) compliance to air pressure. An ear-tight probe containing a small speaker, microphone, and air pump is placed into the external auditory canal. The probe then determines the flexibility of the TM in response to positive and negative pressure levels. The normal result is a mountain peak plotted on a graph depicting the positive and negative pressure levels. A flat or absent mountain peak suggests a conductive hearing loss due to obstruction.

NURSING CARE. Appropriate treatment for the hearing loss is based on underlying pathological conditions, presence of organic diseases, the severity of the hearing loss, the degree of frequency loss, and any CNS abnormalities.

Figure 29-12 A routine otoscopic examination of the child is also performed by a health care provider to evaluate the presence of a middle ear effusion or otitis media.

Ear infections are treated with appropriate antimicrobial therapy with close follow-up to monitor for the hearing loss or language delays as well as to monitor response to therapy. Children who have chronic ear infections may have surgery to restore inner ear function with myringotomy tubes placed in the tympanic membrane for effusion drainage and pressure equilibrium.

Simple conduction loss due to cerumen (ear wax) impaction can be treated with over-the-counter preparations, water irrigations and foreign body removal. Stapedectomy (excision of the stapes to improve the hearing) and tympanoplasty (restores function to the sound-transmitting mechanism of the middle ear) have been shown to be effective in restoring the hearing for conduction disorders. Severe to profound hearing loss is treated using cochlear implants that provide sound awareness and support speech development. Cochlear implants carry a risk of meningitis.

Amplification aids (hearing aids) are small microphones that amplify sounds. Amplification devices are fitted to infants as young as 4 weeks old. Most children with mild to moderate hearing loss require some form of amplification. The amplification frequency and ranges are predetermined.

The amplification device is placed in the child's ear, turned on, and then the volume of amplification is adjusted to the child's comfort level. In preverbal children nonverbal cues of irritability such as crying, restlessness, or agitation may signal the need to adjust the volume. Care and maintenance of the hearing aid involve keeping the unit clean and dry with a dry cloth, avoiding water immersion and replacing batteries frequently. Background noise can be distracting to infants wearing a hearing aid. Hearing aids can be removed while sleeping. High-pitched sounds called acoustic feedback can also be disrupting. This sound may not be realized by the hearing-impaired child but can be easily remedied by turning the volume down on the hearing aid, removing the aid, and inspecting the ear for cerumen impaction, cleaning the device or securing proper installation in the external ear canal.

Nurses provide emotional, educational, and collaborative support for the child with a hearing loss and his family. Sign language services may be required as well as visual aids that support nonverbal communication and lip reading. The family needs to investigate home safety measures that protect the hearing impaired child from inadvertent injury. Supervision may be required at all times. Other assistive communication techniques that may be used include lip reading, finger spelling, and cuing. The family can use cued speech, a visual communication system that uses hand and mouth shapes along with gestures to cue a sound or a consonant. This serves as a supplement to lip reading and sign language. Adolescents should be encouraged to turn down radios, stereos, personal music devices such as Ipods, MP3 players, and cell phones in order to prevent the hearing loss.

Be sure to — Follow rules set forth in the Individuals with Disability Education Act of 2004

Children identified with a hearing loss should begin school at an early age in order to prevent early developmental delays in speech and language development. All levels of education should have hearing conservation and loss prevention curricula. The school nurse plays a pivotal role in initiating and monitoring these programs (Folmer, 2003). Early intervention services are implemented in the family using a multi-tiered approach. The Individuals with Disability Education Act of 2004 (IDEA) (<http://idea.ed.gov/>) ensures that children older than 3 years receive assistive services through out the school years up to age 21.

The hearing impaired child needs support services in school and elsewhere to communicate and learn. Early recognition, prevention, treatment, and support services combined with healthy family and individual coping ensures optimal growth and development for the child with a hearing disorder. The hearing impaired children can have the same cognitive ability as children who have no hearing loss. Hearing loss accounts for most language delays seen in children.

Nursing Insight— Communicating with the hearing impaired child

- Recognize behavioral cues suggestive of hearing loss.
- Obtain the child's attention before speaking.
- Face the child when talking.
- Position yourself at the child's eye level.
- Talk slowly and loudly.
- Modify the environment; unnecessary noises should be reduced.
- Offer emotional support: a child with a hearing loss may face a potential stigma associated with their communication difficulty.

Language Disorders

Communication is a process of complex interaction involving the exchange of information, feelings, ideas, and interactions. Verbal speech together with a language framework provides the basic component of communication. Nonver-

bal gestures, tones and body movements provide as much if not more communication than words. Language development is a process of giving and receiving of information and processing and organization of meaning in order to exchange information, thoughts and feelings. The ability to understand what is said is receptive language. The ability to clearly speak to other is expressive language. Speech impairment is an inability to make voice sounds or produce quality; children may experience any combination of hearing speech and/or language disorders.

Children understand more than they can express at a very early age as language is learned last. The majority of a child's speech should be clearly understood by 3 to 4 years of age. Most communication skills are learned by age 5. Approximately 5% of all children have a language disorder.

Nursing Insight— A language quick reference tool

The child's language should be understood

- 50% of the time by age 2 years
- 75% by age 3 years
- 100% by age 4 years
- There may something wrong if the child is not talking appropriately for his age.
- Sentences should be as long as their age.

Jacobsen, C. (2007). Director Hearing and Speech Clinic, Children's Mercy Hospital, KC, MO. Personal communication January 17, 2007.

SIGNS AND SYMPTOMS. Language disorders can be related to physical, emotional, environmental, social, neurological and/or cognitive influences or any combination of these. For some children, delayed competency of language milestones persist into the school age years and slows academic achievement (Dale, Price, Bishop, & Plasmin, 2003). Hearing, cognition, and oral motor ability must be present for language to develop.

DIAGNOSIS. Early detection and intervention for young children with a language disorder prevents many forms of delay in child development. A communication disorder is considered delayed when the child is not meeting predictable developmental sequencing for their age.

NURSING CARE. Speech and language difficulties have been positively correlated with occupational and academic success as well as personal, social, and emotional health.

The nurse is in a key position to recognize speech and language developmental delays. Knowledge about development milestones assist the nurse in recognizing children who are at risk or experiencing a difficulty. The overall nursing goal of early recognition is to prevent a communication, language, and literacy delay that significantly impacts the child at an early age and potentially for life.

nursing diagnoses Language Disorders

- Social Isolation related to inability to communicate, decreased level of consciousness and/or hospitalization
- Impaired Verbal Communication related to articulation difficulties or environmental deprivation
- Parental Knowledge Deficit related to lack of understanding of normal language development

Family Teaching Guidelines... Language Disorder

How To: Tell family that a language disorder is impairment in the child's ability to understand or use words correctly, an ability to express ones self, follow directions, understand words, or any combination of these conditions

ESSENTIAL INFORMATION

- ◆ Help the child learn how to say speech sounds correctly.
- ◆ Help the child improve language comprehension such as increasing their vocabulary.
- ◆ Help the child with conversational and story-telling skills.
- ◆ Help the child and family understand the disorders may impact the child's educational and social interactions.
- ◆ Advise the family about how to find a speech pathologist in the community; schools, rehabilitation, community and private clinics and home services may be utilized to meet the child's needs (American Speech-Language-Hearing Association, 2007).

summary points

- ◆ Unconsciousness is a state where there is a depression of a child's cerebral function. Unconsciousness ranges from a stupor (only aroused with vigorous or unpleasant stimulation) to a coma (state of unconsciousness when the child cannot be aroused).
- ◆ A persistent vegetative state is a complete unawareness of the environment accompanied by sleepwake cycles. The primary causes of a persistent vegetative state are developmental malformations, metabolic and degenerative disorders affecting the nervous system and acute traumatic and non-traumatic brain injuries.
- ◆ The pediatric patient may experience minor or major complications with increased Intracranial Pressure (ICP).
- ◆ Increased ICP can be fatal if not treated because of the effect of edema on the brain. A seizure is caused by an imbalance in the normal inhibition and excitement of neural tissue. Seizure activity is classified according to the area of the brain experiencing the abnormal electrical activity and the neuromuscular sensory and psychogenic alteration from the electrical conduction disturbance.
- ◆ Encephalitis is usually viral in origin and occurs with an acute febrile illness characterized by cerebral edema and infection of surrounding meninges. Signs and symptoms of encephalitis include disorientation, confusion, headache, high fever, photophobia, lethargy, aphasia, hallucinations, seizures, nuchal rigidity and coma.
- ◆ The child with Reye syndrome will normally be a previously healthy child and is usually recovering from a recent viral infection such as varicella (chickenpox), influenzae B, gastroenteritis or an upper respiratory infection. The child may progress through all of the stages of Reye syndrome or may stop at any stage if treatment is effective.

- ◆ Guillain-Barré syndrome (GBS) is a rare self-limiting disease characterized by clinical manifestations of ascending muscle weakness and/or paralysis.
- ◆ There are two categories of hydrocephalus. Communicating hydrocephalus occurs when there is full communication between the subarachnoid space and ventricles. Noncommunicating hydrocephalus occurs when CSF flow within the ventricular system or the ventricular outlets to the arachnoid space is prevented. Most cases of hydrocephalus are obstructive.
- ◆ Cerebral palsy is a nonprogressive neurological disorder that results from brain injury occurring before cerebral development is complete.
- ◆ When caring for a patient admitted with near drowning, a priority nursing responsibility is assessing and maintaining the airway.
- ◆ The primary causes of pediatric traumatic brain injuries are motor vehicular crashes, bicycle accidents, sports trauma, violence, and falls.
- ◆ The priorities of trauma care for a child with a spinal cord injury are initiated with primary attention to airway management, breathing and/or ventilatory support, circulation support, disability identification and exposure of known and unknown physical limitations.
- ◆ Headaches can occur in 90% of children. However, most causes of a childhood headache are based on a simple etiology such as minor trauma, emotions, genetic predisposition, illness, environmental factors or even food and beverages.
- ◆ Children may experience a myriad of common eye disorders which may present as an abrupt change or changes in vision function; eye function may never be identified unless screened for by health care professionals.
- ◆ Hearing loss is diagnosed in approximately 12,000 children per year, resulting in speech and language difficulties, social and developmental delays and slowed academic progress with psychological and occupational difficulties.
- ◆ Early detection and intervention for young children with a language disorder prevents many forms of delay in child development.

review questions

Multiple Choice

1. The pediatric nurse is offering a health prevention lecture to the community. Included in the teaching should be:
 - A. The use of DEET (*N,N*-diethyl-*m*-toluamide) containing products is contraindicated in school-age children.
 - B. Avoiding areas infested with mosquitoes can be helpful in preventing encephalitis.
 - C. The incidence of Reye syndrome has increased due to the use of acetaminophen (Children's Tylenol).
 - D. The *Varicella* vaccine should not be given to children with arthritis or Kawasaki disease.

2. A 3-year-old with a history of hydrocephalus has recently undergone a ventriculo-peritoneal shunt insertion. The pediatric nurse is aware that postoperative care should include:
 - A. Assessing for signs of peritonitis, such as abdominal pain and tenderness.
 - B. Maintaining the head of the bed at a 90-degree angle to facilitate drainage.
 - C. Encouraging the patient to lie on the operative site to decrease pressure.
 - D. Encouraging the patient to lie flat in bed for the first 24 to 48 hours.
3. A 7-month-old, who was born at 28 weeks of gestation, is admitted for a neurological work-up. While obtaining the nursing history, the nurse assesses that the infant has poor sucking and swallowing, continues to have head lag and has increased muscle tone. The nurse suspects that this infant has:
 - A. Spina bifida
 - B. A seizure disorder
 - C. Hydrocephalus
 - D. Cerebral palsy
4. The pediatric nurse is admitting a child with a history of seizure activity. The nurse is aware that seizure precautions must be assembled at the bedside, which includes:
 - A. A ventilator machine
 - B. Suction equipment
 - C. A padded tongue blade
 - D. Intubation equipment.

Select All that Apply

5. A child is admitted to the intensive care unit following a motor vehicle accident. The pediatric nurse utilizes the Pediatric Glasgow Coma Scale to evaluate the child's neurological status. Which assessments does this scale include?
 - A. Verbal response
 - B. Vital signs
 - C. Eye opening
 - D. Motor response
6. A child with a history of recurrent episodes of ear infections has suffered hearing loss. The pediatric nurse is aware that children with hearing loss may also suffer from which of the following?
 - A. Language deficits
 - B. Visual disturbances
 - C. Social delays
 - D. Developmental delays

True or False

7. The pediatric nurse is aware that the unconscious child with a neck injury may have respiratory involvement. The nurse should use caution when suctioning this child in order to prevent a rise in intracranial pressure.
8. Infants whose fontanels have closed are able to compensate for increased intracranial pressure for a longer time period than infants with open fontanels.
9. A 16-year-old is being discharged after a 4 month hospitalization due to a spinal cord injury. Included in the discharge teaching instructions to the parents,

the pediatric nurse stresses that the parents should monitor the adolescent for signs of depression and feelings of isolation.

10. The use of prolonged video gaming has been found to be a high risk precipitating factor for seizures in children.

Fill-in-the-Blank

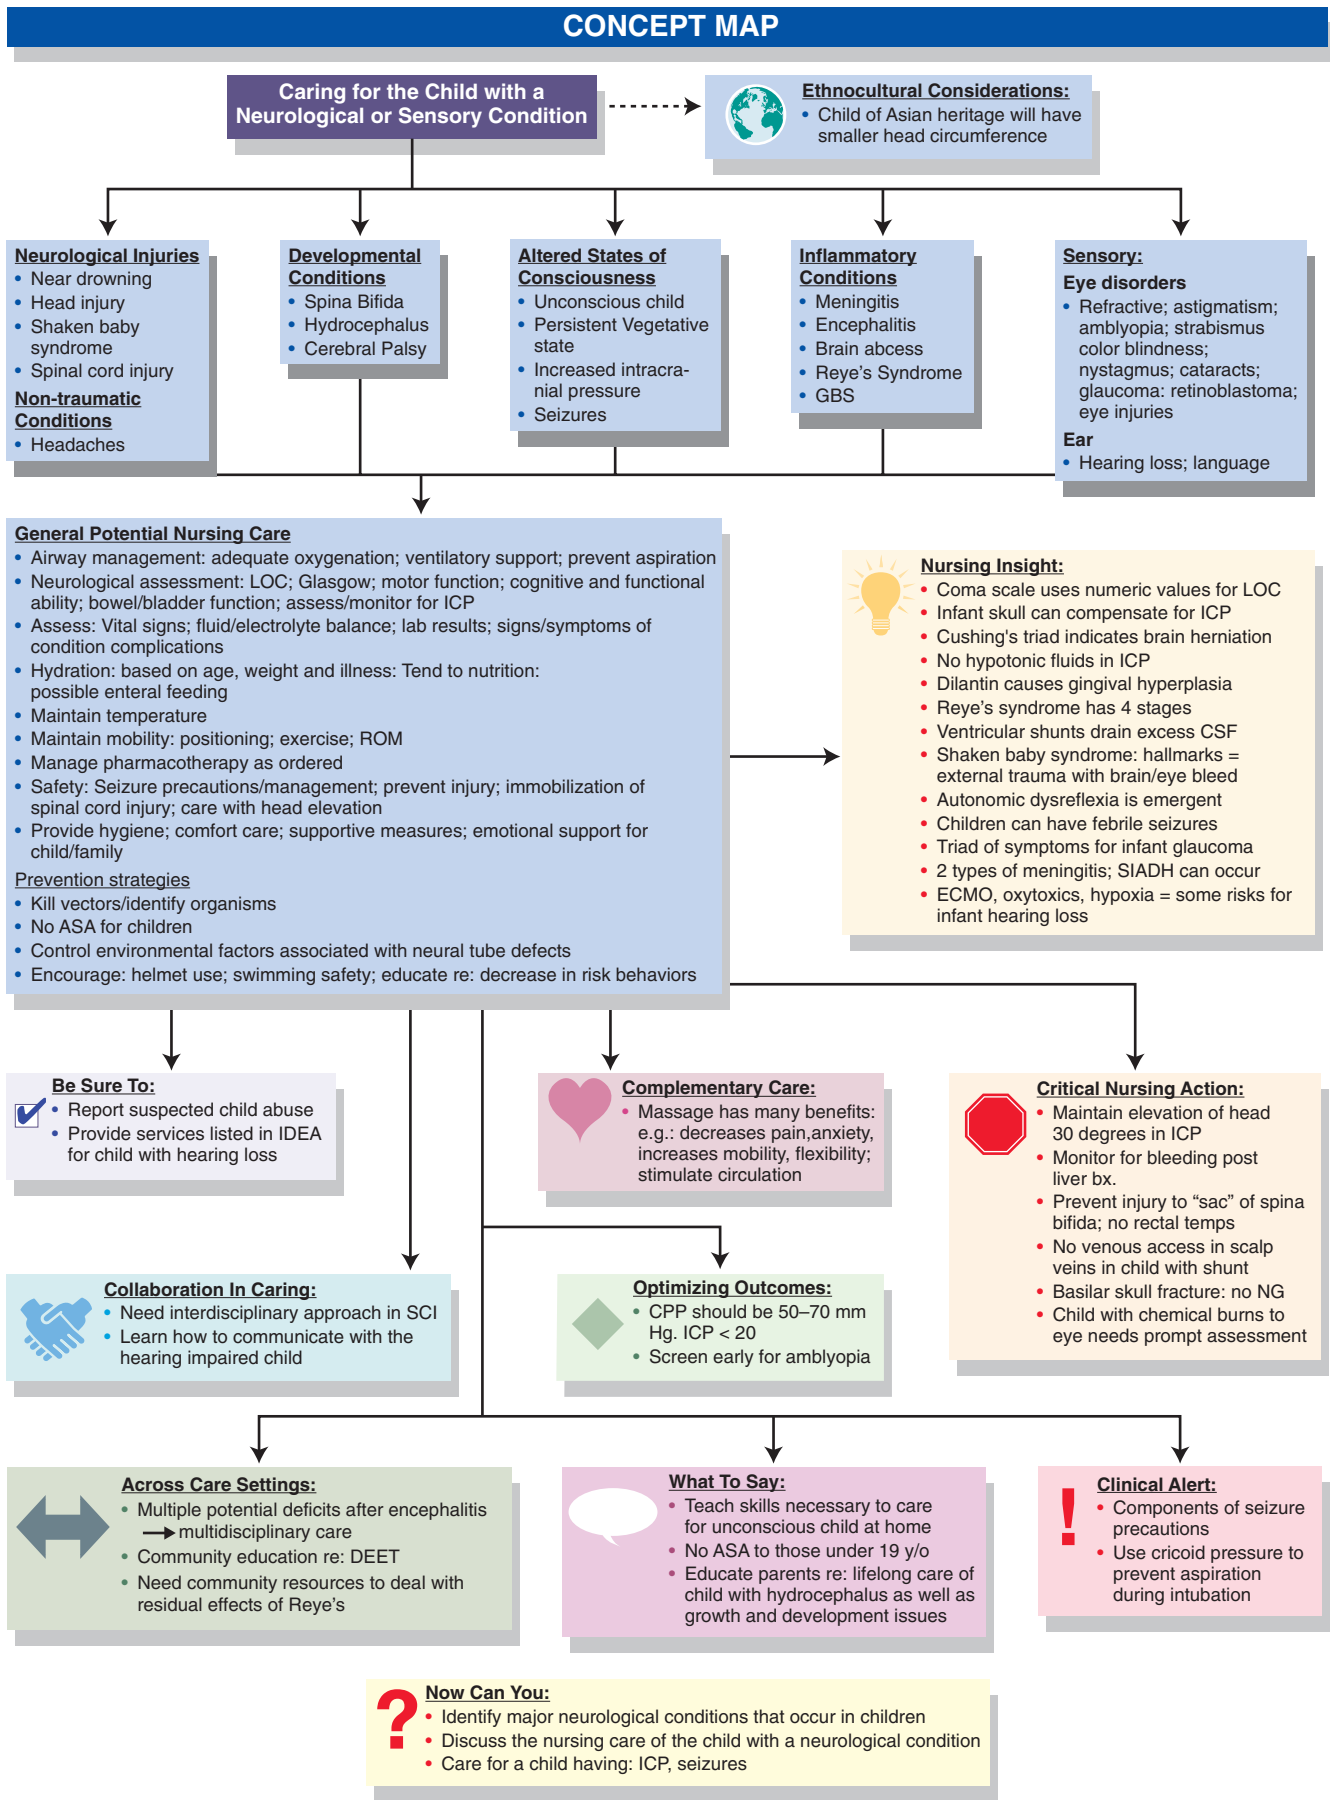

11. When a pediatric nurse is performing a neurological assessment of a child, the assessment must be tailored to the child's _____ and _____.
12. _____ - _____ syndrome is the most common form of acquired acute paralysis in children.

chapter 30

Caring for the Child with a Musculoskeletal Condition

Our bodies are our gardens, to which our wills are gardeners

—William Shakespeare (1564–1616)

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Describe the major structural or functional anomalies of the musculoskeletal system.
- ◆ Describe the signs and symptoms for children with different musculoskeletal conditions.
- ◆ Explain diagnostic procedures for children with musculoskeletal conditions.
- ◆ Examine therapeutic communication techniques for children with musculoskeletal conditions.
- ◆ Apply the nursing process in caring for children with musculoskeletal conditions.
- ◆ Teach health promotion strategies to the family for children with musculoskeletal conditions.
- ◆ Identify community resources for the families' with children who have musculoskeletal conditions.
- ◆ Apply teaching, learning principles in developing a plan for home care for children with musculoskeletal conditions.
- ◆ Identify common pharmacological treatments and side effects used in children with musculoskeletal conditions.
- ◆ Identify complementary therapies used for children with musculoskeletal conditions.
- ◆ Identify across care settings appropriate for children with musculoskeletal conditions.

moving toward evidence-based practice Use of Calcium in Children with Juvenile Rheumatoid Arthritis

Stark, L.J., Davis, A.M., Janicke, D.M., Mackner, L.M., Hommel, K.A., Bean, J.A., Lovell, D., Heubi, J.E., & Kalkwarf, H.J. (2006). A randomized clinical trial of dietary calcium to improve bone accretion in children with juvenile rheumatoid arthritis. *The Journal of Pediatrics*, 148, 501–507.

The purpose of this study was to investigate the impact of behavioral intervention (BI) on the bone mass and maintenance of calcium intake at 6-month and 12-month periods in children diagnosed with juvenile rheumatoid arthritis (JRA).

Study participants were recruited from the outpatient rheumatology centers of three pediatric medical centers in the Midwest. The children who were selected ranged in age from 4 to 10 years. Children who were excluded: (1) had other conditions that affected growth, (2) had non-English speaking parents, (3) had used systemic corticosteroids within the previous 3 months, or (4) were taking calcium supplements. Of 194 eligible families, 49 families agreed to participate, met the criteria, and continued in the study until its completion.

The study design was a randomized trial that compared a group of children who received a six-session BI to a group of children who received a three-session Enhanced Standard of Care (ESC). Three-day diaries were kept to assess calcium intake. Dual energy x-ray absorptiometry (DEXA) was used to assess total bone mineral content (BMC), arm and leg BMC, and lumbar spine bone mineral density.

Separate but simultaneous baseline group sessions were held for both the BI and ESC participants. The meetings were held to instruct parents on how to record and keep a food diary. Fun activities and high-calcium snacks were provided for the children during the sessions.

(continued)

moving toward evidence-based practice (continued)

Intervention with both the ESC and BI groups was initiated with identical dietary counseling. Over an 8-week period, families in the ESC group attended three sessions; families in the BI group attended six sessions. The dietary goal of increasing calcium intake to 1500 mg/day was set for both the ESC and BI groups along with encouragement to consider achieving 400 mg at each meal and 300 mg at each snack time during the day.

Specific Group Interventions**Enhanced Standard of Care (ESC) group**

Sessions for the ESC group included (1) a baseline assessment and training, (2) individual treatment session, and (3) individual posttreatment assessment and feedback. Information about optimal calcium intake and JRA was provided to parents and their children during the second session. Families received graded feedback documenting their child's average calcium intake at each meal and a notebook with informational materials about foods high in calcium.

Behavioral Intervention (BI) group

Sessions for the BI group included (1) a baseline assessment and training, (2) four weekly treatment sessions, and (3) a post-treatment assessment during the 8th week. Information about nutrition and child behavior management strategies aimed at assisting the child in meeting daily calcium intake goals was provided.

Parents in the BI group were instructed:

- To avoid using consequences, coaxing, or commenting when the goals were not met.
- On the use of a technique termed "shaping" —the gradual introduction of a new food.

Children in the BI group received:

- Instruction about the importance of a high-calcium diet.
- A meal at each session with the goal of consuming their calcium goal for which a prize was earned.

Both groups were instructed to record food intake in a diet diary. They were also educated about behavioral management techniques such as praise and encouraged to place stickers on the child's meal chart when calcium goals were met. Calcium intake and bone mass were evaluated for both groups at 6 and 12 months after the treatment sessions.

Data Collection

Self-report questionnaires and charts were reviewed at baseline and at 12 months to compare the number and types of medications and the number of inflamed joints. Seven-day food records were reviewed in the food diaries at baseline, after treatment, and at the 6- and 12-month follow-up visits. Intake was evaluated by a dietician for daily calcium, calories, protein, carbohydrates, and fats.

Total body and lumbar spine bone mass was measured using a dual energy x-ray absorptiometer at baseline and at 6 and 12 months posttreatment. Each child's height, weight, and body-fat measurements were also taken at each of the three points of time. Vitamin D concentration was measured using a Dia Sorin 25-OH-D assay, also at baseline and 6 and 12 months posttreatment.

Results

- The groups were predominantly composed of female Caucasian children.
- The average age of the children in the ESC group was 6.8 years; in the BI group the average age was 6.1 years.
- The children in the ESC group maintained a baseline calcium intake of 1300 mg/day at both 6- and 12-month follow-up visits.
- The children in the BI group maintained an average calcium intake of 1500 mg/day at both the 6- and 12-month follow-up visits. This amount represented an increase from the 972 mg/day calculated at the baseline. The difference between groups was not significant.
- Total body bone mineral content gain of the BI group was 4% greater at the 6-month follow-up visit and 2.9% greater at the 12-month follow-up visit than the gains of the ESC group.
- The bone mineral content gain for arms and legs of the BI group was 7.1% greater at the 6-month follow-up visit and 5.3% greater at the 12-month follow-up visit than the gains of the ESC group.
- The children in the BI group grew an average of 2.91 inches (7.4 cm) between baseline and at the 12-month assessment, compared to 2.88 inches (7.3 cm) in the ESC group. This increase in growth was not significant.
- Children in the BI group gained an average of 8.14 lbs. (3.7 kg), compared to 7.7 lbs. (3.5 kg) for the ESC group. The increase in weight was not significant.
- The average serum 25-OH-D concentration did not vary between or within the groups at any assessment point.
- The study findings revealed that there was a greater total body bone mineral content increase in the children with an increased dietary calcium intake.
- The researchers concluded that use of BI is effective in increasing calcium intake in children with JRA over a 12-month period.

1. What might be considered as limitations to this study?

2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

Children are by nature very active and their musculoskeletal system plays a major role in their growth and development. When their ability to interact with the environment is impaired, possibly through a musculoskeletal system disorder, they are at risk for impaired growth and development. Alterations in the musculoskeletal system may be related to a congenital defect such as muscular dystrophy, clubfoot, or osteogenesis imperfecta. Other alterations may be related to an acquired defect such as Legg–Calve–Perthes disease, slipped femoral capital epiphysis, fractures, soft tissue or sports injuries, Osgood–Schlatter disease, osteomyelitis, juvenile arthritis, scoliosis, tetanus, or osteoporosis.

This chapter discusses some of the more common alterations in mobility among children, the challenges they face, and the short-term and long-term goals. It also covers diagnostic analysis for the child with musculoskeletal conditions.

A & P review

Movement is made possible by the musculoskeletal system, which consists of the bones, joints, ligaments and tendons and muscles. These structures provide protection for the vital organs inside the body. Children are more likely to suffer from conditions of the musculoskeletal system because their musculoskeletal system is still growing. On the positive side, because the bones are still growing in a child, a fracture heals much faster than in an adult. Conversely, if the fracture penetrates the growth plate in a child, growth of that bone is interrupted. Some conditions involving the musculoskeletal system may have only a slight effect on the child's ability to mobilize and be short-term. Other conditions may have a significant affect, be debilitating and long term.

Bones

Bones are classified by their size and shape. Long bones are found in the extremities, including the fingers and toes. Most childhood disorders are located in the long bones. Short bones are located in the ankle and wrist. Flat bones are located in the skull, scapulae, ribs, sternum, and clavicle. Irregular bones are the vertebrae, pelvis, and facial bones. Long bones consist of the epiphysis (rounded, end portion), the diaphysis (long, central portion), and the metaphysis (thin portion between the epiphysis and the diaphysis). Long bones grow in length at the epiphyseal plate (cartilage segment) when the cartilage segment cells grow away from the shaft of the bone. The cartilage cells are replaced by bone. The diaphysis of the long bones is covered by periosteum (an outer, sensitive layer). The width of the bone is increased by pressing against the periosteum. Some disorders, such as osteomyelitis, cause damage to the periosteum and can interrupt bone growth.

Bones need nutrients in order to grow. Calcium is a main component of bones and is required for bone formation, resorption (bone breakdown), and remodeling (new bone replacing old bone). Calcitonin, parathyroid hormone, vitamin D, other minerals, and enzymes all play a role in the processes of resorption and remodeling. The central part of a long bone contains the marrow. Red marrow is responsible for production of red and white blood

cells and platelets. Yellow marrow is responsible for the production of fat cells. Bones have an excellent blood supply, which enable the production of blood components for the body. Bone cells die and the necessary production of blood components is interrupted if there is no blood supply to the long bones.

Ligaments and Tendons

Ligaments are fibrous bands of connective tissue linking two or more bones, cartilages together. They provide stability to a joint during both movement and rest. The blood supply to ligaments is very small and they lack elasticity. Therefore, an injury to a ligament can take a long time to heal. Tendons are also fibrous connective tissue that attaches muscles to bones and other parts. There is also very little blood supply to the tendons and an injury to a tendon can also involve a lengthy recovery.

Muscles

Muscles consist of striated muscles and smooth muscles. Skeletal muscle is a type of *striated muscle* that attaches to tendons.

Skeletal muscles are used to create *movement* through contraction by applying *force* to *bones* and *joints*. These muscles can contract voluntarily (by somatic *nerve* stimulation) or can contract involuntarily through *reflexes*. *Smooth muscle* is a type of muscle found in the walls of all the hollow organs of the body (except the heart). Smooth muscles are involuntary muscles and are under the control of autonomic nervous system. For example, smooth muscles regulate the flow of blood in the arteries, move food through the *gastrointestinal tract* and expel urine from the bladder. ♦

Nurses play an important role in assisting the parents to find methods to help the child maintain normal growth and development as well as adapting or overcoming musculoskeletal system impairment. The nurse understands that casts, skin traction, skeletal traction, and distraction devices are ways to immobilize an extremity. The nurse evaluates the child through physical assessment. Laboratory studies and diagnostic tests can help establish the cause and nature of the musculoskeletal injury or condition. The results of these tests are then used to help the nurse develop an appropriate plan of care.

diagnostic tools Orthopedic Imaging Tests

Diagnostic Imaging Test	Benefits	Limitations
Radiograph	Easily available Visualizes fractures well No sedation needed Inexpensive	Two-dimensional Does not visualize soft tissue such as cartilage Patient must be positioned properly Radiation exposure
Fluoroscopy	Guides many orthopedic procedures Can be used with contrast Real-time radiography Inexpensive	Radiation exposure
Arthrography	Provides visualization of joints Three-dimensional view	Risk of reaction to contrast Depends on the skill of the radiographer Radiation exposure

diagnostic tools Orthopedic Imaging Tests—cont'd

Diagnostic Imaging Test	Benefits	Limitations
Computed tomography (CT scan)	Cross-sectional view of anatomy Clearer than radiographs Software programs can show reconstruction Can use contrast	Expensive May require sedation Risk of reaction to contrast
Bone scan (nuclear medicine)	Excellent at finding changes in bone as a result of infection, trauma, or tumor	Takes 4 hours Not always available on emergency basis Cannot distinguish benign from malignant tumors Radiation exposure to entire body IV access required
Ultrasound	Easily available No radiation No sedation needed Good for visualizing soft tissue masses and cysts Painless Inexpensive	Limited use Depends on the skill of the radiographer
Magnetic resonance imaging (MRI)	Visualizes hard and soft tissue and bone marrow No radiation	Not readily available No metal can be present in the vicinity Sedation may be needed Need experienced radiologist to read MRI

Immobilizing Devices

The nurse understands that casts, skin traction, skeletal traction, and distraction devices are four different methods to immobilize an extremity. Each of these methods is effective in treating musculoskeletal conditions in the child. There are benefits and risks associated with each of these methods. Specific nursing interventions need be initiated with each of these immobilization devices.

CASTS

Casts are a solid mold applied for immobilization purposes for fractures, dislocations, and other injuries. Casts are made of either a synthetic material such as fiberglass or plaster of Paris. Fiberglass is preferred because it is lighter in weight and dries within 30 minutes. Plaster of Paris casts take about 10 to 72 hours to dry.

There are four categories of casts: upper extremity, lower extremity, spinal or cervical, and total body. An upper extremity or lower extremity cast provides absolute immobility of the affected extremity (Fig. 30-1). A complex or extensive fracture may require rigid spinal or cervical cast for a long period of time. A total body cast such as a hip spica cast (also called a spica cast) immobilizes the hips and thighs so that bones or tendons can heal properly after hip surgery. A bilateral long leg cast with an abduction bar (crossbar connects the cast together at ankle level) is also used for significant immobilization. Both the hip-spica and bilateral long leg cast with an

Labs: Blood and Body Fluid Analysis for the Child with Alterations in Musculoskeletal Conditions

Diagnostic Test	Function of the Test	Indications	Normal Values
Complete blood count (CBC)	Blood sample evaluates many aspects.	Platelets indicate a bleeding disorder	Platelets: 150,000–400,000/ μ L
CBC differential	Breaks down WBC into various types (five total). Numbers indicate a percentage of total WBC Indicates the type of infection.	>WBC indicates a bacterial infection or septic arthritis Monocytes indicate a long-term infectious process. Lymphocytes indicate an increase in viral illness. Eosinophils indicate an allergic or parasitic condition. Basophils indicate a chronic inflammatory condition. Neutrophils (polys) Bands are immature neutrophils. Segs are mature neutrophils. (Left-shift describes an increase in the band neutrophils.) Suggests a severe bacterial infection such as sepsis.	WBC: 4500–10,000/ μ L 0% for bands and 31–57% for segs Presence of bands is highly indicative of a bacterial infection.
C-Reactive protein (CRP)	Measures a protein in blood that is released when an infection is present.	>0.9 indicates an infection or septic arthritis.	<1.0 mg/dL
Calcium and phosphate	Measures the amount of these minerals.	Low levels may indicate rickets.	Calcium: 8.5–11 mg Phosphorus: 3.0–4.5 mg/dL
Rheumatoid factor (Rh factor)	Measures the body's autoimmune response to an antigen.	If positive, may indicate juvenile arthritis. Not all children with juvenile arthritis have a positive Rh factor.	Negative
Erythrocyte sedimentation rate (ESR)	Measures the speed at which RBCs settle out in solution.	Elevated indicates septic arthritis. May also indicate infection.	0–10 mm/hr
Blood cultures	Measures whether microorganisms grow out in the lab.	Can identify an organism causing infection. Forty percent of children with septic arthritis have a positive blood culture.	No growth
Bone biopsies	Diagnose tumor or infection of the bone.	Osteomyelitis Bone tumor	Normal bone cells
Fluid aspiration from joints	Diagnose an infection of the joint or drain fluid from joint to relieve pressure	Drainage is purulent. Culture of fluid is positive.	Clear fluid No growth from culture

abduction bar encase the trunk up to the nipples and both legs to the toes.

When a child is placed in a total body cast, parents have a much easier time caring for a child in a bilateral long leg cast that has an abduction bar than a child in a hip-spica cast. The nurse can teach parents that periodically, the cast needs to be changed. The two most common reasons to change a cast are when it becomes soiled or wet. Also, incision sites under a cast need to be assessed for infection. This includes checking for a foul odor, drainage from inside the cast, or staining through the cast.

Cast Complications

Complications can occur when a child is immobilized in a cast. The major complication is **compartment syndrome**. Compartment syndrome is caused by an accumulation of fluid in the fascia. This increases the pressure on the muscles, blood vessels, and nerve tissue that the fascia surrounds. Too much pressure can cause tissue ischemia, nerve damage, and necrosis. Unchecked compartment syndrome can result in the loss of the limb and possibly the loss of the child's life. A fasciotomy (surgical incision where a division of a fascia occurs) may be necessary to relieve the pressure. Pressure sores secondary to a tight cast or poor padding are another complication.

When a child is placed in a hip-spica cast, cast syndrome can occur. **Cast syndrome** occurs when a portion of the duodenum is compressed between the superior mesenteric artery and the aorta, causing vomiting, abdominal distention, and bowel obstruction.

critical nursing action Cast Syndrome

Cast syndrome can be prevented by three nursing interventions:

- Frequent repositioning
- Fluids and increased fiber in the child's diet
- Cut a "belly hole" or a window in the cast to allow for abdominal expansion

Figure 30-1 A cast is applied to the affected extremity to keep it immobile while healing.

Nursing Care

Nursing care of the child in a cast begins with pre-application teaching to the child and family. For example, allow a preschool-age child to apply a cast to a doll. Then, give the child time to play with the casted doll before actually applying the cast to the child. When a child has any type of cast the nurse performs a neurovascular assessment with vital signs. An assessment is also done any time neurovascular compromise is suspected. A nursing assessment for a child with a cast includes the 5 "P"s: pain, pulse, pallor, paresthesia, and paralysis.

After the cast is applied, the nurse can facilitate drying of the cast by leaving the cast open to air. The cast has a hollow sound when it is dry. The nurse understands that it is never acceptable to use a hair dryer to facilitate drying. The heat from the hair dryer can cause a burn injury under the cast. The nurse can instruct the family that careful handling of the cast is an important intervention that prevents dents in the cast. Dents can cause pressure points on the tissue under the cast and ultimately result in a pressure sore.

Children treated with a plaster of Paris hip-spica cast are placed on a Bradford Frame, which elevates the child off the bed and facilitates drying of the plaster cast. The frame is secured to the bed and the child is secured to the frame. There is a hole in the frame to allow for elimination. Children treated with a fiberglass hip-spica cast are placed in the bed with pillows to support the lower extremities.

During the course of the drying phase and ongoing cast care, the child is turned every 2 hours. Frequent turning helps to facilitate drying and prevent cast syndrome if the child is in a hip-spica cast. At times, the cast may be bivalved meaning that it is cut down one or both sides with scissors to allow for expansion. The bivalved procedure is done to alleviate pressure, monitor for infection, or to help maintain proper hygiene. After the cast is bivalved, the affected extremity is elevated when the child is in bed, in a chair, or a wheelchair.

Elevation of the affected extremity helps with the child's pain control and prevents damage caused by pressure. If the child has a single-extremity cast, a waterproof plastic sleeve can be used to protect the cast and provide a seal with the skin proximal to the cast. It is also important for the nurse to explain to parents of a child in a cast that the child needs to be held. The nurse can help parents adjust to holding their child with a cast.

Hygiene is a major concern for a child in any type of cast but especially a hip-spica cast or bilateral long leg casts with an abduction bar. The nurse understands that protecting the proximal edges of the long leg casts and the perineal area of the hip-spica cast from soiling is a key hygienic intervention that is achieved by petaling the cast (Procedure 30-1).

Nursing Insight— Modifications for a child in a hip-spica cast

Modifications need to be made for a child in a hip-spica cast. The hip-spica cast prevents the child from sitting normally; therefore, parents need a way to help their child adapt. One suggestion for modification is a toddler car seat that does not have sides. Toddler car seats are designed to help the small child with a hip-spica cast to sit fairly normal. They also have

Procedure 30-1 Petaling a Cast

Purpose

The purpose of petaling a cast is to promote good hygiene by protecting the proximal edges of the long leg casts and the perineal area of the hip-spica casts from soiling.

Equipment

Moleskin
1-inch waterproof adhesive tape
Plastic bag to place adhesive tape on
Scissors

Steps

1. Use scissors to cut 1-inch wide by 1 1/2 to 2 inches long strips of moleskin.

RATIONALE: *Cutting the material ahead along with the proper size of moleskin facilitates application.*

2. Use scissors to cut 1-inch wide strips of waterproof adhesive tape. The length of the waterproof adhesive tape should be about 1 1/2 to 2 inches long.

RATIONALE: *Waterproof adhesive tape helps provide a protective barrier for the skin.*

3. The edge on one end of both the moleskin and waterproof adhesive tape must be rounded.

RATIONALE: *Rounded edges keeps the moleskin and waterproof adhesive tape edges from rolling.*

4. Place strips of the 1-inch waterproof adhesive tape on the plastic bags.

5. Apply the first strip of waterproof adhesive tape to any edge of the cast that is likely to become soiled by urine or stool. Place the rounded ends of the moleskin and adhesive tape over the cast edge to the outside.

6. Tuck the straight (unrounded) end inside the cast.

7. With your forefinger, gently ensure that the inside end is flat and not sticking to the child's skin.
8. Repeat the procedure, overlapping each additional strip, until all rough edges are completely covered.
9. Begin the same procedure with the moleskin to edges of the cast that are not likely to become soiled by urine and stool.

Clinical Alert It is a good idea to petal the edges of the cast that are likely to be soiled by urine and feces on the first postoperative day and preferably before the Foley catheter is removed.

Teach Parents

The nurse can teach the parents that diapering needs to be modified. To achieve this, a small diaper or peripad is placed in the perineal area with all edges of the cast outside this small diaper. Then a larger diaper is placed outside the smaller diaper and taped in the normal fashion. The nurse needs to ensure that the perineal edges of the cast remain outside of the diaper.

Documentation

1/9/10 0900 Upper edge of cast soiled and moist. Cast petaling performed. Waterproof adhesive tape to the upper edge of the cast, then moleskin applied. After petaling; the cast is noted to be clean and dry. No adverse reactions noted.

-M. O'Connor, MS, RN

a 5-point restraint system. Another suggestion is allowing a child to sit in a wagon with siderails. Feeding a child in a hip-spica cast can also be a challenge. Placing the child in the prone position on the floor is a good modification and makes it easier for the child to feed herself. Allowing the child to have supervised time while prone on a blanket helps the child to maintain developmental milestones.

Bathing the child with a cast is also an important nursing intervention. If the child has a small extremity cast a typical bath can be taken as long as the cast is protected from water. A large plastic bag can be placed over the cast during the bath. If the child is in a bilateral long-leg cast with an abduction bar, or a hip-spica cast, the nurse can teach the parent how to bathe the child by giving a sponge bath. In addition, frequent diaper changes help prevent complications such as skin breakdown and infection. Good perineal care is essential for children for all ages.

During the casting period, the child may be prone to constipation due to inactivity. The nurse can teach the family about the importance of good fluid intake and calling the health care professional about laxatives or stool softeners if needed.

Sometimes the child experiences some itching under the cast. Itching can be prevented by keeping the skin in good condition by turning the child every 2 hours and keeping the cast clean and dry. It is important for the nurse to tell parents that some children try to push items under the cast to scratch the area. The nurse can teach parents and the child that absolutely nothing should be placed under the cast. If the itching is severe, the nurse can instruct the parent to call the health care provider about medication.

Cast care also includes taking care of the cast when it is being removed. The nurse must explain to the child that the sound of the cast saw is loud and can be frightening. It is difficult for the child to believe that the saw will not cut his or her skin. Reassure the child that she will not be injured with the cast removal. When the cast is removed, the child's skin is dry and flaky and the muscles are weak and possibly stiff. It is important to consider the child's emotions about the cast because the child may have grown used to it and think of it as a part of him or her.

Principles of Traction

The nurse recognizes that the main principle of traction is to reduce dislocations and immobilize fractures in the child. During the application of traction, one body part is pulled in one direction (traction) against a counterpull in the opposite direction (countertraction). The traction and the countertraction are the actual weights and pulleys. There are two main types of traction: skin traction and skeletal traction.

SKIN TRACTION

Skin traction is used for an extremity with a type of strapping material applied to the limb. Skin traction is used for short periods of time. Bryant's traction is one type of skin traction and is used to treat developmental dysplasia of the hip, shortened limb, and femur fractures in children

younger than 2 to 3 years of age. The child must weigh less than 26.4 lb (12 kg) to use Bryant's traction. In Bryant's traction, the child lies supine with thighs flexed and the hips slightly off the bed. Moleskin straps are applied to the child's calves and the pull is in only one direction. The nurse understands that the child's body is in the countertraction. In modified Bryant's traction, the hips remain on the bed, but the legs are abducted.

Russell's traction is another type of skin traction that is used when the child weighs more than 26.4 lb (12 kg). It is most often used to stabilize femur fractures until a callus forms or with Legg–Calve–Perthes disease. With this type of traction, the child lies supine with hip flexed and abducted. There are two lines of pull in Russell's traction and the hips need to remain in alignment (Fig. 30-2). The child should have a trapeze secured on a cross-bar above the bed to assist with repositioning and maintaining upper body strength. In this type of traction a sling is placed under the knee. The placement of the sling is assessed frequently. Countertraction is increased with the foot of the bed elevated and the head of the bed flat.

Balanced suspension is used to suspend and immobilize the leg without traction to the rest of the body. Balanced suspension is achieved by attaching the Pearson attachment to the Thomas splint. This allows the leg to be "suspended" over the bed. A footplate can be attached to the end of the bed to reduce the incidence of foot drop. The nurse ensures that the bed remain flat to decrease the flexion in the hip. If the child has the bed in semi-Fowler's position, the head of the bed is lowered for 20 minutes per day.

Nursing Care

Nursing care for the child in skin traction requires a neuromuscular assessment to the affected extremity every 4 hours. Watch for web space numbness in fingers and toes. Web space numbness may indicate compartment syndrome. For any child in traction, it is necessary to assess circulation, sensation, pain, pallor, cyanosis, movement, and decreased pulse every 2 to 4 hours.

The nurse must ensure that the traction weights are checked and hanging free and that the child is in alignment with the traction. Skin traction needs to be removed and reapplied every 4 hours.

Perform skin care every 4 hours. The skin under the straps needs to be inspected and treated with rubbing alcohol to remove the body oils, which might cause the straps to slip. The nurse pays particular attention to the bony prominences that can break down easily. Do not

Figure 30-2 The child in Russell's traction (with trapeze).

massage bony prominences and ensure protective foam is in place. If the child has Ace wraps, protect the Ace wraps from urine and stool. The nurse can have two sets of Ace wraps for the child. Keep one set washed and ready to be used in case the other set becomes soiled. While the child is in traction, the nurse can initiate diversional activities to keep the child occupied while in traction (e.g., movie videos, board and video games, puzzles, blocks, and other toys that are easy for the child to handle).

SKELETAL TRACTION

Skeletal traction is used when more pulling force is needed than can be withstood by skin traction. Since the advent of newer orthopedic devices that achieve similar outcomes as skeletal traction and allow the child to be cared for at home rather than in the hospital, skeletal traction of traction is used much less frequently. However, skeletal traction is still used when the weight of the traction needs to be more than 5 pounds.

In children, skeletal traction is used for long periods of time until the bone is ready for casting or **open reduction** (surgery to place the bones in their proper position). Many children needing skeletal traction have sustained multiple injuries. In skeletal traction, a pin is placed through the bone distal to the fracture. It is extremely important to note that with skeletal traction, the weights cannot be removed. There are three common forms of skeletal traction: Crutchfield tongs, 90/90 femoral traction, and Dunlop traction.

Crutchfield Tongs

Crutchfield tongs are used in the treatment of cervical and thoracic fractures. The tongs are placed into the child's skull (Fig. 30-3). The pull is along the axis of the spine. The traction usually hangs off the head of the bed. The countertraction is the body. The tongs need to be assessed every 8 hours and as needed for placement and looseness. The nurse uses log rolling to turn the child in Crutchfield tongs. When this type of traction is used, pin care (gently cleansing the wound with saline-moistened gauze and applying antibiotic ointment with a cotton-tipped applicator if prescribed by the physician) needs to be done every shift. Neurovascular signs need to be assessed every 4 hours (more often if needed) due to the pressure on the spinal cord. Other important nursing care measures include pain control, meeting nutrition and elimination needs, providing proper hygiene, maintaining developmental milestones, giving emotional support and allowing for spiritual care. The family can be encouraged to express feelings of worry, helplessness, and frustration.

Figure 30-3 Crutchfield Tongs are used in the treatment of cervical and thoracic fractures.

Figure 30-4 The 90/90 femoral traction is most commonly used to treat femur fractures and complicated femur fractures.

90/90 Femoral Traction

The 90/90 femoral traction is most commonly used to treat femur fractures and complicated femur fractures. A pin is placed in the femur, distal to the fracture. Weights are attached to a sling that supports the calf and also to the pin that causes the traction (Fig. 30-4). The body is the countertraction. Femoral traction is more effective in children older than 6 years of age. Often femoral traction is used for the first 2 to 3 weeks after a femur fracture until enough of a callus forms. After a callus forms, a hip-spica cast is applied. The nurse needs to perform pin care every shift or according to the hospital policy. The nurse also needs to meet the holistic health needs of the child and family.

Maintaining the child in this type of alignment can be challenging. Sometimes there is a need for restraints to keep the child in proper alignment. If restraints are needed, hospital policy needs to be strictly followed and the nurse needs to obtain an order from the physician. Generally, a hospital restraint policy states that the restraints need to be removed every 2 hours for 10 minutes while the child is awake and every 4 hours for 10 minutes while the child sleeps. The restraint order also needs to be renewed by the physician every 24 hours. A better solution that restrains is constant supervision by parents, family members, friends and hospital staff. Often a hospital will have a volunteer program or a child-life specialist who can help with diversion activities.

Dunlop Traction

Dunlop traction is used in the treatment of a supracondylar fracture of the humerus. In this type of traction, a pin is placed in the humerus, distal to the fracture. Weights are attached to the forearm and to the pin that causes the traction. The body is the countertraction (Fig. 30-5).

Figure 30-5 Dunlop traction is used in the treatment of a supracondylar fracture of the humerus.

Volkman's ischemia can occur with children in Dunlop traction. The child complains of numbness, tingling, and a decreased sensation in the fingers. An important nursing intervention is to ask the child to wiggle the fingers to help relieve the discomfort.

Nursing Care

Assessment is the key nursing care measure for a child in skeletal traction. Neurovascular status must be assessed carefully and every 1 to 2 hours for the first 48 hours and then every 4 hours after that if there is no compromise in circulation. The nurse needs to know the symptoms of compartment syndrome and report them to the physician immediately.

Nursing Insight— Performing the neurovascular assessment

- **Pain**—Does the child complain of pain in the affected limb? Is it relieved by narcotic medication? Does it become worse when fingers or toes are flexed? If yes, notify physician *immediately* (compartment syndrome).
- **Sensation**—Can the child feel touch on the extremity? Is two-point discrimination decreased? If yes, notify the physician immediately (compartment syndrome).
- **Motion**—Can the child move fingers or toes? Lack of movement may indicate nerve damage.
- **Temperature**—Does the affected limb feel warm? Does it feel cool? A cool extremity may change to feeling warm if a blanket is placed over it and the extremity is elevated. If the extremity is still cool after these interventions, there is poor circulation.
- **Capillary refill time (CRT)**—Apply brief pressure to the nail bed and note how quickly pink color returns to the nail bed. CRT of less than 3 seconds is the norm. If CRT is greater than 3 seconds, circulation is poor (Fig. 30-6).
- **Color**—Note the color of the affected limb. Compare it to the color of the unaffected limb. Pink is the norm. If the color is paler than in the unaffected limb, circulation is poor.
- **Pulses**—Check pulses distal to the injury or cast. If the pulse is difficult to locate, assess with a Doppler. If the cast covers the foot or hand, it may not be possible to check the pulse but the other neurovascular assessment can be implemented.

The nurse also needs to understand the principles of traction and the reason why the traction has been applied. Other nursing care measures include maintaining the traction, maintaining the alignment of the traction with the child, preventing skin breakdown, providing pin site care, managing pain, maintaining good nutrition and elimination, preventing complications and preparing the family for discharge,

Maintaining the traction involves assessing the desired line of pull with the relationship between the distal part and the proximal part. The nurse ensures that:

- The ropes are in the center part of the pulley, taut, and are intact, without knots.
- The pulleys are checked often to be sure they are in their original place and that the wheels of the pulley move freely.

Figure 30-6 The nurse assesses capillary refill time.

- The amount of the weights is correct and that they are hanging freely.
- The bed is positioned with the head or the foot of the bed elevated as ordered so that the correct amount of pull is achieved with the traction and countertraction.
- The skeletal traction is not removed. If a child needs to be moved or if the traction needs to be adjusted, the nurse contacts the surgeon.

Maintaining the alignment of the traction with the child can be a challenge. By nature, children are unable to remain still in bed for extended periods of time. The nurse needs to realign the child in the bed often. Emphasis is on ensuring that the shoulder, hip, and leg are in a straight line with the lines of traction. Diversional activities are essential in assisting the child to maintain proper alignment. Collaboration with the child-life specialist also helps the child.

To prevent skin breakdown, place the child on an alternating-pressure mattress or a foam mattress overlay. A nursing assessment of the child's body is done to look for redness or breakdowns, especially on bony prominences receiving the greatest pressure. The nurse can wash and dry the child's skin daily or more frequently if needed. The nurse can also stimulate circulation with gentle massage over pressure areas and change the child's position every 2 hours to relieve pressure.

The nurse assesses pin sites every 8 hours for signs and symptoms of infection to prevent osteomyelitis.

Managing the child's pain is essential and the nurse can use pharmacological and nonpharmacological care measures. The nurse must use good judgment about the administration of pain medication by not waiting too long to administer pain medication and being alert for any adverse side effects. Effective pain control methods include epidural with bupivacaine (Marcaine) and a narcotic such as morphine sulfate (Astramorph) or hydromorphone (Dilaudid), patient-controlled analgesia (PCA) with morphine sulfate (Astramorph), or hydromorphone (Dilaudid). Antispasmodics such as diazepam (Valium) will give relief to the child with muscle spasms. The nurse can also ask the parents to participate in pain

where research and practice meet: Pin Care

Pin site infection has been a problem for nursing practice. Hospital policy and procedure manuals each have a specific procedure to follow to help prevent this problem. Few multicenter studies have been done to determine which method is in fact most effective. Patterson (2005) completed a multicenter, prospective, randomized pin-care study over a 2-year period. The goal was to determine which of seven different methods is most effective in preventing pin-site infections:

1. Half-strength hydrogen peroxide cleansing and gauze wraps
2. Half-strength hydrogen peroxide cleansing and Xeroform wraps
3. Saline cleansing and gauze wraps
4. Saline cleansing and Xeroform wraps
5. Antibacterial soap and water cleansing and gauze wraps
6. Antibacterial soap and water cleansing and Xeroform wraps
7. Stable dressings with no pin cleansing

The results showed that 527 pins had an average infection rate of 20%. Ninety-eight pins had stage II infections and 12 pins had stage III infections. None had a deep infection or osteomyelitis.

The conclusion of this study suggests that there may be some factors involved in pediatric pin-site infection that were not covered in this study. It is clear that half-strength hydrogen peroxide and Xeroform wraps were superior to antibacterial soap and water cleansing. This was a pilot study and indicates a need for further research in this area.

assessment and pain management by offering comfort measures. Diversional activity also might help manage pain. The nurse can involve the child-life specialist in this aspect of care. The nurse can work collaboratively with the physical therapist to perform passive and active range-of-motion exercises to prevent weakness in uninvolved extremities. If pain is under control, the child may be able to perform minimal activities of daily living while on bed rest.

Maintaining good nutrition is essential for the child in skeletal traction. The hospital nutritionist can visit with the family to discuss healthy meals. The child may tolerate six small meals and health snacks instead of the traditional meal schedule. The nurse can offer the child healthy drinks and snacks. A sticker reward chart may be an effective measure to encourage good nutrition and reward healthy food choices. The child also needs to be assessed for regular elimination to ensure she does not become constipated or acquire a urinary tract infection.

The nurse must be alert to the child in skeletal traction, as serious complications can occur. Osteomyelitis (inflammation of bone and marrow, usually caused by infection) is a major, serious complication. The nurse also helps to prevent complications such as pneumonia, circulatory compromise, ischemia, and problems of disuse with uninvolved extremities. Any circumferential dressing has a potential to cause impaired circulation so dressings are assessed for tightness. Any restrictive bandages or devices are also assessed to ensure that they are neither too tight nor too loose. The nurse needs to assess for the 5 P's. Any notation of these symptoms may indicate circulatory compromise and possible ischemia. A burning sensation is associated with ischemia and can be an early indicator of neurovascular problems.

Nursing Insight— Preventing pneumonia

Respiratory care includes assessment and methods to increase lung expansion to prevent pneumonia. An incentive spirometry can be used for the school-age and adolescent child (Fig. 30-7). Younger children are not able to understand how to use the incentive spirometer, but the nurse can use creative measures to encourage expansion of the lungs (e.g., blowing a pinwheel, bubbles, a musical instrument, or a small folded paper triangle across the bedside table).

Preparing the family for discharge is essential to ongoing care of the child as the child will most likely have long-term casting or continued immobility. While the child is hospitalized, the nurse can coordinate a care conference to help plan discharge and home care. The family needs to learn about making adaptations in the home environment to ensure a safe environment and allow the child as much movement as possible. The family also needs psychosocial support in order to assist them in coping with the child's ongoing musculoskeletal condition. The nurse can help the family and the child achieve the best possible psychosocial outcome by arranging for home nursing care, physical and/or occupational therapy along with how to obtain durable medical equipment.

Nursing Insight— Distraction devices

Distraction devices are usually used to lengthen a bone. The surgeon performs an osteotomy (cuts through a bone) and places the distraction device. A distraction device can be placed in any long bone such as the femur and mandible, as well as in bones in the hand and the foot. Nursing care of the child with a distraction device is much the same as for the child in skeletal traction.

Now Can You— Discuss nursing care for musculoskeletal conditions?

1. Discuss the nursing care for a child with a cast?
2. Perform a Neurovascular Assessment?
3. Describe the principles of traction?
4. Describe the nursing care for skin and skeletal traction?

Figure 30-7 Blowing into incentive spirometer helps expand the lungs and prevent pneumonia.

Common Musculoskeletal Conditions found in Children

CLUBFOOT

Clubfoot is a foot deformity diagnosed in newborns. In children who have not had effective treatment, the most severe form of this condition resembles a “club.” There are about one dozen different types of clubfoot. The most severe form and most commonly known is talipes equinovarus. The foot defect can be unilateral (more common) or bilateral. Talipes equinovarus affects boys twice as often as girls. Clubfoot deformities tend to run in families and is associated with spina bifida.

Signs and Symptoms

In clubfoot, the foot is plantar-flexed with an inverted heel and adducted forefoot. The defect is rigid and cannot be manipulated into a neutral position. There is a possibility that the position of the fetus in utero influences the formation of clubfoot.

“What to say” — *Talipes equinovarus (clubfoot)*

A mother has just delivered a baby with clubfoot. The parents are in the delivery room and are visibly upset. The parents are most likely in a state of shock and denial. The family does not understand what implications this has for their newborn.

The nurse can ask questions such as:

“How are you feeling at this time?”

“Do you know what this condition is called?”

“Do you know anything about clubfoot?”

“Can I stay with you to offer support while you hold the baby?”

“After you rest we can talk more about the baby’s condition.”

Diagnosis

Diagnosis of clubfoot is made by visualization during the newborn nursing assessment.

Nursing Care

Treatment is begun as soon as possible after birth. Clubfoot can be treated with serial casting (replacing plaster casts) on the affected extremity(s) at specified intervals to permit progressively greater ranges of joint motion so that the maximum range needed for function may be restored (Venes, 2009). While casted, the affected extremity is manipulated into a more normal position and a cast is applied to hold this position. In the beginning, the cast is changed frequently and eventually reduced to a weekly basis until overcorrection of the position is achieved. Overcorrection is the goal for serial casting because the ligaments and muscles are shortened and when the casts are finally removed, there is a tendency for these muscles and ligaments to pull the foot back into the clubfoot position. Overcorrection enables this pull to level off at a normal position. The nurse communicates to the family that exercises, splints, special shoes, or casts may be prescribed on a long-term basis.

where research and practice meet: Clubfoot Casting Techniques

Lifelong atrophy of the calf is common for children with clubfoot, requiring long-term follow-up care. A study by Ippolito, Farsetti, Caterini, and Tudisco (2003) compared two different techniques for treatment of congenital clubfoot. The authors found that serial casting followed by an open heel–cord lengthening and a limited posterior ankle release had much better long-term results than the group of children who received serial casting followed by an extensive posteromedial casting (Venes, 2009).

Nursing care for a child undergoing nonsurgical management of clubfoot includes passive range of motion (ROM) and care of the daily cast application after manipulation. Since manipulation of the affected extremity with serial casting can cause discomfort because the muscles and ligaments are being stretched, pain medication is indicated. Neurovascular assessments must be done every 1 to 2 hours for the first 24 to 48 hours after cast application and every 4 hours thereafter, until a new cast is placed. The nurse needs to assess for swelling. The cast is left open to air to aid in the drying process, and the extremity is elevated. The nurse must teach parents important neurological assessments and cast care.

Family Teaching Guidelines... The Child with Clubfoot Who is Wearing a Cast

HOW TO:

The nurse can teach the parents how to care for their child with a clubfoot who is wearing a cast. The nurse can instruct the parents to:

- ◆ Give the child emotional support and reassurance that she will return to her normal activities soon after the cast is removed.
- ◆ Maintain the child’s normal development by playing, reading, and spending time with the child.
- ◆ Keep the cast and surrounding area clean and dry and reposition her every 2 hours.
- ◆ Elevate an extremity and use good hygiene to prevent skin breakdown.
- ◆ Notify the health care provider if she has a fever, signs and symptoms of infection, or unrelieved pain.
- ◆ Take her to the health care professional if the cast is damaged (soft, loose, or cracked) or cast syndrome is suspected.

ESSENTIAL INFORMATION

- ◆ Follow-up care is essential.
- ◆ Inform the parents that there may be a potential for reoccurrence of the clubfoot.
- ◆ Teach the parents about the importance of monitoring their child for cast complications.

Severe cases of clubfoot may require surgery when the infant is 9 to 12 months of age. An orthopedic surgeon lengthens the tendons to help ease the foot into a more normal position. Postoperative care involves assessing the neurovascular status. The nurse also needs to observe for swelling in the ankle and foot. The key to preventing swelling is to elevate the ankle and foot. The nurse must assess for drainage from the cast as well as signs of infection, including purulent drainage, fever, and chills. The nurse is aware that pain management is important postoperatively. Pain medication is initially administered intravenously with morphine sulfate (Astramorph). When the child can tolerate fluids and food, they can be switched to oral pain medication.

In either case serial casting or surgery, the nurse needs to keep the cast clean. The young child needs to be diapered in such a way that the cast is outside of the edges of the diaper. Double diapering and changing the diaper frequently are also methods to keep the cast clean. The older child may have to change underwear frequently. It is not feasible to bathe the child in a tub of water with bilateral long leg casts with an abduction bar so a sponge bath is given. The nurse can provide the family with emotional support. Distraction techniques and age appropriate toys can help the child to handle the long recovery process.

Collaboration in Caring— Clubfoot

Collaboration with the surgical team is required in the care of the child with clubfoot. The orthopedic surgeon directs the serial casting. In some cases, surgery is needed after the serial casting. Collaboration with physical therapy is essential since the physical therapist directs the passive range-of-motion exercises. The nurse teaches the parents about the serial casting process and how to provide home care. The nurse helps direct the family to a respite care center and parenting help line.

- Impaired Physical Mobility related to external devices (casts)
- Impaired Parenting related to growth and development lag
- Risk for Impaired Skin Integrity related to external devices (casts)
- Knowledge Deficit related to treatment and home care

LEGG–CALVE–PERTHES DISEASE

Legg–Calve–Perthes disease (LCPD) is a self-limiting disease that has an insidious onset and traditionally had been accepted as a disorder of growth. It affects boys five times more frequently than girls. Most cases are boys ages 4 to 8 years and are blue-eyed with very fine light-colored hair and of shorter stature. It is an aseptic necrosis (necrosis occurring without infection) of the femoral head. It can take 18 months to 4 years for this condition to resolve.

There are four stage of LCPD:

- Aseptic necrosis (flattening of the femoral head)—lasts several weeks, presents with synovitis and a decrease in ossification in the nucleus of the femoral head secondary to ischemia

- Revascularization—lasts 6 to 12 months; increased joint space, increased cartilage thickness, decrease in size and density of femoral head
- New bone formation—lasts 1 to 2 years, collapse and superolateral displaced head, avascular bone is reabsorbed
- Regenerative phase—reconstitution of femoral head with remodeling and final healing

Signs and Symptoms

The child complains of hip or knee soreness or stiffness. This pain increases with activity and decreases with rest. The child presents with a painful limp and may also have quadriceps muscle atrophy. There may also be joint dysfunction and limited ROM.

Diagnosis

A radiograph establishes the initial diagnosis LCPD. The definitive diagnosis is made by MRI, which shows osteonecrosis.

Nursing Care

The goal of treatment is to keep the femoral head in the acetabulum. There is an initial period of non-weight-bearing for 7 to 10 days. During this time, traction, braces, or a hip-spica cast may be used. Obtaining a history is important in assessing the child with possible LCPD. This history will uncover how long the child has been limping and the severity of the pain. The nurse understands that the child will describe the pain as increasing in intensity with activity and decreasing with rest. The nurse's assessment of ROM will determine limitations on abduction and internal hip rotation. An assessment of the thigh and buttock area will reveal a wasting of the muscles. A shortening of the extremity on the affected side indicates that the femoral head has collapsed. The orthopedic surgeon directs the care and decides when surgery is needed.

When the child is receiving conservative treatment, the nurse needs to assess the skin in the brace, traction, or cast. The nurse needs to prepare the child and family for an x-ray exam and MRI. If the child is being treated with a brace, collaboration with the Orthotics team (a team of experts who teach others how to use orthopedic appliances) is required. The child needs to be maintained on bedrest to reduce the inflammation and restore motion. Pain management needs to be included in the nursing plan of care. The nurse can communicate to the family that the child will need to avoid weight-bearing activities and that mobility restrictions need to be maintained. While the child has mobility restrictions, passive and active ROM need to be implemented.

Ongoing treatment consists of conservative therapy for 1 to 3 years in non-weight-bearing (NWB) braces or serial casting. Neurovascular assessments need to be done while the child is in traction or a cast. If the child has undergone surgery for an osteotomy and a hip-spica cast is required the nurse needs to implement the usual postoperative care measures in addition to the care of a child in a cast. Pain relief is achieved with the administration of nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen (Children's Advil).

Since it is very difficult for a child to remain on bedrest, emotional support and diversional activities are essential. It is also important for the nurse to teach the family about home care. The nurse can discuss the importance of adaptive play. After the physician has communicated that the condition has resolved the child can return to normal activity in about 3 to 4 months.

Across Care Settings: Visiting nurse

After hospitalization, when the child with Legg–Calve–Perthes disease is dismissed to home the visiting nurse can:

- Assess the family support systems while the child and the family are in their own environment.
- Ensure that the family is able to provide the care needed.
- Ensure compliance with the use of the conservative devices.
- Ensure the non-weight-bearing status of the child.
- Assess the knowledge of the parents and child about ongoing care.
- Encourage the use of creative quiet activities and hobbies.
- Ask the family about follow-up care with the physician.

nursing diagnoses A Child with Legg–Calve–Perthes Disease

Knowledge Deficit related to treatment and home care

SLIPPED FEMORAL CAPITAL EPIPHYSIS

Slipped femoral capital epiphysis (SFCE) affects 2 to 10 per 100,000 children. It occurs two to five times more frequently in males than in females. A higher proportion of children with SFCE are obese. SFCE occurs more frequently in the Eastern United States and in African American children. The cause is unknown, but there is a genetic component and it may be related to endocrine abnormalities.

When this condition occurs, the capital femoral epiphysis (top of the femur) slips through the epiphysis (growth plate) in a posterior direction.

assessment tools Slipped Capital Femoral Epiphysis

The nurse understands that capital femoral epiphysis is classified by stage and severity:

Stage

- Preslip—The child complains of weakness in the leg. Pain in knee or hip when standing or walking for long periods of time.
- Acute slip—The child falls and then reports hip pain.
- Chronic slip—The femoral head gradually slips off the femoral neck and then remodels for the incorrect position.
- Acute on chronic slip—Slow progressive slip that then becomes more displaced when the child falls.

Severity

- Grade I: Preslip—There is a widening of the physis without any displacement of the epiphysis.

- Grade II: Minimal slip—There is a one-third displacement of the femoral head from the femoral neck.
- Grade III: Moderate slip—There is more than one-third but less than one-half displacement of the femoral head from the femoral neck.
- Grade IV: Severe slip—There is more than one-half displacement of the femoral head from the femoral neck.

Signs and Symptoms

Symptoms appear gradually. Pain in the groin or referred pain to the thigh or knee is the child's primary presenting complaint. This occurs because the child is externally rotating the leg to relieve pressure on the hip joint. The parent usually notices that the child is limping and favoring that extremity. During examination, the child complains of pain during internal rotation of the hip. Other conditions associated with SFCE are hypothyroidism, renal osteodystrophy, and postradiation therapy.

Acute slip symptoms are present for less than 3 weeks. Chronic slip symptoms are present for more than 3 weeks or even months. Along with the expressed symptoms, the hip does not fully rotate internally and abduction is limited. The affected leg may be shorter if the child has a moderate or severe slip.

Diagnosis

A radiograph reveals a slipped epiphysis and the diagnosis is made.

Nursing Care

Once a child has been diagnosed with SFCE, no weight bearing is permitted. The goal of nursing care is to prevent further slippage. No ROM should be attempted if the child has an acute slip because it may cause further damage. The nurse can communicate to the family that the hip cannot be reduced manually as that will cause further damage to the femoral head. Forced bedrest with the child in traction decreases synovitis (inflammation of a synovial membrane) in the hip. If the child has an acute slip, split Russell's traction may be instituted for a few days before surgery.

Surgery (pinning) is the intervention of choice for a child with mild to moderate SFCE. The pinning consists of a percutaneous insertion of a large screw or pin into the femoral head to hold it in place. There is a small incision and the child stays in the hospital for less than 24 hours. After 1 week, the child may bear full weight and the pin is removed at a later date.

With severe SFCE, an osteotomy is required, which consists of a breaking and resetting of the bone. This prevents further slippage and restores hip motion to normal. It is a much more extensive surgery, requiring a longer hospitalization and prolonged immobilization.

The nurse needs to assist the family in adjusting to the sudden hospitalization, non-weight-bearing status of the child, and the impending surgery. After surgery, postoperative pain management is managed with intravenous narcotics and changed to oral narcotics once the child is tolerating liquids and solid food. The nurse also monitors the neurovascular status frequently.

After surgery, the nurse collaborates with physical therapy to teach the child crutch walking. The physical therapy initiates ambulation with crutches. After that, the nurse needs to continue to ambulation with the child using crutches until discharge.

The child is discharged when pain is controlled with oral narcotics and the child can ambulate safely with crutches. It may be helpful to arrange for a visiting nurse to ensure that the child can ambulate safely with crutches at home. If the child still needs assistance with ambulation at home, a physical therapist can visit the home and reinforce teaching.

FRACTURES

Fractures occur when a bone undergoes more stress than it can absorb. Skeletal fractures account for 10% to 15% of all childhood injuries. The most common causes of fractures are falls, motor vehicle accidents, and bicycle accidents. There are differences between a fracture in a child and a fracture in an adult. A child's bone heals faster because of a higher metabolic rate and because the epiphyseal plate (growth plate) is still open. However, any damage to the epiphyseal plate can result in a limb length discrepancy, joint incongruity, and a progressive angular deformity of the limb. During birth, an infant can suffer a fracture of the collarbone. Otherwise, fractures in infancy are rare because the infant has limited mobility. During the first 2 years of life, fractures may be the result of physical maltreatment.

Signs and Symptoms

Fractures are characterized as open and closed. With an open fracture, the bone has penetrated through the skin. It is designated type I, II, or III, based on the degree, severity of soft tissue damage, size of the wound, and amount of contamination. The potential for infection is greatest with an open fracture. A closed fracture involves no break in the skin. Classification of fractures involves identifying the locations and descriptive nature of the fracture. The location is where the fracture occurs along the shaft of the bone. Fractures can be described in terms of the amount of injury.

assessment tools Classification of Fractures by Location

Epiphyseal

Type I

- Separation of epiphysis
- May be mistaken for a sprain
- Does not usually affect growth

Type II

- Fracture separation of the epiphysis
- Circulation remains intact
- Does not usually affect growth

Type III

- Fracture through the epiphysis into the joint
- Does not usually affect growth if reduced properly

Type IV

- Fracture through epiphysis into the joint and the metaphysis
- Open reduction and internal fixation necessary
- Can prevent growth disturbance

Type V (rare occurrence)

- Crush injury to epiphyseal plate
- Results in premature closure of the epiphyseal plate
- Growth arrest occurs

Diaphysis

- Proximal
- Midshaft
- Distal

assessment tools Classification by Type of Break

Transverse

Line crosses the shaft at a 90-degree angle

Spiral

A diagonal line coils around the bone
Caused by a twisting force

Oblique

A diagonal line across the bone

Greenstick

Bone is bent, but not broken
More common in children

Comminuted

Three or more fracture fragments

Compression

Bone becomes wider and more flat
Usually seen in the spine

The severity of the fracture depends on the amount of force placed on the bone and the strength of the bone, the size of the bone, and the direction of the force. Once a bone is fractured, inflammation happens. Osteoblasts (bone-forming cells) activate within 24 hours to begin making new bone. A callus forms during the first few weeks. Complete callus formation and establishment of compact bone takes 4 to 12 weeks. Remodeling (rounding off angles and filling in hollows) continues for up to 1 year. In children, the ends of the bone do not need to be perfectly aligned because the bone has an enhanced ability to remodel.

Diagnosis

A fracture is suspected by presenting symptoms, trauma history, and physical examination of the child. X-ray exam is the primary method to diagnose fractures. When an x-ray film is taken, the nurse understands that there needs to be at least two views (anteroposterior and lateral). The joints above and below the suspected fracture must be included in the radiographic evaluation. CT scans, MRI, fluoroscopy, and myelograms may also be used to diagnose fractures.

Nursing Care

The nurse obtains a history from the child and family describing how the injury occurred. In cases where maltreatment may be involved, it is helpful to ask the child how the injury occurred in the absence of the caregiver. Depending on the type and location of the fracture, children generally heal without complications. Nursing care involves preventing complications such as limping, decreased ROM, and nerve deficits.

Specific treatment depends on the type and location of the fracture. If the bones are not displaced, no reduction of the fracture is needed. If the bones are displaced, a reduction of the fracture is needed, in which the ends of the bone are placed close together or aligned. A **closed reduction** aligns the fractured ends by manually manipulating the extremity or traction. This is performed by a physician under conscious sedation or general anesthesia. The goal is to reduce the fracture as soon as possible.

An **open reduction** is performed when the fracture cannot be reduced by closed methods or when torn muscles or ligaments need to be repaired. Internal fixation is used to stabilize the bone ends until healed. Internal fixation is achieved with percutaneous pins or with screws, plates, or rods. For example, an intramedullary fixation rod can be placed in the shaft of the femur. After the bone has healed, the hardware can be removed.

After closed or open reduction, the fractured bone must be immobilized to maintain the position of the fracture, prevent rotation and shearing of the fracture, and permit active muscle contraction. Immobilization is achieved with splints, braces, casts, external fixators, or traction. Immobilization relieves pain and allows for ease of movement of the unaffected areas of the body. It is important to mobilize the child as quickly as possible in order to avoid hazards of immobility.

Open fractures present additional concerns. The potential for infection from contamination is great. Antibiotics must be administered in the emergency

department and continued for at least 3 days after the injury. Surgery for wound cleansing, débridement, and stabilization of the fracture needs to be performed urgently. If the wound is small, the surgeon may surgically close the wound. Most often, the wound is left open and draining until the infection is eradicated. The child may have to return to surgery later for more débridement or closure of the wound.

clinical alert

Complication of the child with a fracture

The classic sign of compartment syndrome is unrelenting pain that is unrelieved by narcotics. The nurse must notify the physician immediately. The priority intervention for compartment syndrome is prevention. Prevention is achieved by elevating the extremity to prevent excessive swelling and frequent neurovascular checks.

After open or closed reduction, the nurse needs to perform frequent checks to assess for pain, numbness, or tingling. Nursing actions that can help to prevent complications and restore function are frequent neurovascular assessments, notifying the surgeon of any changes, elevating the affected extremity above the level of the heart, and applying cold packs (15 minute intervals) for the first 24 hours after the injury. The nurse can teach the family that nutrition can be addressed by providing a well-balanced diet with protein, calcium, and iron. A child in a hip-spica cast should eat small, frequent meals to avoid abdominal distention. The child should also increase fluids and fiber in the diet to prevent constipation.

critical nursing action Caring for a Child with a Fracture in a Cast

- Elevate the extremity with the cast on pillows for at least the first 24 hours.
- Avoid indenting the cast.
- Assess the extremity for swelling and discoloration.
- Observe the extremity for sensation and movement.
- Notify a health care professional immediately if abnormalities are noted.
- Follow activity restrictions.
- Do not allow the affected limb to hang down for any length of time.
- Prevent the child from putting anything inside the cast.
- Keep a clear path for ambulation.
- Ensure the child uses crutches appropriately.
- Encourage rest.
- Encourage good nutrition to promote healing.
- Encourage quiet activities.
- Ensure child moves joints above and below cast.

After surgery, if the child has any open wounds or pins from traction or a distraction device, the nurse assesses the wound(s) and performs pin care every 8 hours to prevent infection. For any type of fracture it is critical that the nurse assesses and treats pain frequently. Intravenous opioids are administered for the first 24 hours. Once the child is tolerating liquids and a regular diet, pain medication is switched to the oral route. Acetaminophen (Tylenol) with codeine or oxycodone (Percocet) are the preferred

narcotics. The nurse may supplement the medication with regular acetaminophen (Tylenol) to reach the maximum safe dose to achieve the best pain control during hospitalization. It is important for the nurse to differentiate between pain and muscle spasms with a child who has had a fractured femur. Muscle spasms are extremely painful. Diazepam (Valium) is the best choice for an antispasmodic medication. Muscle spasms generally subside after the first week.

The child and family may experience anxiety related to the unplanned hospital admission and possible surgery. It is important for the nurse to provide emotional support to the child and the family.

Collaboration in Caring— *Caring for a child with a fracture*

- A child-life specialist can initiate play to help reduce the anxiety of a child with a fracture. He can assist the child with working through fears and frustrations with medical play, art therapy, and distraction.
- Social services personnel may also be available to assist the family on admission to the emergency department and can continue to support the family during the child's hospitalization. At discharge, they can arrange for transportation as well as identify helpful community resources.
- A school teacher or tutor can assist a child who is hospitalized for an extended period of time.

Complications that can occur with fractures are shock, fat emboli, deep vein thrombosis, pulmonary embolism, and infection. Late complications that can occur are malunion, nonunion, refracture, joint stiffness, reflex sympathetic dystrophy, loss of reduction, posttraumatic arthritis, delayed union, and pseudoarthritis.

Discharge teaching helps parents feel more comfortable caring for their child at home. It is important to review the treatment plan, principles of bone healing, how to perform a neurovascular assessment and cast care. Parents need to be aware that adaptations to the home environment need to be in place to ensure the child's safety. The physical therapist can help the family learn methods for transfer and use of assistive devices at home.

case study The Child with a Fracture Who Has Complications

A 12-year-old child was admitted with a femur fracture the previous night. He has a morphine sulfate (Astramorph) PCA that has a dose that is safe and effective. The leg is elevated on two pillows and ice packs are in place. The nurse performs the neurovascular assessments with the first morning vital signs. During the following hour, the child complains that on the numerical pain scale, the pain is 10 out of 10. The nurse checks the history on the PCA pump and finds that the child has requested numerous doses, but has received the maximum number of doses possible in the past hour. The neurovascular assessment reveals that the pulse is absent and the extremity is cool and pale. The capillary refill time is greater than 3 seconds.

critical thinking questions

1. Describe compartment syndrome?
 2. What should the nurse do first?
 3. What is the priority intervention for compartment syndrome and how it is achieved?
- ◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

SOFT TISSUE INJURIES

Soft tissue injuries (sprains and strains) are unusual in young children. These injuries are more often seen in the adolescent age group. The growth plate of the epiphysis is weaker than the ligaments in younger children because of the new bone formation and is prone to fracture rather than sprains or strains. With puberty, skeletal growth declines and the growth plates begin to close. The growth plates become less susceptible to injury and the ligaments and tendons become more susceptible to injury. The ankle is the most frequently sprained or strained joint. The prognosis is good for first- and second-degree sprains. Severe sprains (third-degree) have an increased risk of recurrent injury, persistent instability, and traumatic arthritis.

Signs and Symptoms

Signs and symptoms of a sprain include pain, swelling, bruising, instability, and loss of the ability to move and use the joint. Signs and symptoms of a strain are pain, limited motion, muscle spasms, muscle weakness, swelling, cramping, and inflammation.

Diagnosis

A history needs to be obtained from the child as well as the parents. The history reveals important information about the injury, swelling and local hemorrhage at the injury site. The child's most painful area is examined last. An x-ray exam is performed if there is an obvious fracture or misalignment.

assessment tools Sprains are Classified According to Severity

First Degree

Mild; ligament is stretched and the affected joint is stable.
Minimal pain, swelling, ecchymosis
Full ROM and weight bearing

Second Degree

Moderate; ligament is partially torn and joint laxity is present.
Moderate pain, swelling, and ecchymosis
Motion is slightly limited and painful.
Mild joint laxity with tenderness over the joint
May be unable to bear weight

Third Degree

Severe; ligament is completely torn and joint is unstable.
Significant swelling and severe ecchymosis occurs within the first 30 minutes.
Severe pain over the joint makes examination difficult.
Cannot bear weight or otherwise use the extremity.

Nursing Care

Immediately after the initial injury, it is most important for the nurse to use the RICE acronym (Fig. 30-8):

- R**—Rest; resting the injured extremity prevents further injury and allows the ligament to heal
- I**—Ice; ice for the first 48 hours, keep ice packs in place for 15-minute intervals to decrease swelling
- C**—Compression; apply an Ace wrap or some other method to apply pressure to the affected joint to help reduce swelling of the joint
- E**—Elevation and early motion of the affected joint; elevation reduces swelling and early motion of the affected joint helps keep the full ROM of the joint

Immobilization of the joint is recommended based on the severity of the injury. Mild sprains are immobilized with external support with an elastic bandage, brace, or ankle lacer. Moderate sprains require a posterior splint or cast for 2 to 3 weeks in conjunction with crutches. Severe sprains require conservative or surgical treatment with a cast for 4 to 6 weeks and no weight-bearing activities. Early motion after the injury, with gentle stretching and a strengthening program, speeds recovery.

Collaboration with the physical therapist is necessary in caring for the child with a soft tissue injury. The physical therapist teaches the patient quadriceps and hamstring exercises, a range-of-motion program for ankle injuries, and crutch walking. To prevent nerve damage, the physical therapist ensures that the patient bears weight on his hands, not the axillae.

The nurse has an important role in teaching home care for the child with a soft tissue injury. The nurse teaches the proper technique for wrapping the affected joint and ensures that it is followed. The nurse communicates to the caregiver that it is important to start wrapping the area distally and work up to the proximal area beyond the level of the injury. The child needs a physical activity restrictions school note for the physical education teacher and coach. If the child has a mild sprain, sports activities can be resumed in 2 to 3 weeks. If the child has a moderate sprain, the child can participate in partial weight-bearing activities using crutches and return to full weight-bearing and sports activities gradually. If the child has a severe sprain, sports activities can be resumed in approximately 4 to 8 weeks.

Figure 30-8 The nurses uses the “RICE” acronym.

Sports Injuries

Sports injuries occur as a result of competitive sports in three quarters of all middle and high schools in the United States. One-half of boys and one quarter of girls ages 8 to 16 have participated in competitive sports. The increase in popularity of competitive sports, recreational sports, and cheerleading has significantly increased the number of over-use injuries, sprains, strains, and dislocations. The causes of these injuries may be a result of inadequate health physicals, hazardous practice and play areas, training and practice errors, improper safety equipment, improper nutrition, overtiredness, and a limited awareness or concern for the possible risk factors. Sports injury may involve fractures, sprains and strains as well as knee and elbow injuries.

A child who participates in sports where the legs are being used, such as skiing, soccer, football, or track is at risk for a knee injury such as a tear in the anterior cruciate ligament (ACL). The injury occurs when the ACL is stretched or torn during a sudden twisting motion when the feet stay planted one way and the knee turns the opposite way.

A child who participates in sports where the arms are being used, such as baseball, basketball, tennis is at risk for an elbow injury. Each of these sports involves a repetitive forward motion of the arm and the child is not able to extend the elbow fully. This is due to injury to the muscle consisting of tiny tears and contractures.

Signs and Symptoms

A ruptured or torn ACL causes instability and pain in the knee. In an elbow injury, pain and tenderness as well as the loss of full extension of the elbow occur 24 to 48 hours after the injury. This injury is commonly known as “Little Leaguer’s elbow.”

Diagnosis

Diagnosis of a sports injury is based on an x-ray exam followed by an MRI.

Nursing Care

Treatment for a knee injury depends on whether the injury is mild or severe and whether there was a twisting action involved in the injury. A mild injury is treated with bedrest and ice. A topical anesthetic may be applied locally to minimize pain and oral pain medication can be given. After 24 hours, heat is applied, which aids in healing. If the injury is more severe and the knee joint fills with fluid a physician will aspirate the excess synovial fluid. A cast may need to be applied in order to completely immobilize the joint. It takes the same length of time for a severe ligament injury to heal as a bone, therefore the cast remains in place for about 8 weeks. Arthroscopy can be performed to see the joint and repair torn ligaments or cartilage.

If the injury involved a severe twisting motion, the kneecap may be dislocated (slips around to the posterior side of the knee). The knee appears deformed and a physician slides the kneecap back into place immediately. The child is placed in a leg immobilizer for about a week. If this type of injury occurs frequently, surgery on the ligaments is necessary. Quadriceps exercises, which consist of straight leg raising exercises, help prevent a kneecap dislocation from occurring again.

For an elbow injury, exercises to strengthen the flexor muscles help prevent further injury. Children need extra protection against injury to the epiphyseal plates until they have fused (between the ages of 14 and 17 years of age). To prevent elbow injuries, children who participate in ball sports need time to warm-up. Pitching breaking balls and curve balls should be discouraged. Pitching should also be limited to six innings per week with a 3-day rest period between games. Treatment of the ‘Little Leaguer’s Elbow’ consists of applying ice for 15 minutes three times per day. Administering an anti-inflammatory agent may help the child be comfortable. Cortisone injections into the joint can also be helpful, but only a limited number can be used. Treatment for a more severe case consists of rest and immobilization of the elbow until pain, tenderness, and limited movement disappear. Permanent damage to the epiphyseal line and an elbow deformity can be the result of inadequate treatment for this injury.

OSGOOD–SCHLATTER DISEASE

Osgood–Schlatter disease is a painful prominence of the tibial tubercle. It is a common problem in active older school-age children and adolescents. It is a self-limiting disease, which is more prevalent in boys. It occurs in boys between the ages of 10 and 15 years in boys and girls between the ages of 8 and 13 years. It can occur bilaterally or unilaterally.

Osgood–Schlatter disease is caused by a repetitive injury and repair to the tibial tubercle where the patellar tendon attaches. There is a strong quadriceps contraction and an immature ossification center resulting in inflammation and small avulsions (tearing away) of the bone. The cycle continues with new bone forming each time the injury and the body attempts to heal itself (Cassas & Cassettari-Wayhs, 2006). Osgood–Schlatter disease does not result in long-term complications and the prognosis is good.

Signs and Symptoms

The major symptom is pain below the kneecap that is aggravated by activity and relieved by rest. Symptoms resolve around the time skeletal growth ceases (about puberty). The child experiences pain when asked to squat or extend the knee against resistance.

Diagnosis

An x-ray exam of the knee is performed to rule out a tumor. History and the presenting symptoms assist in making this diagnosis. Pain that occurs when the child is asked to squat or extend the knee against resistance is a good indicator of Osgood–Schlatter disease.

Nursing Care

Pain control is an important nursing action for a child with Osgood–Schlatter disease. The pain medication of choice is an NSAID. The knee should be iced after exercising. An elastic wrap or neoprene sleeve over the knee during activity also helps to relieve the pain. Surgical management is rare, unless a piece of bone has completely torn free from the tibial tubercle. Surgery would consist of excision of this bone fragment. The surgery is performed after the child has reached bone maturity to avoid damage to the epiphyseal plate.

The nurse teaches the family that the child is to have limited activity. Once the symptoms improve, the child may return to normal activities. The nurse can provide support to the child by helping the child to cope with the activity restrictions and social interactions. The nurse collaborates with the physical therapist to teach the child exercises to strengthen the upper body. The physical therapist also teaches the child to perform lower extremity isometrics. These exercises help the child maintain strength while the injured knee heals.

Osteomyelitis

Osteomyelitis is an infection of the bone and the tissues around the bone.

clinical alert

Osteomyelitis

The nurse understands that osteomyelitis needs immediate treatment.

Osteomyelitis most commonly occurs in healthy children. Osteomyelitis can cause massive destruction of bone, sepsis, and possibly death. Osteomyelitis often involves the long bones in the lower extremities in children, but it can involve any other bone in the body. Many bacteria can cause osteomyelitis, most commonly *Staphylococcus aureus*.

Nursing Insight— Osteomyelitis

Acute osteomyelitis can be caused by the following:

- An open fracture
- Penetration of the skin by a contaminated object
- A septic joint
- An infected wound
- Bacterial infection from somewhere else in body, like dental caries
- Blunt trauma
- Premature babies and infants with birth complications during the 1st year of life

Osteomyelitis occurs when bacteria lodge and multiply in the middle of the bone where circulation is sluggish. The infection spreads to the ends of the bones and can destroy the epiphyseal plate in children. The inflammatory process produces pus, edema, and vascular congestion in the area of infection (Fig. 30-9). Pressure in the bone increases and eventually cuts off the blood supply, causing necrosis. The body attempts to lay down new bone over the necrotic bone. The prognosis is good if the osteomyelitis is treated promptly with intravenous antibiotics.

Signs and Symptoms

The signs and symptoms of osteomyelitis can be overt or subtle. The child comes to the clinic with pain in the affected bone. The child’s history may reveal a fall or bumping of the affected extremity. History also reveals a

Figure 30-9 Sequence of osteomyelitis development. **A.** Infection begins. **B.** Blood flow is blocked in the arc of infection and an abscess with pus forms. **C.** Bone dies within the infection site and pus continues to form.

recent infection such as a cold or otitis media. Sometimes the child has a fever. The child is irritable and guards the affected limb. There is localized tenderness, redness, warmth, and pain on palpation. Occasionally, there is soft tissue swelling around the area.

Diagnosis

Osteomyelitis is suspected when the child presents with the clinical manifestations. X-ray exam and a bone scan confirm the diagnosis. Blood cultures help determine the causative bacteria.

Nursing Care

Treatment for osteomyelitis is a course of broad-spectrum antibiotics. Antibiotics are begun after blood cultures are drawn. The exact antibiotic prescribed will depend on the causative bacteria. The child is hospitalized on antibiotic therapy. It is important for the nurse to evaluate the child's response to the antibiotic therapy about 2 or 3 days after the initial dose. If the child demonstrates a response to the intravenous antibiotic therapy at this point, more blood cultures are drawn, intravenous antibiotics are stopped, and the child continues therapy on oral antibiotics for 4 to 8 weeks at home. If the child demonstrates poor response to the intravenous antibiotic therapy, antibiotic therapy is continued for a much longer period. The nurse monitors the erythrocyte sedimentation rate (ESR). This lab study is a good indication of whether the infection is resolving. As the infection resolves, the ESR decreases to normal. Palliative measures such as rest, oral pain medication, good nutrition and diversional can also help. The nurse can also teach parents about the importance of antibiotic compliance.

clinical alert

Chronic osteomyelitis

Chronic osteomyelitis is uncommon and occurs when bone tissue dies as a result of the lost blood supply. The frequency of chronic osteomyelitis has diminished due to an increased awareness of the need for prompt, aggressive treatment. However, children with chronic osteomyelitis have had symptoms for longer than 3 weeks and there is a history of prior bone infection within weeks or months after surgery or trauma. The treatment for chronic osteomyelitis is prolonged, painful, and frustrating for the child and family. Pain control is an important nursing action for the child

with chronic osteomyelitis. The nurse understands that it is important to make the child as comfortable as possible. For the first few days of hospitalization, the affected limb is placed in a splint. Oral analgesics, including acetaminophen (Children's Tylenol), ibuprofen (Children's Motrin), or narcotic analgesics such as acetaminophen with codeine (Percocet) can be used to manage pain. The intravenous site should be monitored for infiltration because the antibiotics used to treat osteomyelitis are caustic to the veins. A peripherally inserted central catheter (PICC) or tunneled central line is placed if intravenous therapy continues for more than 2 to 3 days. Diversional activities should be employed while the child is in the hospital and at home while activity is limited.

The nurse has an important role in teaching home care for the child with osteomyelitis. The child may be discharged on a regimen of home intravenous antibiotics. This requires a sustained commitment from the family. The nurse needs to assess if a family member can maintain the child at home on intravenous therapy. Antibiotics that can be scheduled every 8 to 12 hours may have a better compliance rate than more frequently scheduled antibiotics. A parent who has to administer one or two antibiotics every 4 to 6 hours can become sleep deprived very quickly. The child may return to school if the antibiotics are on a 12-hour schedule. A home school teacher or tutor is needed if the antibiotics are scheduled more frequently.

Now Can You— Discuss osteomyelitis?

1. Describe the symptoms of osteomyelitis?
2. Describe the critical nursing actions for a child with osteomyelitis?

JUVENILE ARTHRITIS

Juvenile arthritis is an autoimmune, inflammatory process with unknown origin, but is thought to be triggered by an infection. Peak onset occurs in two different age groups (between 1 and 3 years or age and between 8 and 12 years of age). Females are affected twice as frequently as males. Symptoms can range from very mild to very severe. Juvenile arthritis is the leading cause of blindness and disability in children. Juvenile arthritis is not a childhood version of rheumatoid arthritis. The prognosis of juvenile arthritis is considered good. Success related to how the child and family cope with the condition is based on how well the child meets developmental milestones. If juvenile arthritis occurs in a younger child, growth retardation usually occurs.

Human leukocyte antigens (HLAs) play a role in the disease. There is chronic inflammation of the synovial membrane with effusion and destruction of the articular cartilage. Immune complexes in the blood and synovial tissue initiate the inflammatory response by activating the plasma protein complement. Excessive fluid is produced that is watery, thin, and lacks mucin. The synovium swells and thickened villi and nodules protrude into the joint cavity. The nurse understands that a restriction in the joint capsule and ligaments lead to a decreased joint movement and tendonitis. Ankylosis (adhesions) also develop between joint surfaces, which can further limit joint mobility.

The prognosis for children with juvenile arthritis is that 60% to 70% will have remissions. Approximately 45% will still have active disease 10 years after diagnosis, which results in disability in adulthood.

Signs and Symptoms

The child with juvenile arthritis has joints that are swollen, tender, and warm to touch, and limited ROM. The joints are stiff and have loss of motion, especially in the morning. Intermittent joint pain that lasts longer than 6 weeks should be suspect for juvenile arthritis. The child may also present with a rash. The child may try to protect the affected joint and may even refuse to walk, if the joint is a weight-bearing joint. Systemic symptoms include malaise, fatigue, and lethargy. There is a history of a late afternoon fever with a temperature spike up to 105.1°F (40.6°C). Infection, injury, and surgery may precipitate a flare-up. There are many types of juvenile arthritis. Three different types are described in Table 30-1.

Diagnosis

There is no actual test for juvenile arthritis; therefore, diagnosing juvenile arthritis may be difficult. The diagnosis is made by excluding other conditions that may cause similar symptoms or other possible causes such as viral infections. The white blood cell (WBC) and erythrocyte sedimentation rate (ESR) are important laboratory values to monitor. The character, frequency, and severity of systemic and articular (joint capsule) manifestations are critical factors in diagnosing juvenile arthritis. Radiographs or bone scans to detect changes in bones and joints may be used. Any joint swelling or pain that has lasted longer than 6 weeks should be assessed for possible juvenile arthritis. The child with juvenile arthritis has a pattern of remissions and exacerbations.

Nursing Care

Medications are a key factor in the management of the child with juvenile arthritis. The nurse can teach the child and the family about the different medications required in the treatment of juvenile arthritis.

The outcomes of the nursing interventions for JA are to prevent injuries and identify exacerbations. This requires teaching the child and family about the disease and proper care. The nurse can teach the caregiver how to assess the child's for warmth, tenderness, pain, and limitations in ROM. The family must be alert for increasing irritability, guarding, and refusal to bear weight and take action by encouraging rest. The nurse can help parents learn proper positioning of the inflamed joints occurs and the appropriate application of heat or cold. A physical therapist can design an exercise program with isometric exercises and passive ROM. Part of home care includes the need for a diet high in fiber, protein, calcium, and adequate fluid intake. The nurse also needs to develop a plan of care that aids parents in providing age-appropriate activities and reinforces independent activities. After an exacerbation the child needs to be encouraged to resume pre-exacerbation activities. The parents need to break the cycle of dependence, but this can be very difficult. It is best to involve the child in the decision-making process as much as possible. Psychosocial adjustment of the child is assessed by school performance and peer activities. Attending professional counseling sessions or support groups can be encouraged.

nursing diagnoses A Child with Juvenile Arthritis

- Chronic pain related to joint inflammation
- Impaired physical mobility related to joint discomfort and stiffness
- Altered family processes related to a situational crisis (child with a chronic illness)

Table 30-1 Types of Juvenile Arthritis

	Polyarticular	Pauciarticular	Systemic Onset
Number of Joints Involved	Five or more	Four or fewer	Any number
Joints Affected	Usually small joints of fingers and hands Weight-bearing joints Same joint on both sides	Usually large joints, knees, ankle, elbow Usually particular joint on one side of body	Any joint
Sex Affected	Girls more than boys	Girls more than boys (most common type)	Boys and girls equally
Body Temperature	Low-grade fever	Low-grade fever	High spiking fever lasting for weeks or months
Other Symptoms	Stiffness and minimal joint swelling Rheumatoid nodules on elbow or other body area receiving pressure from chairs, shoes (+) Rheumatoid factor in 20% of cases (+) ANA titer is possible Elevated WBC, complement and erythrocyte sedimentation rate	Iridocyclitis (eye inflammation) Painless joint swelling with little redness (+) ANA titer (possible) (+) HLA antigen (possible in boys)	Macular rash on chest, thighs Inflammation of heart and lungs Anemia Enlarged lymph nodes, liver, and spleen Rarely (+) rheumatoid factor and ANA titer Elevated WBC

medications: Treatments for Juvenile Arthritis

- NSAIDs (nonsteroidal anti-inflammatory drugs). Only a few NSAIDs have been approved for use with juvenile arthritis. The approved NSAIDs are ibuprofen (Children's Advil), naproxen (Aleve), tolmetin (Tolectin), and choline magnesium trisalicylate (Trilisate). Other NSAIDs commonly used are indomethacin (Indocin) and diclofenac (Cataflam). If an NSAID is selected, it is usually chosen based on dosing schedule, patient preference, or medication taste because there is a lack of agreement on the best NSAID for patients with juvenile arthritis.
- Disease-modifying antirheumatic drugs (DMARDs) are agents that prevent or relieve rheumatism. Some of the more commonly used DMARDs are methotrexate (Rheumatrex), cyclophosphamide (Cytoxan), sulfasalazine (Azulfidine), and infliximab (Remicade). Methotrexate (Rheumatrex) is most frequently prescribed for juvenile arthritis patients. It is effective in polyarticular JA and has been used for the past 10 years. The most common side effect of methotrexate (Rheumatrex) is gastrointestinal symptoms.
- New drugs potentially available for use with juvenile arthritis are leflunomide (Arava) and etanercept (Enbrel). Leflunomide is an immunosuppressant. The side effects of these drugs are diarrhea, elevated liver enzymes, alopecia, and rash. They have been approved for use in adult patients with adult RA, but have not yet been approved for use with children. There is a teratogenic potential that would be of concern with children, particularly adolescent girls. The other new drug, etanercept (Enbrel), has been found to reduce the signs and symptoms of moderately severe to severe polyarticular juvenile arthritis. It is a potent inhibitor of tumor necrosis factor (TNF), which is a key proinflammatory cytokine found in the synovial tissue of patients with juvenile arthritis (Ilowite, 2002).
- Infliximab (Remicade) is another TNF-neutralizing agent. Efficacy data are limited for use of this medication. There needs to be a large-scale evaluation of the effectiveness of this drug (Ilowite, 2002).
- Prednisone (Deltasone) and other corticosteroids are very potent and should be administered at the lowest possible dose and for the shortest possible period of time. Side effects, such as Cushing syndrome, osteoporosis, increased risk of infection, glucose intolerance, cataracts, and growth retardation can occur.

MUSCULAR DYSTROPHIES

Muscular dystrophies (MDs) are a group of muscle disorders that cause the gradual wasting of symmetrical groups of skeletal muscle. It is the most common group of muscle disorders in childhood. All muscular dystrophies are a result of a genetic defect that causes the degeneration of muscle fibers. Most muscular dystrophies are identified in early childhood. Thirty percent of the time, muscular dystrophy is caused by a spontaneous mutation and 65% of muscular dystrophy cases are sex-linked recessive disorders. Muscular dystrophies are divided into three types: pseudohypertrophic muscular dystrophy (Duchenne's muscular dystrophy), congenital myotonic dystrophy and facioscapulohumeral muscular dystrophy.

Duchenne's is the most common and serious type of muscular dystrophy. Duchenne's muscular dystrophy is a sex-linked recessive disease, so it generally only affects males. Duchenne's muscular dystrophy affects 1 in 3600 males. Females are usually carriers. In a case such as a female child with Turner's syndrome, where the child

receives only one X-gene from the mother, the female child could have Duchenne's muscular dystrophy.

Congenital myotonic dystrophy is an autosomal dominant inherited disease. The disease process begins while the fetus is in utero. The infant usually dies before 1 year of age due to the inability to maintain respiratory function. Facioscapulohumeral muscular dystrophy is an autosomal dominant trait carried on chromosome 4. Symptoms progress slowly, making a normal lifespan possible.

Signs and Symptoms

There is a belief that a protein is absent from the muscle. The muscle fibers degenerate and are replaced by fat and connective tissue. Muscle wasting and contractures of the calf muscle are replaced by fat. There is a progressive symmetrical muscle wasting and weakness without loss of sensation.

In Duchenne's muscular dystrophy, the symptoms first appear after the child is able to walk, usually about 3 to 7 years of age. Duchenne's muscular dystrophy most often affects the pelvis and shoulders. The child develops a waddling, wide-based gait. The calf muscles become weak and hypertrophied.

With congenital myotonic dystrophy, the newborn may already have severe muscle weakness at birth. Muscle degeneration continues until there is inadequate respiration. Symptoms of facioscapulohumeral muscular dystrophy occur after the child is 10 years old. The main symptom is facial weakness. The child becomes unable to wrinkle the forehead and cannot whistle.

assessment tools Gower Maneuver

A child with muscular dystrophy uses the Gower maneuver to rise from the floor. The Gower maneuver is when the child must move to a kneeling position with hands also on the floor to stabilize. Then the child, while keeping hands on the floor, rises to feet. The child comes to a standing position by using the hands to walk up the legs until in a standing position.

Diagnosis

Children with a positive family history are at risk for Duchenne's muscular dystrophy. These children should be monitored for clinical symptoms that do not usually appear until preschool years. Serum creatinine kinase (CK) levels should be monitored. CK levels are elevated in the early stages of the disease. As muscle bulk decreases, the CK levels also decrease. Definitive diagnosis is made by muscle biopsy (the removal of muscle tissue for microscopic examination and chemical analysis) and electromyogram (EMG, a graphic record of resting and voluntary muscle activity as a result of electrical stimulation) (Venes, 2009). Diagnosis of congenital myotonic dystrophy is based on serum enzyme analysis and muscle biopsy. Muscle biopsy and serum enzyme analysis are used for diagnosing facioscapulohumeral muscular dystrophy.

Nursing Care

Treatment for muscular dystrophy is aimed at maintaining independent living for the child as long as possible. These children rarely live beyond 20 years of age. Since death is usually a result of respiratory complications,

the key is to prevent respiratory infections. Monitoring the respiratory status is critical. Any respiratory infection must be treated quickly and aggressively with antibiotics, postural drainage, and chest physiotherapy (CPT).

The nurse also needs to monitor the child's skin. As the child's mobility decreases, the skin can deteriorate quickly. It may be necessary to arrange for a special bed with an air cushion that can assist the caregiver in turning the child frequently. The nurse can teach the family to provide meticulous skin care.

Transferring the child in and out of bed and into a chair may eventually need to be performed with a Hoyer lift. Toileting can become an issue when the child is no longer able to ambulate and is required to wear diapers. Safety factors are essential in the care of the child with MD.

Nutrition is another focus for the nurse. The nurse should monitor the child's weight gain. A diet that is low calorie and high protein helps prevent obesity. A high-fiber diet and adequate fluid intake help prevent constipation. The nurse can teach the caregiver to begin a regimen of stool softeners and laxatives to help prevent constipation.

Assessment of the child's mobility is an important nursing action to help the child maintain ambulation for as long as possible. Active and passive ROM is also performed. Splinting and bracing may be recommended by the physician to prevent contractures.

The nurse can help foster independence and self-care. It is important to teach the child how to achieve an optimal level of functioning. The nurse can teach the child how to make adaptations so he can participate in self-care measures. Encouraging the child to be involved in activities that will maintain independence is important. For example, swimming is a good activity to achieve independence because when he is in the water, exercises can be done without the child feeling the weight of his body.

The nurse recognizes that the child and family need emotional support. The nurse should encourage the child and family to participate in support groups. The Muscular Dystrophy Association is an excellent resource for these families and children (<http://www.mda.org/>). Parents should be referred for genetic counseling. With muscular dystrophy, the parents must watch their child pass away gradually.

Collaboration in Caring— A child with muscular dystrophy

Coordination of the child's health care requires collaboration with physicians, physical therapists, nutritionists, social workers, medical equipment companies, faith communities and the family. The nurse should assess the family's ability to cope with their child's chronic illness and poor prognosis. The nurse assesses the support and resources available to the family. The nurse can help the family find proper community and online resources because the child will eventually need an electric wheelchair, Hoyer lift, and modifications to the home environment.

Complementary Care: Muscular dystrophy

Children who suffer from muscular dystrophy often turn to alternative or complementary therapies since there is no cure. Wenneberg, Gunnarsson, and Ahlstrom (2004) performed a quantitative and qualitative study using a qigong. The conclusion from this two-part study was that qigong was accepted as a new, innovative exercise program. Qigong may lower the rate of decline in general health.

nursing diagnoses A Child with Muscular Dystrophy

- Impaired Physical Mobility related to chronic degenerative disease process
- Self-care Deficits; Bathing/Hygiene, Dressing, and Grooming related to chronic degenerative disease process
- Risk for Injury related to decreasing mobility secondary to chronic degenerative disease process
- Fatigue related to increased energy expenditure
- Altered Grieving related to chronic and terminal illness
- Altered Family Processes related to chronic and terminal illness
- Impaired Gas Exchange related to diminishing muscle function secondary to muscular dystrophy
- Altered Nutrition related to chronic and debilitating disease process

SCOLIOSIS

Scoliosis is a nonpainful lateral curvature of the spine and is the most common spinal deformity in children. The spine either curves laterally in only one direction ("C" curve) in two opposite directions ("S" curve). There is a lateral deviation and rotation of each vertebra, which accentuates the deformity. Idiopathic scoliosis is common in female children and in families in which another member has been affected by scoliosis. Idiopathic scoliosis is the predominant form and there is no recognizable cause. Unequal leg lengths, such as untreated developmental dysplasia of the hip (DDH), can cause scoliosis. Congenital scoliosis is related to vertebral anomalies. It can also be associated with other congenital anomalies, such as myelomeningocele (spina bifida), osteogenesis imperfecta, or muscular dystrophy. Paralytic scoliosis occurs in association with neuromuscular diseases such as cerebral palsy, paraplegia, and quadriplegia.

Signs and Symptoms

Scoliosis may first be suspected by the child's parents or the school nurse. The school nurse performs scoliosis checks on all children between 9 and 15 years age. The primary care practitioner also assesses the child for alignment of the midline of the neck, shoulders, and hips. The child is asked to bend at the waist with arms hanging loosely. This is called the Adam's position or the bend over test (Fig. 30-10). The nurse practitioner assesses for unequal shoulder heights, scapulae prominences and heights, waist angles, rib prominences, chest asymmetry, and leg length discrepancy. It is also necessary to assess the skin for hairy patches, nevi, café au lait, lipomas, and dimples. A neurological and cardiac exam may be performed to rule out Marfan syndrome.

Nursing Care Plan The Child with a Musculoskeletal Disorder

Nursing Diagnosis: Impaired Physical Mobility related to physical disability or mechanical restrictions.

Measurable Short-term Goal: The child will engage in activities appropriate to current physical limitations

Measurable Long-term Goal: The child will regain maximum mobility

NOC Outcomes:

- Mobility (0208) Ability to move purposefully in own environment independently with or without assistive device
- Transfer Performance (0210) Ability to change body location independently with or without assistive device

NIC Interventions:

- Activity Therapy (4310)
- Environmental Management (6480)
- Self-Care Assistance: Transfer (1806)

Nursing Interventions:

1. Monitor the child for complications of immobility (specify, e.g., peripheral pulses, capillary refill, skin integrity, muscle weakness).
RATIONALE: Provides prevention or early recognition of complications to decrease their severity.
2. Allow the child to make as many realistic choices as possible and encourage independence in activities of daily living.
RATIONALE: Empowers the child by allowing him or her to exercise as much control as possible over self and the environment.
3. Select appropriate transport for the child and promote as much mobility as possible (specify, such as a wheelchair, crutches, stretcher, go-cart, or stroller).
RATIONALE: Mobility promotes normality and helps prevent feelings of isolation.
4. Encourage the child to go to the playground if possible or arrange for the child-life therapist to visit the child.
RATIONALE: Increases child's mobility and decreases isolation. The child-life specialist promotes normal growth and development.
5. If the child is immobile for a long period of time, plan periodic rearrangement and redecoration of the room with input from the child as appropriate.
RATIONALE: Change breaks up the monotony of the immobilization and provides an opportunity for engagement and creativity.

Figure 30-10 The child is asked to bend at the waist with arms hanging loosely. This is called the Adam's position or the bend over test. Scoliosis is obvious in this adolescent.

Diagnosis

Diagnosis is confirmed by radiography. The physician looks at the Cobb angle (a measure of the curvature of the spine in degrees). The number of degrees helps the physician decide what type of treatment is necessary. A scoliosis curve of 10 to 15 degrees is normal and the child will continue to be assessed for scoliosis at regular checkups until pubertal maturation and growth are complete. The primary health care provider monitors a curve between 10 to 40 degrees (mild) will generally suggest a back brace. A curve of more than 40 degrees (severe) revealed by x-ray exam requires treatment and the child is referred to an orthopedic surgeon.

Severe scoliosis can lead to respiratory compromise, as the lung under the shortened side of the body will not be able to fully expand. Severe scoliosis can also have a negative effect on the hips and knees.

Nursing Care

Scoliosis screening is a critical nursing action. Bracing and exercise are the usual treatments for mild cases of scoliosis. Bracing stops the progression of scoliosis. The molded

brace is worn 23 hours per day. The patient may only remove the brace to shower. The adolescent wears a special T-shirt under the brace to prevent skin irritation. The nurse can communicate to the child and family that compliance with bracing improves the outcome for this condition. The major problem with bracing is body image. Many adolescents do not want to wear the brace at school or while they are with their friends. The nurse can communicate to the family that the best way to increase compliance is to include the adolescent in decisions. Exercises recommended by a physical therapist help the muscles in the back gain strength.

Complementary Care: Exercise and bracing

Thompson (2004) revealed outcomes from exercises alone and chiropractic therapy are rarely therapeutic in managing scoliosis. Transcutaneous electrical stimulation has also proved ineffective. Exercises are of benefit when used in conjunction with bracing to maintain and strengthen the muscles of the back and abdomen.

Surgical treatment is necessary when pulmonary function becomes compromised, sitting or walking becomes difficult because of poor balance, pain, curves are noted as severe by x-ray exam, and for cosmetic reasons. The surgical method is reserved for the most severe cases of scoliosis. The surgeon can approach either anteriorly, posteriorly, or both. When both approaches are used, the anterior approach is done first and then 1 week later, the posterior approach is done. In severe cases, halo traction may be used before surgery to better align the vertebrae. Surgery should be delayed as long as possible because the fusion of the vertebrae will stop spinal growth.

When surgery is scheduled, the nurse should explain to the child and parents what to expect. Prior to surgery, a tour of the ICU can help alleviate the child's anxiety. It is also important to stress that after surgery the child will have an indwelling urinary catheter in place. The nurse can also teach range-of-motion exercises before surgery.

In the postoperative phase, the child remains in the ICU overnight. The nurse assesses vital signs and neurological status every 1 to 2 hours after surgery. Once the child is stable she is transferred to the inpatient area where vital signs and neurological assessments continue to be performed every 4 hours. The nurse also understands the importance of monitoring fluid balance. Renal function is monitored because the kidneys are hypoperfused during surgery. The child may also have had blood transfusions.

Pain is controlled with narcotic analgesics and the child should not wait to long to communicate that they are in pain. Pain is controlled with a PCA. While the child is receiving narcotics, the nurse monitors oxygen saturation (Fig. 30-11). The child will also have a nasogastric tube hooked up to low suction. When the child's bowel sounds return, the nurse discontinues the nasogastric tube. The child's diet then advances from clear liquids to a regular diet.

Figure 30-11 While the child is receiving narcotics, the nurse monitors oxygen saturation.

The child may have a chest tube in place. The chest tube will be hooked up to suction at first and then placed on water seal. When drainage has ceased, the chest tube is removed. Radiography is usually performed the day after chest tube removal to ensure that no pneumothorax is developing. Incentive spirometry, chest physiotherapy (CPT), and coughing and deep breathing exercises are used to prevent atelectasis and pneumonia. The nurse must also assess for signs of symptoms of infection every 4 hours, such as fevers, chills, redness and pain at the incision site, and drainage from the incision site.

critical nursing action Logrolling

Positioning of the patient is also an important nursing action. The patient must be turned using the logrolling technique. Logrolling involves two or more nurses turning the patient in complete unison. The head, shoulders, hips, and legs are turned as one unit, thereby keeping the back in a straight line as the patient is turned (Fig. 30-12).

Figure 30-12 The patient must be turned using the logrolling technique.

The surgeon may require the patient to wear an orthotic brace. Collaboration with the orthotist is necessary to ensure that the brace fits properly. The nurse checks for pressure points under the brace for the first couple of days after implementation of the brace. Range-of-motion exercises are also performed to keep the uninjured extremities from becoming weak.

A nutritionist helps prevent constipation by suggesting adding fiber and fluids to the diet. Foods high in iron, folate, and vitamin C should be added to the patient's diet. Psychosocial aspects of care for this child include nursing actions that maintain or build his or her self-esteem. Because some musculoskeletal conditions have visible deformities, the nurse should address body image concerns and anxiety. Certain situations may create an inability for the child to interact physically or socially, or may cause the child to feel alienated from the peer group. Other psychosocial concerns related to the family are daily living routines and family functions, continued care of other siblings and financial burdens. Compliance with the treatment regime is important to ensure the best outcome for the child.

Discharge teaching is done after assessing the level of knowledge by the patient and the family. Discharge teaching should include a variety of topics. The physical therapist will continue to be involved with this child on an outpatient basis for rehabilitation. The school nurse should be notified about the patient's activity restrictions as the adolescent will have activity restrictions for 6 to 9 months postoperatively. Activities such as bike riding, roller blading, skiing, mowing the lawn, shoveling snow, or any lifting of more than 10 pounds is not allowed until the activity restriction is lifted.

The nurse can teach the parents to be alert for unfavorable signs such as pain, infection and difficulty breathing. Teaching the family about the brace including the signs and symptoms of skin breakdown is important. Be sure to instruct that the patient's head should not be raised more than 30 degrees without the jacket brace. Provide the family with information on community resources available to them and arrange for counseling for the adolescent, particularly if compliance with wearing the brace is an issue. The nurse can encourage the adolescent to be as active as possible and keep follow-up appointments.

case study Scoliosis

An 11-year-old girl has a history of idiopathic scoliosis. She is otherwise healthy. She has just arrived from the PACU after a posterior spinal fusion with instrumentation. The child had a blood loss of 1200 mL and received PRBCs (packed red blood cells) and 450 mL of cell saver in the operating room. She also received 2 L of lactated Ringer's solution in the PACU. She has a central line for intravenous access. Her vital signs are: heart rate, 120–130 beats/min; blood pressure, 92/48; temperature 97.2°F (36.2°C). Her face, hands, and feet are edematous. She denies discomfort and appears relaxed.

critical thinking questions

1. After attaching the patient to the apenic and bradycardia monitor (A & B monitor) and obtaining report, what would the nurse's initial assessment include?

2. What assessments place the child at risk?
 3. What additional information should the nurse consider?
 4. What other problem might the nurse anticipate?
 5. Taking into consideration the characteristics of the middle childhood stage of growth and development, what can the nurse do to optimize the plan of care?
 6. What are important home care instructions?
- ◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

KYPHOSIS

Kyphosis is a nonpainful spinal curvature in the sagittal plane. It is commonly described as “hunchback.” Slight kyphosis is found in the normal spine. Families usually seek treatment when the kyphosis becomes noticeable. In children, kyphosis is caused by a congenital or acquired condition. Some congenital causes of kyphosis are ankylosing spondylitis, metabolic disorders, osteogenesis imperfecta, spina bifida, Paget's disease, and Scheuermann's disease, which causes juvenile or adolescent kyphosis because there are wedge-shaped vertebrae in the thoracic region. In acquired kyphosis, the child can voluntarily bend the spine to correct the curvature. In addition, there is no underlying evidence of structural changes seen with acquired kyphosis. Kyphosis is potentially serious because of the risk of progressive deformity.

Signs and Symptoms

Parents may first notice uneven shoulder height in their child. The adolescent may also have complaints of pain in the thoracic region.

Diagnosis

Kyphosis is most commonly diagnosed in early adolescence during routine back screening for scoliosis. If kyphosis is suspected, a complete examination should include a complete orthopedic and neurological exam. Radiographs confirm the diagnosis and are used to follow progression of the disease. If the curve exceeds 50 degrees; it is considered abnormal (kyphotic).

Nursing Care

Nonsurgical treatment is recommended for acquired kyphosis when it is between 50 and 70 degrees. It may be possible to treat the child with continued observation and thoracic hyperextension exercises, or a brace may be needed. Surgical treatment is recommended when the curve is greater than 70 degrees. Anterior–posterior spinal fusion is the surgery of choice. The child with congenital kyphosis does not respond well to bracing, so surgery is necessary. The nursing care for the child with a surgical repair for kyphosis is the same as for the child with scoliosis.

LORDOSIS

Lordosis is a spinal curvature in the sagittal plane (Fig. 30-13). It is seen in conjunction with flexion contractures of the hip, scoliosis, obesity, developmental dysplasia of the hip (DDH), and slipped femoral capital

Figure 30-13 Lordosis is present in the normal spine and is not considered a major deformity.

epiphysis (SFCE). Lordosis is present in the normal spine and is not considered a major deformity.

Signs and Symptoms

Lordosis is commonly described as “swayback,” an excessive backward cavity of the spine.

Diagnosis

The parents may first notice that the child’s clothing is not fitting properly. This may precipitate a visit to the primary care provider. If lordosis is suspected, the full diagnostic exam includes a full orthopedic and neurological examination. Radiographs confirm the diagnosis and are used for follow-up progression of the disease.

Nursing Care

Treatment involves reducing the predisposing factors such as obesity. Reducing the predisposing factors can also be temporarily achieved with postural exercises and support garments.

SPINAL FUSION

In spinal fusion the vertebrae are fused together to maintain alignment. This is usually the surgical procedure used to correct scoliosis. Instrumentation (an application of metal screws, bolts, wires to straighten the spine) is usually performed with the spinal fusion. The instrumentation holds the vertebrae in place until the fusion has healed.

Nursing Care

Important nursing interventions for a child who has had a spinal fusion are similar to those for a child who has had a surgical repair of scoliosis. The usual postoperative routines are followed. Vital signs are monitored hourly while the child is in the ICU. Once on the inpatient unit, the vital signs are monitored at least every 4 hours (more frequently if needed). Encourage the child to use the incentive spirometer every hour, or an alternative method if they are not developmentally capable, to expand the lungs.

The nurse also monitors fluid balance. Syndrome of inappropriate antidiuretic hormone (SIADH) is very common in the child who has had a spinal fusion because of change in the fluid volume. Anesthetic medications as

well as the physical and emotional stress of the surgery can lead to SIADH.

The nurse must assess circulation in the child’s lower extremities, the incision, the bowels sounds in all four quadrants along with the softness of the abdomen each time vital signs are assessed. Any changes in the neurovascular status and signs of redness, swelling, drainage, or dehiscence (separation of the suture line) must be reported to the physician.

Pain from a spinal fusion surgery can be severe. Various methods are used to control pain in the postoperative patient. Continuous infusion of an opioid can be used for nonverbal patients. PCA is effective and commonly used for those patients who are able. In some cases, an epidural with bupivacaine (Marcaine) anesthetic alone or combined with an opioid such as morphine sulfate (Astramorph) or hydromorphone (Dilaudid) is used with success. Pain management is usually switched to the oral route by postoperative day three. The oral analgesic of choice is acetaminophen (Tylenol) with codeine. Acetaminophen (Tylenol) with codeine can be administered to children who are too young for oxycodone (Percocet) and is available in a liquid form, if needed. For older children, oxycodone (Percocet) can be used as the oral drug of choice.

Ambulation is permitted (usually about five days postoperatively). Early mobilization is important in the care of the child who has had a spinal fusion to prevent atelectasis, pneumonia, pulmonary emboli, phlebitis, and skin breakdown. The nurse should also perform passive ROM to all extremities. To turn the patient, the nurse needs to use the logrolling technique.

Nutrition is important for wound and bone healing. A regular diet with added calcium, fiber, and fluids is maintained. Encourage the child who has had a spinal fusion to increase fluid intake and consume foods high in fiber to help to relieve constipation. Docusate (Colace) can be administered to soften the stools. Vitamin C and protein help the healing process and should be added to the child’s diet. Calcium supplements should be considered if the child’s diet is not well balanced. The child may need iron supplementation to augment anemia caused by the surgery.

Collaboration with physical therapy is necessary to assist with ambulation training in addition to ROM exercises. The physical therapist also teaches strengthening and isometrics exercises. The wheelchair may need to be adjusted if the child is wheelchair-bound. The orthotist fabricates the orthotic brace and makes any necessary adjustments.

The nurse arranges for home care for the child. A caregiver needs to be home with the child at all times. The child will need durable medical equipment for the home environment, such as an elevated toilet seat and shower chair. A hospital bed may also be needed in some circumstances. The nurse can explain activity restrictions to the child and caregivers (no twisting or bending, no lifting of heavy objects, no contact or high-impact sports for 2 years). The child may return to school about 4 to 6 weeks after surgery.

Tetanus

Tetanus (lockjaw) is a preventable, acute, and potentially fatal disease. Tetanus occurs when an exotoxin, which is produced by an anaerobic, gram-positive bacillus

(*Clostridium tetani*) forms spores. The spores are found in soil, dust, and human gastrointestinal tracts. These spores enter the body through wounds such as burns, stabs, minor, unnoticed break in the skin, and the umbilical cord of a newborn.

Ethnocultural Considerations— Tetanus

Spores entering through the umbilical cord of the newborn are seen more often in developing countries, where women are not immunized against tetanus, contaminated instruments are used to cut the umbilical cord, or poultices are made from cow dung or fermented milk and used for cord care. The greatest incidence of tetanus is during warmer months when people are outdoors more frequently.

Prevention of tetanus is the best defense. For the organism to grow in the human, four requirements must be fulfilled: a presence of tetanus spores, an injury to the tissues, wound conditions that enable multiplication of the spores, and a susceptible host. When the natural defense mechanisms fail, the organism proliferates and forms exotoxins known as tetanospasmin. Tetanospasmin affects the central nervous system through the neuron axons and the vascular system.

Across Care Settings: Tetanus prophylaxis

Tetanus prophylaxis through immunization is the key to preventing tetanus. The nurse plays a key role in ensuring that the immunization is complete. The school nurse and the nurse in the primary care provider's office are in the best position to ensure that complete tetanus immunization occurs.

Signs and Symptoms

Symptoms of tetanus can develop between 5 and 15 days after the initial wound. The child initially presents with a progressive stiffness and tenderness of the muscles in the neck and jaw and has trismus (difficulty opening the mouth). Risus sardonius (a peculiar grin) is also present due to facial muscle spasms.

As the disease progresses, there is more involvement of the muscles in the body. Opisthotonus posturing occurs when there is a rigid and severe arching of the back, with the head thrown backwards. There is also a board-like rigidity of the abdomen and limb muscles. The child develops difficulty swallowing. The child becomes hypersensitive to stimuli such as a slight noise, bright lights, and gentle touch. These stimuli trigger paroxysmal muscular contractions lasting from seconds to minutes. As the disease progresses further, the contractions recur with increasing frequency until they are almost continuous. Laryngospasm and tetany of the respiratory muscles develops. As a result, secretions accumulate, atelectasis and pneumonia develop, and finally respiratory arrest occurs. During all of these phases of symptomology, the child remains alert. Pain and distress can be determined through the child becoming tachycardic, sweating, and an anxious expression. Generally, the child remains afebrile. If a fever occurs, it is only a mild fever.

Diagnosis

Diagnosis is based on patient history and physical examination findings.

Nursing Care

Prophylactic therapy is administered after trauma. Tetanus antitoxin (TAT) is no longer available in the United States. An unprotected or inadequately immunized child who has sustained an injury that is prone to tetanus needs to be given tetanus immune globulin (TIG). Tetanus toxoid (tetanus toxin modified so that its toxicity is reduced, while retaining its capacity to promote active immunity) is administered (Venes, 2009). The child continues to receive the complete immunization for tetanus at the correct intervals. The nurse communicates to the family that antibiotics will be prescribed to control the proliferation of exotoxin. Antibiotics of choice are penicillin G (Pfizerpen) or erythromycin (Erythrocin). Tetracycline (Sumycin) may be used in older children whose dentition is complete.

If prophylaxis is not used, treatment in the acute phase of the disease is through aggressive support in the ICU. The child is closely monitored and given respiratory support in a quiet environment. Fluids and electrolytes, as well as caloric intake, are monitored closely. The nurse initiates nasogastric (NG) enteral feedings for the child. In the case of severe laryngospasm, total parenteral nutrition or enteral feedings through a gastrostomy tube (GT) may need to be initiated. Recurrent laryngospasm may necessitate endotracheal intubation and mechanical ventilation.

One key to providing nursing care for the child with tetanus is to control or eliminate stimulation from light, sound, and touch. The nurse understands the importance of avoiding unnecessary handling and sudden or loud noises. The nurse must perform frequent neurological and vital sign assessments. Assess oxygen saturation and arterial blood gases regularly. Emergency equipment must be placed close to the child's bed. Oropharyngeal suctioning is done when there is an accumulation of secretions. The nurse assesses for excessive central nervous system depression and for muscle spasms. Medication administration is an important nursing action to keep the child as comfortable as possible. If a neuromuscular blocking agent is being used, the nurse needs to pay close attention to the effects of those agents (see Medication box).

Nursing Insight— Neuromuscular blocking agent

Important ideas to remember when caring for a child treated with a neuromuscular blocking agent:

- The child has total paralysis, including respiratory function.
- The child is not able to communicate.
- The child is anxious.
- The child is aware of all activity around him or her.
- The child is terrified.
- The nurse needs to anticipate the child's needs.
- The nurse needs to explain all procedures.
- The nurse should never leave the child alone.
- The nurse should reduce anxiety in the child by
 - Using a calm, reassuring manner
 - Support and understand the child's fear
 - Encourage the parents to stay with the child
- The nurse needs to medicate the child with an anxiolytic (antianxiety agent)

medications: Pharmaceuticals Used for Tetanus

Medications are used to alleviate the muscle spasms and seizures.

- Diazepam (Valium) is the drug of choice to control seizures. It is a benzodiazepine, anxiolytic and an anticonvulsant (Robertson and Shilkofski, 2005).
- Lorazepam (Ativan) may also be used. It is also a benzodiazepine anticonvulsant. It may cause respiratory depression especially when used in combination with other sedatives. Onset of action is 1–5 minutes intravenously, 30–60 minutes intramuscularly, and 20–30 minutes orally with a duration of action of 6 to 8 hours. Flumazenil (Romazicon) is the antidote (Robertson and Shilkofski, 2005).
- Intrathecal baclofen (Lioresal) is a centrally reacting skeletal muscle relaxant and can be effective in treating these children. Abrupt withdrawal of the medication should be avoided. Oral doses should be administered with food or milk. Should be used with caution in children with a seizure disorder or impaired renal function (Robertson and Shilkofski, 2005).
- Dantrolene sodium (Dantrium) is a skeletal muscle relaxant and can be effective. Caution should be used when administering to a child with cardiac or pulmonary impairment. Unnecessary exposure to light should be avoided. This medication should not be allowed to extravasate into the surrounding tissue. Discontinue if benefits are not evident in 45 days (Robertson and Shilkofski, 2005).
- Midazolam (Versed) is a benzodiazepine and can also be effective. Contraindicated in patients with narrow angle glaucoma and shock. It causes respiratory depression, hypotension, and bradycardia. Cardiovascular monitoring is necessary. Doses should be reduced when given in combination with narcotics or in patients with respiratory compromise. Serum concentrations may be increased by cimetidine (Tagamet), erythromycin, itraconazole, ketoconazole, and protease inhibitors. Sedative effects may be antagonized by theophylline. The effects of the medication can be reversed with flumazenil (Romazicon) (Robertson and Shilkofski, 2005).
- Neuromuscular blocking agents are used when the child is suffering severe unresponsive tetanus. These two are nondepolarizing neuromuscular blocking agents.
- Rocuronium (Zemuron) may cause hypertension, hypotension, tachycardia, and bronchospasm. There is a risk of increased neuromuscular blockade when administered in conjunction with aminoglycosides, clindamycin, tetracycline, magnesium sulfate, quinine, quinidine, succinylcholine, and inhalation anesthetics. There is a risk of a reduction in neuromuscular blocking effects when used in conjunction with carbamazepine, phenytoin, azathioprine, and theophylline. Peak effects occur in 0.5–1 minute. Duration is 30–40 minutes (Robertson and Shilkofski, 2005).
- Vecuronium bromide (Norcuron) may cause arrhythmias, rash, and bronchospasm. It should be used with caution in patients with renal or hepatic failure and neuromuscular disease. Infants from 7 weeks to 1 year of age are more sensitive to the medication and may have a longer recovery period. Children from 1 to 10 years may need higher and more frequent doses. Potency can be increased with administration of enflurane, isoflurane, aminoglycosides, magnesium salts, tetracyclines, bacitracin, and clindamycin. Neostigmine, pyridostigmine, and edrophonium are antidotes. Onset is 1–3 minutes. Duration is 30–90 minutes (Robertson and Shilkofski, 2005).

The nurse assesses hydration and nutrition. The child must be maintained on total parenteral nutrition (TPN) or enteral feeds through a NG tube or gastrostomy tube.

The nurse collaborates with the respiratory therapist and physician to ensure that the child receives adequate respiratory support and that seizures are kept under control. The nurse needs to collaborate with the pharmacist

regarding the administration of the medications to eradicate the exotoxin from the child. Nursing care should be clustered so that the child has a chance to rest and recover from the stress of the intervention.

Now Can You— Discuss tetanus?

1. Describe the prophylaxis treatment for a child at risk of tetanus?
2. Describe the symptoms of tetanus?
3. Describe the critical nursing actions needed to care for a child with tetanus?
4. Describe the medications and the important facts regarding the medications for a child with tetanus?

OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta (OI), or brittle bone disease, is the most common genetic disorder of the bone. Osteogenesis imperfecta is a group of autosomal dominant diseases characterized by excessive fragility of the bones causing a high rate of fracture. It occurs equally in all races and is equally prevalent between males and females. It is a biochemical defect that causes a decrease in the synthesis of collagen. It affects all connective tissue in the body. Children may become disabled as a result of the severe deformities.

Signs and Symptoms

In OI, the joints are lax and the muscles are small and weak. Any undue stress on the bone causes a fracture (e.g., changing the infant's diaper can cause a femur fracture). The fracture heals within the normal period, but the bone lacks the normal strength. Bone deformities such as bowing and growth pattern disturbances occur. Some newborns die of complications caused by the extreme fragility of the bones.

Diagnosis

Reliable prenatal diagnosis about OI is not currently available. Diagnosis is based on the severity of clinical symptoms and the level of disability. There are five major types of OI that are based on severity and the mode of genetic transmission (Table 30-2).

A unique feature of this disease is that there is very little bruising or swelling, only tenderness at the fracture site. Laboratory studies are not useful in the diagnosis of osteogenesis imperfecta. Radiographic studies show multiple normal callus formations at new fracture sites, evidence of previous fractures, and skeletal deformities. In addition, radiographs will reveal generalized osteopenia, which is an insufficiency of bone. A collagen biopsy will confirm the diagnosis.

Nursing Care

Treatment can include surgery to reduce fractures, correct spinal deformities, and straighten long bones. Intramedullary rodding of the femur is not a perfect solution, but can provide stability to a deformed bone. A solid intramedullary rod is easier to insert, but does not grow with the child and needs to be replaced every 2 to 4 years. A telescoping intramedullary rod is more complicated to insert, but can be adjusted as the child grows.

Table 30-2 Major Types of Osteogenesis Imperfecta

Type I	Type II	Type III	Type IV	Type V
Autosomal dominant Subtypes A, B, and C Blue sclerae present	Autosomal recessive Lethal Stillbirth at 50%	Most autosomal recessive Few autosomal dominant Blue sclerae at birth Less blue with age	Autosomal dominant Subtypes A and B Normal sclerae in both subtypes	Autosomal dominant Normal sclerae
Subtypes A and B have severe bone fragility with spontaneous decrease in fractures during adolescence. Subtype C has no bone fragility Subtype B and C have dentinogenesis imperfecta instead of normal teeth	Thin, fragile skin Multiple rib fractures Diffuse osteopenia in face and skull	Severe bone fragility Fractures present at birth Death in childhood	Subtype A has mild to moderate bone fragility, short stature, variable deformity Subtype B has mild to moderate bone fragility, short stature, variable deformity PLUS dentinogenesis imperfecta instead of normal teeth Subtype B is about 6% of all cases	Clinically similar to type IV Hyperplastic callus Collagen mutation is negative
Hearing loss between 20 and 30 years of age Flat feet Kyphosis as an adult Excessive hyperlaxity of ligaments Mild short stature Two-thirds of cases classified as type I	Beak-like nose Short, bent, and deformed limbs 10% of cases classified as Type II	Development of kyphoscoliosis Skull deformity Short stature Generalized osteopenia Diaphoresis	Bowing of lower limbs Generalized osteopenia	Bowing of lower limbs Generalized osteopenia

In an article by Rauch and Gilorieux (2004, p. 1377) the most important therapeutic advance is the introduction of bisphosphonate (Reclast). Bisphosphonate (Reclast) is an inhibitor of osteoclastic bone resorption and used in treatment for moderate to severe forms of OI. The best treatment regimen and the long-term outcomes of bisphosphonate (Reclast) therapy are unknown. Treatment with bisphosphonate (Reclast) is an adjunct therapy for children with OI and should be used in conjunction with physical therapy, rehabilitation, and orthopedic care.

When caring for an infant who presents with a fracture, it is important to rule out OI as well as child abuse. In many instances, the diagnosis of OI is made after the family has been evaluated for possible child abuse or neglect. This can be a very difficult time for the family.

where research and practice meet: Osteogenesis imperfecta

Nonsurgical treatment with olpadronate (a bone-resorption inhibitor) therapy has been studied in a blinded placebo-controlled trial with a 2-year follow-up in the Netherlands. The study concluded that fracture risk was decreased. Patients who were treated with olpadronate had greater increases in spinal bone mineral content and bone mineral density (Sakkers et al., 2004).

“What to say” — Osteogenesis imperfecta

An important nursing intervention for the nurse is to teach the parents of an infant just diagnosed with osteogenesis imperfecta to watch for signs of a fracture. The nurse can communicate that the signs of fracture include irritability, fever, and refusal to eat. The nurse should tell parents of an older child that signs to watch for are pain, swelling, and possible deformity at the site.

If the child is going for surgery to reduce and immobilize a fracture, ensure that the child is adequately hydrated with intravenous fluids. Postoperative care involves frequent vital sign and neurovascular assessments. Pain management is also an important critical nursing action. Intravenous narcotics are administered as indicated. If the child is old enough to use a patient-controlled analgesia (PCA), it should be used to keep pain control at a more constant, therapeutic level. When the child is able to tolerate solid food, pain medication is changed to an oral narcotic such as acetaminophen (Children's Tylenol) with codeine. Children with OI have excessive fluid loss through their skin, so they have a much greater need for hydration. The nurse assesses hydration status with every vital sign assessment.

Social development may be delayed in a child with OI because of increased dependence on parents and decreased social interactions. Play and physical therapy should be

used with these children. Family can play with the child. The physical therapist directs range-of-motion exercises and muscle-strengthening exercises. The physical therapist also helps the child regain mobility after surgery or a fracture and ensures that the child can use the ambulatory devices safely. If deformities are present, ambulatory devices such as a walker or wheelchair may be necessary.

Most families are unaware of the different types of OI and the prognosis for each type. Encourage parents to receive genetic counseling. Causing a fracture is the biggest fear of these parents. Focus information toward the specific type of OI. Specific instructions about how to hold their infant, change the infant's diaper, and position their infant to reduce the possibility of fracture should be reviewed to help parents feel comfortable caring for their infant. The goal is to achieve a balance between protecting the child from fractures and allowing the child to live as normal a life as possible.

Osteoporosis

Osteoporosis is a condition that develops in postmenopausal women. The bones lose density and calcium and become brittle. Fractures of the hip and vertebrae are common in women with osteoporosis. Adequate intake of calcium and vitamin D are very important during the adolescent years when bone formation is maximized. This helps prevent osteoporosis in later years. Many adolescents do not ingest the necessary requirements of calcium and vitamin D, which puts them at risk for osteoporosis later in life. Some lifestyle choices also put adolescents at risk for osteoporosis (e.g., smoking, using alcohol, drinking excessive amounts of soda, keeping their weight very low).

A study by Lypaczewski, Lappe, and Stubby (2002) showed that the intake of calcium in school-age and adolescent girls plays an important role in preventing the development of osteoporosis. It is important for nurses to educate parents and children about the need to have adequate calcium intake in childhood as a means to prevent osteoporosis in adulthood.

Children can develop osteoporosis related to imbalanced nutrition or some pathological conditions. Osteopenia or low bone mass, between 1 and 2.5 standard deviations below the norm, precedes osteoporosis. Premature, very low birth weight infants often suffer from osteopenia of prematurity because bone mass is acquired in the last weeks of gestation. These infants may have an inability to ingest sufficient nutrients due to their prematurity or other health problems related to their prematurity. Physical activity helps increase bone mass. Activity is often less in premature infants so there is a decreased amount of mechanical loading on their bones.

Older children can also present with osteoporosis as a result of decreased mechanical loading. Children who have a health condition that results in decreased ambulation or minimal pressure on the long bones are at risk for osteoporosis. Children with any of the following diseases are at risk for osteoporosis: spina bifida, cerebral palsy, juvenile arthritis, osteogenesis imperfecta, diabetes, growth hormone deficiency, and Turner syndrome. Immobilization can also lead to osteoporosis, so children who are immobilized in traction or children who are wearing a cast are at risk.

Signs and Symptoms

The precursor to osteoporosis is osteopenia. Osteoporosis is a disease that strikes silently. Signs or symptoms may not become apparent for years. It may become apparent when an infant or child suffers a fracture and the x-ray exam confirms this diagnosis.

Diagnosis

Diagnosis includes complete blood count (CBC), sedimentation rate, urinalysis, chemistry panel, arthritis panel, serum protein electrophoresis, and x-ray of the involved bones. A skeletal survey may be necessary. Bone scans are often useful.

Nursing Care

Nursing care includes encouraging dietary intake of calcium and vitamin D and physical activity to promote bone strength.

Ethnocultural Considerations—Caring for a Hispanic child

Families of Hispanic background believe in *mal ojo* or “the evil eye.” They believe that the *mal ojo* is an illness that affects children and occurs when someone with special powers looks at or admires a child, but does not touch the child. For this reason, it is very important for a nurse to touch the child when making an admiring statement about him or her. The parents may call a *curandera* or *curandero* to treat the child through touch and prayer. They may have the child wear special amulets or charms to protect him or her from the *mal ojo*. Hispanic families believe that the saints help their sick child recover. They may place holy pictures of saints on or near their child. It is very important for the nurse to respect this practice and not replace the pictures, amulets, or charms on or near the child in the absence of the parents. (Information retrieved from personal communications with R. Spector, PhD [2006], who has performed extensive research on cultural competence and with a Hispanic student from the Dominican Republic.)

summary points

- ◆ Growth and development of the musculoskeletal system play a major role in the normal growth and development of the child.
- ◆ The nurse understands that casts, skin traction, skeletal traction, and distraction devices are effective methods in treating musculoskeletal conditions in the child.
- ◆ Complications can occur when a child is immobilized in a cast. The major complication that can occur is compartment syndrome, which is caused by an accumulation of fluid in the fascia.
- ◆ A nursing assessment of a child in a cast includes the 5 P's: pain and point to tenderness, pulse present at the distal site, pallor, paresthesia, and paralysis.
- ◆ The nurse recognizes that the main principle of traction is to reduce dislocations and immobilize fractures in the child.

- ◆ When caring for a child with a musculoskeletal condition a neurovascular status must be assessed carefully and every 1 to 2 hours for the first 48 hours. A thorough neurovascular status consists of pain, sensation, motion, temperature, capillary refill time, color, and pulses.
- ◆ The nurse understands that symptoms of compartment syndrome include a burning sensation, pain, pallor, pulselessness, paresthesia, and paralysis.
- ◆ Distraction devices are usually used to lengthen a bone where the surgeon cuts through a bone and places the distraction device.
- ◆ Clubfoot is a term used to describe a foot deformity diagnosed in newborn infants. The most severe form of this condition resembles a “club” and is called talipes equinovarus. It requires long-term follow-up since there is a residual lifelong atrophy of the calf muscle.
- ◆ There are four stages of Legg–Calve–Perthes disease (LCPD); aseptic necrosis, revascularization, new bone formation and the regenerative phase. It is a self-limiting disease that can take between 18 months to 4 years for the child to emerge from it. The child needs to participate in non-weight-bearing activities during the course of the disease.
- ◆ Nursing care of the child with slipped femoral capital epiphysis (SFCE) includes bedrest, assisting the family in adjusting to the sudden hospitalization, non-weight-bearing status of the child, and the impending surgery. After surgery, the nurse also needs to monitor the neurovascular status frequently and manage pain.
- ◆ Nursing diagnoses for a child with a fracture include risk for injury related to external devices, impaired physical mobility related to external devices, and risk for impaired skin integrity related to external devices.
- ◆ Soft tissue injuries are sprains and strains and are unusual in young children. Sprains and strains are often seen in the adolescent age group.
- ◆ The increase in popularity of competitive sports, recreational sports, and cheerleading has significantly increased the number of overuse injuries, sprains, strains, and dislocations.
- ◆ The nurse understands that all types of osteomyelitis require immediate treatment.
- ◆ The child with juvenile arthritis will have joints that are swollen, tender, and warm to touch and limited ROM. The joints will have a loss of motion and will be stiff, especially in the morning. Intermittent joint pain that lasts longer than 6 weeks should be suspect for juvenile arthritis.
- ◆ In Duchenne’s muscular dystrophy, the symptoms first appear after the child is able to walk, usually about 3 to 7 years of age. The child develops a waddling, wide-based gait and uses the Gower maneuver to rise from the floor.
- ◆ Positioning of the child after surgery for scoliosis is an important nursing action. The child must be turned using the logrolling technique.
- ◆ Early mobilization is important in the care of the child who has had a spinal fusion. Early mobilization prevents atelectasis, pneumonia, pulmonary emboli, phlebitis, and skin breakdown.
- ◆ Prevention of tetanus is the best defense; tetanus prophylaxis through immunization is the key to preventing this condition.
- ◆ Reliable prenatal diagnosis about osteogenesis imperfecta (OI) is not currently available. Diagnosis is based on the severity of clinical symptoms and the level of disability.
- ◆ Research shows that an intake of calcium in school age and adolescent girls plays an important role in preventing the development of osteoporosis.

review questions

Multiple Choice

1. The pediatric nurse is caring for a 5-year-old child in traction related to a broken femur. The nurse understands the importance of performing a neurovascular assessment every 4 hours. (*Select all of the following nursing interventions that apply to a neurovascular assessment.*)
 - A. Assess the child’s respiratory rate.
 - B. Assess the child’s abdominal pain.
 - C. Assess the child’s ability to move his toes.
 - D. Assess the child’s color of the affected leg.
 - E. Assess the child’s pedal pulse.
2. The nurse is preparing a 7-year-old child to have a cast removed from his leg. The nurse can prepare the child for cast removal with which statement?
 - A. “As soon as the cast comes off, you can get up and move around.”
 - B. “The sound of the cast removal instrument will be very loud.”
 - C. “You must sit very still so we don’t accidentally hurt your leg.”
 - D. “Don’t worry, you will be asleep during the cast removal.”
3. An 8-year-old boy is admitted to the hospital to rule out Legg–Calve–Perthes disease. During the admission interview, the parent tells the nurse that her son has been complaining of hip pain for the past 2 weeks. Which of the following assessment findings helps the nurse confirm the diagnosis of Legg–Calve–Perthes disease? (*Select all that apply.*)
 - A. The child reports that the pain increases when resting.
 - B. The nurse notices that the child limps when he walks.
 - C. The thigh and buttock area reveals muscle wasting.
 - D. The parent reports that the child currently has a fever.
 - E. The affected leg is shorter than the unaffected leg.
4. The nurse is experiencing some difficulty when caring for a child who is immobilized due to traction. The nurse consults the child-life specialist and a plan

is developed to decrease this child's anxiety as well as provide stimulation. The priority intervention is:

- A. Providing art therapy and distraction techniques
 - B. Allowing tutoring and assigned homework
 - C. Consulting the social worker and pastor
 - D. Administering pain medication every 4 hours
5. A 10-year-old child is being discharged home with a diagnosis of juvenile arthritis. The pediatric nurse is aware that the family will need discharge teaching. Which of the following care measures should the nurse include in the discharge teaching plan?
- A. Teach the family about passive range-of-motion exercises.
 - B. Teach the family that most children develop other disabilities.
 - C. Teach the family about corticosteroid medication therapy.
 - D. Teach the family that the prognosis for remissions is 100%.

True or False

6. The pediatric nurse is aware that a fracture in a child will occur when the bone undergoes more stress than it can absorb.
7. When a child falls and damages the epiphyseal plate, the affected limb can suffer length discrepancy and deformity.
8. The pediatric nurse is aware that the best treatment for compartment syndrome is prevention.
9. Based on the bone structure of an infant who has osteogenic imperfecta, the nurse knows that changing the infant's diaper usually results in a femur fracture.

Fill-in-the-Blank

10. When caring for a child with a broken leg, it is important for the nurse to perform pin care in an effort to prevent _____.
11. The child with a slipped femoral capital epiphysis will complain of pain in the _____ or referred pain to the _____ of the affected _____.
12. A compression fracture usually occurs in the _____.

See Answers to End of Chapter Review Questions on the Electronic Study Guide or DavisPlus.

CONCEPT MAP

Caring for the Child with an Integumentary Condition

In almost all diseases, the function of the skin is, more or less, disordered; and in many most important diseases, nature relieves herself almost entirely by the skin. This is particularly the case with children. However, the excretion, which comes from the skin, is left, unless removed by washing or by the clothes. Every nurse should keep this fact constantly in mind: if the nurse allows the sick to remain unwashed, or their clothing to remain on them after being saturated with perspiration or other excretion, the nurse is interfering injuriously with the natural processes of health just as effectually as if the nurse were to give the patient a dose of slow poison by the mouth. Poisoning by the skin is no less certain than poisoning by the mouth—only it is slower in its operation.

—Florence Nightingale

LEARNING TARGETS: At the completion of this chapter, the student will be able to:

- ◆ Discuss the pathophysiology and normal function of the skin.
- ◆ Identify common pediatric skin diseases and conditions.
- ◆ Explore nursing care for various skin conditions and diseases.
- ◆ Plan care for a child with skin diseases and conditions.
- ◆ Identify types of wounds and wound healing.
- ◆ Identify common pharmacological treatments for skin disorders.
- ◆ Plan care for a pediatric client with a burn injury.
- ◆ Discuss pressure formation and treatment in children.

moving toward evidence-based practice Nonchemical Head Lice Treatment

Goates, B.M., Atkin, J.S., Wilding, K.G., Birch, K.G., Cottam, M.R., Bush, S.E., & Clayton, D.H. (2006). An effective nonchemical treatment for head lice: A lot of hot air. *Pediatrics*, 118, 1962–1970.

The purpose of this study was to examine the effectiveness of various methods that use hot air to kill head lice infestation and the nits (the egg of a louse or another parasitic insect). The literature review identified that the incidence of head lice infestation is on the increase.

There are three common approaches for treating head lice infestations: chemical shampoos, specialized louse combs, and home remedies. However, each approach has its limitations. The researchers asserted that treatment with hot air provides a fast, safe effective method for killing both the lice and the nits.

Infested children were solicited from area elementary schools. Children younger than 6 years of age and individuals who had

used head lice shampoos or home remedies within the preceding 2 weeks were excluded from the study. One hundred and sixty-nine children who demonstrated evidence of infestation were interviewed. Confirmation of infestation was determined by the researchers through carefully combing the subjects' hair and noting the presence of one or more living, moving lice.

In addition, the parent/guardian of children in area elementary schools was asked to participate in a telephone interview that elicited information regarding a past history of treatment for head lice infestation.

Study participants received one of six hot air treatment methods. Treatments were conducted by the researchers in the home and

(continued)

moving toward evidence-based practice (continued)

each required approximately 1 hour. The hot air treatment methods included the following: a bonnet-style hair dryer; a handheld blow-dryer with a diffuser; a handheld blow-dryer with directed heating; a wall-mounted dryer (similar to those found in public restrooms for drying hands), a “LouseBuster” with sections; and a “LouseBuster” with hand piece.

The “LouseBuster” was described as a “custom-built, high-volume, hot-air blower” developed for the study. The “LouseBuster” with sections was compared to a wall-mounted dryer with a long flexible hose that could be aimed at the participant’s scalp. The “LouseBuster” with sections was designed to deliver twice the volume (of hot air) of a handheld blow dryer. The “LouseBuster” with hand piece included a comb-like attachment with coarse teeth that could be pulled through the hair during the treatment. Before implementation of the hot air treatment, each participant’s hair was carefully combed with a LiceMeister comb until infestation was confirmed by the presence of one or more living, moving lice. Next, the hair on one side of the scalp was thoroughly combed to remove all lice and eggs. The retrieved nits were placed in an incubator. When no additional lice or nits were found, the child’s entire scalp was treated via one of the six hot-air methods. After the hot air treatment was completed, the other side of the scalp was combed for the same length of time spent on the first side. Lice and nits obtained from the second hair combing were collected and incubated for later comparison.

A tally was made of the number of live versus dead lice retrieved from each side of the scalp. The retrieved lice were reexamined periodically for 18 hours to check for the “resurrection effect,” in which lice appearing to be killed are not actually dead. The effectiveness of the treatment method was determined “by comparing the percentage of dead lice and non-hatching eggs on the pretreatment and post treatment sides of the scalp (p. 1964).”

The median age of the participants was 10 years; 94.1% were female. The total duration of treatment for each method ranged

from 30 to 35 minutes. The mean recorded temperature for the six hot air devices ranged from 130.6°F to 141.4°F (54.8°C to 60.8°C); the mean temperature delivered with all six treatment methods was 131°F (55°C), which has been reported to effectively kill hatched lice.

Treatment method and louse and egg mortality were as follows:

Treatment method	Louse mortality (%)	Louse Egg mortality (%)
• Bonnet-style hair dryer	10.1	88.8
• Handheld blow-dryer with a diffuser	20.8	96.7
• Handheld blow-dryer with directed heating	55.3	97.9
• Wall-mounted dryer	62.1	96.5
• “LouseBuster” with sections	76.1	94.0
• “LouseBuster” with hand piece	80.1	98.0

All six hot air methods had an effect on the presence of lice and/or nits. The percentage of killed lice (louse mortality) varied considerably with the percentage of unhatched eggs (egg mortality). The hot air method was effective regardless of hair length or hair thickness and worked equally well for children from diverse ethnic backgrounds, though no data were available regarding participants’ hair length or ethnicity. The researchers concluded that one 30-minute application of hot air could effectively and safely eradicate head lice.

1. What additional information would you want to consider before recommending the LouseBuster hot air treatment for children with head lice infestation?
2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

The skin is the largest organ in the body; its main purpose is to protect the deeper tissues from injury and from foreign matter invasion. The skin also protects the body from exposure to a variety of environmental, pest, tactile, and chemical irritants on a daily basis that can disrupt the effectiveness of the skin as a protective barrier.

Other functions of the skin include synthesis of vitamin D from ultraviolet light, aid in water retention, and rid the body of toxins. The skin also helps regulate temperature and initiates the sensations of touch, pain, heat, and cold in the body. While most skin conditions are common across the age span, children are often at a higher risk for certain skin conditions based on their large body surface area and still maturing immune system.

This chapter provides an overview of skin conditions that are common during infancy, childhood, and adolescence. Varieties of treatment regimens with appropriate

nursing actions for treating a child with a skin condition are discussed. Complementary regimens and other insights for the nurse are also included.

A & P review The Skin

The skin has three layers: the epidermis, the dermis, and the subcutaneous fatty layer (Fig. 31-1). These three layers act to provide the body with a barrier against external invaders. Each layer of the skin contains specific properties. The epidermis is the outlet for the sweat glands and the hair follicles protrude through this layer. The dermis contains the nerves, muscles, connective tissue, sebaceous and sweat glands, blood vessels, and lymph channels. The subcutaneous fatty layer separates the skin from the underlying tissue as well. While all the accessory structures of the skin; the hair, sebaceous glands, exocrine glands, and apocrine glands, are present at birth, most are immature and cannot function to their full potential until middle childhood (Jarvis, 2005) (Table 31-1). ♦

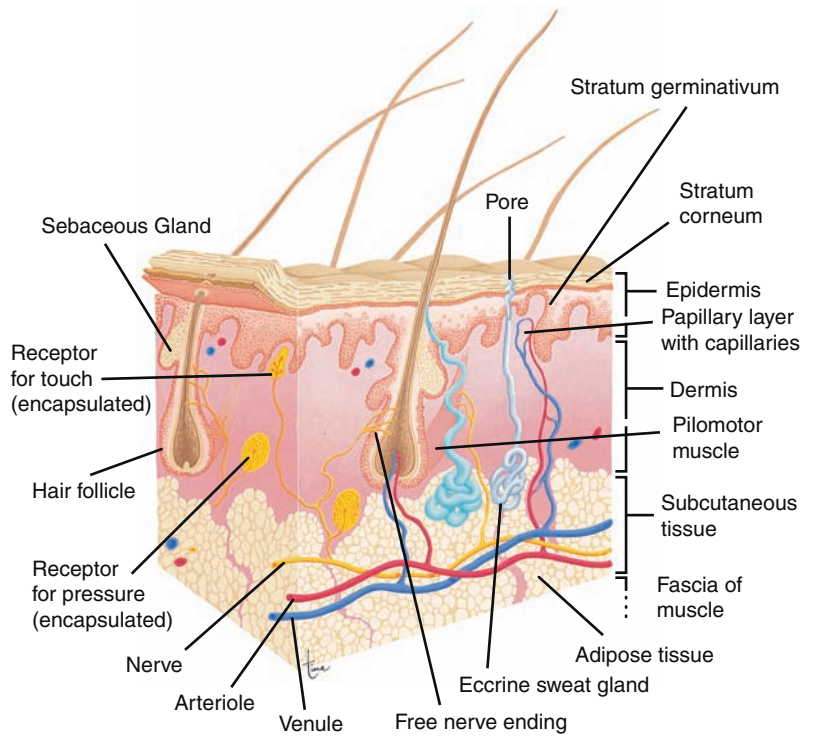

Figure 31-1 The skin has three layers: the epidermis, the dermis, and the subcutaneous fatty layer.

Nursing Insight— Infant skin and temperature

An infant’s skin is very thin and contains very little subcutaneous fat. For this reason, temperature regulation becomes an important issue, as the infant tends to lose heat rapidly. Take care not to leave an infant uncovered and exposed for a prolonged time. Owing to their immature neurological system and large body surface area, infants have more difficulty in regulating their body temperature.

Table 31-1 Integumentary Changes as Children Grow

Newborn	Child	Adolescent
Skin is thin.	Skin thickens with age.	Skin reaches adult thickness.
Friction can cause blistering easily.	Friction and shear are not as destructive to the child’s skin, but skin is still developing the bond between epidermis and dermis.	The epidermis and dermis are bound together and firm.
Eccrine sweat glands are functional.	Eccrine sweat glands are functional.	Eccrine sweat glands are fully functional and testosterone increases sweating in the male.
Apocrine sweat glands are not functional.	Apocrine sweat glands grow larger preparing for pubescence.	Apocrine sweat glands are mature at puberty.
Color is lighter than normal for race/ethnicity. Newborns/infants should avoid direct exposure to the sun.	Color is normal for race/ethnicity. Skin is easily sunburned, especially in fair-haired, fair-skinned children.	Color is normal for race/ethnicity functional at adult levels. Melanin is normal and provides some UV protection; however, protection from direct sun is still important.

Skin Lesions

A skin lesion is a circumscribed area of altered tissue (Venes, 2009). When assessing the skin for a skin lesion, it is important to note the size, shape, color, and texture. The two main types of lesions are primary and secondary. Primary lesions include macules, papules, patches, nodules, tumors, vesicles, pustules, bullae, and wheals. Macules, papules, and nodules are found in children and adolescents with acne. Vesicles and pustules are seen in the child with chickenpox and impetigo. Wheals are often seen in the child with an allergic reaction. Secondary lesions are those that happen as a result of changes from the primary lesions. They include crusts, scales, lichenification, scars, keloids, fissures, erosions, and ulcers (Table 31-2).

Notably visible lichenification or the thickening of the skin with hyperpigmentation is often found on children who have atopic dermatitis. Ulcers may be associated with cancer. Scars are the result of a wound. Keloids, seen mainly in persons of color, result from hypertrophy of the scar tissue that extends beyond the wound edges (Venes, 2009).

Nursing Care Plan The Child with Eczema

Nursing Diagnosis: Impaired Skin Integrity related to inflammatory processes

Measurable Short-term Goal: The child will regain skin integrity

Measurable Long-term Goal: The child will not experience secondary infection

NOC Outcomes:

- Tissue Integrity: Skin and Mucous Membranes (1101)
Structural intactness and normal physiological function of skin and mucous membranes.
- Allergic Response: Localized (0705) Severity of localized hypersensitive immune response to a specific environmental (exogenous) antigen

NIC Interventions:

- Infection Protection (6550)
- Skin Care: Topical Treatments (3584)
- Pruritis Management (3550)

Nursing Interventions:

1. Review family history for allergies or eczema.
RATIONALE: Assists with diagnosis of lesions as infantile eczema is often associated with familial tendencies.
2. Assess child's skin lesions for location, size, type, drainage, signs of secondary infection, and any precipitating factors.
RATIONALE: Provides baseline data from which to evaluate improvement or worsening of the condition. Intense itching and scratching may disrupt skin integrity further and lead to secondary infections
3. Administer cool compresses or medications as ordered to relieve itching and treat secondary infection (specify drug, dose, route, and times)
RATIONALE: Cold helps reduce irritation. Antihistamines and/or topical steroids may be prescribed to reduce inflammation and pruritis and antibiotics may be required for secondary infection.
4. Teach the family to promote skin hydration by bathing child in a lukewarm bath without harsh soaps and to apply emollient lotions to damp skin.
RATIONALE: Hot water and harsh soaps may exacerbate the skin irritation. Emollient lotions help trap moisture next to the skin to reduce irritation and itching.
5. Teach the family to dress child in light, soft, nonirritating clothing and to keep the child's fingernails short, smooth, and clean.
RATIONALE: Overheating and irritating fabrics may increase pruritis and inflammation. Nail care may help prevent secondary infection from itching.
6. Assist the family to identify and remove potential irritants from the child's environment, including harsh detergents, perfumes, rough fabrics, and animal dander.
RATIONALE: A nonirritating environment helps reduce flare-ups of the condition.

Wounds and Wound Healing

Typical wounds found in the child are a result from cuts, scrapes, burns, and can be secondary to surgical intervention. When an injury has occurred, skin healing has three phases and these often overlap. The first stage, inflammation, reflects the skin's initial healing response and lasts about 2 to 5 days. This is a preparatory stage for repair. Under normal circumstances, the wound seals itself with blood coagulation, followed by vasodilatation that allows the leukocytes to ingest the bacteria and debris at the site of the injury (Fishman, 2006). In the second phase, proliferation, the blood flow is reestablished to the site and natural débridement occurs. In this phase, lasting 2 days to 3 weeks, the wound contracts and a fine layer of epithelial cells cover the site of new collagen (Fishman, 2006). Finally, during remodeling, the third phase, collagen production occurs that allows for scar formation. This phase, lasting 3 weeks to 2 years, allows the collagen to increase the tensile strength of the newly mended tissue. Scar strength is only 80% as strong as the original tissue (Fishman, 2006) (Fig. 31-2).

Nursing Insight— Superficial wound management

As a pediatric nurse, it is important to note that in the area of superficial wound management wounds are often closed with tissue adhesives (DERMABOND) that work like glue. While the adhesive is effective in wound closure, the cosmetic outcome is not statistically different from suturing (Ong, Jacobson, & Joseph, 2002). Tending to wounds in this way has decreased both child and parent anxiety.

Skin Infections

A number of invaders can affect the skin and these can be bacterial, viral, or fungal in nature. While most of the skin conditions resulting from these invaders respond quickly to treatment, others require an extended time for healing. The specific pathogens that are responsible for the infection, as well as the treatment and sequelae of the infection, affect

Table 31-2 Common Skin Lesions and Associated Conditions—cont'd

Lesion Name	Description	Associated Condition (example)
Vesicles 	Raised, circumscribed, superficial, filled with serous fluid, <1 cm in diameter	Varicella, herpes zoster (shingles)
Pustules 	Raised, superficial, like vesicle, but fluid is purulent	Impetigo, acne
Bullae 	Vesicle >1 cm in diameter	Blister
Wheals 	Raised, irregular shaped, cutaneous swelling, solid. Diameter is variable (usually transient)	Urticaria, insect bites, allergic reaction
Secondary Lesions Crusts 	Dried body fluid on the skin surface: serum, pus, or blood	Disease where the skin weeps: eczema, impetigo, seborrhea

Table 31-2 Common Skin Lesions and Associated Conditions—cont'd

Lesion Name	Description	Associated Condition (example)
Scales	Raised cluster of keratinized cells, irregular, diameter is variable, can be thick or thin, dry or oily	Seborrheic dermatitis, dry skin, skin flaking after allergic reaction
		
Lichenification	Rough, thickened epidermal area often in the flexor surface of extremity	Chronic dermatitis
		
Scars	Fibrous tissue, thin or thick, coloration may be lighter or darker than surrounding skin	Healing wound of any etiology
Keloids	Fibrous tissue, (scar) of irregular shape, raised and grown beyond the boundary of the original wound	Post operative wound healing. (More common in persons of color)
		
Fissures	Linear crack in the epidermis may be deeper. Moist or dry	Athlete's foot. Cracks at the corner of the mouth, or anus
		

Continued

Table 31-2 Common Skin Lesions and Associated Conditions—cont'd

Lesion Name	Description	Associated Condition (example)
Erosions	Depressed, moist, loss of part of the epidermis	After rupture of vesicle or bulla, e.g., Varicella
Ulcers	Concave, moist, loss of epidermis and dermis	Ulceration: stasis, decubitus

Source: Potter, P.A., & Perry, A.G. (2004). *Fundamentals of nursing* (6th ed.). St. Louis, MO: C.V. Mosby.

both the treatment regimen and the healing response. Three specific pathogens are identified as the most frequent causes of bacterial skin infections: *Staphylococcus aureus*, *Streptococcus*, and *Pseudomonas*. Viral infections can be caused by any number of viruses but those encountered the most often include a member of the poxvirus group, herpes simplex I or II, and the human papilloma virus (HPV). Fungal infections are also caused by a wide variety of pathogens, the most common being *Candida albicans*.

BACTERIAL INFECTIONS

Acne

Acne vulgaris is the most common bacterial skin disorder (Fig. 31-3). Although acne generally begins in the teen years, it can begin earlier in some children. The onset of

adrenal androgenic hormones in the prepubertal child is the primary reason for the occurrence of acne.

SIGNS AND SYMPTOMS. With increase in the androgenic hormones, there is an increase in the size of the sebaceous glands and consequently more sebum secreted. With the increase in sebum secretion, the follicle (a small secretory sac) enlarges, placing the person at risk for a keratin plug. These plugs result in the presence of a comedo that is called a “whitehead.” At times, the comedo becomes inflamed and creates enough pressure to rupture. If a follicle is dilated enough to reach the skin surface, a comedo may form what is often called a “blackhead.” Hyperpigmentation (increase in color) in the area of insult will remain for weeks to months. If the area is aggravated by mechanical means, such as scratching, squeezing, or harsh chemical cleansers, a scar may form. When inflammation deepens into the dermis, there is a potential for scarring. Often, adolescents who have excessive sebum present, as sebum is a growth medium for *Propionibacterium acnes* (*P. acnes*) (Lehman, 2001).

DIAGNOSIS. A thorough skin assessment is the method of diagnosis for acne along with a complete history. For an assessment, the nurse can prepare the teen by making sure

Figure 31-2 Three phases of wound healing. A. Inflammation. B. Proliferation. C. Remodeling.

Figure 31-3 Acne generally begins in the teen years.

her face, scalp, chest, and back are exposed. Laboratory tests may be ordered when an underlying endocrine disorder is suspected.

NURSING CARE. Adolescents may suffer a psychological burden related to their acne. The nurse must realize that it is important to elicit information from the adolescent about his or her feelings and relationships and if acne is affecting these relationships. If necessary, the nurse can refer the adolescent for further support and intervention.

“What to say” — Assessing acne in an adolescent

When assessing acne in an adolescent the nurse can ask specific questions that may help guide the acne treatment regimen.

- “When did your acne begin?”
- “What types of cleaning products, makeup, or moisturizers and hair care products are you currently using?”
- “What medications you are taking, including over-the-counter and natural products?”
- “What type of foods do you eat?”
- “Have you noticed certain foods, activities, or environmental factors that affect your acne?”
- “Do you notice a change in your acne related to your menses?”
- “What other dermatologic problems have you had recently or in the past?”
- “Can you tell me how you feel having acne?”

Acne treatment can be as simple as decreasing the use of abrasive cleansers and harsh products or as involved as minor surgery. Most adolescent acne improves with cleansing and proper moisturizing with a water-soluble moisturizer.

critical nursing action Cleansing the Adolescent's Face

The nurse can follow these steps when cleansing the adolescent's face:

1. Use a warm moist cloth with antibacterial soap to soak away some of the crusting and then gently wipe away as much crusting as possible before applying the antibiotic topical ointment.
2. Apply the prescribed antibiotic topical ointment with a cotton swab or the finger of a gloved hand.
3. Apply a water-soluble moisturizer.
4. Encourage good hand washing techniques before and after the cleansing.

Note: If the teen is cooperative, allow her as much autonomy in cleansing and treating the area as possible.

If the cleansing approach is not successful, acne washes with benzoyl peroxide may be used. Often if over-the-counter preparations have not been effective, the adolescent seeks advice from a physician. The physician may then prescribe topical antibiotics such as erythromycin (E-Mycin), clindamycin (Cleocin), and tetracycline (Sumycin). The next line of treatment includes topical

retinoids, including tretinoin (Retin-A), adapalene (Differin), or tazarotene (Tazorac). These treatments tend to be very drying and must not be covered with moisturizers or makeup. Teaching the teen to use these medications at bedtime may increase adherence (Table 31-3).

Nursing Insight— Tetracycline (Sumycin)

Tetracycline (Sumycin) will autofluorescence in the presence of ultraviolet light, thus making the person noticeably “glow” in environments that are lit by black lights. Tetracycline (Sumycin) can also darken the teeth in children younger than the age of 8 years and should not be used in this age group.

When cleansing and topical treatments are ineffective, systemic oral antibiotic therapy may be necessary for teens with especially difficult to resolve acne. The primary systemic medications used are antibiotics, including tetracycline (Sumycin), minocycline (Minocin), doxycycline (Vibramycin), and erythromycin (Erythrocin). If the acne is excessively inflammatory, the incidence of scarring increases and a more potent oral medication may be used. The primary acne medication for inflammatory acne is isotretinoin (Accutane) (Cullen & Lucky, 2001). Follow up, teaching, and monthly visits to the dermatologist are imperative for the adolescent and family when this medication is prescribed.

Be sure to— Isotretinoin (Accutane)

Isotretinoin (Accutane) has been shown to cause severe birth defects. Therefore, women must not take this medication if there is any chance of becoming pregnant. Be sure to discuss this with any adolescent where pregnancy is a possibility. Pregnancy tests must be performed before treatment with this medication, monthly during treatment, and 1 month after the cessation of treatment. Women considering this treatment must use two forms of birth control. Visit iPLEDGE: Committed to Pregnancy Prevention program at <http://www.ipledeprogram.com/> to view the information appropriate for clients undergoing isotretinoin (Accutane) treatment. Other side effects include hypercholesterolemia, drying of the mucous membranes, decreased night vision, headaches, depression, and liver damage.

Give adolescents strict instructions not to share this medication with peers and to report any change in mood. Suicidal tendencies have been linked to isotretinoin (Accutane) therapy. If a teen is under the legal age limit, the parents or guardians must read, complete, and sign a designated form that proves they have been informed

Labs: Liver Enzymes

Liver enzymes must be drawn once a month to ensure that liver damage is not occurring from the isotretinoin (Accutane). Medication refills are not authorized unless the individual submits to the pregnancy testing guidelines and has blood testing of the liver enzymes. Teens are particularly difficult to manage because they often feel invincible and because they are not as likely to be compliant with this treatment unless a direct effect is seen quickly in their acne improvement.

Table 31-3 Medications for Acne

Name	Indications	Actions	Therapeutic Effect	Contraindications and Precautions
Erythromycin (E-Mycin)	Treatment of acne	Inhibits protein synthesis of bacterial ribosome	Anti-infective	Hypersensitivity, known alcohol intolerance
Clindamycin (Cleocin)	Treatment of skin infections: acne	Inhibits protein synthesis of bacterial ribosome	Anti-infective	Hypersensitivity, previous pseudomembranous colitis, severe liver impairment
Tetracycline (Sumycin)	Treatment of various infections: acne	Inhibits protein synthesis of bacterial ribosome	Anti-infective	Hypersensitivity, known alcohol intolerance, pregnancy, lactation.
Tretinoin (Retin-A)	Acne, acute promyelocytic leukemia, wrinkles	By stimulating the transcription process, it increases epidermal cell mitosis and epidermal cell turnover.	Anti-acne, antineoplastic, retinoid	Hypersensitivity
Adapalene (Differin)	Acne, chloasma, keratosis	Thought to normalize epithelial cells	Retinoid like effect	Hypersensitivity
Tazarotene (Tazorac)	Acne, psoriasis, wrinkles	Studies suggest: inhibits growth of human keratocyte	Retinoid	Hypersensitivity, pregnancy
Minocycline (Minocin)	Treatment of various infections: acne	Inhibits protein synthesis of bacterial ribosome	Anti-infective	Hypersensitivity, known alcohol intolerance, pregnancy, lactation.
Doxycycline (Vibramycin)	Treatment of various infections: acne Treatment of anthrax	Inhibits protein synthesis of bacterial ribosome	Anti-infective	Hypersensitivity, known alcohol intolerance, pregnancy, lactation.
Isotretinoin (Accutane)	Acne	Reduces sebaceous gland size and inhibits sebaceous gland activity	Anti acne, retinoid	Hypersensitivity, pregnancy

Adverse Reactions and Side Effects	Route and Dosage	Nursing Implications
Nausea/vomiting, rashes	Topical and systemic	Assess child for infection. Obtain specimen for culture and sensitivity before dosing Assess for improvement in the child's condition.
Diarrhea, rashes, pseudomembranous colitis	Topical and systemic	Assess child for infection. Obtain specimen for culture and sensitivity before dosing. Monitor bowel elimination. Assess for improvement in the child's condition.
Nausea/vomiting, diarrhea, photosensitivity	Systemic	Assess patient for infection Obtain specimen for culture and sensitivity before dosing Monitor liver and kidney functions. Assess for improvement in the child's condition.
Oral: Dysrhythmia Topical: Erythema, scaling, dryness, itching, photosensitivity	Systemic and topical Oral: Capsule, liquid filled: 10 MG Topical cream: 0.02%, 0.025%, 0.05%, 0.1% Topical Gel/Jelly: 0.01%, 0.025%, 0.04%, 0.1% Topical solution: 0.05% Usually used one time a day before bed	Assess patient for sensitivity. Assess for super infection. Assess for improvement in the child's condition.
Erythema, scaling, dryness, itching, photosensitivity	Topical Gel 0.1% Solution 0.1% Usually used one time a day before bed.	Assess patient for sensitivity. Assess for super infection. Assess for improvement in the child's condition.
Topical: Erythema, scaling, dryness, itching, photosensitivity	Safety not established in children <12 years old Topical cream: 0.05%, 0.1% Topical gel/jelly: 0.05%, 0.1%	Assess patient for sensitivity. Assess for super infection. Assess for improvement in the child's condition.
Nausea/vomiting, diarrhea, photosensitivity	Systemic	Assess patient for infection Obtain specimen for culture and sensitivity before dosing Observe for change in skin pigmentation Monitor liver and kidney functions Assess for improvement in the child's condition.
Nausea/vomiting, diarrhea, photosensitivity	Systemic	Assess patient for infection Obtain specimen for culture and sensitivity before dosing Monitor liver and kidney functions Assess for improvement in the child's condition.
Dermatologic: Cheilitis, dry skin, itching. Endocrine metabolic: Serum triglycerides raised Hepatic: Hepatotoxicity Psychiatric: Aggressive behavior, depression, violent behavior	Systemic Safety and effectiveness in children less than 12 yrs not established 1 mg/kg/day ORALLY in 2 divided doses	Obtain a pregnancy test, two tests at baseline, followed by tests monthly during therapy, at the completion of therapy and 1 month after the discontinuation of therapy Assess for depression, psychosis, suicidal ideation, or aggressive behavior Monitor hepatic function by obtaining a lipid panel; weekly or biweekly intervals Register for iPLEDGE Program: www.ipledgeprogram.com . Assess for improvement in the child's condition

about the risks associated with isotretinoin (Accutane). The iPLEDGE Program is designed to ensure safe administration, prescription, and consumption of this medication. There are exact guidelines that must be followed when filling the prescription. The physician informs parents or guardians about the specific rules and regulations associated with this medication (iPLEDGE, 2005).

Impetigo

Impetigo is a highly contagious bacterial infection. The child is predisposed to the infection via dry or cracked skin where bacteria may invade. Impetigo may be caused by *Staphylococcus aureus* (*S. aureus*) and *Streptococcus pyogenes* (*S. pyogenes*) or both (Watkins, 2005). On rare occasions, other bacteria may be responsible for the skin infection. Infants and children who have a less developed immune system are more prone to this condition as well as children who are in close contact with other children through daycare and school associations (Hill, 2003).

SIGNS AND SYMPTOMS. Impetigo is a bacterial infection of the skin often found on and around the mouth of the child or elsewhere on the face (Fig. 31-4). It can also appear on the hands, neck, trunk, buttocks, or extremities. The lesions begin as a vesicle or pustule surrounded by edema (swelling) and erythema (redness) a common sign of inflammation (Watkins, 2005). Later these lesions erupt, leaving honey-colored exudate. This exudate becomes crusty in appearance and sticky to the touch. The child may experience pruritus (itching) that is not usually painful. Over time, impetigo clears leaving no residual scarring (Watkins, 2005).

DIAGNOSIS. Impetigo is diagnosed through assessment. Rarely does the diagnosis require laboratory testing by culture. A diagnostic culture may be needed if the health care provider is unsure of the exact diagnosis, and is investigating a differential diagnosis such as contact dermatitis or herpes virus (Watkins, 2005).

NURSING CARE. Impetigo is very contagious and passed by touch from the infected child to others. Treatment options vary. Some practitioners may allow for spontaneous resolution by encouraging strict hygiene measures if the child is home and not requiring day care or school involvement. Mupirocin (Bactroban), a topical antibiotic, may be used if the skin lesions are limited (Watkins, 2005). If the skin infection is widespread, the child is required to stay home from school for 24 hours after the induction of the oral antibiotic. Oral antibiotics are given for widespread infections. Dicloxacillin (Dynapen) is most commonly used for a 7-day regimen. If the child is allergic to this medication, a cephalosporin or Macrolide antibiotics may be used.

Figure 31-4 Impetigo is a highly contagious bacterial infection.

“What to say” — Teaching about impetigo

When the nurse is caring for the child with impetigo, it is important to teach the child and caregiver:

- “Do not be embarrassed.”
- “It is very important to wash your hands.”
- “Try not to scratch the lesions.”
- “It is not nice to make fun of other children.”

Cellulitis

Cellulitis is a spreading bacterial infection that enters via existent openings in the skin caused by dermatological conditions or trauma that then spreads into the interstitial space. The most common bacteria causing cellulites are *S. pyogenes* and *S. aureus* (Venes, 2009), particularly *S. pyogenes*. The most frequent location of cellulitis is the face and extremities, particularly the lower legs, but cellulitis can occur anywhere on the body (Venes, 2009).

SIGNS AND SYMPTOMS. The infected area is edematous (swollen), erythematous (red), and hot to the touch. It is likely that the child will experience discomfort on palpation of the indurated area. Often the child experiences malaise, fever, and chills. Lymphadenitis (inflammation of the lymph nodes) may or may not be present in the region.

DIAGNOSIS. A complete history and physical is the usual method of diagnosis. Lab tests, radiological testing, or

Family Teaching Guidelines... Cellulitis

HOW TO TEACH THE CAREGIVER TO:

- ◆ Administer all antibiotics as ordered. Stress to the caregiver not to stop the antibiotics when the skin appears to have improved. The caregiver must realize that failure to finish the antibiotics may result in recurrence of the infection.
- ◆ Use warm moist packs to relieve discomfort as needed. If cool moist packs relieve discomfort, this is acceptable.
- ◆ Use analgesics such as ibuprofen (Children’s Advil) or acetaminophen (Children’s Tylenol) if necessary for comfort. If the skin infection is in a limb, elevate the limb to provide comfort and decrease swelling.
- ◆ Contact the physician if the redness or edema appears to be worsening, if the child’s pain is increasing, or if the temperature remains above 101.5°F (38.6°C) 48 hours after the beginning of antibiotic administration.

ESSENTIAL INFORMATION

Cellulitis is an infection of the skin caused by a bacterium. Cellulitis does not spread from person to person. The bacterium enters the skin and infects the soft tissue through a sore or a cut. If the cellulitis is around the eye, the original infection may have begun in the nose or sinuses. The infected area may look red or purple and be swollen; it will also be tender to pressure. The child may have a fever.

surgical biopsy is used only in the presence of severe infection. Complete blood counts and blood cultures are ordered to rule out septicemia (infection of the blood).

clinical alert

Group A *Streptococcus*

Group A *Streptococcus* can cause necrotizing fasciitis (flesh-eating bacteria). Be alert to the following clinical manifestations of necrotizing fasciitis: bruising, crepitus, or bullae filled with bluish/purple colored fluid over the induration (an area of hardened tissue). (Venes, 2009).

NURSING CARE. Benzathine penicillin G (Pfizerpen) orally is usually the antibiotic of choice. Children allergic to penicillin may be given first-generation cephalosporins, then Macrolide antibiotics. One-time intramuscular benzathine penicillin G (Bicillin L-A) may be given in the practitioner's office.

Optimizing Outcomes— Family compliance

The best outcome for a child receiving an antibiotic is for the family to be adherent and administer the entire medication as prescribed. If the family has a history of nonadherence to a medical plan, or if the child cannot take the medication as prescribed, the nurse must notify the health care provider immediately. The health care provider may then choose to order a single dose of intramuscular penicillin instead of the oral medication. Using a topical anesthetic such as EMLA (lidocaine/prilocaine) at the injection site at least an hour before the injection can help decrease the pain.

If a child has a severe case of cellulitis, hospitalization and intravenous antibiotics may be necessary. In addition, steroids to decrease inflammation such as prednisolone (Pediapred) may be ordered but are not routine. Another nursing intervention for symptom control is the administration of an anti-inflammatory medication such as ibuprofen (Children's Advil).

nursing diagnoses Cellulitis

- Impaired skin integrity related to inflammatory process damaging skin
- Pain related to inflammatory changes in tissues from infection
- Ineffective tissue perfusion: peripheral related to edema.

VIRAL INFECTIONS

Human Papillomavirus

Human papillomavirus infections (warts) are common among children. The human papillomavirus can cause warts by invading the epithelial cells in the skin. The wart is transmitted by direct skin-to-skin or mucous membrane contact as well as from hard surface areas such as plantar warts from gymnasium floors. The usual incubation period is 2 to 6 months but in some cases there is a latency period. Three types of warts occur in children: common wart (*verruca vulgaris*); the plantar wart (*verruca plantaris*); and the flat wart (*verruca plana*).

medication: Benzathine Penicillin G (Bicillin L-A)

Benzathine penicillin G (ben-za-theen, pen-i-sill-in, gee)
Bicillin L-A

Pregnancy Category: B

Indications: Treatment of a wide variety of infections: pharyngeal/ tonsil/skin as well as prophylaxis for rheumatic fever.

Actions: Binds to bacterial cell wall, resulting in cell death.

Therapeutic Effects: Bacteriostatic action against susceptible bacteria spectrum: *Streptococci*, *Staphylococci*, and some gram-negative organisms

Pharmacokinetics:

ABSORPTION: IM delayed and prolonged to sustain therapeutic blood levels.

Contraindications and Precautions:

CONTRAINDICATED IN: Hypersensitivity

Adverse Reactions and Side Effects:

Pain at injection site

GASTROINTESTINAL: diarrhea, epigastric distress, nausea/vomiting

ENDOCRINE: Rash

RESPIRATORY: Anaphylaxis

Route and Dosage:

IM: Children >27 kg, 900–1.2 million units (single dose)

IM: Children <27 kg, 300,000–600,000 units (single dose)

Nursing Implications:

Assess for history of hypersensitivity.

Observe patient for signs of anaphylaxis for a minimum of 15 minutes after injection.

Reconstitute with D5W or 0.9% NaCl.

Administer deeply in a well-developed muscle mass.

Data from Deglin, J.H., & Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

SIGNS AND SYMPTOMS. Warts are a cutaneous elevation of the skin (Venes, 2009). The warts are rough, raised, and flesh-colored and can occur anywhere on the body (Fig. 31-5). Flat warts generally occur on the face or legs and are sometimes flesh-colored and rarely rough. Plantar warts are found on the soles of the feet on weight-bearing surfaces. They are difficult to differentiate from corns and calluses but usually have a small dark dot near the center secondary to thrombosed vessels. Warts are usually not painful, nor do they itch unless other skin irritation is present. Occasionally, plantar warts cause foot pain if they grow large, and can be surgically removed if painful and not responding to other treatments.

Figure 31-5 Warts are a cutaneous elevation of the skin.

DIAGNOSIS. Diagnosis is based on presenting signs, symptoms, and visual inspection. Often the family makes a diagnosis at home and treats the wart with over-the-counter medications before seeking medical advice. Physician advice is usually sought after a long period of failed resolution, or an increase in the number or size of the warts.

NURSING CARE. The nurse can communicate to the caregiver that most of the time no intervention is needed for warts because 75% of warts resolve on their own within 2 years. Several medications, both over-the-counter and prescription, are available for wart treatment (Table 31-4).

Now Can You— Discuss bacterial, viral, fungal skin infections?

1. Name one condition in each category of skin infection?
2. Discuss the priority nursing interventions for the named condition?

Complementary Care: Topical agents

Topical agents that promote healing are frequently used for rashes: cow udder balm (bag balm), green tea extract, vitamin E preparations, aloe vera, milk, calamine, and colloidal oatmeal (Beltrani, 2002).

Herpes Simplex

The herpes simplex virus causes herpes infections. There are two types of herpes virus. Herpes simplex virus 1 (HSV-1) is the common cold sore (Fig. 31-6). HSV-1 can cause painful blisters on mucosal surfaces of the skin, and the most common location for HSV-1 is on the face, usually on the lips and in or near the mouth and nose. HSV-1 can also affect the sclera or the eyelid (Hurtado, 2005; Venes, 2009). Herpes simplex virus 2 (HSV-2) is genital herpes (Fig. 31-7).

Figure 31-6 Herpes simplex virus 1. Cold sore.

Figure 31-7 Herpes simplex virus 2. Genital warts.

Table 31-4 Human Papillomavirus

Type of Wart	Common warts (verruca vulgaris)	Flat Warts (verruca plana)	Plantar Wart (verruca plantaris)
Treatment and Description	<p>Topical: keratolytic acids (OTC)</p> <p>This topical treatment is applied by dropper or cotton swab. Source: Krusinski, P.A., & Flowers, F.P. (2000, March). Common viral infection of the skin. Retrieved from http://merck.micromedex.com/index.asp?page=bpm_brief&article_id=CPM02DE404&highlight=herpesvirus.

SIGNS AND SYMPTOMS. An infection by a herpes simplex virus is evident by watery blisters in the skin or mucous membranes of the mouth, lips, or genitals. After the virus has been introduced into the body, it establishes a latent infection. Based on a variety of stimuli such as a febrile illness, emotional stress, sexual contact, or ultraviolet light exposure, a lesion appears. The lesions are tender, burn, tingle, or itch before the sore actually appears. The sore usually begins as a red rash progressing on to blisters (vesicles) that open up, leaving a painful ulceration. These ulcerations are virulent and highly contagious (Hurtado, 2005).

DIAGNOSIS. When the child and family arrive at the clinic, the nurse can communicate to them that no specific diagnostic testing is required and that visualization of the lesion is often the only procedure required to diagnose the condition. A family history may reveal that the virus has recently affected other family members. If a differential diagnosis is needed, the practitioner may perform a viral culture of an open area to determine if the lesions are the herpesvirus or a different virus such as the varicella virus (chickenpox) which is similar in appearance.

NURSING CARE. Even though there are no treatments that can cure this viral infection, there are medications that decrease the length of the outbreak and/or increase the intervals between outbreaks. Acyclovir (Avirix) is a prescribed oral medication that can be prescribed for a child older than the age of 2, for their first outbreak or for outbreak suppression. Over-the-counter topical preparations such as docosanol (Abreva) can be used by children older than the age of 12 for local relief of symptoms and potentially to limit the length of the outbreak.

Family Teaching Guidelines... Herpes Simplex Virus (HSV-1)

HOW TO:

The child and family need to understand how to decrease transmission of this virus and prevent subsequent outbreaks.

ESSENTIAL INFORMATION

- ◆ Teach the child to keep his or her hands away from the face
- ◆ Teach the child good hand washing techniques. To wash the proper amount of time, young children can be taught to sing the alphabet song while rubbing their hands together.
- ◆ Decrease stressful situations.
- ◆ Avoid prolonged sun exposure.
- ◆ Moisturize the lips and use a moisturizing sunscreen on the lips during the summer months (Hurtado, 2005).

Across Care Settings: Supporting the child during treatment

- The community nurse has an important role in supporting the child and family during treatment. Tell the child and family the origin, signs, and symptoms of the virus in age-appropriate language.
- Create an environment of trust; allowing the child to keep a parent close may help the child cope with the clinic visit better.
- Monitor pain response throughout the visit to determine if the parent will need information about adequate pain control such as acetaminophen (Children's Tylenol).

FUNGAL INFECTIONS

Cutaneous Candidiasis

Candida albicans is the most common of the *Candida* fungi (yeast). It lives naturally in the gut and oral mucosa but is not a threat to intact skin. *Candida* overgrowth can occur in newborns who acquire this fungal infection during the birth process from the vaginal canal of an infected mother. Children who have an immune disorder are at risk for developing oral (thrush) or diaper area candidiasis. Children who use corticosteroid inhalers for allergy and asthma prophylaxis and treatment may develop oral candidiasis as well. Rinsing the mouth after each inhaler dose decreases the likelihood of developing oral candidiasis. Immunocompromised children may develop candidiasis more easily than healthy children.

SIGNS AND SYMPTOMS. The fungal rash appears in the infant's mouth or diaper area and occasionally in the folds of the axillae or the groin. In the mouth, the lesions appear as white or gray plaque that cannot be removed. The plaque can be on the tongue, buccal (cheek) area, or gingival (gums). On the skin, the rash is a fine red and slightly raised with a scallop-like border. A few stray papules may be present near the border of this moist rash area.

DIAGNOSIS. A thorough history of the mother and child's existing conditions as well as a current visualization of the lesions helps diagnose this condition. If there is a need for a differential diagnosis, a fungal culture can be obtained (Procedure 31-1).

NURSING CARE. Oral candidiasis is treated with kinesinetic nystatin (Mycostatin) orally after each feeding or two or three times per day. The nurse has a gloved hand and uses a swab to apply the medication to the insides of both cheek. Remember to use a separate swab for each cheek. Topical treatment for skin infections includes nystatin (Mycostatin), clotrimazole (Lotrimin), miconazole (Monistat), or ketoconazole (Nizoral) ointment applied with a gloved finger applied in a thin layer on the infected area two or three times per day.

Nursing Insight— How to tell oral thrush from formula or breast milk on the tongue of an infant

Sometimes after an infant drinks formula or breastfeeds, a white film is noted on the tongue. To differentiate the formula or breast milk from oral thrush the nurse can use a tongue

Procedure 31-1 Obtaining a Fungal Culture

Purpose

The purpose of obtaining a fungal culture is to test for the presence of fungi, and, if found, identify the type.

Equipment

Gloves
Tongue blade
Sterile cotton swab
Sterile test tube

Steps

1. Explain the procedure to the child in age-appropriate terms.
RATIONALE: *A simplified explanation may help decrease anxiety.*
2. Gather all supplies.
3. Aseptically place a sterile cotton swab against a plaque.
RATIONALE: *Using a tongue blade to keep the child's mouth open and the tongue out of the way.*
4. Vigorously rub the plaque with the cotton swab.
RATIONALE: *Twirling the swab so that all sides of the swab are exposed to the plaque.*
5. Place the swab into a covered, sterile test tube provided by the laboratory and place in a biohazard bag.
RATIONALE: *Maintains universal precautions.*

6. Have the specimen transported to the lab within 15–30 minutes.

RATIONALE: *Timely delivery will help ensure accuracy of test results.*

Clinical Alert The nurse must remember that attempting to remove the oral thrush can cause the lining of the oral mucosa to bleed.

Teach Parents

The final culture is not available for 48–72 hours; preliminary culture results may be available sooner.

Note

The specimen must have a label with the child's name, identification numbers, date/time of collection and the nurse's name or initials.

Caution: Monitor the child's mucosa for bleeding.

Documentation

9/25/10 1500 An oral culture was obtained. Child tolerated the collection without difficulty; no pain or bleeding noted.

-C. Kildare, RN

blade to gently scrape the white film. If the nurse can remove the film, it is formula or breast milk. If the nurse cannot remove the film, it is thrush.

Ringworm

Ringworm (dermatophytoses) is a fungal infection that affects the skin, hair, or nails (Fig. 31-8). Children of all ages are affected. It may be spread person to person or from animal to person. Ringworm may also be spread by contact with inanimate objects such as clothing, furniture, bed linen of another infected person. Some children may be colonized but remain asymptomatic.

Figure 31-8 Ringworm is a fungal infection that affects the skin, hair, or nails.

The most common ringworm infections are as follows:

Tinea capitis—involves the hair of the scalp, usually seen in pre-pubertal children between the ages of 1 and 10 years.

Tinea corporis—involves the skin of the body, except the scalp, groin, hands and feet; seen in children and adolescents

Tinea cruris—known as “jock itch”; involves the inner thighs, inguinal creases, or perineal area (rare before adolescence)

Tinea pedi—athlete's foot, involves the kinesthetic webbed areas of the toes and feet, seen in children and adolescents

SIGNS AND SYMPTOMS. Symptoms include round, scaly lesions. These areas may be red or inflamed. The patient may have areas that appear bald, due to hair that has broken off. There may be small black dots on the scalp. The child may experience slight itching.

DIAGNOSIS. Ringworm diagnosis is made by visual inspection using a Wood lamp that discloses yellowish gold fluorescence coloration. A potassium hydroxide (KOH) preparation of scrapings is also diagnostic, demonstrating groups of thick-walled spores and myriad short thick angular hyphae resembling spaghetti (Behrman et al., 2004).

NURSING CARE. An oral antifungal agent is usually prescribed for tinea capitis. The medication must be taken for at least 6 weeks to be effective. Absorption of the medication is enhanced if it is given with a high-fat meal. Other drugs such as miconazole (Monistat), fluconazole (Diflucan), and terbinafine (Lamisil) are not yet approved for children (American Academy of Pediatrics [AAP], 2003). Antifungal shampoo is often recommended. The child is checked periodically throughout treatment to be sure a proper response is noted. The nurse must stress that everyone in the family needs to be treated and it is essential not to share hair brushes or bath towels. Specifically, with tinea capitis the effected area of hair growth may take 6 to 12 months to grow or it may not grow back at all. The nurse can provide emotional support and suggest hairstyles to help conceal tinea capitis.

DERMATITIS

Dermatitis is an inflammatory rash marked by itching and redness that occurs due to numerous conditions. There are three common classifications of dermatitis in children: contact, atopic, and seborrheic.

CONTACT DERMATITIS

Contact dermatitis can occur if an allergen or skin irritant is encountered (Venes, 2009). In children, the irritative agents that cause this type of skin sensitivity are often soaps or detergents. For infants, the diaper area is especially prone and could be the result of diaper perfumes, cloth diaper detergents, or diaper wipes (Fig. 31-9) (American Academy of Family Physicians [AAFP], 2005). Children playing out of doors may encounter varying plant life that can cause contact dermatitis, specifically poisonous oaks, ivies, or sumacs.

Signs and Symptoms

In the case of contact dermatitis, the skin becomes irritated, inflamed, and pruritic within 48 hours of contact with the offending agent. Vesicles and bullae may be present in this area as well. Vesicles may rupture and weep a serous fluid. The presence of urticaria (hives) is expected (Beltrani, 2002).

Figure 31-9 Contact dermatitis can occur if an allergen or skin irritant is encountered.

Diagnosis

A complete history of contacts both in and out of doors for a child appearing in the community health clinic helps determine the diagnosis. If a differential diagnosis is required because there are atypical lesions, a biopsy may be performed (Beltrani, 2002). If the offending agent is not easily determined, an allergist may be the next appropriate referral to determine if allergic contact dermatitis is the diagnosis. One method of determining an allergy is by completing patch testing. The allergist prepares the proper concentration of allergens in a paraffin base and places this on the child's skin, usually the back, holding it in place with hypoallergenic tape. The patch is left in place for varying times based on the type of allergy being assessed (48 hours of wear is a standard). After the time has passed, the skin is assessed for reaction that is measured by redness and edema.

Nursing Care

On diagnosis, if the nurse notices that there are weepy lesions, a drying agent such as an over-the-counter product such as Domeboro powder (active ingredient, aluminum sulfate) may bring relief. For pruritic relief cool baths are effective. For a longer effect, a low dose of over-the-counter hydrocortisone (A-Hydrocort) cream can be applied with a gloved finger. Oral steroids such as prednisone (Deltasone) are used only if more than 10% of the child's body surface area is involved (Beltrani, 2002). If discomfort from agents such as poison ivy or oak is the concern, a topical anesthetic such as Dermoplast may bring relief. The nurse must remember that children suffering from severe pruritus may require a sedative for sleeping purposes.

Collaboration in Caring—A severe allergic reaction

The parents and community nurse must notify the school nurse, day care providers, coaches, and other adult leaders who spend time with the child about the diagnosed allergy. Everyone must be informed on how to use an EpiPen or EpiPen Jr. (epinephrine). EpiPens are usually kept in the school nurse's office. During sports activities, a second EpiPen may be given to the coach or the assistant. Along with documentation of the allergy, contact information, and the EpiPen that is on-hand, ready access to a phone for emergency medical assistance is a necessity.

nursing diagnoses Contact Dermatitis

- Impaired Skin Integrity related to allergic reaction
- Acute Discomfort related to inflammation of the skin
- Alteration in Sleep Pattern related to pruritus

ATOPIC DERMATITIS

Atopic dermatitis is a chronic skin condition with no known etiology. This condition is found in children with allergies, children whose family has a history of allergies, asthma, and rhinitis. Approximately 50% of persons with atopic dermatitis present in the first year of life and an additional 30% in the years between ages 1 and 5. Although the etiology may be genetic, the child may also

have immunological impairment. It is also possible for the etiology to be environmental in nature (e.g., pollution, indoor allergens such as cigarette smoke, or infections).

Signs and Symptoms

The child with atopic dermatitis has a red, raised rash that is both pruritic and painful with red papules that may have a serous exudate (clear fluid) during an acute phase. The rash is dry and easily cracks and excoriates in the sub-acute phase. As the disease progresses and the rash become chronic, the skin thickens, lichenification is present, and the papules become fibrotic. In the infant, the rash usually presents on the head, face, and lateral arms and legs. In the older child, the rash presents in the folds of the arms and legs, occasionally on the eyelids and neck.

Diagnosis

A complete family history and visual assessment of the child reveals the common signs of this condition. Blood tests reveal an increase in circulating IgE antibodies.

Nursing Care

critical nursing action Preventing Atopic Dermatitis Secondary Infection

When a child has atopic dermatitis, prevention of secondary infection is very important. Prevention of a secondary infection requires good hygiene processes, following prescribed treatment protocols, and maintaining skin hydration. Close and frequent monitoring and assessment of the rash is an important nursing measure.

SEBORRHEIC DERMATITIS

Chronic seborrheic dermatitis affects 2% to 5% of the population. Although it can affect young children, the peak incidence occurs in persons aged 18 to 40 years. There are many theories about the etiology of seborrheic dermatitis. This condition may have a genetic predisposition. In immunosuppressed *Pityrosporum ovale* may be the offending fungus.

Signs and Symptoms

The child who comes to the community health clinic with red to pink patches with loose yellow greasy scaling has seborrheic dermatitis. This skin rash is found on the face, across the cheekbones, in the fold around the nostrils, and behind the ears. It is also found on the scalp and eyebrows and may be found on the chest and back as well.

Diagnosis

The child who is diagnosed with seborrheic dermatitis has the defined rash. The nurse must understand that it may be necessary to differentiate between other conditions such as lupus, rosacea, and atopic or contact dermatitis.

Nursing Care

The nurse is aware that antifungal therapy is used if the etiology is *Pityrosporum ovale*. If the condition is not fungal in nature, topical corticosteroids may be used intermittently. It is important for the nurse to remember that low-dose corticosteroid topical applications are to be used on the face and other thinner skin surfaces. For the hair, antiseborrheic

shampoos that contain one of the following active ingredients can be used: coal tar, ketoconazole (Nizoral), selenium sulfide (Exsel), or zinc pyrithione (Denorex). It is more efficacious if the child or adolescent rotates types of shampoos. The nurse can communicate to the family that some of these shampoos with these active ingredients are marketed as “anti-dandruff” shampoos.

CUTANEOUS SKIN REACTIONS

Cutaneous skin reactions are a manifestation of an allergic response. The offending allergen can be introduced into the system in a variety of ways such as ingestion, inhalation, or coming into direct contact.

Signs and Symptoms

There are four basic types of skin reactions in an allergic response: exanthema (eruption), urticarial (itching), blistering (swelling), or pustular (a small elevated skin lesion filled with white blood cells) (Venes, 2009). It is paramount that the nurse look beyond the outer surface of the skin and assess for the root of the problem that may be a life-threatening condition associated with a systemic allergic response. An allergic reaction can be mild or a severe immediate hypersensitivity to an excessive release of chemical mediators affecting the entire body from medications, insects, foods, immunizations, diagnostic contrast media, or the administration of blood products. During the assessment phase, the nurse must appraise the face for swelling, especially around the lips, and including the tongue. It is essential that the nurse check the throat, using a light, but avoid using a tongue blade. Use of a tongue blade may stimulate more oral/pharyngeal swelling. Check nasal passages for edema (swelling) and erythema (redness) to ensure a patent airway. Airway compromise is a medical emergency.

critical nursing action Assessing for a Systemic Allergic Response

The nurse must recognize the key assessments in a systemic allergic response. Any edema or laryngospasms in the airway has the potential to cause blockage. If airway obstruction is noted, the Emergency Medical System must be initiated and airway, breathing, and circulation (ABCs) are begun. The nurse must assess for cyanosis as well as listening for audible sounds of upper airway respiratory distress such as wheezing or stridor. Assessing the vital signs, specifically, hypotension, which may lead to vascular collapse and cardiac arrest, is a critical indication that the allergic response may be systemic. Other important treatment measures include administering epinephrine (Adrenalin), keeping the child lying flat and warm with the feet slightly elevated, and administering oxygen if available. Immediate transport to an emergency medical facility is essential.

Once the possibility of compromised airway is dismissed, the nurse needs to assess whether the reaction is systemic. The nurse can then evaluate the skin lesions thoroughly determining the exact type of skin reaction.

Diagnosis

Visual assessment along with a complete history may help the nurse determine the cause. The nurse can find out specific details such as time and place of onset,

ingested prescription medications, over-the-counter medications, bug bites, use of herbal/cultural remedies, and their relationship to the cutaneous eruptions. A non-judgmental approach helps the nurse obtain the essential information that is necessary to determine which agent is the cause of the reaction. It is important to note that medication reactions can occur with the first dose of medication or even with a medication that the child has taken for months or years.

clinical alert

Stevens Johnson syndrome (erythema multiforme)

Stevens Johnson syndrome (erythema multiforme) or toxic epidermal necrolysis is a serious reaction that may result in death (Venes, 2009). The condition may be triggered by infections or certain medications such as anticonvulsants, nonsteroidal anti-inflammatory medications, or antibiotics. The leading cause of Stevens Johnson syndrome is severe allergic response to a medication. The syndrome often begins with a nonspecific upper respiratory system infection. The defining signs of this condition are bullae that appear on the lips, mouth, eyes, and genitalia, often in a target-like pattern. Purulent conjunctivitis is common as well as skin lesions that may rupture. Fever, neutropenia, chills, malaise, weakness, and anemia may occur. Once this condition has been diagnosed, it is essential to eliminate the causative agent, and treat the skin lesions using aseptic technique along with an air/fluid-filled bed, nutritional support, IV fluids, and pain management. Antibiotics can be given for secondary infections. An ophthalmologist should be contacted to assess for lesions in the eyes. These fluid-filled lesions begin to erupt and then slough off. This sloughing can occur internally as well as externally. It is vital to ensure a patent airway. This may progress to the necessity of intubation and mechanical ventilation. As these lesions rupture, large amounts of body surface area may become exposed. The child may experience large fluid losses and must be treated similar to a burn patient.

Nursing Care

Nursing care of a nonsystemic allergic reaction must also begin immediately. The nurse can emphasize the immediate discontinuation and avoidance of the offending agent. Administering oral antihistamines and topic corticosteroids decreases the symptoms of rash and pruritis. The nurse can also communicate to the parents that children returning to school after diagnosis may benefit from non-sedating antihistamines.

Across Care Settings: Prevention

The pediatric community health nurse can create a detailed record for each child including a history and a list of all allergies. Asking specific questions about medications, insects, foods, immunizations, diagnostic contrast media, or the administration of blood products may help decrease the chance of serious reactions in the future. When a certain allergy is identified, the nurse can teach the child and parent about the allergy and ways to avoid contact with the offending agent. The information can also be passed along to the school nurse or other adults such as coaches or group leaders who are in contact with the child.

Infestations

LICE

Lice (pediculosis) is a common childhood condition that can be passed among friends and family. Approximately 10 to 12 million people are infested yearly; one fourth of them are children in elementary school. Females are at higher risk because they are more likely to share combs, brushes, and hair accessories (Wiederkehr & Schwartz, 2003). There are three kinds of lice: scalp (pediculosis capitis), body (pediculosis corporis), and pubic area (pediculosis pubis). The louse pierces the skin and sucks blood. The bites can cause severe itching and can predispose the child to a secondary infection.

Signs and Symptoms

Lice (pediculosis) and their eggs (nits) can infest the body in any of the aforementioned locations but primarily choose areas that have longer hair. In children, one is most likely to find lice on the head and the live bugs tend to live near the nape of the neck and behind the ears. They lay their eggs at the base of the hair shaft, where they can be seen as pearlescent tear drops.

Diagnosis

For lice, the clinical presentation and identification of the mite and/or its eggs is important. Persistent itching of the head is the classic sign.

Nursing Care

The nurse can instruct the parents that visual inspection of the home, including clothes and bedding, is important but it is often difficult to see lice because of their small size.

MITE INFESTATION

Mite infestation (scabies) results from an infestation with *Sarcoptes scabiei* and is typically seen in children with a weakened immune system. Scabies is transmitted by close personal contact with an infected person and is more common in persons who live in crowded conditions or share a bed. The scabies mite cannot survive for more than 3 days away from the skin. Although scabies mites are found in the United States, there are significantly more documented cases in South America and Central America and infestation is endemic in some developing countries (Wiederkehr & Schwartz, 2003). This condition is highly contagious and while children of all ages are affected, it is most commonly seen in children younger than 2 years of age.

Signs and Symptoms

In this condition, the female arachnid scabie burrows into the outer layer of the epidermis and lays her eggs, leaving a trail of debris and feces. The larvae hatch in approximately 2 to 5 days and proceed to the surface of the skin. This cycle repeats every 7 to 14 days. The original mite dies in the burrow after 4 to 5 weeks. The scabies rash is red streaked and appears linear from the burrowing. The mites, eggs, and their excrement cause intense itching, especially at night. There are also signs of papules that are a result of inflammation secondary to infestation (Wiederkehr & Schwartz, 2003).

Family Teaching Guidelines...

Lice (Pediculosis)

HOW TO TREAT LICE (PEDICULOSIS)

- ◆ Assess for lice using good lighting and examining the child's head to identify both live lice (very small and brown or black) and nits.
- ◆ Separate sections of the hair to go through. Particularly pay attention to the area behind the ears and the nape of the neck.
- ◆ Teach the family member that this dandruff like appearance cannot be easily removed by combing because of the sticky adherence of the nit.

If the family member is unsure of what to do, they can call their primary care provider. The primary care provider instructs them to purchase an over-the-counter pediculicide shampoo with the active ingredient is either permethrin, for an infant/young child or malathion or lindane for older children.

The nurse can instruct the family to wash the hair according to the product's instructions. If a child is unable to tolerate these shampoos, former remedies including the use of asphyxiants like petrolatum and food oils (e.g., olive oil may be used) (Wiederkehr & Schwartz, 2003). Once the shampoo is rinsed from the hair, remove nits by backcombing with a fine-tooth comb (nits are easier to remove when the hair is damp).

The nurse can also instruct the family member to remove nits from eyelashes by applying petrolatum jelly to the eyelashes twice a day for 8 days. (Nits on the eyelashes of a child are sometimes a sign of sexual abuse. The nurse must report any suspicious findings.)

The nurse can stress to the family member to implement house cleaning (dust, vacuum, scrub) wash clothing and

bedding and wipe off hats, bicycle helmet and toys. If a soft or cloth toy like stuffed animals is not washable, it must be bagged in a sealed plastic bag and away from family members' rooms for 14 days.

Launder all bed linens in hot water and then placed in the dryer. Pillows should be thrown away if used by the child to avoid reinfestation. Anti-lice sprays can be used for furniture and other environmental objects that are not disposable.

Hair care items can be boiled (hot water above 140°F) or soaked in anti-lice shampoo and **never** shared.

The family member can check the school's anti-lice policy; children must remain home from school until lice-free. The child may be required to be checked by the school nurse or day care provider before returning.

Instruct the family member that the child should be rechecked for infestation in 7–10 days if the itching resumes, interferes with the child's sleep, or if the condition does not clear after 1 week of treatment

ESSENTIAL INFORMATION

To prevent the spread of acquire head lice (pediculosis) the nurse can have the mother:

- ◆ Ask other family members if there is a recent history of another family member with infestation.
- ◆ Remind family members and friends that because they may acquire head lice (pediculosis) from the affected child, they should take the same actions (listed above) if they are in close contact with or sleep in the same bed with the child. (The National Pediculosis Association, Inc., 2008).

Diagnosis

In assessing for scabies, it is essential to check all pruritic areas for the primary burrows and secondary inflammatory papules (raised, circumscribed lesions) (Wiederkehr & Schwartz, 2003). A skin scraping may be viewed under the microscope for evidence of the mite, eggs, or feces. As an alternate assessment tool, the nurse can use a fountain pen and place the tip at the opening of a suspected burrow. "If the ink seeps into the skin, the burrow will look different than the surrounding skin, thus identifying a burrow" (Wiederkehr & Schwartz, 2003). If scabies are not identifiable by visual inspection, skin scrapings, or other clinical testing, and an IgE blood level may be drawn. Eosinophilia (large number of eosinophils) may be present with scabies infestation (Wiederkehr & Schwartz, 2003).

Nursing Care

Treatment of scabies is similar to pediculosis and requires a scabicide that is applied only to the scalp and forehead of infants. First a warm soap and water bath is given, then 5% permethrin cream (Elimite) or lotion is applied. Treatment is repeated in 1 week. All persons in close contact with the child should be treated concurrently (Wiederkehr & Schwartz, 2003). The nurse can suggest to the parents that a dishwasher with no other contents works well for cleaning

washable toys and hair items. Treating all clothing, bedding, towels, and cloth toys by washing them in hot water and then placed in the dryer is necessary to kill all scabies.

nursing diagnoses Lice and Mite Infestation

- Altered Comfort related to pruritis secondary to infestation
- Potential Altered Health Maintenance related to nonadherence of cleaning regimen
- Potential for Social Isolation related to isolation from peers during treatment
- Pain related to secondary infection
- Risk for Infection related to impaired skin integrity, primary infestation, secondary pruritus

Bites and Stings

INSECTS

The most common insect bite comes from the mosquito. Spider and tick bites are also prevalent among children. The stings experienced most frequently are from bees, wasps, and hornets, and in some parts of the United States, scorpions. Other insects are also likely to bite, such as some types of flies, fleas and fire ants.

Signs and Symptoms

The mosquito bite causes discrete, red papules and edema at the site that produces itching, burning, and minimal discomfort. A spider's bite can cause local reaction (e.g., erythema, itching, and pain at the site that is usually self-limiting).

Nursing Insight— The brown recluse and black widow spiders' bite

The bite of the brown recluse spider begins with itching, pain, and erythema and then due to the venomous sting advances into a purple lesion that signals the beginning of necrosis. The site becomes red with blisters, has a white ring and is surrounded by irregular erythematous.

Black widow spider's bite leaves a stinging sensation at the time of the bite along with two fang bite marks, edema, petechiae, and erythema. The neurotoxin is usually self-limiting, but can result in more severe anaphylactic reaction. A systemic reaction from the neurotoxic venom can occur in 1 to 3 hours, with symptoms peaking in 3 hours and then diminishing in 72 hours. A systemic reaction includes muscle rigidity of the abdomen and torso, muscle cramps near the bite, malaise, sweating, dizziness, restlessness, insomnia, nausea and vomiting, hypertension, arrhythmias, and oliguria (low urine output).

A tick bite produces a reddened area of the skin that can be raised and itchy. A tick bite may cause a general sick feeling with fever, headache and nausea. The tick can stay on the skin and carry a risk of Rocky Mountain spotted fever or Lyme disease (Table 31-5).

Bee or wasp/hornet stings cause a mild local reaction that includes pain, erythema, and edema. If the reaction is systemic generalized urticaria (hives), flushing, and angioedema occur. Wheezing can be seen in some children but anaphylaxis is rare.

Diagnosis

Diagnosis of insect bites and stings are based on the child's history and physical findings.

Nursing Care

To protect against insect bites and stings the nurse can stress that children and adolescents adhere to the following directives when out of doors: wear light-colored clothing with minimal patterns, wear minimal perfumes or colognes, and cover the skin whenever possible to decrease the chance of insect bites and stings.

clinical alert

A severe reaction to a bite

A child who has had a severe reaction to bees or wasps should wear a medical alert bracelet or necklace and carry an EpiPen (epinephrine) or EpiPen Junior.

Specific care measures for mosquito bites and therefore, mosquito-borne illnesses are the use of bug sprays applied sparingly to the child's clothing to help decrease bites and therefore lower the risk for contracting West Nile virus, a

significant mosquito-borne illness in the United States today. The CDC (CDC, 2005b) is now recommending two new repellants that do not contain *N*-diethyl-*m*-toluamide (DEET), a common ingredient in most bug sprays. The two new repellants are oil of lemon eucalyptus (Repel) and picaridin (KBR3023) (Cutter Advanced Insect Repellent), easily found in local stores that carry brand name bug repellent sprays (CDC, 2005b).

Now Can You— Identify the types of insect bites

1. Identify the local symptoms of insect bites and stings?
2. Identify which spider bite may produce an anaphylactic reaction?
3. Discuss specific care measures for mosquito bites?

ANIMAL BITES

Dog bites account for the majority of animal bites to children. In fact, in the United States, approximately 800,000 dog bites are reported each year and 50% of them involve children. Boys are bitten more often than girls and children between the ages of 5 and 9 are most at risk (National Center for Injury Prevention and Control 2008). Most often times the child knows the animal and may have been bitten due to improper behavior such as interfering with feeding, playing, or taunting. Dog bites are sharp lacerations whereas cat bites cause deep puncture wounds.

Signs and Symptoms

When assessing animal bites it is important that the nurse consider the location, redness and swelling, number of puncture wounds, abrasions, and lacerations. Remember that any drainage or redness or swelling that extends beyond the primary site of the bite may be a sign of a complication such as cellulitis. The nurse must also assess for damage in the nervous, muscular, and vascular systems.

Diagnosis

Diagnosis of animal bites is based on patient history and physical findings. To diagnose a more severe problem, a radiographic evaluation or CT scan may be required.

Nursing Care

The nurse must take an accurate history about the incident and gather information about the exact injury, circumstances surrounding the attack, and location of the animal if known. The animal bite requires a good cleaning with soap and water and thorough rinsing. The nurse can then cover the wound with a topical antibiotic and clean dry dressing that helps protect it from infection. Small wounds can be closed with adhesive strips (Band-Aid) and larger wounds may need suturing. Wounds over the joints must be elevated and immobilized.

If the wound was a crushing injury from a larger or stronger animal, an evaluation in the provider's office or an emergency department is required to rule out damage to deeper structures. A tetanus booster is required if the child has not had one in the last 5 years (Stump, 2006). Rarely do animal bites require oral antibiotics, but the wound should be assessed daily for signs of infection.

Table 31-5 Insect Bites

Bite	Local Reaction	Treatment for Local Reactions
Mosquitoes and Fleas Systemic reaction is possible: Allergic reaction; wheezing urticaria, laryngeal edema, shock.	Red papules Itching, sometimes burning Local swelling (from foreign proteins) Minimal pain	Cleanse Cold compresses to the site Antihistamines, oral or topical
Bees, Wasps, and Hornets Systemic reaction is possible: Urticaria, flushing, angioedema, pruritis, wheezing	Redness and swelling (from venomous enzymes) Mild pain	Remove stinger quickly by scraping, not pinching. Cleanse Cold compresses to the site Elevate the extremity. Antihistamines A dash of meat tenderizer with a drop of water on the sting, massaged in for approximately five minutes will decrease pain.
Fire Ants Systemic and anaphylactic reaction is possible.	Redness, swelling, and induration (from neurotoxin, creates a histamine response) Red, itchy wheal that turns into a cloudy vesicle within 24 hours.	Cleanse. Cold compresses Antihistamines, oral or topical Elevate extremity
Ticks Systemic allergic reaction is possible Lyme disease is possible: Bulls-eye rash with erythema migrans, follow fatigue, malaise and joint pain	Tick is usually found with head burrowed into the skin. The tick must be removed. Area is generally reddened, and occasionally itchy.	Remove tick. Cleanse. Cold compresses Monitor for rash over the next month.
Brown Recluse Spider Systemic reaction is possible in 12–72 hours: Fever, chills, malaise, arthralgia, nausea, and vomiting Intravascular hemolysis resulting in anemia.	Red swollen “bulls eye” wound that turns purplish with an outer area of white induration. Skin necrosis occurs (the venom is proteolytic and cytotoxic) Painful	Cleanse. Ice to the site Apply topical antibiotic cream or lotion. Seek emergency assistance.
Black Widow Spider Systemic reaction possible in 1–3 hours, diminishing within 72 hours: Muscle rigidity, malaise, sweating, nausea and vomiting, hypertension, arrhythmia, oliguria, restlessness, insomnia	Redness and swelling Fang marks Petechiae branching out from site Stinging sensation	Cleanse. Ice Antihistamine, orally Hydrocortisone topically Seek emergency assistance to manage any neurotoxic symptoms

Source: CDC (2005).

It is essential that the nurse find out if the animal is rabid. Human rabies immune globulin (HRIG) or human diploid cell rabies vaccine (HDCV) should be given to all children who have been bitten by an unknown wild or domestic animal that is positive for rabies or bitten by an animal in which rabies cannot be excluded (Merlin & Bertolini, 2005). Unknown dogs or other mostly domesticated animals may not require rabies prophylaxis. The local health department has information regarding best practice based on reported rabies cases in the local area (Stump, 2006).

“What to say” — Animal bite prevention

The nurse can teach the following safety tips to children and parents when encountering dogs or other unfamiliar animals:

- Never leave a child alone with an animal.
- Never put your face close to an animal.
- Spay or neuter the pet to reduce aggression.
- Avoid dogs and animals that you do not know.
- Seek permission to touch or pet an animal.

- Avoid any contact with wild animals
 - Do not run away from aggressive animals. Lie down in a ball, protecting the face, and remain quiet.
 - Never overexcite or tease an animal.
 - Only play with animals, with adult supervision.
 - Report any strange behavior from an animal, even if it is a familiar animal
 - Do not disturb animals that are eating, sleeping, or nursing their young.
- (National Center for Injury Prevention and Control 2008)

HUMAN BITES

Human bites can be quite common and usually occur in toddlers and young children. Human bites carry a higher risk for infection than do animal bites. Further, human bites may carry blood-borne diseases such as hepatitis B or C and human immunodeficiency virus (HIV).

Signs and Symptoms

A human bite displays as redness, swelling, a break in the skin, fever, and signs of infection.

Diagnosis

Diagnosis of a human bite is based on patient history and physical findings.

Nursing Care

The nurse must take an accurate history about the incident and gather information about the exact injury. After the bite, if the skin is broken, the nurse communicates to the family that both the biter and the bitten are at risk for blood-borne diseases. Both children need to be tested according to blood-borne pathogen exposure precautions. The nurse irrigates the wound with Ringer's solution or with soapy water. Vigorously scrubbing of the wound is not recommended. After irrigation, a topical antibiotic is gently applied to the wound followed by a clean dry dressing. The extremity is elevated and the area must be monitored daily for an infection. If any infection is noted, the primary health care provider must be notified. The child's immunization record needs to be evaluated by the nurse for status of tetanus coverage. The child can be cared for at home, alerting the parents to signs and symptoms of infection and proper wound care.

Diseases from Bites

LYME DISEASE

Lyme disease is a tick-borne infection with multiple system involvement. It is an inflammatory response to the spirochete *Borrelia burgdorferi* and is the most common vector-borne disease in the United States. Lyme disease has been found in 49 of the 50 states. Eighty percent of the Lyme disease cases occur in the Northeastern, Mid-Atlantic, and North Central states (CDC, 2005d). Deer ticks, which carry this disease are located in the Midwestern, Northwestern, and Southwestern states.

Nursing Insight—Lyme disease in California

Western black-legged ticks are the vector ticks responsible for Lyme disease in California (CDC, 2005d).

Exposure occurs in any outdoor setting where ticks are endemic. Animals such as dogs and cats can also have the disease. Lyme disease occurs year round, with the highest incidence of infection in the summer. Children between 5 and 14 years of age are at highest risk because of outdoor activities. Infection does not induce immunity. Nymph (young) ticks feed on mammals in the spring, summer, and fall. The tick must feed for 36 hours to transmit the disease. It takes 48 hours after contact with a human to introduce the spirochete into the feeding site where the tick has buried its head. Any rash that appears before 48 hours is an allergic reaction or infection, not Lyme disease. The infection is not contagious from person to person.

Signs and Symptoms

During the history and physical, the nurse must always ask the family member if there has been an occurrence of a tick bite. The bite is often found in the groin, axilla, or thigh.

assessment tools Lyme Disease Presents in Three Stages

In the first stage, days to weeks after the tick bite, the child has a mild local rash. The rash from Lyme disease may occur as a bulls-eye rash or as disseminated erythematous (red) rash and erythema migrans (bulls-eye rash) (CDC, 2005d). Erythema migrans occurs in up to 90% of cases within a month of the bite. Other symptoms include headache, nuchal rigidity (stiff neck), and joint and muscle pain.

In the second stage, the disease may last from a few days to up to 10 months after the tick bite. During stage 2, the infection spreads through the blood and the child may exhibit signs of arthritis (especially in the knees), arthralgia (muscle pain), cardiac dysrhythmias, lymphadenopathy, pericarditis, or meningoencephalitis.

In the third stage, lasting from weeks to years after the tick bite (chronic stage), the child develops mild to severe arthritis. Neurological symptoms that occur in stage 3 include cranial nerve palsy, depression, meningitis, neuropathy, radiculopathy, and encephalopathy.

Diagnosis

After a tick bite, the nurse assesses the bite area for the distinguishing bulls-eye rash. Assessing joints for inflammation is necessary. A child's knees are the primary site for sudden onset arthritis, and it occurs without prior arthralgia (muscle pain), as in the case of chronic arthritis. Differentially, small joints are rarely inflamed in Lyme disease as they are in rheumatoid arthritis.

Lab testing may be performed to determine if the condition is present. The enzyme-linked immunosorbent assay (ELISA) and follow-up of positive results with the Western blot for confirmation of Lyme disease, if seroconversion has occurred. The ELISA methods may sometimes provide a false-positive result because of cross-reactive antibodies to other spirochetal infections (Behrman et al., 2004). Seroconversion takes at least 6 weeks in Lyme disease, so the child is treated symptomatically while waiting for lab confirmation. The child will have specific IgM antibodies that will appear first at 3 to 4 weeks and peak at 6 to 8 weeks, then usually decline. The IgG antibodies

appear at 6 to 8 weeks, peak after 4 to 6 months and may remain elevated indefinitely (Behrman et al., 2004).

Nursing Care

The first step is to remove all ticks immediately and properly. The nurse must remember to tell parents to remove a tick, grasping it gently but firmly with a fine-point tweezers where the mouth part is attached. Pulling gently to avoid squeezing of the tick's body (to avoid leaving tiny tick parts in the host) until it releases is important. Then the nurse can teach the family to clean the area with soap and water (AAP, 2003). The nurse explains to the parents to save the intact tick in a sealable bag in the freezer with the date of the bite recorded (in case the tick needs to be tested for disease).

A 2-week course of oral antibiotics is given if infection is suspected. Amoxicillin (Amoxil) or cefuroxime (Ceftin) are the most often used antibiotics in children 8 years of age or younger. Doxycycline (Vibramycin) or tetracycline (Sumycin) is given to children older than the age of 8 years. If recurrent arthritis, central nervous system complications, or carditis occurs, treatment lasts for 4 weeks with intravenous ceftriaxone (Rocephin), cefotaxime (Claforan) or penicillin G (Pfizerpen). With early detection and treatment, the prognosis is good; however, relapse can occur.

ROCKY MOUNTAIN SPOTTED FEVER

Some ticks, the dog tick and the Rocky Mountain wood tick, harbor the organism *Rickettsia rickettsii* that can be transmitted to the human host after a tick bite. Rocky Mountain spotted fever (RMSF) has been found in 38 of the 50 states, with a highest incidence in Oklahoma and North Carolina (CDC, 2005c). Between 250 and 1200 cases of RMSF are confirmed in the United States each year, with 90% diagnosed between April and September (CDC, 2005c). The peak age for RMSF is 5 to 9 years of age, with more than two-thirds of the cases occurring in children younger than 15 years (CDC, 2005c). The incubation period lasts 2 to 12 days after the bite of an infected tick.

Signs and Symptoms

RMSF is a multisystem disease that can be mild, moderate, or severe. The onset can be either gradual or sudden. Sudden onset is characterized by nausea, vomiting, lack of appetite, abdominal pain, malaise, deep muscle pain, and severe headache along with a diffuse red macular (flat, circumscribed) rash that blanches with pressure, occurring 3 to 5 days after the onset of fever (CDC, 2005c).

The rash starts on the extremities, including the palms of the hands and soles of the feet and moves to the trunk. The classic petechial spotted rash does not occur until approximately 6 or more days after the initial symptoms. Along with the rash, diarrhea, and joint pain also occur (CDC, 2005c). The child may have splenomegaly, hepatomegaly, and jaundice.

Diagnosis

Diagnosis is based on the classic triad of presenting symptoms includes the rash, fever, and history of a tick bite (CDC, 2005c). Often symptoms are vague and particularly difficult to diagnose if the child or parents do not recall a tick bite. Laboratory testing may prove useful.

Labs: Results and Rocky Mountain Spotted Fever (RMSF)

The nurse can expect elevations in white blood cell (WBC) count, thrombocytopenia (low platelets), hyponatremia (a decreased concentration of sodium in the blood), and elevated liver enzymes (CDC, 2005c). The child's WBCs will likely remain low in the early stage and rise to slightly abnormal in later stages.

WBCs: 5000–10,000/mm³. Later stage: 10,000–12,000/mm³

Platelets: 150,000–400,000/mm³. Thrombocytopenia <150,000/mm³

Na: 136–145 mEq/L. Hyponatremia <136 mEq/L

Bilirubin (total): 0.3–1.0 mg/dL. Hyperbilirubinemia >1.0 mg/dL.

Urine testing may reveal red cells and protein (Gandhi, 2005).

Nursing Care

Treatment should begin based on clinical symptoms and epidemiology. An indirect immunofluorescence assay specific for RMSF antibodies or a skin biopsy using immunostaining procedure is conducted (CDC, 2005c). Tetracycline (Sumycin) is effective against RMSF. The earlier it is administered, the quicker the patient responds to antibiotics and experiences fewer sequelae (CDC, 2005c; Gandhi, 2005). Tetracycline (Sumycin) therapy is continued for 3 days after the fever subsides. If tetracycline (Sumycin) cannot be used (in the case of children younger than the age of 8 years), doxycycline (Vibramycin) can be used and chloramphenicol (Chloromycetin) is the next alternative (CDC, 2005c; Gandhi, 2005). Supportive therapy for other symptoms may include antipyretics, anti-inflammatory medication, and IV fluids.

CAT SCRATCH DISEASE

Cat scratch disease (CSD) is a self-limiting illness lasting 6 to 12 weeks that begins with a scratch or bite from a cat (CDC, 2006). Domestic cats are reservoirs for the bacillus *Rochalimaea henselae*, which causes the disease response in humans (CDC, 2006).

Signs and Symptoms

The symptoms of cat scratch disease include tender lymphadenopathy (swollen lymph nodes) in the region of the scratch or bite that begins 1 to 3 weeks after the initial inoculation (CDC, 2006). Most children experience general malaise and low-grade fever. Some children experience nausea, vomiting, and weight loss. Others may experience sore throat and anorexia. Generalized rashes and thrombocytopenia purpura have been noted in some children. Some children may experience all of these symptoms (CDC, 2006).

Diagnosis

During the assessment, the nurse asks the parent or child about a recent history related to a cat scratch or bite. A positive response to CSD specific antigen, a confirming lymph node biopsy, and other lab findings that conclude another etiology for lymphadenopathy are used to confirm or refute the diagnosis (CDC, 2006).

Nursing Care

Antibiotics are used to treat CSD. Other treatments and care are not typically indicated.

Burns

The skin is the most important organ system to protect the body from infection, regulate body temperature, and serve as a barrier to prevent body fluid loss. Damage from burns causes major alterations in the skin. Burns occur every day in the United States; more than 1 million persons seek care for burns each year (American Burn Association, 2006). Burns that affect children can be accidental or the result of intention to harm and are the third leading cause of death (after motor vehicle crashes and drowning). Boys between the ages of 1 and 4 are twice as likely as girls to be burned, and the average of pediatric burn patients is 32 months of age (Perry, 2003). Thirty-three percent of all burns affect children younger than the age of 19 years (American Burn Association, 2006). Some children are at higher risk for burns due to their environment, their behavior, and their age. Burns are a result of either chemical, electrical, radiation, or thermal insult. The most common burns affecting children are thermal. Infants and children younger than 5 years are most likely to suffer burns from scalding. The risk of injury from fire is highest in the 5- to 20-year-old population (American Burn Association, 2006).

Nursing Insight— Development

Children at different developmental stages are at risk for different types of burns:

- Infants—incur burns by scalding liquids and house fires
- Toddlers—incur burns by spilling hot liquids on themselves
- Preschool children—incur burns by appliances (irons, curling irons) or scalding liquids
- School-age children—incur burns by playing with matches, climbing tress or high-voltage towers and chemical burns from curious experimentation
- Adolescents—incur burns by thermal, chemical, and electrical means, but primarily fire

THERMAL BURNS

Thermal burns are the most common type of burn in childhood. Thermal burns occur as a result of flame, flash, scalds, or contact with hot objects, or radiation. In the toddler age group, scald burns from hot liquid or hot grease is common and account for 80% of all thermal injuries. This type of burn accounts for a majority of childhood burn hospitalizations in this age group (Reed & Pomerantz, 2005).

Nursing Insight— Common Causes of Burns

- Flame Ignition of combustible materials and contact with fire, fireworks, candles, campfires
- Flash Caused by explosions especially with combustible fuels like gasoline, kerosene, and charcoal lighter, fireworks, hairspray
- Scald Occur when hot liquid is spilled on a child (oil, grease, coffee, hot tea, soup) or from hot tap water in sinks and bathtubs or from steam
- Contact Exposure to a hot object like an oven, hot iron, radiator, hot light bulb, or heating device.

Four out of five U.S. fire deaths occur in the home (Karter, 2001). This accounts for 82% of all civilian fire deaths (National Fire Protection Agency, 2007). Cooking is the most common cause of residential fires, with the leading cause of fire related deaths linked to smoking (Ahrens, 2001).

Ethnocultural Considerations— Vulnerable populations

African Americans and Native Americans (CDC, 2006), and persons living in rural areas (Ahrens, 2001) are most vulnerable to fire-related injuries and death.

Nearly one half of all home fire deaths are in homes without smoke detectors (Ahrens, 2001). Smoke detectors have a major impact on decreasing the likelihood of death from a house fire, and all homes should be equipped with at least one smoke detector per floor (U.S. Fire Administration, 2005). Thermal injuries from campfires occur when children fall into the fire or by touching the embers around an already extinguished fire. A lack of adult supervision is usually responsible for this type of injury (Klein, Heimbach, Honari, Engrav, & Gibran, 2005).

Across Care Settings: Burn prevention

Nurses can remind parents to be sure to check that their home hot water heater is set at no higher than 120°F to prevent scald injuries. Nurses should also remind parents to turn the pot handles inward when cooking and to make sure all cords from cooking appliances are not dangling and are away from children's reach (American Burn Association, 2007).

where research and practice meet: Pediatric Scald Burns

A study by Greenhalgh et al. (2006) looked at the design flaws in instant cup of soup containers. With scald injuries being the most common type of burn injury in children, heating prepackaged soups are a frequent cause. All pediatric scald burns caused by soup between June 1997 and August 2004 were examined. Safety statements and recommendations as to use of the microwave oven were documented but were inconsistent. During the study period, 99 admitted patients and 80 outpatients who were treated for burns caused by soup were examined. Of the 13 different types of soups, 11 required the addition of hot water and 2 were prepackaged to eat out of the container. Twelve containers had round bases and were tall and narrow and one was short and rectangular. Their height/base area ratio was measured. The most significant contributor to the ease of tipping over was the height of the container. Instant soups are packaged in containers that are tall with a narrow base that predisposes them to being knocked over and spilled. Simple redesigning of the instant soup packages with a wider base and shorter height, along with the requirements for warnings about the risk of burns, would reduce the frequency of soup burns.

CHEMICAL BURNS

Between 25,000 and 100,000 chemical burns are reported in the United States each year, collectively burns have a morbidity and mortality rate of less than 1%. Children and adults are reported to have similar rates of exposure. More than 25,000 different chemicals can produce either acid or alkali burns. The burn usually results from a direct chemical injury, but there may also be components of a thermal burn caused by an exothermic reaction (Reed & Pomerantz, 2005).

Chemical burns can be divided into the following categories: acid, alkali, oxidants, and other. Children are likely to be burned as they explore the environment. Acids tend to cause self-limiting tissue damage by denaturing protein, whereas alkalis cause fat saponification and the burning continues into deeper tissue (Cox, 2005). In any chemical burn, immediate flushing of the skin can significantly decrease the burn injury (Cox, 2005). Chemical burns require a visit to the emergency department for full decontamination, for the chemical to be neutralized, and for a complete evaluation (Cox, 2005).

Household chemicals that are available to children are the most frequent cause of chemical burns (Whetstone, 2005). Acid burns result in coagulation necrosis, which usually limits the depth and penetration of the burn. Some common household examples that contain acid include drain cleaners (sulfuric acid or hydrochloric acid), toilet cleaners (hydrochloric acid or phosphoric acid), and car batteries (sulfuric acid). Sometimes burns involving bases with high pHs are worse than those from acid because they actually produce a type of necrosis called liquefactive, which causes a deeper penetrating and more significant burn. Some common alkalis include lye (sodium hydroxide), cement (calcium, potassium, and sodium hydroxide), oven and drain cleaner (sodium or potassium hydroxide), and various detergents (Reed & Pomerantz, 2005). All household chemicals should be out of the reach of children by placing them on high shelves for children who cannot climb, or locking them in cabinets. Parents who do not understand these basic principles put their children at risk for a chemical burn.

clinical alert

Material safety data sheets

To protect personal and patient safety the nurse must know where to find the material safety data sheets (MSDS) in a health care setting. Many organizations have a special telephone hot line for MSDS information when you encounter chemical exposures. The nurse must also know the phone number of the local poison control center. The poison center provides accurate telephone advice and fax important information regarding the management of chemicals spilled on or ingested by your patients.

ELECTRICAL

Electrical burns result in more than 1500 deaths per year and more than 4000 emergency department visits. Electric burns also account for 2% to 3% of all admissions to hospital burns centers. Up to one-third of electrical burns are

household burns that are seen most often in children. Electrical burns result from thermal energy that is produced as an electrical current passes through the body. The amount of thermal energy is directly related to the degree of electrical current. The longer the individual is in contact with the electrical source, the more severe the injury. Electrical outlets and loose or frayed cords are dangerous for small children and are directly responsible for the majority of electrocutions in children younger than 12 years.

Parents should childproof their homes by keeping all cords away from children, taking appliances with frayed cords out of service and covering all exposed outlets with childproof covers (at least in the first 5 years of a child's life) (Reed & Pomerantz, 2005).

If a child suffers any type of electrical burn, he or she must be treated in the emergency department and monitored for a minimum of 4 hours (O'Conner & Besner, 2004). If low-voltage burn was encountered, the child will not likely have cardiac involvement. Cardiac monitoring should take place in the emergency department while the child is being observed for any other sequelae. If the wound is small and manageable in an outpatient setting, and the child did not have any adverse cardiac events, did not lose consciousness, and did not suffer the injury while the skin was wet, the child can be discharged after observation (O'Conner & Besner, 2004). Typically, low-voltage electrical injuries do not cause a significant internal burn effect (Selvaggi, Monstrey, van Landuyt, Hamdi, & Blondeel, 2005). If the child has any of the aforementioned adverse reactions, he or she must be hospitalized for more intensive monitoring and treatment.

If the child suffers a high-voltage electrical assault he or she is at high risk for a cardiac arrest, and must be monitored. Blood vessels, nerves, and muscles readily conduct electricity and are also destroyed as the electrical current makes its way through the child's body (Selvaggi et al., 2005).

Nursing Insight— Alternating current

The nurse can remember that alternating current is more damaging than direct current, as it causes a “lock-on” effect that does not allow the child to release and stay released from the source (Selvaggi et al., 2005).

RADIATION

The nurse must educate parents how to protect children from the sun by applying a sunscreen of SPF 15 or above. Ultraviolet rays from the sun are most intense between the hours of 10:00 A.M. and 4:00 P.M. Children should be strongly encouraged to play indoors or in shaded areas during these times. Further, infants younger than the age of 6 months should not wear sunscreen and should never be in direct sunlight. Exposure to sun occurs on cloudy days too, so children can protect their skin by covering up with clothing or applying sunscreen on these days as well. Special attention to sunscreen around water is encouraged, as even waterproof sunscreen requires reapplication approximately every hour. Sunscreen should be reapplied per package directions and must completely cover all exposed skin.

CLASSIFICATION OF BURNS (FIG. 31-10)

First Degree

First-degree burns (superficial thickness) are usually erythematous (reddened) and painful (e.g., sunburn from ultraviolet exposure). These burns involve the intact epidermis without blistering. This type involves only the outer layer of the epidermis, and fluid loss is not a problem. Several days after the initial burn, peeling of the skin begins because of superficial cell death. This type of burn heals without scarring in 4 to 5 days (Reed & Pomerantz, 2005).

Second Degree

Second-degree burns (superficial partial thickness, or deep partial thickness) involve partial destruction of the dermis and appear red and painful with blister formation. They have a weeping or moist appearance, and usually heal with minimal scarring in 7 to 10 days. Dark-skinned individuals may lose melanin and develop hypopigmentation on healing (Reed & Pomerantz, 2005).

Second-degree burns involve greater than 50% of the dermis. They destroy nerve fibers and as a result are less

painful. These burns have a white pale appearance and usually take 2 to 3 weeks or longer to heal. It can be difficult to distinguish between this type of burn and third-degree burns. Frequently severe scarring develops and patients are at risk for contractures. These patients are at risk for fluid volume loss. Surgical consultation is necessary because skin grafting is usually required (Reed & Pomerantz, 2005).

Third Degree

This is the most severe burn (full thickness). It appears white, waxy, or leathery and does not bleed or blanch. The skin may also be black in color, called eschar. Typically, these burns are less painful because the nerve fibers in the dermis were completely destroyed. Patients with these burns are at high risk for infections and severe fluid volume loss. Patients with this type of burn are immediately referred to a burn center and a surgeon because of risk of significant scarring on healing and they frequently require grafting. This type of burn takes several weeks to heal.

Fourth Degree

Although this terminology is not commonly used, fourth degree burns involve the destruction of the underlying structures such as tendons, muscles, bone, and deep fascia. Most commonly these are seen with severe electrical injuries and in severe thermal injury (Reed & Pomerantz, 2005). This type of burn injury requires immediate transfer to a burn center. Survival of the child depends of several factors such as fluid resuscitation, decreasing the risk of infection, and restoration of function.

Classifying Burns

It is also important to determine the extent of the burn by calculating the total body surface area (TBSA). TBSA can be determined by using several methods. The Lund and Browder Chart or the Burn Calculations Rule of 9's is frequently used and gives a reasonably accurate TBSA when a quick assessment is needed (Uliasz, 2002). The Rule of 9's (modified) calculates the child's body proportions differently than the adult. After 2 years of age, as the child's proportions change, percentages are deducted from the head (1%) and added to the legs (0.5% to each leg). For example, in an infant their head and neck make up 18% of the TBSA and each lower extremity accounts for 14% of the TBSA (Fig. 31-11). Burns are also categorized according to severity (Table 31-6).

Figure 31-10 Classification of burns. A. Partial thickness (superficial). B. Partial thickness (deep). C. Full thickness.

Figure 31-11 Rule of nines.

Table 31-6 Classification of Burn Severity

Mild	Moderate	Severe
First or second degree <10% TBSA	Second degree, 10–20% burn	Second-degree burn >20% TBSA
Third degree <2% TBSA	Third degree but <10% TBSA	Third-degree burn >10% TBSA
<ul style="list-style-type: none"> No area of the face, feet, hands, genitalia burned 		<ul style="list-style-type: none"> Burn on face, hands, feet, genitalia that may lead to functional impairment Smoke inhalation present
Treated in outpatient clinic	Treated in a burn unit or hospital	Treated in a specialized burn center

critical nursing action

Criteria for Transfer to a Burn Center

- Partial thickness burns >10% total body surface area (TBSA)
- Burns that involve the face, hands, feet, or genitalia
- Third-degree burns in any group or category
- Electrical burns including lightning injury
- Chemical burns
- Inhalation burns
- Burn injuries in patients with preexisting chronic conditions that could prolong the burn recovery
- Any patient with coexisting trauma (such as fractures) where burn injury poses a greater risk of morbidity and mortality than the trauma
- Burned children in hospitals without qualified personnel or equipment to care for the care of children
- Burn injury in patients who require special emotional, social, or long-term burn rehabilitation.

(American Burn Association, 2006)

NURSING CARE

Minor Burns

Minor burns are usually treated in clinics or outpatient setting unless there is suspicion of child abuse or neglect.

critical nursing action

Managing Minor Burns

In a clinic or outpatient setting the nurse can use the concept of the six “C’s” to manage minor burns. The nurse can teach this method to parents and other caregivers.

- Clothing—Remove any clothing that is hot or has been in contact with the offending chemical.
- Cooling—Burns need to be cooled immediately with cool (54°F) saline soaked gauze or any available clean cloth soaked in cool water. Caution: Do not use ice!
- Cleaning—Wash wound with mild soap and rinse well with water.
- Chemoprophylaxis—Bacitracin (AK-tracin) may be used topically to prevent infection. Other types of anti-infective agents are used in moderate and major burns. A tetanus booster (Td) is also given.
- Covering—Cover the burn with gauze to prevent infection, to decrease pain, and to absorb drainage.
- Comfort—Give acetaminophen (Children’s Tylenol) or ibuprofen (Children’s Advil) to decrease the pain. Pain medications should be on a schedule to decrease pain in the child who has sleep, play, or mood alterations.

Source: Morgan, E.D., Bledsoe, S.C., & Barker, J. (2000). Ambulatory management of burns [Electronic Version]. *American Family Physician*, 62(9), 2015–2026.

Moderate and Major Burns

Moderate and major burns require hospitalization and some major burns require hospitalization in specialty burn-trauma units. At the site of or a moderate or major burn, there is coagulative destruction of the skin and necrosis if the burn is deep. Interstitial fluids are lost secondary to increased capillary permeability. With the shift of fluids to the site of the burn, there is a hypovolemia (decrease in circulating plasma volume), which increases plasma viscosity. Increased plasma viscosity decreases cardiac output. With a decrease in cardiac output, there is a decrease in blood pressure. Breakdown of the muscle tissue in full thickness burns results in an increase in myoglobin, which decreases kidney perfusion. Increases in myoglobin are most likely in partial to full-thickness burns and when the burn is a result of electrical shock. If chemicals are swallowed, the internal burn presents as dyspnea, stridor, wheezing, and drooling (Cox, 2005). Immediate attention to the child’s airway is critical. These critical burns assault the entire body system and create a stress that demands increased energy metabolism to compensate, putting the child at risk for shock.

Optimizing Outcomes— Overall goals of burn treatment

The best outcomes for a burned child include interventions from the following categories:

- Burn assessment
- Fluid resuscitation
- Adequate nutrition
- Pain management
- Meticulous wound care
- Burn recovery

ASSESSMENT. Assessment of the burn history is vital. The initial nursing assessment includes emergency care related to airway, breathing, and circulation (ABCs). After the ABCs are addressed and the child is being safely transported to an emergency room, the nurse or emergency medical technician (EMT) removes all clothing and jewelry to decrease continued burning at any site.

Once the child is in a hospital, burn wounds are decontaminated and assessed for depth, surface area, and severity. Depth of the wounds is measured by millimeters or centimeters, circumference measurements are also necessary to provide a full clinical picture. The surface of the burn wound is assessed for color, blanching, desiccation (dryness), turgor/elasticity, blisters, or sloughed blisters. TBSA and all

other skin assessments are taken into consideration to help classify the burn. For some burn assessments, wounds are photographed with a camera that has a measurement graphing lens. If the burn injuries are severe and encompass large areas of the TBSA, some burn or emergency departments use video charting to record the clinical assessment.

“What to say” — Gathering important information

The nurse can ask these questions to gather important information:

- “What was the offending agent?”
- “When did this burn occur?”
- “Who was present or witnessed the injury?”
- “What first aid was given?”
- “How did the burn feel when it first occurred?”
- “How does the burn feel now?”
- “Has the child had any like accidents or injuries before?”
- “What other medical history is important?”

FLUID RESUSCITATION. Children with burns greater than 15% of TBSA require intravenous fluid resuscitation to maintain adequate perfusion. The IV fluid of choice is lactated Ringer’s solution (Behrman et al., 2004). Fluid resuscitation is necessary to increase the patient’s plasma volume and maintain blood pressure. The Parkland Formula is one means of determining the fluid needs of the child with a burn injury (Box 31-1) (Bollero, Stella, Calcagni, Guglielmotti, & Magliacani, 2000). Effectiveness of fluid resuscitation is monitored by adequate urine output. Normal urine output for children is 1 to 2 mL/kg per hour. If adequate urine output is not achieved, additional fluid resuscitation may be required.

NUTRITION. When a child has a burn, it is essential that adequate nutrition be maintained. Burn injuries place a child in a hypermetabolic state. The caloric requirement for a patient with a >30% burn is 2000 to 2200 calories/day. In major burns enteral nutrition (fed by a tube passed into the stomach) is necessary to keep up with the increased energy demand of the body, secondary to the stress response (Rimdeika et al., 2006). Enteral feeding is often initiated within 6 hours of the burn injury to support the child’s increased needs. These children often need nearly twice the basal metabolic caloric requirement and nearly 2 g/kg of protein. Adequate caloric intake in the acute phase of the

burn and burn treatment decreases complications, treatment length, and mortality rates (Rimdeika et al., 2006).

PAIN MANAGEMENT. Pain management is an important nursing care issue for children with burns. Pain is usually mild to moderate in children with superficial burns. As the burn depth increases, to full thickness, the pain is diminished as the nerve endings are burned and no longer conducts pain messages back to the brain. The areas surrounding full-thickness burns where the tissue is viable are hypersensitive to pain reception (Selvaggi et al., 2005). It is important to provide adequate analgesia and anti-anxiety medication along with proper psychological support to reduce early metabolic stress and decrease the potential for posttraumatic stress disorder. Children with burn injuries show wide fluctuations in pain intensity. Appreciation of pain depends on the depth of the burn, stage of healing, age and stage of emotional development, cognition, experience and efficiency of the treating team, use of analgesics and other drugs, pain threshold, and interpersonal and cultural factors. From the onset of treatment, preemptive pain control during dressing changes is of utmost importance. Initially morphine sulfate (Duramorph) is most commonly used for pain. The use of anxiolytics such as midazolam (Versed) or lorazepam (Ativan) is usually very helpful and can have a synergistic effect (the interaction of elements that when combined produce a total effect that is greater than the sum of the individual elements) (Dictionary.com, 2008).

The problem of undermedication most often occurs with adolescents who fear the development of drug dependency. This may affect treatment and adequate pain relief (Behrman et al., 2004). It is important to explain to the child and the parent that withholding medications because of the fear of dependency is not a valid concern. Reassurance and education are needed for families in the area of pain management. The use of nonpharmacological interventions as well as pharmacological agents need to be used (Behrman et al., 2004).

Complementary Care: Distraction

The nurse can use distraction as a good technique when changing the dressings for a child with burns. The type of distraction used is based on age and developmental stage (e.g., singing, counting, watching television, focusing on picture, talking about familiar events or places, playing games or blowing pin-wheels or bubbles). If the child is anxious or has severe pain, medication may be required before and during distraction. The nurse must remember to praise the child when the dressing change is complete, with the focus on all of the positive behaviors that the child displayed.

Box 31-1 The Parkland Formula

4 mL of IVF \times weight in kg \times %TBSA

Give $\frac{1}{2}$ of the total IVF volume over the 1st 8 hours.

Give the second $\frac{1}{2}$ at an even rate over the next 16 hours.

Example: A child weighing 110 lb. (50 kg) with a 20%, TBSA burn requires:

4 mL \times 50 kg \times 20% TBSA = 4,000 mL

1st 8 hours IVF = 2000/8 hours = 250 mL/hr

next 16 hours IVF = 2000/16 hours = 125 mL/hr

WOUND CARE. Prevention of infection is the priority outcome when providing meticulous wound care. Wounds are initially decontaminated. Subsequent burn wound care includes cleansing the wound with a special solution or débridement (cutting away dead tissues). Escharotomy (incision into a burn in order to lessen its pull on the surrounding tissue) if a burn is circumferential may be required if circulation or perfusion is impeded. If escharotomy is required, the child is provided with conscious sedation or general anesthesia if not already sedated.

The nurse can assess the child’s wound and if no eschar or devitalized tissue is present, the wound can be treated

with antibiotic cream and re-dressed. If the wound needs to be cleansed, the nurse cleans it at the bedside with antibacterial products. The wound is softened by soaking the site with saline soaked gauze for 15 minutes. Antibiotic ointment is applied and the wound is then re-dressed. Wounds can also be cleansed in a tub or a whirlpool, allowing the movement of the water to soften skin, and gently removing some loose dead skin. Some of the dead skin needs to be scrubbed and cut away to create clean vitalized margins.

Other methods of débriding include the use of the enzyme collagenase. This enzyme speeds débridement, resulting in earlier wound closure and a decrease in scarring (Frye & Luterman, 2005). Collagenase has been used only in wounds that do not require grafting (Frye & Luterman, 2005).

Some dressings have occlusive ability (a thin sheet of plastic that prevents air entry and retains moisture, heat, body fluids, and medication). These are used for a longer period of time than gauze-type dressings. These dressings are often transparent, so the wound can be assessed easily for signs of infection, but can remain in place if the wound is healing adequately.

IMPREGNATED DRESSINGS. Acticoat™ is an antimicrobial nanocrystalline film of pure silver. Its surface is nonadherent and nonabrasive. Acticoat™ provides a sustained release of ionic silver, which maintains the antimicrobial properties, which is effective against more than 150 pathogens. This silver-coated polyethylene mesh can be used over débrided burns, grafts, and donor sites. It is applied to the cleansed wound and sometimes wrapped in to place with sterile water-soaked gauze or sometimes placed on dry depending on the facility's standard protocol (Ülkür, Oncul, Karagoz, Yeniz, & Celikoz, 2005).

Sterile saline cannot be used to moisten Acticoat™ because the saline reacts with the silver and may precipitate the salt out of the dressing. Do not use any topical antimicrobials with Acticoat™ as it may alter its antimicrobial properties. Acticoat™ is also available in a moisture absorbent dressing (Smith & Nephew, 2006).

Silvadene™ is a sulfonamide with broad-spectrum coverage. Silvadene™ is the most commonly used burn cream to both prevent and treat burn infection. This medication comes in tubes and in impregnated gauze wraps as well. Silvadene™ is usually applied one to two times a day and then the wound is wrapped in a gauze dressing. The nurse can instruct the family that residue is washed off with each dressing change. This cream is contraindicated for a child with a sulfa allergy (Deglin & Vallerand, 2009).

TEMPORARY SKIN REPLACEMENT. Biobrane™ is a semipermeable temporary skin substitute that is a nylon fabric with an outer silicone film, which is saturated with porcine collagen. The collagen peptides on the nylon bind to wound surface fibrin and collagen resulting in the initial adherence. Small pores in the structure allow for drainage of exudates and provide permeability for topical antibiotics. Biobrane™ is clinically indicated in superficial to mid- to partial thickness burns but can be used on excised wound beds with or without mesh autografts. This temporary skin substitute can also be used on donor sites and in partial thickness slough disorders (Demling, DeSanti, Dennis, & Orgill, 2000).

Transcyte™ is a human fibroblast-derived temporary skin substitute that is made of silicone. It consists of a

polymer membrane and neonatal human fibroblast cells cultured under aseptic conditions in vitro on a nylon mesh. The membrane provides a transparent epidermis when applied. As the fibroblasts proliferate within the nylon mesh, they secrete human dermal collagen, matrix proteins, and growth factors. It can be used on primary mid-dermal to intermediate depth wounds that may heal without grafting (second degree burns). Transcyte™ may be used as a temporary barrier before grafting. It also can be used safely with or without additional dressings (Smith and Nephew Acticoat™ Antimicrobial Barrier Dressing; Silcryst, 2008).

PERMANENT SKIN REPLACEMENT. There are three main types of grafting or permanent skin replacement. An allograft is cadaver skin. Cadaver skin is skin taken from a skin bank that can be used as a grafting host when autografting is not possible of a full thickness wound. Allografts are bilayer skin (both epidermis and dermis) aid in revascularization, which makes it a favorable choice (Demling, DeSanti, Dennis, & Orgill, 2000). Allografting has the disadvantages of potential disease transmission, rejection, and difficulty in obtaining and storing it (Demling, DeSanti, Dennis, & Orgill, 2000).

Autografting is using the child's own healthy skin taken from an area not burned. Autografting harvests the child's own skin and then grafts into a new position on the child's body. The skin can be used as is or, if necessary, it is processed a meshing machine that enlarges the surface area of the harvested skin and creates small slits for the passage of fluid and for better adherence (O'Conner & Besner, 2004). Autografting does cause permanent scarring along the slits made by the meshing machine, so it should be limited to areas of the body that clothing will cover (O'Conner & Besner, 2004).

Xenografting is the use of nonhuman skin. Xenografting is necessary for full-thickness skin loss. This type of grafting may be used in partial-thickness wounds also. Since 1965, xenograft has been limited to pigskin (Demling et al., 2000). Pigskin has a dermal layer that adheres to a partial thickness wound, providing collagen to the cleaned wound surface. Its disadvantages include potential for disease transmission and it does not always revascularize, resulting in sloughing (Demling et al., 2000).

Integra™ is a bioactive bilayer manmade permanent skin replacement. Integra™ is lined with a collagen-glycosaminoglycan matrix that biodegrades. It has a thin silicone second layer that acts as a barrier to control fluid movement in and out much like normal skin (Demling et al., 2000). Integra™ is limited, as it is only a temporary measure that allows some epithelialization and then the silicone layer is removed and autograft or cultured epithelial cells are placed (Demling et al., 2000).

For severe burn treatment, there are now cultured epithelial autografts (CEAs). This is the child's own skin cells that are grown in a laboratory. A 2 × 6 full-thickness biopsy is extracted from the child's own viable skin. The skin biopsy is sent to the genetics laboratory and grown for about 2 weeks. During the 2-week period, the child is covered with a synthetic dressing to enhance wound bed growth. The synthetic dressing autologous keratinocytes is co-cultured with irradiated murine cells to form epidermal autografts. The delivery of these sheets is coordinated with the burn surgeon and placed as an autograft.

where research and practice meet: Growth Hormone

Studies have shown that intramuscular injection of growth hormone allows for rapid regeneration of the donor sites and thus more rapid reharvesting (O'Conner & Besner, 2004).

This treatment is used for patients with full-thickness burns extending over 30% of TBSA or larger. The treatment can be very expensive because these epidermal autographs are grown from the patient's own skin cells. The advantage is that they are usually not rejected by the patient's immune system. Genzyme is just one company that develops this product (Epicel) (Genzyme, 2006).

In large burns, it is difficult to find enough autodonor tissue, so the alternate methods of temporary and permanent skin replacement must be used. Postoperative orders include the appropriate dressing change for graft site and graft donor site.

BURN RECOVERY. Burn injuries for children are managed by phases of recuperation as well as the type and severity of burns. The acute, or early phase, is from the time of the initial assault until wound closure. The second phase, recovery is from the time of wound closure until scar maturation, which could be as long as 16 months (Selvaggi et al., 2005). It is important to remember that for some children burn recovery may last a lifetime.

Caring for a hospitalized child with burns involves the family and the health care team. The health care team can typically comprise a nurse, a pediatrician, and a physician with a specialty in burn treatment and/or surgery. Plastic surgeons often have this role. As part of discharge planning, the nurse can contact a social worker for parental and child support to help manage home care issues.

During the long-term recovery phase as the child reenters the world, there remains a need for the integrated burn team. The child may have compression garments and splints that need to be altered with growth. The child continues to need to be seen by a physical and occupational therapist to continue the work of range of motion and decrease any possibility of contracture. Scar revision may be necessary, especially if contracture occurs. When this happens, the child needs to be admitted to the hospital and treated by the plastic surgeon. Optimal functioning with minimal scarring and minimal negative psychological impact are the goals of care.

Collaboration in Caring— A team approach

The care of a burned child requires a team approach. During hospitalization, the nurse provides essential nursing care and acts as the advocate for the child and her family. The nurse can also coordinate care of other health care professionals such as a physical therapist who helps the child maintain or regain physical function. A dietician plans appropriate nutrition for immediate and long-term nutritional intervention. An occupational therapist helps the child adapt to activities of daily living. As the child becomes more able to return to activities including school, the case manager, either a social worker or nurse, helps bridge the information gap between agencies. Other long-term therapy

sometimes upwards of 2 years, with rehospitalization and scar revisions, is another reason for an integrative team approach where health care professionals provide optimal care and share their knowledge of the child and family with one another over time (Hubbuck, 2003).

Hypothermia

Hypothermia is secondary to cold air exposure, wet clothes, and immersion in water. Hypothermia is also present in victims of burns, where large amounts of skin are no longer present or the child no longer has the capacity to hold heat. Hypothermia is a condition in which the child's core body temperature falls below 95°F (35°C). Hypothermia is a life-threatening emergency. The body loses heat in one of five ways: radiation, conduction, convection, evaporation, and respiration (McCullough & Arora, 2004) (Table 31-7).

Different developmental stages predispose the child to different types of exposure. Infants and young children are at higher risk due to their immature thermoregulatory system, thinner skin, and lack of subcutaneous fat. Older children are at high risk for hypothermia, as they may lack the cognitively ability to evaluate risky situations. Adolescents are at risk for hypothermia due to risk-taking behaviors such as participating in outdoor activities without proper clothing and potentially the ingestion of alcohol or other illicit drugs. In children of any age, a trauma, brain disorder, or severe sepsis can also cause hypothermia because these conditions interfere with the thermoregulation system.

Nursing Insight— Protecting Children from Hypothermia

Monitoring children closely so they do not leave the house in inclement weather without adequate protection is essential information to pass along to parents. Teaching children to avoid walking on frozen lakes and ponds unless they are sure they are adequately frozen is very important. Emphasize to

Table 31-7 Types of Heat Loss

Radiation	Heat loss from the head and areas with less subcutaneous fat and thin skin; e.g., prematurity of the newborn This is the most rapid method of heat loss and accounts for at least 50% of heat loss.
Conduction	The transfer of heat away from the body by direct contact with a cooler surface; e.g., wet clothing or immersion
Convection	The transfer of heat away from the body by the movement of air over the skin surface; e.g., wind and drafts
Evaporation	The transfer of heat away from the body; e.g., skin moisture turned to vapor as it is dried by the movement of air
Respiration	Expiration of heat from the lungs; e.g., cold and windy weather

parents the need to protect the child from all bodies of water, especially in the cooler temperatures, to avoid both the incidence of accidental drowning and immersion hypothermia.

clinical alert

Other etiologies of hypothermia

The nurse must understand that metabolic or neurological etiologies may be the cause of hypothermia in children. The cause of hypothermia is investigated when no environmental explanation for hypothermia exists.

Nursing Insight— Hypothermia

Hypothermia is also associated with near drowning. When the child's body is immersed in water, heat is lost quickly. During a near drowning, the body tries to maintain core body temperature at the expense of losing heat in the extremities. Shivering is the body's way to rewarm the blood. Increased muscle tone and increased metabolism also occur.

Signs and Symptoms

Hypothermia is classified as minor, moderate, or severe (McCullough & Arora, 2004) (Table 31-8).

Classification	Body Temperature	Clinical Symptoms
Mild	93.2°–96.8°F (34°–36°C) (Venes, 2009)	Shivering Rapid heart rate Rapid respiratory rate Vasoconstriction Increased urine output As temperature decreases child becomes apathetic rather than excited, lethargic, and has impaired judgment
Moderate	86°–93°F (30°–34°C) (Venes, 2009)	Decreased heart rate Decreased respiratory rate Hypotension Loss of consciousness Decreased pupillary response
Severe	<86°F (30°C) (Venes, 2009)	Apnea Asystole Coma It may not be possible to readily differentiate between severe hypothermia and death

Diagnosis

A diagnosis of hypothermia in children is based on body temperature. Other signs of hypothermia include slurred speech, poor coordination, poor judgment, and inappropriate behavior. If no etiology of prolonged exposure to the cold, the child will need differential diagnostics to determine if the etiology is neurological or metabolic.

clinical alert

Wet clothing

Wet clothes increase the risk of hypothermia. The nurse or parents must remove wet clothing as soon as possible and replace with dry clothing.

Nursing Care

The nurse initiates emergency medical care by calling the emergency response team and by conducting a complete assessment of airway, breathing, and circulation. Cardiopulmonary resuscitation is initiated if the child's condition warrants. The nurse must record core body temperature. Rectal temperatures are most accurate and are used during the rewarming process (McCullough & Arora, 2004). Important nursing care measures include removing all cold and wet clothing, wrapping the child in warmed blankets, and administering warmed oxygen and warmed intravenous fluids to promote cardiac output. Vital signs and urine output are also monitored during the rewarming process. Electrocardiograms are used to give essential information about the heart. The nurse must remember that ventricular or atrial dysrhythmias are possible in hypothermia. After these critical measures are implemented, the nurse raises the body temperature by using a forced air warming systems (e.g., the Bair Hugger™). This type of system uses convection to heat the trunk area first (McCullough & Arora, 2004).

case study Hypothermia

Eight-year-old Billy and his friends are planning to ice fish on a small farm pond about 100 yards from his back yard. Billy and his friends are cutting a small hole in the ice, about 10 feet from the shore of the pond when a cracking sound sends Billy's friends running to shore. Billy has always been braver and he continues his work to open an ice hole. In a little while, Billy's friends return to see his progress. As his friends watch from shore, they see Billy fall into the water nearby the edge of the pond. Billy's friends run to the house to tell Billy's mother. Billy's mother calls 911, then runs down to the pond, and pulls him out. Her cold limp son lies on the ground while she waits for the emergency medical team to arrive. While she waits, she remembers that it is best to remove any wet clothing and begins to frantically undress Billy. She then covers him in the blankets that the friends have brought down to the pond. When the medical team arrives, they find him not breathing and nonresponsive. Billy has no signs of respirations or heartbeat and his body temperature is very cold. The team begins CPR and Billy is transported to the local emergency room.

Critical Thinking Questions

1. What are the priority nursing actions that you will perform when Billy enters your emergency department?
 2. Billy's heart monitor shows asystole and his rectal temperature is 71.6°F (22°C). What is the status of Billy's condition?
 3. Is external rewarming the most effective method of rewarming after severe hypothermia?
- ◆ See Suggested Answers to Case Studies in the text on the Electronic Study Guide or DavisPlus.

Frostbite

Frostbite in children is an injury that results from prolonged exposure (more than an hour) to severe cold and usually affects the outer extremities (ears, cheeks, nose, hands, and feet). Crystal formations occur in the tissue and blood cells, which result in dehydration of the cells and ischemic damage.

Signs and Symptoms

Symptoms of frostbite depend on the severity and depth of the cellular damage. Signs of frostbite include red, blue, or pale (waxy) skin. There is a prickling or painful sensation with superficial frostbite and painless rigid skin with deep frostbite.

Diagnosis

Frostbite can be identified by the hard, pale, and cold quality of skin that has been exposed to the cold. As the exposed skin warms and thaws, the flesh becomes red and painful.

Nursing Care

Treatment for frostbite is much like core hypothermia treatment. Place the child in a warm area, remove all wet and cold clothing, and replace with warm ones. If frostbite is in the hands or feet, they are immersed in warm tap water (100°F) for up to one half hour (McCullough & Arora, 2004). The nurse must check the water temperature frequently, as the body part cools the tub of water. Do not run warm water directly from the tap over the area, as tap water can change in temperature rapidly based on use by other household members. The water must also be monitored closely so a secondary burn does not occur in the process of rewarming. Do not rewarm the frozen part with massage or dry heat (McCullough & Arora, 2004). Massage causes the crystals that have formed in the capillaries to break through causing damage in the area. After rewarming is complete, the extremity is wrapped in a soft cloth and the child can be encouraged to rest. If no subsequent problems arise, the child can remove the soft cloth and return to inside activities. If parents suspect continued problems the health care provider is called.

nursing diagnoses Frostbite

- Impaired Skin Integrity related to freezing of the skin
- Ineffective Thermoregulation related to extended exposure to a cold environment
- Pain related to decreased circulation from prolonged exposure to cold

Pressure Ulcers

Pressure ulcers are the result of compression on one or more areas of the body for an extended period. This subsequently injures both the capillary bed and the soft tissues, allowing for decreased perfusion and subsequent breakdown. Owing to this compression, the skin cells are deprived of nutrients and needed oxygen. Metabolic waste products then accumulate, causing the injury. Any delay in intervention may cause a deep sore to form.

Pressure ulcers occur in children with decreased mobility. Premature infants, infants who have motor delays and cannot easily move their head or extremities, and children with paralysis or other forms of limited mobility are at risk. Children who use mobility devices (e.g., crutches, walkers, and wheelchairs) are at risk for developing pressure ulcers in the weight-bearing tissue used while navigating with these devices. Children and adolescents in casts or body braces are also at risk if the apparatus is ill fitting, or if the areas of pressure are not properly padded. Infants, children, and adolescents who are malnourished or have infections or anemia are at higher risk for ulceration. In addition, when children are bed bound for any period of time such as are children with low cardiac output are at risk for ulceration. Children with decreased sensation to pressure or pain may also be at risk of developing skin breakdown and pressure ulcers. Friction and shear from caregivers moving the immobile child is yet another way to injure the skin and decrease local perfusion.

Signs and Symptoms

The four stages of ulcer formation can assist the nurse in through skin assessment (Fig. 31-12). The earliest sign of skin damage is a reddened area on the skin that does not disappear within 30 minutes of removing the cause of the pressure or irritant. The skin can appear to have an abrasion and look raw or rubbed. Further damage extends through the dermis forming the ulcer.

Ethnocultural Considerations— Pressure ulcers

In children with dark pigmented skin, the area can look red or purple upon blanching.

Figure 31-12 Stages of pressure ulcer. A. Stage 1. B. Stage 2. C. Stage 3. D. Stage 4.

Diagnosis

Diagnosis is based on a good nursing assessment using reliable tools. The Braden Scale (bradenscale.com) is used to assess pressure ulcer risk every 3 to 4 days. The major components assessed in the scale are sensory perception, skin moisture, physical activity, mobility ability, nutrition, and friction and shear (Braden & Bergstrom, 1988). A standardized assessment tool such as the Neonatal Skin Condition Score for neonates may also be used as an assessment tool for at-risk neonates (Lund & Osborn, 2004).

Nursing Care

Careful inspection of child's skin at least three times a day is essential. The nurse can note the color of the affected area, signs of infection, character of the skin lesion, wound edges, drainage, measure the diameter, and determine the depth of the pressure ulcer. The nurse proactively addresses anemia. A diet high in iron may help prevent pressure ulcers. Keep bed clothing straight and wrinkle-free to decrease areas of

pressure. Air, water, or gel mattresses and pads decrease pressure areas. The nurse must keep the child's skin both clean and dry. The nurse also addresses the exact condition affecting the skin before a pressure sore actually develops. A variety of topical treatments are available (Table 31-9).

Stage one and two pressure ulcers are cleansed and allowed to dry. The nurse must also keep the child off the affected area as much as possible. With time and protective management, the wound resolves. Stage three ulcers may heal spontaneously as well. Some hydrophilic gels or hydrocolloidal dressings may be used. In stage 4 ulcers, surgical débridement and closure may be the treatment of choice.

Prevention of pressure ulcers is essential and begins by routinely moving and shifting the weight of the child off bony prominences on a regular basis. Movement must occur at least every 2 hours for the child who is confined to bed. A child in a sitting position (e.g., in a wheelchair) should shift his or her weight every 15 minutes, independently, or with assistance. If the child wears braces, the skin is

Table 31-9 Topical Treatments

Classification	Names	Precautions
Anesthetics	Benzocaine (Americaine)	Allergy
	Lidocaine and prilocaine (EMLA)	Do not use over wounds
		Do not use over large areas: avoid the eyes
Antibacterial	Bacitracin and polymyxin B (AK-Poly-Bac)	Allergy
	Neomycin (Myciguent)	Existing infection (for prevention of infection)
	Mupirocin (Bactroban)	Antibiotic resistance Use for only minor: cuts/scrapes/burns
Antifungal	Clotrimazole (Lotrimin)	Cautious use in nail and scalp infections
	Ketoconazole (Nizoral)	
	Miconazole (Aloe Vesta)	
	Nystatin (Mycostatin)	
Anti-itch	Diphenhydramine (Benadryl)	Allergy Photosensitivity
Emollients	White petrolatum jelly	Allergy Choose fragrance free products
	Mineral oil	
	Lanolin	
	Glycerin	
Steroids	Varying strengths	Allergy
	Strongest group I: betamethasone (Diprolene)	Repeated use in the same area of the skin will cause thinning of the skin
	Group II: desoximetasone (Decadron)	
	Group III: triamcinolone 0.5% (Kenalog)	May inhibit the skin's ability to fight infection
	Group IV: fluocinolone (Lidex)	Should be used in lowest strength on the thin skin of the face and genitalia
	Group V: hydrocortisone 0.2% (A-Hydrocort)	
	Group VI: desonide (Tridesilon)	Avoid the eye area: places the client at risk for glaucoma or cataract formation
Group VII: hydrocortisone 1% (A-Hydrocort)

inspected for redness or irritation at least once a day. If any redness is noted, the nurse must not reapply the brace and notify the physician immediately.

summary points

- ◆ Children are often at risk for certain skin conditions based on their large body surface area and maturing immune system.
- ◆ The specific pathogen that is responsible for a bacterial, viral, or fungal infection affects both the treatment regimen and the healing response.
- ◆ Contact, atopic, and seborrheic dermatitis is an inflammatory rash on the skin marked by itching and redness that occurs due to numerous conditions.
- ◆ The offending allergen in a cutaneous skin reaction, causing an allergic response, can be introduced into the system in a variety of ways such as ingestion, inhalation, or coming in direct contact with the allergic child.
- ◆ Burns that affect children can be accidental or the result of intention to harm and are the third leading cause of death. Some children are at higher risk for burns due to their environment, behavior, or age.
- ◆ Hypothermia is a life-threatening emergency and the body loses heat in one of five ways: radiation, conduction, convection, evaporation, and respiration.
- ◆ Pressure ulcers are the result of compression on one or more areas of the body for an extended period; this subsequently injures both the capillary bed and the soft tissues, allowing for decreased perfusion and subsequent breakdown. A pediatric prevention plan for skin breakdown provides a simple tool to assist with pressure ulcer management.

review questions

Multiple Choice

1. A 3-week-old infant treated for sepsis is on three different types of antibiotics. The mother is concerned when she notes white, patchy spots in the infant's buccal area and tongue. She tries to rub them off, but is unsuccessful. The pediatric nurse recognizes these lesions as:
 - A. *Candida* fungi
 - B. Cellulitis
 - C. Herpes simplex virus
 - D. Varicella
2. A 6-year-old child is admitted from the emergency department to the pediatric unit. The pediatric nurse assesses the child and finds a rash over the abdominal area. The mother states that the child has recently complained of pain in her knees. The nurse notes that the child lives in a rural area and likes to play outdoors in the woods. Based on this information, the nurse suspects that this child has:
 - A. Rocky Mountain spotted fever
 - B. Cat scratch disease
 - C. Lyme disease
 - D. Diphtheria

True or False

3. The pediatric nurse recognizes that impetigo is usually found on the child's lips and around the face.
4. The child with atopic dermatitis has a red, raised nonpruritic rash on the face and arms.
5. Females are more likely than males to develop lice infestations because of shared combs and hair accessories.
6. Lice and their nits can infest only a child's scalp or hair.
7. Human bites carry a greater risk for infection than the bites of animals.

Fill-in-the-Blank

8. The most common location of cellulitis can be found on a child's _____ and _____. The area infected will be red, _____ and _____ to the touch.
9. Before the eruption of the herpes simplex virus, burning, _____ or an _____ usually occurs on the _____ or near the mouth.

Case Study

10. Beth, a 17-year-old girl, is diagnosed with acne on her face, chest, and back. She tells the pediatric nurse that she is very unhappy with "all of these ugly pimples all over my body. It's getting to the point that I don't even want to go out with my friends anymore!" What is the most therapeutic response by the nurse?
 - A. "Don't worry about the acne. It will go away soon."
 - B. "I'll speak with the doctor to order some medication to treat the acne."
 - C. "Tell me what bothers you the most about your acne."
 - D. "Let's discuss what you can do to prevent more acne from erupting."
11. What is the priority diagnosis for a 17-year-old girl with acne?
 - A. Impaired skin integrity
 - B. Body image disturbance
 - C. Anxiety
 - D. Social isolation
12. The pediatric nurse provides health promotion teaching to Beth, a 17-year-old girl with acne who is given a prescription for isotretinoin (Accutane) to treat the acne. The nurse teaches her:
 - A. That she must drink two full glasses of water with this medication.
 - B. That she must refrain from sexual relationships while on this medication.
 - C. That she must use two forms of reliable birth control while on this treatment if sexually active.
 - D. That she must eat a high-protein diet while on this medication.

CONCEPT MAP

Caring for the Child with a Renal, Urinary Tract, or Reproductive Condition

chapter 32

Children are one-third of our population and all of our future.

—Select Panel for the Promotion of Child Health, 1981

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Examine fluid and electrolyte balance in children
- ◆ Discuss the four signs and symptoms of a urinary tract infection.
- ◆ Compare the differences between acute and chronic glomerulonephritis.
- ◆ Examine the most common cause and spread of bacterial infection that can lead to hemolytic-uremic syndrome.
- ◆ Describe the nursing care and nursing diagnoses associated with renal transplant and dialysis in children.
- ◆ State the pathophysiology and clinical symptoms of vesicoureteral reflux.
- ◆ Describe how testicular torsion is considered a medical emergency.
- ◆ Explain the diagnosis and risks of cryptorchidism.
- ◆ Describe a variety of genitourinary abnormalities in male and female children.
- ◆ Examine the most common causes of amenorrhea in female adolescents.

moving toward evidence-based practice Compliance with Care for Urinary Tract Infection

Cohen, A.L., Rivara, F.P., Davis, R., & Christakis, D.A. (2005). Compliance with guidelines for the medical care of first urinary tract infections in infants: A population-based study. *Pediatrics*, 115(6), 1474–1478.

The purpose of this study was to describe the medical care received by children enrolled in a state Medicaid program after their first urinary tract infection. The study also aimed to determine predictors for prescribed care during the child's first year of life. It is estimated that 6.5% of girls and 3.3% of boys experience a urinary tract infection (UTI) during their first year of life, with vesicoureteral reflux present in 30% to 40% of these children. The long-term impact of UTI may include a variety of conditions such as risk for recurrent urinary tract infections as well as renal scarring, disease, and hypertension. These conditions may be prevented by effective evaluation and treatment. This study was based on the American Academy of Pediatrics (1999), practice guidelines which include "timely anatomic imaging,

timely imaging for reflux, and adequate antimicrobial prophylaxis."

- Anatomical imaging was defined as "urinary tract ultrasonography or renal scan within 3 months of initial diagnosis" (p. 1475).
- Imaging for reflux was defined as "voiding cystourethrography or renal scan within 3 months of initial diagnosis" (p. 1475).
- Antimicrobial prophylaxis was defined as "antibiotic therapy after diagnosis until imaging for reflux was performed" (p. 1475).

The retrospective cohort study used statistics obtained from a state Medicaid program database. Medicaid insurance is
(continued)

moving toward evidence-based practice (continued)

offered “to all children living within the state whose families earn <200% of the federal poverty level” (p. 1471).

The following inclusion criteria were used for each child:

- Born between January 1, 1999 and September 30, 2000.
- Continuously enrolled in the Medicaid program from birth through age 15 months.
- Diagnosed with a UTI during the first 12 months of life as determined by either provider-billed diagnosis (for inpatient) or provider-billed diagnosis and an antibiotic prescription filled within 1 week of diagnosis (for outpatient).
- In the case of multiple diagnoses, only children with UTI listed as the primary diagnosis or secondary diagnosis were included.
- When UTI was listed as a secondary diagnosis, the primary diagnosis was reviewed. If conditions predisposing to urinary catheterizations were present, those children were excluded.

Analysis of data examined medical management, age, gender, race, primary language of the parent, Medicaid program plan (managed care or fee-for-service), and location of household (rural or urban).

The findings were as follows:

- Of a potential 38,793 Medicaid-eligible children, 780 met the criteria for the study based on the diagnosis of a UTI during the first year of life.
- Of the 708 eligible children:
 - 38.7% (302) were hospitalized for the UTI.
 - 59.7% were female.
 - 17.7% were ≤90 days old.
 - 29.7% lived in a rural area.
 - 64.6% were participants in a managed care plan.
- The sample was representative of the following racial mix:
 - Caucasian 43.5%
 - Hispanic 27.8%
 - African American 3.3%

Asian American 3.0%
American Indian 2.3%
Other 8.2%

11.9% not specified

- English was the primary language for all but 29% of the participants.
- UTI was the primary diagnosis for 83% of the participants.
- Febrile seizures, fever, and bronchiolitis were the most common primary diagnoses for those with UTI as the secondary diagnosis.
- Forty-four percent received timely anatomical imaging and 39.5% received imaging for reflux during the first year of life, as prescribed by AAP guidelines.
- Both anatomical imaging and imaging for reflux were performed in 28.2% (220) of children diagnosed with UTI.
- Anatomical imaging was performed in only 15.8% (123) and imaging for reflux only was performed in 11.3% (88).
- Fifty-one percent received an adequate course of antibiotics, according to AAP guidelines.

Children who were hospitalized for UTI were more likely to receive anatomical imaging and imaging for reflux. Children 90 days of age or younger were less likely to receive antimicrobial prophylaxis. Females were more likely to receive imaging for reflux. Children were less likely to receive appropriate imaging after the first UTI if they came from families in which English was not the primary language and if they lived in rural locations.

The overall conclusion was that there was poor compliance with AAP guidelines for children enrolled in the Medicaid program whose first UTI occurred during the first year of life.

1. What might be considered as limitations to this study?
2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

Renal and reproductive conditions in children are attributable to a variety of causes: a genetic predisposition, a condition that may have occurred during fetal development, infection, trauma, or a neurological problem. No matter what the cause, pediatric nurses must be knowledgeable about the pathophysiology of the renal system, common and uncommon renal disorders, as well as associated reproductive anomalies that can occur in children. This chapter provides a short review of the anatomy and physiology of the renal system followed by a discussion of fluid and electrolyte balance. An examination of the acute and chronic renal diseases and reproductive system problems common in children is presented. Information on diagnostic tests, medications prescribed, and developmentally appropriate nursing intervention is provided together with information about patient/family education. Preventive measures taught

by nurses are provided because they can be influential in reducing the incidence of fluid and electrolyte imbalance and renal and reproductive disease.

A & P review The Kidneys

The kidney is divided into an outer cortex and inner medulla. The outer cortex is composed of the glomeruli and convoluted tubules of the nephron and blood vessels. The medulla is composed of the renal pyramid. Urine leaves the papilla of a pyramid to collect in a minor calyx. The minor calyces come together to make the major calyces and then the renal pelvis (Hansen & Koepfen, 2002).

Each kidney is surrounded by adipose tissue to protect it from trauma, although kidneys can be injured by blows to the abdomen and such trauma as motor vehicle accidents.

Kidneys receive their blood supply through a single renal artery that comes from each side of the aorta, one to each kidney. The renal artery subdivides into five segmental

arteries that feed each kidney. Each segmental artery further subdivides into multiple branches several times; the smallest of these are the afferent arterioles, which feed the glomeruli (Porth, 2004).

The glomerulus is a tuft of capillaries in a thin-walled capsule termed Bowman's capsule. While blood flows into the glomerulus through the afferent arteriole, it leaves through the efferent arteriole. Fluid and blood particles are filtered through capillary membranes into a fluid-filled space in Bowman's capsule. The filtered blood is termed the filtrate.

The tubular components of the nephron are divided into four parts. The first part is a very coiled portion termed the proximal convoluted tubule, and this drains Bowman's capsule. The second part is a thin loop termed the loop of Henle, while the third part is the distal convoluted tubule. The fourth and final part is the collecting tubule, which joins several tubules together to collect filtrate. About 85% of the nephrons are cortical nephrons, so termed because they are on the superficial portion of the cortex. The remaining 15% of the nephrons penetrate deeper into the medulla and are involved with urine concentration (Porth, 2004) (Fig. 32-1). ♦

Fluid and Electrolyte Balance

Fluid balance means that the liquid in the body is regulated in such a way to maintain homeostasis (a state of equilibrium). The body's intake and output of fluid in a 24-hour period is approximately the same. A fluid deficit occurs when fluids are lost by diaphoresis, vomiting, diarrhea, or hemorrhage. A fluid overload occurs from conditions that create impaired fluid excretion, such as kidney disease or congestive heart failure. Fluid overload also can occur due to excessive administration of intravenous fluids (Venes, 2009). Fluid balance is measured by daily discrepancies in body weight and by monitoring fluid intake and output.

Figure 32-1 Anatomy of the kidney.

clinical alert

Calculation of daily maintenance fluid requirements

There are two methods of fluid maintenance:

The surface area method is the most common and used for children >22 lb (10 kg): 1500–2000 mL/m² per day.

Child's Weight	Daily Maintenance Fluid Requirement
0–10 kg (0–22 lbs.)	100 mL/kg of body weight
11–20 kg (24.2–44 lbs.)	1000 mL + 50 mL/kg for each kg >10
>20 kg (>44 lbs.)	1500 mL + 20 mL/kg for each kg >20

Note: The method used to measure normal urinary output is 1–2 mL/kg per hour.

Children are at a greater risk for fluid and electrolyte imbalance than adults because they have a proportionately greater amount of body water, require more fluid intake and subsequently excrete more fluid.

Nursing Insight— Compared to adults, children are at a greater risk for fluid and electrolyte imbalance

Children have:

- A greater body surface area
- A higher percentage of total body water (the volume of total body water decreases with increasing age)
- A greater potential for fluid loss via the gastrointestinal tract and skin
- An increased incidence of fever, upper respiratory infections and gastroenteritis
- A greater metabolic rate
- Immature kidneys that are inefficient at excreting waste products
- Kidneys that have a decreased ability to concentrate urine
- Increased risk for developing hypernatremia based on their inability to verbalize thirst

The body is continually losing water in the urine, stool, and by evaporation from the skin and lungs. If the child is not taking in enough fluids to make up for the amount lost, they can become dehydrated. Dehydration occurs when the amount of fluids leaving the body is greater than the amount of fluids being taken into the body.

clinical alert

Types of dehydration

Depending on the cause of the fluid loss, a child will lose water and electrolytes.

Dehydration is classified as isotonic, hypotonic, or hypertonic.

Isotonic dehydration occurs when electrolyte and water deficits are present in balanced proportions (sodium and water are lost in equal amounts). Serum sodium remains in normal limits 130–150 mEq/L. This is the most common type of dehydration. Hypovolemic shock is the greatest concern.

Hypotonic dehydration occurs when the electrolyte deficit exceeds the water deficit. Serum sodium concentration is <130 mEq/L. Physical signs are more severe with smaller fluid losses.

Hypertonic dehydration is the most dangerous type and occurs when water loss is in excess of electrolyte loss. Sodium serum concentration is >150 mEq/L. Seizures are likely to occur.

Assessment is a priority nursing action when caring for the child with a fluid and/or electrolyte imbalance. The astute nurse must recognize fluid deficit and excess as well as electrolyte imbalance and then provide the proper care. Sometimes emergent care is required where IV replacement of fluids and electrolytes is essential.

Nursing Insight— Fluid deficit and excess

Fluid deficit (to determine normal values use calculation of daily maintenance fluid requirements)

Causes	Signs and symptoms	Nursing care
Diminished fluid intake	Dry skin	Determine underlying cause
Diaphoresis	Sticky mucous membranes	Replace fluids
Vomiting	Poor skin turgor	Replace electrolytes
Diarrhea	Thirst	Oral hydration
Nasogastric suction	Poor perfusion	IV hydration
Fever	Decreased urinary output	Measure intake and output
Hemorrhage	Weight loss Fatigue Tachycardia Tachypnea Decreased blood pressure High urine specific gravity High hematocrit	Monitor vital signs Monitor laboratory values (electrolytes)

Fluid excess (to determine normal values use calculation of daily maintenance fluid requirements)

Causes	Signs and symptoms	Nursing care
Excessive oral/IV intake	Pulmonary edema (crackles)	Determine underlying cause
Hypotonic fluid overload	Weight gain (fluid retention)	Decrease fluid intake
Kidney disease	Lethargy Decreased level of consciousness Slow, bounding pulse Low urine specific gravity Decreased hematocrit	Administer diuretics Monitor vital signs Monitor laboratory values (electrolytes)

In the early phases of dehydration, extracellular fluids with some electrolytes are lost. If the fluid loss continues, loss of intracellular fluids can occur. Hypovolemic shock

occurs when there is an insufficient amount of fluid in the circulatory system and subsequent death can result.

clinical alert

Pathophysiology of dehydration

Reasons for dehydration:

Fever	Hemorrhage
Vomiting	Burns
Diarrhea	Trauma
Diaphoresis	Diminished fluid intake

Rapid and sudden extracellular fluid loss

Electrolyte imbalance

Intracellular fluid loss

Cellular dysfunction

Signs of hypovolemic shock:

Tachycardia

Tachypnea

Hypotension

Cool, clammy, or cyanotic skin

Decreased urine output

Death

The main electrolytes are sodium (the primary electrolyte of the extracellular fluid) and potassium (the primary electrolyte of intracellular fluid). These electrolytes keep the body in balance by maintaining muscle contraction, heart rhythm and brain function. Normal values for sodium is 130 to 150 mEq/L and potassium 3.5 to 5.5 mEq/L. An imbalance in one or both of these electrolytes can cause illness in children. Calcium imbalance can also pose problems for children. The normal value for calcium is 8.8 to 10.8 mEq/L.

Nursing Insight— Electrolyte Imbalance

Sodium (Na⁺) deficit (hyponatremia; serum sodium concentration <130 mEq/L)

Causes	Signs and symptoms	Nursing care
Decreased sodium intake	Dehydration	Determine underlying cause
Excessive sweating	Nausea	
Fever	Weakness	Administer IV fluids with the appropriate amount of sodium added
Malnutrition	Lethargy	Monitor laboratory values (electrolytes)
Vomiting	Abdominal cramping	
Diarrhea	Dizziness	
Nasogastric suction	Weak pulse	
Diabetic ketoacidosis	Decreased blood pressure	
Kidney disease		

Sodium (Na⁺) excess (hypernatremia; serum sodium concentration ≥ 150 mEq/L)

Causes	Signs and symptoms	Nursing care
Excessive salt intake	Oliguria	Determine underlying cause
Fever	Nausea	Monitor neurological status
High insensible water loss	Vomiting	Monitor laboratory values (electrolytes)
Diabetes insipidus	Muscle twitching	
Hyperglycemia	Lethargy	
Kidney disease		

Potassium (K⁺) deficit (hypokalemia; serum potassium concentration ≤ 3.5 mEq/L)

Causes	Signs and symptoms	Nursing care
Diuresis	Muscle weakness	Determine underlying cause
Starvation	Muscle cramping and stiffness	Monitor vital signs
IV fluid without potassium added	Hypotension	Offer high-potassium foods
Diarrhea	Hyporeflexia	Administer oral potassium supplements (assess for adequate output before administration)
Vomiting	Cardiac arrhythmias (tachycardia or bradycardia)	Administer IV potassium slowly
Nasogastric suction	Fatigue	Obtain ECG (for IV potassium bolus)
Administration of diuretics or corticosteroids	Drowsiness	Monitor laboratory values (electrolytes)
Burns that are healing		Evaluate acid-base status
Alkalosis		

Potassium (K⁺) excess (hyperkalemia; serum potassium concentration ≥ 5.5 mEq/L)

Causes	Signs and symptoms	Nursing care
Increased intake of potassium	Muscle twitching	Determine underlying cause
Severe dehydration	Muscle weakness	Monitor vital signs
	Flaccid paralysis	Obtain ECG
Rapid administration of IV potassium chloride	Hyperreflexia	Administer IV fluids as ordered
Potassium sparing diuretics	Oliguria	Administer IV insulin to facilitate potassium moving into cells (if ordered)
Burns	Apnea (respiratory arrest)	Monitor laboratory values (electrolytes)

Kidney disease (failure)	Bradycardia	Evaluate acid-base status
Adrenal insufficiency (Addison disease)	Ventricular fibrillation (cardiac arrest)	
Metabolic acidosis		

Calcium (Ca²⁺) deficit (hypocalcemia; serum calcium concentration < 8.8 mEq/L)

Causes	Signs and symptoms	Nursing care
Inadequate dietary intake	Tetany	Determine underlying cause
Vitamin D deficiency	Convulsions	Administer oral calcium supplement as prescribed
Feeding cow's milk to infants	Neuromuscular irritability	Administer IV calcium slowly and monitor IV site (irritation)
Advanced adrenal insufficiency	Hypotension	Monitor laboratory values (electrolytes)
	Tingling (nose, ears, toes and fingertips)	
	Cardiac arrest	

Calcium (Ca²⁺) excess (hypercalcemia; serum calcium concentration > 10.8 mEq/L)

Causes	Signs and symptoms	Nursing care
Excessive vitamin D intake	Weakness	Determine underlying cause
Acidosis	Fatigue	Obtain ECG
Immobilization (prolonged periods of time)	Constipation	Monitor laboratory values (electrolytes)
Increased bone catabolism	Anorexia	
Hyperthyroidism	Nausea	
Kidney disease	Vomiting	
	Thirst	
	Bradycardia (cardiac arrest)	

Nursing care centers on recognizing the underlying cause and then replacing water loss and electrolytes. Another nursing care measure is education. The nurse explains to parents the signs and symptoms of dehydration, the importance of offering clear liquids as ordered and home care.

 **Nursing Insight—** Fluid and electrolyte balance nursing interventions

- Obtain daily weights (same scale, same time, and wearing the same clothing) (infants are weighed naked and often older children are weighed only in their underwear).
- Measure intake and output (weigh diapers to assess output).

- Assess hydration status which includes assessing for presence of tears, skin turgor, anterior fontanel (up to 18 months), sticky mucous membranes, sunken eyeballs, urine and stool output, weight loss, tachycardia, tachypnea, decreased blood pressure, temperature and thirst.
- Laboratory tests include specific gravity, hematocrit, blood urea nitrogen (BUN), creatinine, Na⁺, K⁺, and Ca²⁺.
- Assess the type of acid–base disturbance (metabolic acidosis, metabolic alkalosis, or respiratory acidosis) (see Chapter 24).
- Administer oral clear liquids as ordered (1–2 oz. every hour).
- Start an IV for fluid and electrolyte replacement as ordered.
- Before administering intravenous potassium (K⁺), ensure the child has voided (to prevent tubular necrosis).
- Cleanse perineal area and apply protective topical ointment.
- Encourage the parents to be involved in the care of child.
- Educate the parents about signs and symptoms of dehydration, rehydration and when to call the doctor.
- Encourage parents to be compliant with follow-up appointment(s).

Disorders of the Renal and Urinary Systems

URINARY TRACT INFECTIONS

An acquired infection of the urinary system caused by a bacterium, virus, or fungus is referred to as a **urinary tract infection** (UTI). Often the infection is acquired in association with newborn bacteremia seeding into the renal circulation or by the ascending route via the urinary system (Lebel, 2004). Urinary tract infection is the second most common form of bacterial infection in children, ranking only behind upper respiratory problems (Snyder, 2002). It is thought that 8% of girls and 2% of boys will have a UTI during childhood. UTIs are a serious threat to the health of any newborn, infant, preschooler, school-age child, or adolescent.

Gender, age, race, renal tissue, poor hygiene, constipation, nutritional status, adaptive and resistant qualities of the causative agents, as well as structural abnormalities, catheterization, urinary tract instrumentation, and sexual activity all contribute to the incidence and etiology of this disease (Lum, 2007; Wise & Cardinal-Busse, 2007).

During the first year of life, boys are at a greater risk for a UTI. The higher incidence in boys is partially attributed to the higher rate of congenital abnormalities in the male newborn (Lippincott Williams & Wilkins, 2004). Starting at 6 months, girls are at greater risk until school age and then again when they enter adolescence, owing to their proximity of the anus with fecal flora available to colonize easily within the urethra. Sexually active adolescent girls have a higher incidence of UTIs than do boys, as well as a greater incidence than any age group. The causative agent is *Chlamydia*.

UTIs are also more common in the uncircumcised males (Elder, 2004). Circumcision reduces the risk of UTIs in boys (Lum, 2007). Breastfeeding is also correlated with a decreased incidence of infection of the urinary tract (Lebel, 2004).

Nursing Insight—Renal scarring

Once bacteria gain entrance into the renal medulla, an immune response is stimulated. A substance called superoxide is released and eliminates the bacteria. In the process of killing the bacteria, however, damage occurs to the tubular cell wall that produces renal scarring. Scarring causes decreased usable space in the renal parenchyma and loss of function. End-stage renal disease can occur due to scarring (Bernstein & Shelov, 2003, p. 605).

The most common invading bacterium responsible for UTIs is *Escherichia coli*, with *Klebsiella*, *Proteus*, enterococci, and *Staphylococcus saprophyticus* (Stead, Matthews, & Kaufman, 2004). *Pseudomonas aeruginosa* and *Staphylococcus epidermidis* also commonly cause UTI in children (Snyder, 2002).

Any alteration that interferes with elimination creates a risk for UTI. Conditions associated with chronic perineal irritation such as poor hygiene, bubble baths, soaps, pinworms, or perineal trauma that experienced cyclists, dirt bikers, or equestrians may experience are important associations to consider in predisposing the individual to UTIs. Conditions such as constipation, neurogenic bladder, and voiding dysfunction, or a history of abnormal voiding patterns are potential underlying etiological factors. It is important to consider anatomical abnormalities such as posterior urethral valves and ureterocele (Kennedy, 2003).

A child with a UTI may also have an anatomical abnormality called vesicoureteral reflux (VUR). In this condition, there is a backward (retrograde) flow of urine from the bladder into the ureters and nephron components. It is a common underlying cause of febrile UTI in infants and very young children.

Nursing Insight—Urinary tract infections

- The higher the infection in the urinary system, the greater is the risk for morbidity and significant long-term deteriorating health alterations.
- Within the first 2 years of life, infections that progress into the renal parenchyma frequently cause scarring, resulting in hypertension leading to chronic renal failure (inability of the kidneys to function adequately) (Elder, 2004).
- There is a high occurrence of UTIs in the newborn period followed closely by ages 1 to 3 months; the most frequent pathogen is *E. coli*.
- Children with indwelling Foley catheters or on continuous antibiotics frequently can contract a UTI.

SIGNS AND SYMPTOMS. Unique age-related signs and symptoms in the neonate are failure to thrive, jaundice, fever or hypothermia, poor feeding, or vomiting. The infant usually is a poor feeder, has fever, strong-smelling urine, vomiting, and diarrhea. The preschooler often presents with anorexia and sleepiness along with vomiting, diarrhea, abdominal pain, fever, strong-smelling urine, enuresis, dysuria, urgency, or frequency. The school-age child has new enuresis, strong-smelling urine, urgency, or flank pain and some changes of personality. Adolescents often experience fatigue and flank pain. Visual inspection of external genitalia for irritation,

pinworms, sexual abuse, trauma, or vaginitis is important (Egland & Egland, 2006).

Nursing Insight— Urinary tract infections

Adolescents are more likely to have classic adult symptoms of cystitis that is concurrent with vaginitis (35%) rather than only a UTI (17%) (Egland & Egland, 2006; Luxner, 2005). Dull flank pain and costovertebral angle is associated with renal involvement (Newberry, 2003).

DIAGNOSIS. Owing to the long-term consequences of a UTI in childhood, early accurate diagnosis and treatment are of paramount importance. Early diagnosis is essential and is based on signs and symptoms as well as urine collection to obtain the culture (Kennedy, 2003; Schwartz, 2005). A complete blood count (CBC) with differential is done, as well as a test for blood urea nitrogen (BUN) and creatinine.

To localize the actual infection, imaging studies are delayed for 3 to 6 weeks after an infection for follow-up. If, however, obstruction is suspected, imaging studies are done.

diagnostic tools Determining Problems with the Urinary Tract

- The renal ultrasound depicts the ureters but does not discern if there is an infection.
- A voiding cystourethrogram (VCUG) depicts urethral and bladder anatomy.
- An intravenous pyelogram assists with identifying the size, shape, and position of the urinary system as well as elimination function by noting length of time for passage of contrast material through the kidneys.
- Nuclear cystography visualizes the bladder and is good for detecting VUR.
- Nuclear cortical scanning detects tubular damage and scarring (Egland & Egland, 2006; Pagana & Pagana, 2003).

NURSING CARE. The goals of nursing care are to collaborate with the patient, family, and other health care providers along the continuum of care needed to diagnose and treat the urinary tract infection. Concurrent with every diagnostic test, medications prescribed, and developmentally appropriate nursing intervention provided is the underlying goal of patient/family education that explains each step of the treatment process.

The nurse obtains a history that identifies risk factors, clinical manifestations, medications given, nutritional and fluid intake needed, and output parameters required for healing to occur.

Typically, patients who require IV fluids or IV antibiotics, neonates, and infants identified as high risk are admitted to the hospital. All infants younger than 1 month with suspected UTI, even if not febrile, are admitted. There

where research and practice meet: **Urinalysis**

Since approximately 20% of patients with UTIs have a normal urinalysis, a urine culture and sensitivity should be obtained and sent to the lab (Cincinnati Children's Hospital Medical Center, 2005; Egland & Egland, 2006).

may be other reasons for admission based on the health care provider and/or family's collaborative decision (Cincinnati Children's Hospital Medical Center, 2005; Egland & Egland, 2006).

Parenteral antibiotics are used to treat UTIs. The most common anti-infective agents are listed in Table 32-1.

It is important to keep track of intake and output, as well as any odors associated with the urine. A fishy malodorous aroma without other clinical manifestations may still indicate a UTI and a health care provider is consulted.

Nursing Insight— Broad-spectrum antibiotics

It is important that nurses emphasize the importance and rationale for taking all antibiotics for the entire designated time along with adequate intake of fluids. For children on low-dose antibiotics prophylactically, medication taken at night allows the drug more time in the bladder.

Children who receive broad-spectrum antibiotics that are likely to alter GI and periurethral flora are at increased risk for UTI because these drugs disturb the natural defense against colonization by pathogenic bacteria (Hellerstein, 2007, p. 4).

Nursing Insight— Urinary tract infections

The most significant risk factor for UTIs is the presence of a urinary tract abnormality that causes urinary stasis, obstruction, reflux, or dysfunctional voiding. **Pyelonephritis** (an infection in the renal pelvis) causes renal scarring and, with repeated infections, hypertension or end-stage renal disease.

VESICoureTERAL REFLUX

Normally, urine should flow downward from the kidneys through the ureters into the bladder and urethra. In vesicoureteral reflux (VUR) the urine backflows from the bladder to the ureters and back to the kidneys. The disorder occurs at the vesicoureteral junction, which normally creates a one-way valve for the urine to enter the bladder without being refluxed back into the ureters or kidney. VUR is found as a common cause of children with UTI, and it is most frequently diagnosed between ages 2 and 3. VUR is more common in girls, is familial and is more common in Caucasians. It is a cause of UTI in infants and children, and is more commonly diagnosed after the first or second UTI episode.

Primary Vesicoureteral Reflux

A child may be born with a valvular defect at the ureter and bladder junction, due to insufficient fetal growth of the ureter. The resultant valvular defect allows urine to backflow from the bladder to the ureters. As a child grows and the ureters lengthen, this type of VUR may resolve spontaneously (National Kidney and Urologic Diseases Information Clearinghouse, 2007).

Secondary Vesicoureteral Reflux

In this category of reflux, there may be an obstruction within the urinary system, possibly related to UTI, which causes ureteral inflammation. The edema itself causes a

Table 32-1 Common Anti-infective Agents, Side Effects, and Nursing Interventions

Anti-infective	Side Effects	Nursing Intervention
Cefotaxime (IV) Claforan	Mild diarrhea, mild abdominal cramping	Monitor fluid intake.
Ampicillin (IV) Marcillin	Nausea, vomiting, diarrhea, rash	Hold and notify MD if rash or diarrhea develops. With prolonged therapy periodically monitor renal, hepatic, and hematology lab work.
Gentamicin (IV) Garamycin	Serious side effect: Ototoxicity and nephrotoxicity	Monitor urinalysis. Therapeutic peak 5–10 mcg/mL and trough 2 mcg/mL The family needs to notify physician of any balance, hearing, urinary, or vision problems even after drug is completed.
Ceftriaxome (IV) Rocephin	Serious side effect: Antibiotic-associated colitis manifested as severe abdominal pain, tenderness, fever, and diarrhea that is severe and watery	Assess bowel pattern or pain. Monitor I & O.
Cefixime (PO) Suprax	Serious side effects: Stevens-Johnson syndrome, nephrotoxicity, blood dyscrasias Superinfections (can occur with any antibiotic)	Monitor BUN and serum creatinine, I & O. Teach how to recognize superinfection, e.g., furry tongue, perineal itching. Taking with yogurt/buttermilk to decrease superinfection by maintaining intestinal flora.
Cephalexin (PO) Biocef, Keflex	Serious side effects: Antibiotic-associated colitis and other superinfections; nephrotoxicity with preexisting renal disease, angioedema, bronchospasm, and anaphylaxis especially if allergies to penicillin or cephalosporins	Monitor I & O for nephrotoxicity. Assess bowel activity and stool consistency and increasing GI effects. Take with food or milk if mild GI upset occurs. Assess mucous membranes and tongue for white patches.
Sulfamethoxazole-trimethoprim (PO) Bactrim, Septra, Generic	Serious side effects: Fatalities secondary to Stevens-Johnson syndrome, toxic epidermal necrolysis, fulminant hepatic necrosis and other blood dyscrasias such as agranulocytosis, aplastic anemia	Contraindicated in children younger than 2 months of age; kernicterus may result if used with newborns. Monitor I & O; assess skin for pallor, purpura, and rash or overt signs of bleeding, swelling. Monitor hematology, liver and renal function lab results. Family needs to report new symptoms, e.g., bruising, fever, sore throat, or other skin reactions.
Nitrofurantoin (PO) Macrochantin, Furadantin	Serious side effects: Stevens-Johnson syndrome, liver toxicity, peripheral neuropathy, impairment of pulmonary function	Monitor for peripheral neuropathy, e.g., numbness and/or tingling of extremities. Monitor for liver toxicity signs and symptoms. Monitor respiratory system and chest pain, cough, or difficulty with respirations.
Ciprofloxacin (PO) Cipro	Many IV incompatibilities Serious side effects: Superinfection, nephrotoxicity, cardiac arrest, cerebral thrombosis Arthropathy may occur in children younger than 18 years	Monitor I & O; ensure that appropriate fluid intake maintained Caution regarding sun exposure affecting eyes, skin. If contact lenses, remove if taking ophthalmic solution or ointment.

reflux of urine back to the kidneys. When urine refluxes backwards into the kidneys, it can cause hydronephrosis (distension of the kidney) and risk for pyelonephritis (kidney infection, as opposed to bladder infection).

Gradations of VUR are provided in the International Reflux Grading System, with a range from Grade I to Grade V (Fig. 32-2). These gradations were created based on the appearance of the renal pelvis and calyces on voiding cystourethrograms (VCUG; radiography of the bladder and urethra by use of a radiopaque contrast medium).

Figure 32-2 Gradations of VUR are found in the International Reflux Grading System, ranging from Grade I to Grade V.

Nursing Care Plan The Child with a Urinary Tract Infection

Nursing Diagnosis: Impaired Urinary Elimination related to tissue inflammation

Measurable Short-term Goal: The child will be able to void adequate amounts of clear urine without burning, frequency, or urgency

Measurable Long-term Goal: The child will not experience complications such as pyelonephritis

NOC Outcome:

Urinary Elimination (0503) Collection and discharge of urine

NIC Interventions:

Medication Administration (2300)
Pain Management (1400)
Specimen Management (7820)

Nursing Interventions:

1. Assess history of urinary tract problems, family dynamics, and understanding about urinary elimination and hygiene.
RATIONALE: Recurrent urinary tract infections may indicate lack of knowledge about urinary hygiene or may be an indication of sexual abuse.
2. Collaborate with the physician regarding the collection of a urine specimen for culture and sensitivity and follow-up culture after antibiotic administration is completed.
RATIONALE: A urine culture will help determine the causative organism and the antibiotic that will be the most effective against the organism. Follow-up will help determine if the causative organism has been eliminated by the antibiotic.
3. Instruct family to administer medications as prescribed including antipyretics, analgesics, and the full course of antibiotics (specify drugs, doses, routes, and times).
RATIONALE: An antipyretic is an agent that reduces a fever associated with a urinary tract infection. Urinary tract analgesics provide symptomatic relief from burning pain, frequency, and urgency. Antibiotics must be maintained at a consistent blood level for 7–10 days to kill the causative organism.
4. Assist the caregiver to plan for optimal nutrition and fluid intake, individualized for the child (specify for age).
RATIONALE: Good nutrition and adequate hydration is required for healthy immune response and optimal renal function.
5. Teach the child and/or family about good genital hygiene practices such as wiping from front to back and washing hands before and after elimination.
RATIONALE: Prevents fecal–urinary contamination and the spread of infection.
6. Provide the child and family with education about urinary tract infections, including prevention by obtaining adequate fluids, voiding frequently, UTI signs and symptoms, and the necessity of completing the full course of antibiotics.
RATIONALE: Provides new knowledge for child and family and empowers them to prevent recurrent infections.

diagnostic tools Voiding Cystourethrograms (VCUG)

- Grade I: Urine backs up into the ureter only, and the renal pelvis appears healthy, with sharp calyces.
- Grade II: Urine backs up into the ureter, renal pelvis, and calyces. The renal pelvis appears healthy and has sharp calyces.
- Grade III: Urine backs up into the ureter and collecting system. The ureter and pelvis appear mildly dilated, and the calyces are mildly blunted.
- Grade IV: Urine backs up into the ureter and collecting system. The ureter and pelvis appear moderately dilated, and the calyces are moderately blunted.
- Grade V: Urine backs up into the ureter and collecting system. The pelvis severely dilates, the ureter appears tortuous, and the calyces are severely blunted

(Cendron & Benedict, 2006, p.1)

Grades I, II, and III reflux are considered lower grade and tend to resolve more spontaneously with cautious monitoring. Grades IV and V VUR need to be managed

medically and surgically by a pediatric urologist and/or pediatric nephrologist. Candidates for surgery include children with recurrent breakthrough pyelonephritis (Gaylord & Starr, 2004), severe anatomical deformity at the ureterovesicular junction, antibiotic intolerance, medication noncompliance, and VUR in females after puberty (Montagnino & Currier, 2005).

SIGNS AND SYMPTOMS. The most common presentation for VUR is recurrent UTI. Flank pain, abdominal pain, and enuresis may coexist, although toddlers are seldom capable of describing these symptoms.

The major risk of VUR is the development of acute pyelonephritis, due to the backflow of urine toward the kidney. These children usually have a fever, nausea/vomiting, and possibly, but not always, UTI symptoms. Even one episode of febrile acute pyelonephritis can cause renal scarring in children (Montagnino & Currier, 2005).

Nursing Insight— Children younger than 2 years old

The risks of persistent VUR, especially in children younger than 2 years old, are significant, as the most common cause of UTI and renal scarring. Children with UTI who are younger than 2 years of age may more easily develop sepsis and become gravely ill. Infants with VUR and renal pelvis dilatation were found to usually have low-grade reflux that resolved by age two, as shown on ultrasound (Ismaili et al., 2006). Infants with high-grade reflux do not tend to resolve as spontaneously.

DIAGNOSIS. Diagnosis of VUR is most consistently based on the voiding cystourethrogram (VCUG) radiograph, which identifies the bladder, urethra, and ureters during micturition. Radiographic contrast material is observed as it refluxes back into the ureters and kidneys from the bladder.

NURSING CARE. Nursing care and treatment vary according to the grading of the reflux. In Grades I and II, the mildest types of reflux, the VUR may resolve spontaneously as the child grows. In children with more severe grades of reflux, surgical intervention may be required. This ranges from abdominal surgery to less invasive endoscopic surgery. Typical surgery involves reimplanting the ureter on the top of the bladder, so that the ureter length is long enough to prevent reflux.

Medical management for nonsurgical VUR includes vigilance in preventing and treating UTIs, especially because there is significant risk for the more dangerous pyelonephritis. Renal scarring and damage are hazards of VUR. Many children who are managed medically take prophylactic long-term antibiotics in addition to anticholinergic agents, such as oxybutynin chloride (Ditropan) to reduce bladder pressure.

Nurses have a vital role in educating the parents and family members about signs and symptoms of UTI and the importance of medication in this chronic disorder. Nurses caring for the postsurgical patient must be vigilant in monitoring intake and output as well as maintaining the patient's pain control. All tubing and drainage apparatus must be carefully labeled and monitored for any breaks in the system that could introduce infection (Kenner, Moran, Zebold, Keating, & Amlung, 2007).

where research and practice meet: Prophylactic Antibiotics

Many children with VUR are treated with prophylactic antibiotics, such as a daily low dose of an antibiotic. This is followed by urine culture periodically (every 2 or 3 months). Prophylactic antibiotics are often recommended until the child has been free of infection for a 12-month period (Gaylord & Starr, 2004). However, other researchers disagree and say it may not be necessary for children with VUR to take urinary antibiotic prophylaxis after an episode of acute pyelonephritis (Garin et al., 2006).

Optimizing Outcomes— Children with VUR and UTI

A thorough nursing assessment promotes the best outcome for a child with VUR and UTI. Since infants and small children cannot express urinary discomfort easily, nurses can observe for discomfort during voiding or straining to void, dribbling of urine, and starting and stopping of the stream. Fever of unknown origin and irritability may be suspicious for UTI in nonverbal children especially. Nurses must take extreme care to obtain a reliable clean-catch urine specimen through assisting older children in the collection of the sample and through proper handling of a bagged specimen in younger children. It is useful to explain the urinary system to children old enough to understand it through the use of drawings, models, or dolls (Montagnino & Currier, 2005).

UNEXPLAINED PROTEINURIA

Routine office urinalysis may discover proteinuria (loss of proteins, such as albumin or globulins, in the urine). Proteinuria ranges from simple and reversible etiologies to complex, life-threatening causes.

More benign etiologies of proteinuria include orthostatic (from supine to seated or standing) or postural (affected by posture) proteinuria. This commonly asymptomatic disorder tends to occur after age 8, and is associated with upright activities during the daytime hours. It is necessary to obtain supine urine collections (normally the first morning void if the patient has not arisen during the night), which reveal a lessening or absence of protein in the case of purely orthostatic proteinuria.

Other reversible causes of proteinuria include that occurring after fever or hardy exercise. When the patient temperature subsides or the patient has not exercised heavily for 48 hours, the proteinuria subsides as well.

Nursing Insight— Pathological etiologies for proteinuria

More pathological etiologies for proteinuria include glomerulonephritis, polycystic kidney disease, renal trauma, chronic pyelonephritis, acute tubular necrosis, obstructive uropathy, Henoch-Schönlein purpura, and congestive heart failure. Pregnancy and certain medications can cause proteinuria as well. Associated signs and symptoms for more pathological proteinuria include the potential presence of hematuria, edema, hypertension, fatigue, impaired growth and failure to thrive, dysuria (painful), frequency, oliguria (diminished urine), costovertebral angle (CVA) tenderness or flank pain, and joint pain (King, 2006).

SIGNS AND SYMPTOMS. The incidence of positive proteinuria by dipstick screening is seen in 10% of all children between 8 and 15 years of age. The dipstick must show 1+ (30 mg/dL) or higher level of proteinuria to be considered significant. False-positive readings for proteinuria are possible with highly concentrated urine, with specific gravity >1.015, and in this case, the proteinuria must be 2+ or higher to be considered significant. Proteinuria may also be noted in infected urine, often along with leukocytes, hematuria, and positive nitrates (King, 2006).

The nurse should note potential signs of renal disease, such as periorbital (around the eye orbit) edema and peripheral edema. The nurse also assesses blood pressure, pulse, and growth, which may be impaired with renal disease, in addition to performing an abdominal examination to assess for CVA tenderness and renal masses (Gaylord & Starr, 2004).

DIAGNOSIS. Obtain serial first-voided (the first urine of the morning) specimens for urinalysis at least three times over a 2-week span if orthostatic proteinuria is suspected. It is advisable to send urine for culture and sensitivity to rule out UTI. Any urinalysis containing proteinuria, especially higher than 1+, along with possible hematuria, white blood cells (WBCs), casts, crystals, and bacteria is more suspicious for urological or renal disease. Additional renal serum tests that should be ordered include BUN and creatinine. A 12- or 24-hour urine test for creatinine (a chemical waste product of muscle metabolism) and protein may suggest pathology.

Further diagnostic testing may include renal ultrasound, voiding cystourethrogram (VCUG), and testing for anti-streptolysin titer (ASO) to rule out poststreptococcal glomerulonephritis. Referral to a urologist or nephrologist is necessary when proteinuria is persistent, of a high level, or is associated with other urinary abnormalities.

NURSING CARE. In the outpatient setting, the nurse can instruct the parent or child on how to obtain a first-morning voided specimen to test for orthostatic or postural proteinuria. Make certain the parent understands whether the specimen is to be returned to the office or to a laboratory. Nurses should be able to perform an accurate urine dipstick test by obtaining proper quantities of urine to dip the sticks into, and then by waiting the appropriate amount of time to test each specimen (Fig. 32-3).

Figure 32-3 Nurses should be able to perform an accurate dipstick test.

If patients require further testing in the inpatient or outpatient settings, nurses can be instrumental in educating the parents or caretakers about what each test entails. Sometimes it is possible to obtain educational handouts geared for the lay public to help patients understand what urinary disorders mean and how various urological tests are performed. In this case, the nurse's role is largely that of an educator. Nurses should also make certain that patients receive the proper follow-up after proteinuria is discovered. This may infer return visits to an outpatient setting and the establishment of appointments with a pediatric urologist or nephrologist.

HEMATURIA

Asymptomatic gross (visible) and microscopic hematuria is considered fairly common in children.

Although rare, microscopic hematuria can be the first sign of renal disease. Conversely, gross hematuria in children was more serious. The most common etiologies are poststreptococcal glomerulonephritis, hypercalciuria (with or without calculi), and IgA nephropathy. It is especially important for children with gross hematuria to undergo a significant urological work-up (Bergstein et al., 2005).

Other less common causes of hematuria include renal trauma, coagulopathy (a disorder of blood coagulation), hydronephrosis, epididymitis (inflammation of the epididymis, usually associated with a sexually transmitted infection), and tumor. UTI may cause microscopic or gross (macroscopic) hematuria. It is also important to note that exercise may induce hematuria, as well as viral and bacterial illness. Occasionally, external irritation may cause hematuria (e.g., from bubble baths, soaps, and scratching) (Gaylord & Starr, 2004).

SIGNS AND SYMPTOMS The main sign of hematuria is blood in the urine.

DIAGNOSIS. The color of the urine may be significant; tea-colored or brownish urine, especially if it contains protein and casts, signifies a nephrological disorder. Pink or red urine with or without blood clots, but without protein, usually originates in the lower urinary tract. If higher than 1+ hematuria is present on dipstick, then it is necessary to obtain a microscopic urinalysis to check for red blood cells (RBCs). Pseudohematuria is a condition that shows a false-positive dipstick but no RBCs on microscopic lab examination (Gaylord & Starr, 2004).

where research and practice meet: Hematuria

In a study reported by Bergstein, Leiser, and Andreoli (2005), the most common etiologies for microscopic hematuria were hypercalciuria (calcium deposits in the urine) with or without renal calculi, post-streptococcal glomerulonephritis, and structural abnormalities, including a single kidney. It was significant to note that asymptomatic microhematuria had no identifiable cause in the majority of patients. It was surprising that urinary tract infection (UTI) was not the cause in any of the patients studied. Occasional low-grade vesicoureteral reflux was found in microscopic hematuria.

Urinalysis that reveals hematuria along with casts and proteinuria is highly suspicious for renal disease. UTI may show hematuria along with mild proteinuria, but without casts. Urine culture is suggested to rule out urinary tract infection in cases of hematuria. Further diagnostic work-up may include renal ultrasound, intravenous pyelography (IVP), and voiding cystourethrogram (VCUG). Referral to a pediatric urologist or nephrologist is necessary in cases of hematuria suggesting the potential for renal disease.

NURSING CARE. Depending on the cause of the hematuria, the nurse is called on to educate the child and parent or caregiver about necessary laboratory and procedural tests, in addition to giving understandable explanation of the cause of the hematuria. In the case of UTI, the nurse must educate the child or parent in the proper techniques of collecting a urine specimen (Procedure 32-1).

If the child cannot voluntarily give a urine specimen, the nurse must use appropriate bagging techniques to obtain the specimen, including clean-catch collection in

all cases. The nurse is able to obtain urine specimens by collecting urine from a bag that fits over the perineum in females or over the penis in males (Fig. 32-4). The skin must be dry for the bags to adhere. It is ideal to cleanse the perineum in girls or penis in boys before placing the plastic collecting bag. The bag must be removed as soon as the child voids to avoid fecal contamination. Transfer the urine to a sterile collection container and send it to the laboratory immediately.

The nurse is also responsible for accurately testing the urine with a dipstick, ensuring that there is an adequate sample and allowing the proper time limits for testing.

GLOMERULAR DISEASE

Glomerular disease (glomerulonephritis) can be due to primary kidney disease or secondary multisystem diseases that cause damage to the glomerulus. Both primary and secondary diseases are accompanied with histological evidence that captures the glomerular damage and resultant

Procedure 32-1 Collecting a Urine Specimen

Purpose

The purpose of collecting a urine specimen is to screen for early signs of disease.

Equipment

Packaged urine culture set (usually contains three antiseptic towelettes and a sterile urine collection plastic container)

Steps

1. Wipe (or have the child wipe) the labia or penis with the three provided iodine or antiseptic solution towelettes. In occasional situations, it is considered appropriate to use just soap and water to wash these areas. The customary procedure is to wipe the areas three times. In males, wipe the urethral tip three times in a circular fashion, once with each wipe. In a female, holding the labia open to expose the urethra, wipe the right side top to bottom and discard the wipe. Then repeat this on the left side, discarding the wipe. Wipe top to bottom over the central area where the urethral meatus is and discard that wipe.

RATIONALE: *Cleansing removes normal flora that may contaminate a urine culture and make it impossible to tell which organisms are pathogens.*

2. Ask the child to begin to urinate into the toilet, bedpan, or urinal, and then stop urinating.

RATIONALE: *This action flushes away urine in the distal urethra, which may be contaminated with normal flora from the skin.*

3. Position the sterile urine container so that it catches the "mid-stream" urine, which needs to be about 3 to 4 ounces of urine.

4. Remove the container and cap it, taking care not to contaminate the inner container with your gloved hands.

RATIONALE: *Removing the container keeps the specimen sterile.*

5. Allow the child to finish voiding into the toilet, bedpan, or urinal.

Clinical Alert Do not keep a urine culture at room temperature any longer than 10 minutes. If the specimen cannot be sent to the laboratory immediately, it is necessary to refrigerate it in a plastic specimen bag to prevent the overgrowth of organisms that interfere with the interpretation of the culture and sensitivity to specific antibiotics.

The specimen is plated on a nutrient medium and bacteria that are present are allowed to grow and then are counted. Usually, different antibiotic discs are placed on the inoculated medium to show which ones decrease the colony counts (sensitivity).

Teach Parents

Parents may be responsible for collecting urine cultures on their children at home or in the medical office, so they must be instructed on the sterile techniques of handling the specimen. If the specimen is collected at home, it may need to be refrigerated before bringing it to the laboratory.

Documentation

4/20/10 0800 Specimen collected.

-M. Helming, RN

Note: Time and date of the urine collection must appear on the label and in the chart. The label should also contain the patient's name and other identifying information, such as identification number.

Figure 32-4 The nurse must be able to collect urine specimens in a bag that fits over the perineum in females or over the penis in males.

clinical manifestations and needed treatment. Acquired causes, including genetic, immunological abnormalities, disturbances of coagulation, chemical toxic events, or biochemical defects, interrupt and do varying degrees of damage to the physiological functions of the glomerulus. Acquired immunological abnormalities are the major pathophysiological mechanisms in glomerular disease (Fig. 32-5).

Nursing Insight— Three classic syndromes

There are three classic syndromes that characterize the sequence of events with glomerular renal insult:

- Acute glomerulonephritis
- Nephrotic syndrome
- Hemolytic uremic syndrome

Figure 32-5 The nephron showing glomerular filtration and tubular reabsorption.

The etiology of the renal glomerular insult determines the specific condition, progression, whether acute or chronic, and its prognosis. Regardless of which classical disease or syndrome the patient has, a major concern is the prevention of or early detection and intervention for renal glomerular dysfunction before the condition worsens (Bernstein & Shelov, 2003).

Acute Glomerulonephritis

Inflammation of the glomeruli (tubules of the kidney) is called glomerulonephritis. Interference with the glomeruli filtering waste products from the blood gives rise to acute and chronic clinical manifestations. If the inflammation follows the course of an infection it is called postinfectious glomerulonephritis. If it can be directly attributed to the streptococcus organisms it is called poststreptococcal glomerulonephritis.

Post Streptococcal Glomerulonephritis

Although it is not common, it is possible for children to develop an acute glomerulonephritis within 7 to 14 days following an acute Group A beta-hemolytic streptococcal infection. Antigen–antibody complexes with the streptococcal bacteria form and are deposited in the glomeruli, causing damage. Infections that were missed or not cultured may cause patients to develop this sequela. The nurse must consider not only Group A beta-hemolytic streptococcal pharyngitis, but also other potential sources of this bacteria, such as impetigo.

SIGNS AND SYMPTOMS. Gross hematuria, either tea or coffee-colored urine, develops, accompanied at times by edema, which may be seen in the periorbital region (around the eye orbits). The process of kidney dysfunction causes disturbances in sodium and water retention, which in turn cause edema. If the symptoms become more severe, the child may develop hypertension and headache. Severe disease causes significant proteinuria and possibly even ascites, due to fluid shifting (Lum, 2007).

DIAGNOSIS. If the child has not had a diagnosed streptococcal infection in the previous 2 weeks, it is possible that the physician will order a serum antistreptolysin titer (ASO titer) that will indicate exposure to the bacteria. Serum complement (C3) is another blood test that may be positive. Urine microscopic hematuria may still be noted up to 1 year after this disease resolves. Laboratory tests such as BUN and creatinine are used to assess renal function. If children do not fully recover, they may develop nephrotic syndrome and require a renal biopsy (Lum, 2007).

NURSING CARE. Children with post streptococcal glomerulonephritis require antibiotic therapy if an infection is still found. Fluid imbalances require monitoring of fluid intake and output, as well as possible treatment with diuretic medications and antihypertension drugs. Children with severe glomerulonephritis may require peritoneal dialysis or hemodialysis. Corticosteroids may be useful to manage the acute process. In most cases, the disorder begins to resolve within 2 or 3 weeks. Nurses need to support family members through this frightening and uncommon disorder.

Nurses should assess the child's pharynx and upper respiratory tract for signs of acute infection, and a streptococcal culture is obtained. In addition to a rapid-streptococcal test, it is wise to send a full streptococcal culture swab to the laboratory for a confirmatory exam. Nurses should monitor children for hypertension and urinary output. Children who develop significant oliguria, gross hematuria, and hypertension are hospitalized due to the risk of associated acute renal failure. Nurses may need to educate patients and family members about dietary restrictions such as sodium, potassium, and fluid intake (Kenner et al., 2007).

case study Post Streptococcal Glomerulonephritis

Sara is a 4-year-old girl who is taken to the pediatric emergency department with edematous eyelids and swollen abdomen. Sara's mother reports that along with her daughter's swollen eyelids, her daughter has a decreased appetite and has been very fatigued for the past several days.

Sara's vital signs are normal except for her blood pressure, which is 140/90. The systems review and physical exam are negative except for lesions on her ankles and "doughy" or "dense" feeling to her abdomen, which is slightly firm to touch. The lesions are circular, crusted with sticky yellow drainage, which Sara scratches during the exam. Sara's mother reports that her daughter is allergic to amoxicillin (Amoxil) and develops a rash.

critical thinking questions

1. What is your assessment?
2. What are other questions do you want to ask?

The pediatric nurse practitioner orders a flat abdominal radiograph including the kidneys, ureters, and bladder and bladder, which comes back negative. There are no abdominal masses. She then asks Sara for a urine specimen. There is hematuria and proteinuria.

3. What other laboratory test(s) should you anticipate will be needed?
4. What are two tests that would confirm a diagnosis of post-streptococcal glomerulonephritis?
5. What diet do you anticipate will be ordered for Sara?
6. What antibiotic could be given since she is allergic to amoxicillin?
7. What patient teaching would you want to provide before they go home?

◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

HEMOLYTIC UREMIC SYNDROME

Hemolytic uremic syndrome (HUS) is the most common cause of acute renal failure (ARF) in children. HUS is most commonly associated with children ingesting beef contaminated with *Escherichia coli* (*E. coli*), although other organisms, such as shigella, coxsackievirus, adenovirus, salmonella, ECHO virus, pneumococci, and rickettsia have been implicated. This potentially lethal outcome is most commonly seen in young children between 6 months and 3 years of age, but can occur in all age groups.

clinical alert

E. coli 0147.H7

Undercooked ground beef has been one of the primary sources of *E. coli* 0147.H7 that can cause HUS. Meat should be cooked until it reaches a temperature of 160°F and is no longer pink. *E. coli* outbreaks have occurred in fast-food and other restaurants, and have been found in unpasteurized cider, milk, juice, alfalfa sprouts, strawberries, and most recently, raw spinach.

It is believed that an endotoxin is produced from the dangerous bacteria in the gastrointestinal tract, and results in inflammation causing capillary wall destruction. This occurs also within the glomerular arterioles, and as the endothelium of the glomerulus becomes more edematous, platelets aggregate at the site of injury. A clot then forms that impedes renal circulation. This stimulates increased rennin production, which results in hypertension. These platelets are damaged and this results in thrombocytopenia, or a drop in the platelet count to less than 100,000/ μ L for a period of 1 to 2 weeks. The overall effect damages the glomerular blood vessels, resulting in a lesser glomerular filtration rate, lowered urine output, acute renal failure, and hypertension. The clotting and inflammatory process may also affect the respiratory system and any other body system.

SIGNS AND SYMPTOMS. Signs and symptoms of HUS include, first, gastroenteritis (inflammation of the intestines due to infection) with diarrhea and vomiting, as well as a potential upper respiratory infection. The hemolytic uremic syndrome that may result can endure from several days to two weeks. Classically, HUS must include this triad: thrombocytopenia, anemia, and acute renal failure. Pallor, lethargy, anorexia, anemia, and irritability are included in the presentation. Urine output decreases, and blood chemistries may be altered. Hepatosplenomegaly, dehydration, and bloody diarrhea are possible. The child may suffer from seizures, consciousness alteration, and may require dialysis. Thrombocytopenia (low platelet count) may cause petechiae and purpura formation, as well as ecchymosis.

DIAGNOSIS. Diagnosis of HUS includes critical analysis of laboratory results. In HUS there may be an elevation in BUN and creatinine levels. Hyperkalemia (elevated potassium level) also may occur due to decreased urinary excretion. Serum glucose levels may drop due to increased metabolic needs, but may also rise if the pancreas is affected, and some children require insulin. Other affected electrolytes include calcium, which decreases and phosphorus, which rises.

NURSING CARE. Many of those suffering from HUS are ill enough to be in intensive care. Nurses must monitor level of consciousness, signs of increased intracranial pressure, congestive heart failure, bleeding, and hypertension (Kenner, Moran, Zebold, Keating, & Amlung, 2007). Fluid intake and output is measured every 4 hours, and up to every hour if the child is critically ill. Daily weights are essential and the nurse needs to assess electrolyte balances (sodium, potassium, chloride, and bicarbonate), as well as arterial blood gas measurements. The BUN and creatinine

are important to measure to determine if renal status is worsening and the child may be at risk of needing dialysis. The lungs should be assessed for signs of congestive heart failure, such as rales. Assess for peripheral and periorbital edema, as these are indicators of worsening renal and cardiac status.

The nurse monitors the child's vital signs frequently for hypertension and tachycardia. It is recommended that children with HUS have electrocardiographic monitoring to assess for possible changes such as widened QRS complexes, heart block, and peaked T waves due to hyperkalemia (Kenner et al., 2007).

assessment tools Hemolytic Uremic Syndrome (HUS)

Nurses should be observant for all of these risks of hemolytic uremic syndrome:

- Signs of bleeding, associated with thrombocytopenia, petechiae, epistaxis (nosebleed), prolonged bleeding at venipuncture sites, and ecchymoses.
- Signs of increased intracranial pressure, including change in level of consciousness and risk of seizure.
- Abdominal symptoms are the primary presenting complaints for children, and may occur in the form of diffuse abdominal pain, intussusception (telescoping of the bowel), nausea and vomiting, diarrhea, and fever. These abdominal symptoms may present up to 1 week after exposure to the *E. coli* 0157.H7 toxin (Razzaq, 2006).

Antibiotics are contraindicated in treating HUS as they may worsen the situation. Because very young and very old patients are at highest risk for developing HUS from *E. coli* 0157.H7, it is prudent to investigate whether any patient with diarrheal illness has eaten a risky food. Stool culture for *E. coli* 0157.H7 is available at many laboratories, and should be ordered if there is a suspicion of contaminated food.

Be sure to— Investigate Legal Concerns

Children who have been exposed to undercooked beef or other products containing *E. coli* 0157.H7 may seek legal remedies for their suffering. Severe illness, possibly chronic renal problems, and death have been outcomes of pediatric HUS. Restaurants and food producers who are responsible for contaminated products have legal liability for personal injury. Some years ago, many outbreaks of HUS forced the fast-food industry to cook all beef sufficiently so that no redness persisted and the internal temperature of the thickest portion of the beef reaches 160°F.

HENOCH-SCHÖNLEIN PURPURA

Henoch-Schönlein purpura (HSP) includes a range of mild to severe glomerulonephritis and renal insufficiency. This disease is classified as a vasculitis (inflammation of blood vessels) because there is a component of inflammation in the arteries. HSP typically follows an upper respiratory tract infection during the ages from 4 years old to 10 years old (Olson, 2002).

SIGNS AND SYMPTOMS. Hematuria and hypertension are common features of this disorder. Other symptoms include bloody diarrhea, crampy abdominal pain, and a rash with palpable purpura (raised purpura), features found especially on the lower extremities and buttocks (Lum, 2007).

There may also be joint pain and swelling and scrotal swelling. The glomerulonephritis that develops may not occur until 2 months after the onset of symptoms. About 5% of all affected children may have a gradual progression to renal failure (Olson, 2002).

DIAGNOSIS. Diagnosis is not difficult if the classic symptoms of rash, gastrointestinal complaints or hematuria, and arthritis are present. The diagnosis of Henoch-Schönlein purpura depends on clinical findings and history. There is not a specific laboratory test for the disorder, although an elevated serum IgA level, elevated sedimentation rate, elevated platelet count, and elevated white blood cell count may be present. Urinalysis may show hematuria. A stool guaiac test (a test for unseen blood in stool) may be positive.

NURSING CARE. Although most children recover spontaneously, some can relapse and some can recover very slowly, continuing to show hematuria for up to 2 years later. Corticosteroids seem to assist the abdominal and joint pain as well as the edema, but do nothing to assist the renal compromise. Some children may require immunosuppressant medications and renal transplant.

Children with HSP are at risk of complications of intussusception (telescoping of the bowel), intestinal hemorrhage, intestinal perforation, and central nervous system and severe renal complications (Marino & Devivio, 2002). Nurses must monitor these children for signs of bleeding, pallor, vital sign alterations, abdominal pain, oliguria, and urine abnormalities.

CHRONIC GLOMERULONEPHRITIS

Chronic glomerulonephritis involves several glomerular diseases that, unlike acute poststreptococcal glomerulonephritis, do not have a tendency toward spontaneous recovery but rather are undulant (moving like waves) with primary cause difficult to establish. Advanced pathological damage to the glomeruli silently occurs.

Damage to the glomerular membrane causes permeability and electrical charge changes that permit passage rather than filtering of protein molecules. A persistent abnormal sediment is found in the urine as progressive loss of renal function occurs over time. Proteinuria and hematuria finally surface with a urinalysis obtained during a clinic visit. Renal failure can be an outcome depending degree of damage done to the glomerular membrane (Bernstein & Shelov, 2006).

Most often, chronic glomerulonephritis is due to acquired immunological assaults that occur to the kidney directly. Complement C3, IgG, or IgA is often found embedded in the glomeruli if a renal biopsy is performed.

Other times, chronic glomerulonephritis can be attributed to systemic disease, such as systemic lupus erythematosus, or human immunodeficiency virus infection. Nephrogenic exposure to organic solvents, mercury, and certain nonsteroidal anti-inflammatory agents can also be the etiological finding.

Because chronic glomerulonephritis has been silently undulating over several years, it is common to diagnose this during adolescence during a health care visit. Early childhood years pass without the disease being diagnosed. As the National Kidney Foundation calls for more frequent

routine monitoring of glomerular filtration rate (GFR), there may be a change in how early the chronic glomerulonephritis is discovered.

SIGNS AND SYMPTOMS. A decrease in the adolescent's urine output; the presence of high blood pressure, headaches, and other signs of fluid overload such as periorbital edema; increased abdominal girth; and swelling of the labia or scrotum bring the patient to the attention of the physician. These symptoms are serious enough to warrant hospitalization and aggressive treatment.

DIAGNOSIS. Diagnosing chronic glomerulonephritis includes the use of diagnostic laboratory tests similar to that of acute or chronic renal failure: urinalysis, blood chemistry, blood urea nitrogen, serum creatinine, and pH.

NURSING CARE. Treatment depends on the degree of renal insufficiency or failure (refer to section on Acute and Chronic Renal Failure). The overall management principles for treating chronic glomerulonephritis are related to treating the etiology of primary disease or secondary disease that affects the glomerulus, preventing immune responses (or limiting them) and correcting problems of edema, hyperkalemia, or hyperlipidemia if present. If hyperlipidemia is present, nystatins cannot be given because renal damage prevents proper clearance of the drugs. Dietary management may include restriction of salt and fluid along with instituting low-potassium foods.

The use of plasma exchange may be instituted in severe cases to decrease the amount of circulating immunoglobulin that are damaging the kidney. When hypertension is present, it is generally related to fluid overload, and loop diuretics (e.g., furosemide) (Lasix) may be given to reduce the circulating intravascular fluid volume. Carefully monitoring of urine output, along with weight and abdominal girth is necessary.

The patient must be monitored vigilantly for nephrotic syndrome, chronic renal failure, end-stage renal disease, chronic or malignant hypertension, heart failure, pulmonary edema, chronic or recurrent UTIs, and infection.

Trusting, supportive, developmentally appropriate relationships are established through the caring interventions of the nurse and other health care providers. Long-term follow-up, possible renal biopsies every 2 to 5 years, and vigilant observations for possible renal failure become part of the patient and her family's everyday life. Refer to the section on acute and chronic renal failure for more specificity related to monitoring weight, abdominal girth, electrolytes (e.g., hyperkalemia with potential ECG changes) as well as acidosis and inadequate renal perfusion. If renal failure does eventually occur, the patient and family is prepared for the possibility of dialysis and renal transplant.

Now Can You— Discuss common disorders of the urinary system?

1. Explain why the early diagnosis of urinary tract infections (UTIs) is critical?
2. Describe gradations of vesicoureteral reflux?
3. Discuss hemolytic uremic syndrome and related nursing care measures?

Structural Defects of the Urinary System

Although theoretically the urinary tract system, composed of two ureters, one bladder, and one urethra, appears independent of the kidneys, the two systems are intertwined. Abnormalities with the urinary tract system ultimately affect the other system. The abnormalities may be anatomical, infectious, cellular, inflammatory, functional, or maturational.

Bladder exstrophy, hypospadias and epispadias, and vesicoureteral reflux (VUR) are primarily urinary tract system abnormalities that damage the kidney. For instance a kidney disease known as hydronephrosis is an accumulation of urine in the renal pelvis results from the obstruction. These structural defects also compromise kidney function, resulting in hypertension, metabolic acidosis, inability to concentrate urine, urinary stasis and infection, and chronic renal failure. "Pyelonephritis is considered more severe than a urinary tract infection" (Potts & Mandelco, 2002, p. 617).

Other structural defects of the urinary system are referred to as obstructive uropathy, which are structural or functional abnormalities that also result in retrograde flow of urine back into the renal pelvis. The most common of these obstructive uropathies are ureteropelvic junction obstruction (an obstruction or stenosis of the ureteropelvic valve between the renal pelvis and ureters). The outcome of untreated obstructive uropathy is chronic renal failure due to the damage to the renal parenchyma from hydronephrosis.

RENAL TRAUMA

Injury to the kidney accounts for greater than 47% of the genitourinary injuries. Up to 90% of these injuries are due to blunt trauma. The most common causes of renal trauma are motor vehicle accidents, direct blows, and sports injuries or falls. Due to the larger size of the kidney in children and the greater amount of space it has in the abdomen, children are more likely to sustain renal injury.

SIGNS AND SYMPTOMS. With critical injuries, the children have localized flank tenderness, hematoma, and a palpable mass. There also can be other symptoms related to abdominal injury such as tenderness, peritonitis, paralytic ileus, and resulting hypovolemic shock.

clinical alert

Hematuria

Hematuria is most often considered the cardinal marker of renal injury. The presence of any degree of hematuria should be regarded as a potential indication of underlying renal injury or anomaly. Hematuria out of proportion to the mechanisms of injury should suggest a congenital anomaly or neoplasm.

DIAGNOSIS. Diagnosis of renal trauma is confirmed by history and clinical findings.

NURSING CARE. Because renal trauma is a critical injury, advanced trauma life-support guidelines are followed. The

goal is prevention of renal morbidity and mortality. Blunt trauma, such as bruising without any urinary extravasation (grades I, II, and III), is treated conservatively. Treatment includes bedrest, analgesia, and prophylactic antibiotics. Grades of IV and V renal trauma require referral to a urologist.

Nursing care centers on recognizing a renal injury and the potential urgency. Hematuria is the primary sign of renal injury. The nurse must gather a detailed history of the problem. Sometimes a lengthy admission process is not possible due to the impending surgery. Performing a nursing assessment, including vital signs, growth and development, nutritional and immunization status, along with a thorough physical examination is essential. The nurse also gains crucial information such as the precipitating event, allergies, medications, general state of health, and previous hospitalizations or surgeries.

Surgery may be required if abdominal exploration is needed. The nurse must prepare both the child and family for the surgery and immediate postoperative care. Essential abbreviated information is communicated because the family may not understand the full situation. Serious injury to the urinary system often requires astute observation in the critical care unit. Nursing care must be tailored to the identified problems, in order of importance, and the nurse must develop a care plan that deals with the multifaceted problems. The nurse understands that the child will be placed on bed rest for initial observation and remain on bed rest for 3 days after internal bleeding has subsided. Monitoring vital signs, urinary, respiratory, cardiac, and gastrointestinal status as well as the surgical incision is essential. Priority actions also include monitoring intake and output, measuring weight and abdominal girth, administering intravenous fluids, and pain management. The nurse must report signs of inadequate renal

perfusion (hypotension), acidosis, and observe for edema, oliguria, or anuria.

Psychosocial care of the family is also important and includes encouraging the parents to remain at the bedside, relaying appropriate developmental information, and minimizing stressors experienced by the child. The nurse may have to remind the family to avoid discussions at the bedside that may upset the child. The nurse must respect and support family's decision about medical care but can intervene if the best interest of the child is in question. Notify a hospital chaplain for spiritual care if the family desires.

ACUTE RENAL FAILURE

Acute renal failure (ARF) is a life-threatening syndrome in which there is a sudden decreased capacity of the kidneys to eliminate waste products, resulting in an inability to maintain fluid and electrolyte or acid–base balance (Kline & Milonovich, 2006). Glomerular filtration is reduced or tubular function is decreased, resulting in oliguric renal failure (less than 1 mL/kg per hour in neonates and infants, less than 5 mL/kg per hour in older children) and nonoliguric renal failure, which is more easily missed on diagnosis (Kliegman, Marcante, Jensen, & Behrman, 2006). There are a variety of causes of ARF (Table 32-2).

In the newborn, the major causes of oliguria are congenital heart disease, respiratory distress syndrome, congenital hydronephrosis, acute tubular necrosis, and renal vein thrombosis. For children younger than age 5, the most common cause of oliguria is hemolytic uremic syndrome and poststreptococcal glomerular nephritis. Beyond 5 years of age, the pathophysiology and management is similar to that provided for adults.

Table 32-2 Causes of Acute Renal Failure

Prerenal, Hypovolemic, Hypotension	Intrinsic, Intrarenal, Parenchymal	Postrenal (Obstruction)
Dehydration	Acute tubular necrosis <ul style="list-style-type: none"> • Nephrotoxins (drugs) (reversible if caught early) 	Urethral obstruction <ul style="list-style-type: none"> • Stricture • Posterior urethral valves • Diverticulum
Septic shock	Acute cortical necrosis (not reversible)	Ureterocele
Heart failure	Glomerulonephritis	Extrinsic tumor compressing bladder outlet
Hemorrhage	Interstitial nephritis	Extrinsic urinary tract tumors
Burns	Vascular <ul style="list-style-type: none"> • Renal vein thrombosis • Arterial thromboembolus (umbilical artery catheter) • Disseminated intravascular coagulation • Immune-mediated (scleroderma) 	Tumor lysis syndrome
Peritonitis, ascites, cirrhosis	Pigmented <ul style="list-style-type: none"> • Hemoglobinuria • Myoglobinuria 	

Nursing Insight—Renal failure

Any condition that reduces blood flow to the kidneys is prerenal failure. Intrarenal failure also referred to as intrinsic or parenchymal renal failure, is a result of destruction to the renal filtering components. Obstruction of the outflow of urine from the bladder, ureters, or urethra is the underlying etiology of postrenal failure.

Regardless of type of acute renal failure, the clinical manifestations usually can be seen through three distinct phases: oliguric, diuretic, and recovery.

Nursing Insight—Hemolytic uremic syndrome

The most common cause of acute renal failure is hemolytic uremic syndrome (HUS) in North America due to hemorrhagic colitis from *E. coli*.

SIGNS AND SYMPTOMS. Signs and symptoms of acute renal failure include fever, rash, bloody diarrhea, pallor, vomiting, diarrhea, abdominal pain, hemorrhage, shock, anuria, or polyuria. Other life-threatening signs and symptoms include gastrointestinal bleeding, hypertension, anemia, neurological symptoms, as well as the skin

becoming ecchymotic. Signs and symptoms of electrolyte imbalances are also seen in ARF (Table 32-3).

DIAGNOSIS. Determining if the cause of the acute renal failure is prerenal, intrarenal, or postrenal requires a very careful history, analysis of symptoms, and physical examination. A previous medical history helps to determine any previous infections such as acute glomerulonephritis or neurogenic bladder. Genetic problems such as a horseshoe-shaped kidney or one kidney can be uncovered.

Laboratory data routinely obtained are a urinalysis, blood chemistry, blood urea nitrogen, serum creatinine, and pH (Table 32-4). Common urinalysis associated findings with acute renal failure include a urinary sediment, color ranging from dirty brown, reddish brown, to bilious tinge, proteinuria, and casts (Kline & Milonovich, 2006) (Table 32-5).

Sometimes a renal biopsy is ordered if the cause of the ARF cannot be ascertained. Renal ultrasound may also be used. Renal ultrasound can assist with pinpointing obstructive uropathy. A CBC can help determine if there is thrombocytopenia due to hemolytic uremic syndrome or eosinophilia due to acute interstitial nephritis.

Acute renal failure can also be diagnosed by finding toxins in the blood. Toxins can be found if there has been exposure to heavy metals or organic solvents, which causes acute tubular necrosis. Other epidemiological

Table 32-3 Signs and Symptoms of Electrolyte Imbalances in Acute Renal Failure

Electrolyte Imbalance	Clinical Manifestations	Clinical Treatment
Hyperkalemia (>6.0 mEq/L) Results from inability to adequately excrete potassium derived from diet and catabolized cells. In metabolic acidosis, there is also movement of potassium from intracellular fluid to extracellular fluid	Peaked T waves, widening of QRS on ECG. Dysrhythmias: ventricular dysrhythmias, heart block, ventricular fibrillation, cardiac arrest Diarrhea Muscle weakness	Eliminate all intake of potassium (dietary, parenteral, or TPN) Administration of alkalinizing agents Kayexalate orally or in retention enema when $K^+ > 7.0$ mEq/L (Other drugs may be ordered by physician including Calcium gluconate 10% solution, Sodium bicarbonate, and regular insulin when $K^+ > 7.0$ mEq/L) Dialysis if other methods to reduce the potassium level are ineffective
Hyponatremia In the acute oliguric phase, hyponatremia is related to the accumulation of fluid in excess of solute	Change in level of consciousness Muscle cramps Anorexia Abdominal reflexes, depressed deep tendon reflexes Cheyne–Stokes respirations Seizures	Electrolyte replacement, sodium bicarbonate Dialysis to correct severe electrolyte disturbance
Hypocalcemia Phosphate retention (hyperphosphatemia) depresses the serum calcium concentration. Calcium is deposited in injured cells. Hyperkalemia and metabolic acidosis may mask the common clinical manifestations of severe hypocalcemia.	Muscle tingling Changes in muscle tone Seizures Muscle cramps and twitching Positive Chvostek sign (contraction of facial muscles after tapping facial nerve just anterior to parotid gland)	Calcium gluconate Low phosphorus diet Phosphate binders, e.g., Tums tablets, Calcium acetate and sevelamer. (Aluminum-based binders not utilized to prevent possible aluminum toxicity.) Calcium IV not given except for tetany to prevent calcium salt deposition into tissues Dialysis to correct severe electrolyte disturbance

Table 32-4 Normal Urinalysis

Urinalysis	Normal Values
Appearance	Clear
Color	Amber yellow
Odor	Aromatic
pH	4.6–8.0 (average 6.0)
Osmolarity	50–1400 mOsm/L
Protein	None or up to 8 mg/dL
	50–80 mg/24 hr (at rest)
	<250 mg/24 hr (exercise)
Specific Gravity	Adult: 1.005–1.030 (usually 1.010–1.025)
	Elderly: values decrease with age
	Newborn: 1.001–1.020
Leukocyte esterase	Negative
Nitrites	Negative
Ketones	Negative
Crystals	Negative
Casts	None present
Glucose	Brand new specimen: negative
	24-hour specimen: 50–300 mg/day or 0.3–1.7 mmol/day (SI units)
White blood cells (WBCs)	0–4 per low-power field
WBC casts	Negative
Red blood cells (RBCs)	Up to 2
RBC casts	None

nephrotoxic agents include treatment with aminoglycosides, amphotericin B, contrast, or chemotherapeutic agents (Schwartz, 2005).

Nursing Insight—Renal tubular function

- “The fractional excretion of sodium (FENA) is an index of renal tubular function.
- $FENA = ([UNA/PNA]/U_{creat}/P_{creat}) \times 100$
- An FENA greater than 2 is correlated with acute interstitial nephritis or acute tubular necrosis.
- An FENA less than 1 is correlated with hemolytic uremic syndrome, acute, glomerulonephritis, or prerenal causes”. (Schwartz, 2005, p. 711)

Laboratory differential diagnosis of acute renal failure is also important (Table 32-6).

NURSING CARE. The nursing responsibilities for care of a patient with acute renal failure are multiple and require significant patience for a child who has changing level of consciousness and irritability. Parents need sup-

Table 32-5 Common Urinalysis Findings of Acute Renal Failure

Urinalysis Findings	Interpretation
Urinary sediment	Intrinsic kidney failure
Color	+ “Dirty” brown: Intrinsic renal failure
	+ Reddish brown: Acute glomerulonephritis
	+ Bilious tinge: Mixed hepatic & renal failure
Proteinuria	+ Glomerulonephritis
	+ Interstitial nephritis
	+ Toxic and infectious causes
Casts	+ Red blood cell (RBC) casts:
	Glomerulonephritis or vasculitis
	+ White blood cells (WBC) casts:
	Interstitial nephritis
	+ Granular casts: Glomerulonephritis
	+ Uric acid crystals: Tumor lysis syndrome
	+ Calcium oxalate crystals: Ethylene glycols
	Ingestion:
	+ Acetaminophen (Tylenol) crystals: Acetaminophen (Tylenol)

port, particularly if they are feeling guilty that a postinfectious glomerulonephritis was not prevented by earlier treatment. Administration of medications, monitoring nutritional intake, and meticulous fluid intake and output assessment are critical to help the physician make treatment decisions.

The complications of acute renal failure are variable depending on the underlying etiology (Table 32-7). Renal-limited diseases, such as postinfectious glomerulonephritis, have a mortality rate of less than 1%. Other etiologies such as HUS, tumor lysis syndrome, and acute tubercular necrosis, all have severe multiorgan effects that increase the mortality rate to greater than 90%. Many medications are prescribed to control multisystem complications (Table 32-8).

Collaboration with the health care team is critical so that acute renal failure complications are reduced or prevented from occurring depending on whether the etiology is prerenal, intrarenal, or postrenal. Appropriate key nursing diagnoses are suggested (Bruck & Mayer, 2005; Kline & Milonovich, 2006; Schwartz, 2005).

nursing diagnoses Acute Renal Failure

- Fluid Volume Excess related to fluid retention
- Risk for Injury related to accumulation of electrolytes and nitrogenous waste
- Risk for Infection related to lowered body defenses, fluid overload
- Interrupted Family Processes related to a child with a serious disease
- Knowledge Deficit related to long-term follow-up to monitor the patient’s kidney status

Table 32-6 Laboratory Differential Diagnosis of Acute Renal Failure

	Prerenal		Intrarenal		
	CHILD	NEONATE	CHILD	NEONATE	POSTRENAL
Urine Na ⁺ (mEq/L)	<20	<20–30	>40	>40	Variable, may be >40
FEna* (%)	<1	<2–5	>2	>2.5	Variable, may be >2
Should not be obtained after a diuretic is given as renders the test inaccurate					
Urine osmolality (mOsm/L)	>500	>300–500	>300	>300	Variable, may be <300
Serum BUN-to-creatinine ratio	>20	> or equal to 10	>10	>10	Variable, may be >20
Urinalysis	Normal		RBCs, WBCs, casts, proteinuria		Variable to normal, possible crystals
Comments	History: diarrhea, vomiting, hemorrhage, diuretics Physical: volume depletion		History: hypotension, anoxia, exposure to nephrotoxins Physical: hypertension, edema		History: poor urine stream and output Physical: flank mass, distended bladder

*FEna, Fractional excretion of sodium (%) = [(urine sodium/plasma sodium) ÷ (urine creatinine/plasma creatinine)] × 100.

RBCs, red blood cells; WBCs, white blood cells.

Table 32-7 Complications of Acute Renal Failure

Metabolic	Cardiovascular	Gastro-Intestinal	Neurological	Hematological	Infection	Other
Hyperkalemia	Pulmonary edema	Nausea	Neuromuscular irritability	Anemia	Pneumonia	Hiccups
Metabolic acidosis	Arrhythmias	Vomiting	Asterixis (flapping tremor)	Bleeding	Septicemia	Increased parathyroid hormone
Hyponatremia	Pericarditis	Malnutrition	Seizures		Urinary tract infection	Low total triiodothyronine
Hypocalcemia	Pericardial effusion	Gastrointestinal hemorrhage	Mental status change			Low thyroxine
Hyperphosphatemia	Pulmonary embolism					Normal free thyroxine
Hypermagnesemia	Hypertension					
Hyperuricemia	Myocardial infarction					

Table 32-8 Medications Used to Treat Complications of Acute Renal Failure

Medication	Action/Indication	Nursing Implications
Hyperkalemia	Exchanges sodium for potassium	May require up to 4 hours to take effect.
• Kayexalate	Counteracts potassium-induced increased myocardial irritability	Monitor for ECG changes. Intravenous infiltration may result in tissue necrosis.
• Calcium gluconate 10%	Shifts potassium to the cells	Give by inhalation.
• Albuterol		
Metabolic Acidosis	Helps correct metabolic acidosis by exchanging hydrogen for potassium	Do not mix with calcium. Complications include fluid overload, hypertension, and tetany.
• Sodium bicarbonate or sodium citrate		
Hypocalcemia	Used in the presence of tetany; provides ionized calcium to restore nervous tissue function to control serum phosphorus	Administer slowly to prevent bradycardia. Monitor for ECG changes.
• Calcium gluconate 10%		
Malignant Hypertension (B/P > 95% for age)	Relaxes smooth muscle in peripheral arterioles	Administer by continuous intravenous infusion; fall in blood pressure is seen within 10–20 minutes.
• Sodium nitroprusside, nitroglycerin		

Be sure to— Record accurate weight measurement

An inaccurate weight recorded in a computer charting system can cause life-threatening harm for the patient. It is critical that when delegating to nursing assistants the nurse carefully monitor that the weight measures are being done properly. Obtain weights: same scale, same time, and wearing the same clothing (infants are weighed naked and oftentimes older children only have on their underwear). The weights are ordered once a day, before feedings, and every 12 hours for critical children.

CHRONIC RENAL FAILURE

Chronic renal failure refers to an insidious process of irreversible, progressive deterioration of the glomerular filtration rate that goes through a deteriorating continuum of four stages at variable rates for each individual patient (Table 32-9). Sometimes the process is sudden, as there can be an acute renal failure occurring secondarily in someone who already has chronic renal failure.

Nursing Insight— Recommendation from the National Kidney Foundation

The National Kidney Foundation (2007) recommends patients and families with a background of diabetes, hypertension, or renal disease follow their glomerular filtration rate with their physician to ensure early intervention to slow the process. Reduction of the glomerular filtration results in fluid and electrolyte and acid–base imbalances causing damage and abnormalities of all organ systems.

Ethnocultural Considerations— Kidney failure

“African Americans constitute about 32 percent of all patients treated for kidney failure in the US, but only about 13 percent of the overall US population.” Furthermore, “anyone with high blood pressure, diabetes, or a family history of kidney disease is at risk and should have his or her kidney function tested.”

—Former US Surgeon General Dr. Joycelyn Elders

The etiology of chronic renal failure in children is age related and dependent on the organs that are affected. For children younger than 2 years old, obstructive urop-

athy or renal hypodysplasia is the common underlying problem. For children between 2 and 5 years of age, neonatal vascular accidents, renal hypodysplasia, and obstructive uropathy are factors. For older children and adolescents, glomerulonephritis, lupus nephritis, or reflux nephropathy are the underlying etiologies. Genetic considerations include polycystic kidney disease, congenital nephritic syndrome, and sickle cell disease (Schwartz, 2005, p. 712). The course of the disease is eventually fatal unless dialyses followed by kidney transplantation can be done for the patient.

SIGNS AND SYMPTOMS. Signs and symptoms of chronic renal failure are similar to those of acute renal failure. They include fever, rash, bloody diarrhea, pallor, vomiting, abdominal pain, hemorrhage, shock, anuria, or polyuria.

DIAGNOSIS. The major challenge in diagnosis and treatment is to discern whether the condition is acute or chronic renal failure and in what stage the signs and symptoms are manifesting. Acute renal failure is normally sudden, and chronic renal failure has insidious features characteristic of the system affected.

A carefully elicited history shows that all organ systems are affected to varying degrees (Table 32-10). Ultrasound shows the size of the renal organ. Although renal biopsies are important, they are not always done if the cause and treatment can be outlined without having to do the needle biopsy. The major advantage of a biopsy is that it can also assist with identifying the cause of the chronic failure and provide a map for treatment and counseling (Schwartz, 2005).

Diagnostic tests include serum chemistries, CBCs, urinalysis, parathyroid hormone, chest radiograph, bone films, renal ultrasound, and ECG if the patient is hyperkalemic. Laboratory tests and correlated results that occur with chronic renal failure.

“What to say” — Gathering information from the parents

- “Does your child have any of the following symptoms?”
 - Malaise
 - Poor appetite
 - Vomiting
 - Bone pain
 - Headache (if hypertensive)
 - Polyuria

Table 32-9 Four Stages of Chronic Renal Failure According to Glomerular Filtration Rate (GFR)

Percentage of Reduction of GFR	Stage of Renal Failure	Glomerular Filtration Rate as Applied to Children Age 2 and Older*
35%–55% of normal	1. Reduced renal reserve	≥90
25%–35% of normal	2. Renal insufficiency	60–89
20%–25% of normal	3. Renal failure	30–59
Less than 20% of normal	4. End-stage renal disease (ESRD)	15–29*

*If GFR <15, dialysis is needed.

Table 32-10 Physical Examination Findings Correlated with Underlying Pathophysiological Mechanisms for Chronic Renal Failure

Organ System	Physical Findings	Correlation with Pathophysiological Mechanisms
Skeletal	<p>Osteitis fibrosa (bone inflammation with fibrous degeneration)</p> <p>Bone demineralization (principally subperiosteal loss of cortical bone in the fibers, lateral ends of the clavicles, and lamina dura of the teeth)</p> <p>Spontaneous fractures, bone pain; osteomalacia (rickets or rachitic changes) with end-stage renal failure</p> <p>Edema</p> <p>Absent patella</p>	<p>Bone resorption associated with hyperparathyroidism, vitamin D deficiency, and demineralization</p> <p>Lowered calcium and raised phosphate levels</p>
Cardiopulmonary	<p>Hypertension, pericarditis with fever, chest pain, and pericardial friction rub, pulmonary edema, Kussmaul respirations</p> <p>Flow murmur</p> <p>Gallop</p> <p>Rub</p>	<p>Extracellular volume expansion as cause of hypertension</p> <p>Hypersecretion of renin also associated with hypertension</p> <p>Fluid overload associated with pulmonary edema and acidosis leading to Kussmaul respirations</p>
Neurological	<p>Encephalopathy (fatigue, loss of attention, difficulty problem solving)</p> <p>Peripheral neuropathy (pain and burning in the legs and feet, loss of vibration sense and deep tendon reflexes)</p> <p>Loss of motor coordination, twitching, fasciculations, stupor, and coma with advanced uremia</p> <p>Hypotonia</p> <p>Irritability</p>	<p>Uremic toxins associated with end-stage renal disease</p>
Endocrine and Reproductive	<p>Retarded growth in children (short stature)</p> <p>Osteomalacia</p> <p>High incidence of goiter</p> <p>Sexual dysfunction: menorrhagia, amenorrhea, infertility, and decreased libido in women; decreased testosterone levels, infertility, and decreased libido in men</p>	<p>Decreased growth hormone</p> <p>Elevated parathyroid hormone</p> <p>Decreased thyroid hormone</p> <p>Elevated hormones: luteinizing hormone (LH), follicle-stimulating hormone (FSH), prolactin, and LH-releasing hormone; decreased testosterone, estrogen, and progesterone</p>
Hematological	<p>Anemia, usually normochromic normocytic; platelet disorders with prolonged bleeding times (increase in bleeding gums)</p>	<p>Reduced erythropoietin secretion associated with loss of renal mass, leading to reduced red cell production in the bone marrow; uremic toxins associated with shortened red cell survival</p>
Gastrointestinal	<p>Anorexia, nausea, vomiting</p> <p>Mouth ulcers, stomatitis, ruinous breath (uremic fetor), hiccups, peptic ulcers, gastrointestinal bleeding, and pancreatitis associated with end-stage renal failure</p>	<p>Retention of urea, metabolic acids, and other metabolic waste products, including methylguanidine</p>
Integumentary	<p>Abnormal pigmentation and pruritus</p>	<p>Retention of urochromes, contributing to sallow, yellow color</p> <p>High plasma calcium levels associated with pruritus</p>
Immunological	<p>Increased risk of infection that can cause death; decreased response to vaccination</p>	<p>Suppression of cell-mediated immunity</p> <p>Reduction in number and function of lymphocytes</p> <p>Diminished phagocytosis.</p>
HEENT	<p>Retinal changes</p> <p>Preauricular pits</p> <p>Hearing deficit</p>	<p>Uremic toxins</p>
Abdomen	<p>Palpable kidneys</p> <p>Suprapubic mass</p>	

- “Has your child had any of the following in the past?”
 - Perinatal complications
 - Oligohydramnios
 - Recurrent urinary tract infections
 - Enuresis
- “Is there any family history of renal disease? Hearing impairment?”

NURSING CARE. Once diagnosis is made from a well-taken history and there are laboratory results, patient medications are ordered (Table 32-11). The goals of nursing care for a patient with chronic renal failure are mutually established with the patient and family. Collaboration with the health care team is essential so that the quality of life can be extended as long as possible as the renal capacity diminishes and affects all organ systems. Nutritionists assist with the plan of providing meals that counteract the growth retardation. Pastoral care is helpful for the spiritual input as this chronic disease takes its toll and end-stage renal disease occurs and hopes for transplant rise as dialysis sees the patient through kidney compensation. Meticulous nursing care is required to administer care as the multisystem organ failure begins to take place. Patient teaching along with referral to group support organizations such as the National Kidney Foundation help the patient and family cope more effectively with the renal failure.

Dialysis in Pediatric Nursing

Dialysis is a life-extending procedure for children with severe renal compromise. Dialysis may be done through the peritoneal wall (peritoneal dialysis) or through cleansing

the blood by using a dialysis machine (hemodialysis). It is important to note that while dialysis is usually reserved for children in end-stage renal disease as a result of chronic renal failure, it may also be needed in acute renal failure if BUN and creatinine levels elevate.

PERITONEAL DIALYSIS

This process of dialysis utilizes the peritoneal membrane (abdominal lining) to filter blood and purify it. Using a dialysis solution composed of dextrose sugar and other minerals in water, it is inserted into the child’s abdomen through an abdominal catheter. Through an osmotic process, the dialysis solution draws toxins, excess water, and waste chemicals from the blood into the dialysis solution. From there, it is drained through an abdominal tube out of the abdomen. The amount of time the dialysis solution is in the abdomen is termed the *dwell time*, and the entire process of filling and emptying the abdomen is termed an *exchange*, which normally lasts 30 to 40 minutes.

There are two essential types of peritoneal dialysis: continuous ambulatory peritoneal dialysis (CAPD) and continuous cycling peritoneal dialysis (CCPD). CCPD uses a machine termed a *cycler* to provide numerous exchanges during a child’s sleep time. In the morning, the child has one exchange with a dwell time that lasts for the whole day, with a potential of adding a mid-afternoon treatment. In contrast, CAPD does not require a *cycler* machine. Instead, the dialysis solution is run from a plastic bag through the catheter, and it remains in the abdomen for several hours with a sealed catheter. After this dwell time has passed, the patient’s dialysis solution with the waste products must be drained into a special disposal bag. Then another cycle of dialysis solution is begun. Each

Table 32-11 Medications Commonly Used for Children with Chronic Renal Failure

Medication	Action or Indication	Nursing Considerations
Vitamin and mineral supplement (Nephrocaps)	Add vitamins and minerals missing from heavily restricted diet	Only prescribed vitamins should be used; over-the-counter brands may contain elements that are harmful.
Phosphate binding agents: Calcium carbonate (Tums), calcium acetate (PhosLo), or sevelamer hydrochloride (Renagel)	Reduce absorption of phosphorus from the intestines	Ensure that phosphate binding agent is aluminum free.
Calcitriol (Rocaltrol)	Replace the calcitriol that kidneys are no longer producing to keep calcium balance normal	Monitor serum calcium level. Ensure that calcium supplement is provided.
Epoetin alfa (Epoen, Procrit)	Stimulates bone marrow to produce red blood cells, treats anemia due to CRF	Given by IV or subcutaneous injection Monitor blood pressure as hypertension is an adverse effect. Monitor hematocrit and serum ferritin level according to facility guidelines.
Iron supplementation	Treat iron deficiency when epoetin alfa is prescribed	May be administered orally or IV during hemodialysis.
Growth hormone (rhGH)	Used to stimulate growth in children with CRF	Record accurate height measurements at regular intervals.
Antihypertensive agents: Angiotensin-converting enzyme (ACE) inhibitor (enalapril, lisinopril)	Used with proteinuric kidney disease as it slows the progression to ESRD	Monitor renal function and electrolyte balance.
Loop diuretics	Used when volume overload is present	

cycle lasts at least 4 to 6 hours. Most children have four cycles during the day, but sleep with the solution in their abdomen at night, unlike in CCPD.

NURSING CARE. Community nurses can assist parents and older children in learning peritoneal dialysis. The riskiest problem with peritoneal dialysis is the chance of peritonitis, an infection of the abdominal peritoneum. This is extremely serious and requires urgent antibiotic therapy, hospitalization, and follow-up with the child's nephrologist (National Kidney and Urologic Diseases Information Clearinghouse, 2007). Currently, peritoneal dialysis is considered the best choice in dialysis therapy for children, especially small children (Lum, 2007). Nurses monitor the abdominal catheter sites for signs of infection or malfunctioning equipment and make certain that the returning dialysate solution remains clear. If it is cloudy, it indicates a potential infection or problem. The nurse must notify the physician immediately (Montagnino & Currier, 2005).

HEMODIALYSIS

Children can also receive dialysis through the blood, using a special machine. This is a more complex form of dialysis that may require several months of adjustment for the child. The child's blood is moved through a filter called a dialyzer, which is part of a complex machine (Fig. 32-6). Extra water, extra salt, and toxic waste products are removed, while the blood pressure and electrolytes such as potassium, calcium, sodium, and bicarbonate are kept in balance. A special port is placed in the child, usually in the wrist, for vascular access. Through this port, the blood is removed through tubing into the dialyzer, cleansed, and then returned through a different set of tubes back to the child's body. Three types of ports are used: arteriovenous (AV) fistulas, arteriovenous (AV) grafts, and venous catheters.

The preferred type is the AV fistula, which needs to be placed weeks before starting dialysis, and it may last for a long period. In the AV fistula type, a surgeon connects an artery directly to a vein, commonly in the forearm and

around the wrist. This process makes more blood flow into the vein, so it grows stronger and larger. Eventually, the vein can support repeated hemodialysis connections. A bruit is a noise heard on auscultation that can be heard over an AV fistula to make certain it is patent.

The AV graft is reserved for children with small veins that do not properly form a fistula over time. It requires a synthetic tube to be implanted under the skin of the forearm.

The venous catheter becomes an artificial vein for needle placement with hemodialysis and serves as temporary access for more urgent need to start hemodialysis because there is no time to wait for a fistula to develop. A catheter is inserted into the chest, groin, or neck, with two chambers permitting a two-way blood flow. These catheters are intended to be temporary because they clog easily, become infected frequently, and can cause vein narrowing, but they can be used until an AV fistula begins to form within the months often required (National Kidney and Urologic Diseases Information Clearinghouse, 2007).

Many children must be hemodialyzed three times a week at an outpatient dialysis center. It is possible to arrange for home hemodialysis. Since each treatment can last 3 to 4 hours, it is disruptive to the child's time, although it is possible for the child to read, write, complete homework, play video games, and watch television during this process.

SIGNS AND SYMPTOMS. At the onset of hemodialysis, a child may experience several side effects related to quick alterations in the body's chemical and water balance. Hypotension (low blood pressure) can cause weakness, dizziness, and nausea, while muscle cramps may be caused by electrolyte imbalances (National Kidney and Urologic Diseases Clearinghouse, 2007).

NURSING CARE. It is imperative for pediatric nurses to teach the patient and parents or guardians how to keep the AV fistula, AV graft, or venous catheter clean and safe. First, the access site must be kept clean and used only for

Figure 32-6 The hemodialysis process.

hemodialysis (e.g., no drawing blood from the site). Children must learn they cannot wear jewelry near the access site, cannot have a blood pressure taken on that arm, and cannot bruise the site. Nurses must instruct patients and families to avoid carrying heavy objects on that arm, to avoid sleeping with that arm under the head or body, and to check the pulse at the site daily.

This is a highly specialized form of nursing that requires additional training. The children best suited for hemodialysis have either no one at home that can assist them with peritoneal dialysis, or they live close to a dialysis center. Children on hemodialysis often are faced with missing school and social activities, leading to further isolation and emotional problems. Fluid and dietary restrictions are necessary between dialysis sessions. Hemodialysis has the benefit of rapidly improving uremic children, somewhat normalizing their growth rates, skeletal maturation, and sexual development, which may all be impaired in end-stage renal disease (Montagnino & Currier, 2005).

critical nursing action Arteriovenous Fistulas (AV)

The pediatric nurse provides health promotion teaching to a child and family related to the care of a newly acquired arteriovenous fistula for hemodialysis treatment:

- Wash the access with soap and warm water each day, and always before dialysis.
- Instruct the child to not scratch the area or try to remove scabs.
- Check the area daily for signs of infection, including warmth and redness.
- Check that there is blood flow in the access daily. There should be a vibration (called a thrill) over the access. If this is absent or changes, a health care provider at the dialysis center should be notified.
- Take care to avoid traumatizing the arm where the access is located; do not wear tight clothes, jewelry, carry heavy items, or sleep on the arm.
- Remind health care providers not to take blood or measure blood pressure on the access arm.
- Rotate needle sites on the access. Use gentle pressure to stop bleeding when the needle is removed. If bleeding occurs later, apply gentle pressure; call a health care provider if bleeding does not stop within 30 minutes or if bleeding is excessive.

nursing diagnoses Peritoneal Dialysis

- Acute Pain related to instillation of dialysate, temperature of dialysate
- Chronic Sorrow related to chronic disability
- Risk for Infection, Peritoneal, related to invasive procedure, presence of catheter, dialysate
- Risk for Fluid Volume Excess related to retention of dialysate
- Risk for Ineffective Coping related to disability requiring change in lifestyle

nursing diagnoses Hemodialysis

- Excess Fluid Volume related to renal disease with minimal urine output
- Noncompliance with dietary restrictions related to denial of chronic illness
- Ineffective Health Maintenance related to deficient knowledge regarding hemodialysis procedure, restrictions, blood access care
- Powerlessness related to treatment regimen
- Risk for Infection related to exposure to blood products, risk of developing hepatitis B or C

Renal Transplantation

Children who receive renal transplants receive them from either unrelated donors who have died or from living donors. The living donors may be relatives who have ideal tissue matches or close friends. A person can live with just one full-functioning kidney, so there are healthy living donors who give up one of their kidneys to an ill child. About half of all children who receive kidney transplants obtain them from a living donor, often a parent (National Kidney and Urologic Diseases Information Clearinghouse, 2007). Children usually are maintained on peritoneal or hemodialysis until a donor kidney is available. Children in need of a renal transplant are placed on a waiting list and are registered with the United Network of Organ Sharing (UNOS), which keeps a computer network to link all organ donation centers and transplant centers. A preemptive transplant implies that a child has received a donated kidney before needing dialysis. This is associated with less chance of rejection (destruction of transplanted material at the cellular level) of the new kidney and longer duration of the transplanted kidney.

Children who are eligible for renal transplants are in end-stage renal disease (ESRD) and they include children who have been surviving on peritoneal dialysis or hemodialysis. Children with maple syrup urine disease, a disorder that causes sweet-smelling urine, are now being considered for renal transplant also. With this disease, there is a defect that causes amino acids from proteins to build up to a toxic level in the body, causing cerebral edema, neurological damage, and even death (Children's Hospital of Pittsburgh, 2005). Children must avoid proteins such as eggs, milk, and meat.

Chronic renal failure implies that only 50% or less of normal renal function is present and the renal failure has lasted several months. When chronic renal failure is considered to be permanent and irreversible, the child moves into the category of end-stage renal failure (ESRF). Children with ESRF become transplant candidates if there will be better quality of life for the child, and if the child can withstand the significant surgical risks of transplantation. The child must not be significantly immunocompromised. There is a higher mortality rate for children undergoing renal transplant than for adults (Kenner et al., 2007).

NURSING CARE. Children who receive renal transplants are on long-term medications to prevent rejection of the transplant. These medications are considered immunosuppressive. Medications include such drugs as cyclosporine and steroids. These drugs increase the child's risk for infection and can cause Cushing syndrome by affecting glucocorticosteroids. Steroids can also raise serum glucose level, giving the potential for diabetes mellitus to develop. In addition, steroids affect bone mineralization and strength, which can cause impairments in a growing child. Growth hormone has been used to counteract this problem, but it is controversial. Children receiving transplants frequently are also on antihypertensive and diuretic medications due to the common problem of hypertension causing renal disease because constricted blood vessels impair renal flow. Hypertension may be caused by renal disease related to volume overload, obstruction of the urinary tract, or congenital anomalies of the kidney (Lum, 2007). Diabetic

children may also develop ESRF due to the damage that diabetes inflicts upon the renal system. Children who receive transplants may need to remain on protein-restricted diets to avoid overloading the kidneys.

clinical alert

Signs of kidney transplant rejection

Signs of kidney transplant rejection in children include hypertension, decreased urinary output, fever, weight gain, edema, graft site pain, and increasing BUN and creatinine levels (Kenner et al., 2007).

Across Care Settings: Children who receive renal transplants

Children who receive renal transplants need the services of many members of the health care team: the pediatrician; the nephrologist; dialysis nurses with special training; a transplant coordinator; a social worker for information on financial assistance and transportation, and counseling; a psychologist, psychiatrist, or other counselor to handle the emotional upset children and their families go through with chronic end-stage renal disease, dialysis, and plans for transplant, and a dietician to help the child avoid foods that can cause more toxic waste buildup and to help maintain proper nutrition, as these children are often underweight (National Kidney and Urologic Diseases Information Clearinghouse, 2007).

Now Can You— Describe structural defects of the urinary system?

1. Discuss emergency care that involves crisis nursing management for renal trauma?
2. Examine clinical manifestations of electrolyte imbalances in acute renal failure?
3. Explain nursing care measures for a patient with acute and chronic renal failure?
4. Discuss peritoneal dialysis and hemodialysis along with nursing care?

Functional Disorders of the Urinary Tract

DYSFUNCTIONAL ELIMINATION SYNDROME/ VOIDING DYSFUNCTION

Dysfunctional elimination syndrome (DES), also called voiding dysfunction, is an abnormal but common pediatric elimination pattern associated with bladder and bowel withholding and incontinence. It has been found that UTI and VUR before age 2 is not a cause of DES (Shaikh et al., 2003). There may not be an association between DES and toilet training, but there does appear to be an association between children with encopresis (involuntary loss of bowel contents) and vulnerable children at risk.

Nursing Insight— Voiding disorders

There are numerous types of voiding disorders. Urge incontinence is the most frequently seen type of voiding dysfunction. Urodynamic studies show bladder storage problems and persistent bladder contractions that cause urgency and excess voiding with holding, such as crouching, leg crossing, squatting, or dancing.

Lazy bladder syndrome occurs when children delay voiding, and the detrusor muscle of the bladder weakens, while the bladder itself enlarges. This causes incomplete voiding, minimal urge to void, and voiding infrequently, associated with increased bladder capacity.

Giggle incontinence is the leakage of urine when children are laughing and there may be some bladder instability. Anticholinergic drugs can assist with this, as well as the attention-deficit/hyperactivity (ADHD) drug methylphenidate (Ritalin).

Bladder-sphincter dyssynergia refers to a bladder disorder with elevated bladder pressure but a decrease in urine flow, leaving residual urine. The child may return quickly to the restroom after just leaving it.

Vaginal voiding is associated with dribbling after voiding, due to some urine flowing into the vaginal vault. This urine then dribbles out with standing or activity. This problem may be remedied by weight loss in overweight girls, having the girl sit backwards or straddle a toilet seat so urine is directed downward.

SIGNS AND SYMPTOMS. Symptoms of dysfunctional voiding or DES include frequency in voiding, urinary incontinence, and urgency.

Nursing Insight— Dysfunctional voiding and enuresis

There is a distinction between dysfunctional voiding and enuresis. In enuresis, the child voids normally and fully but not at the socially acceptable time. In voiding dysfunction or DES, there is an abnormal emptying or storage in the bladder.

DIAGNOSIS. Physical examination includes examining the back for sacral hairy tufts and gluteal asymmetry that may be associated with neurogenic bladder issues such as spina bifida. The rectum and abdomen should be examined for evidence of constipation. The genitalia should be examined for physical abnormalities.

Diagnostic tests include VCUG, flat plate of the abdomen to assess for constipation, uroflowmetry to assess voiding flow and velocity, and the addition of electromyography to assess the pelvic floor musculature.

NURSING CARE. Nurses can assist in helping children with voiding dysfunction by identifying issues, asking the child at various times of day if he or she has voided, and asking the child if she can hold her urine if a bathroom is not always available. Monitoring stool elimination is also essential. Nurses should assess for any emotional or social problems resulting from a child's embarrassment or shame associated with voiding dysfunction.

Management includes maintaining a normal bowel regimen, with or without the use of enemas and stool

softeners, such as polyethylene glycol (MiraLax) or lactulose syrup. Children need to sit on the toilet for 1 minute for each year of age after eating, to let the gastrocolic reflex relax to induce bowel elimination. Girls with an inflamed perineum from leaking urine may be soothed with baking soda sitz baths and use of barrier creams. Nurses should promote an adequate water intake in a child to maintain dilute and less acidic urine. If a child suffers from recurrent UTI, he or she may need antibiotic treatment and prophylaxis. Trimethoprim-sulfamethoxazole (Bactrim or Septra) and nitrofurantoin (Macrochantin) are the most common antibiotics used to treat prophylaxis of UTI.

Complementary Care: Behavioral management and biofeedback

Complementary measures may be useful for treating voiding dysfunction. These include behavioral management and biofeedback. Nurses can promote adequate hydration by ensuring that children are hydrated with 8 ounces of water with each meal, and the child should attempt to void every 2 hours. Voiding charts and diaries may assist in behavioral tracking and recording of successes. Biofeedback training assists with gaining control over the bladder muscles and relaxing the external sphincter. Children wear electromyogram (EMG) patches near the perineum or abdomen to assist with biofeedback training. Psychological counseling is vital. Associated psychological and educational problems include learning disabilities, attention deficit hyperactivity disorder (ADHD), low motivation, sensory problems, and family issues. Parents and other family members need much assistance in dealing with these issues.

ENURESIS

One of the most distressing childhood issues is enuresis (bedwetting). The definition of enuresis is the “involuntary or unintentional urination at any age when voluntary control should be present” (Dunn, 2004, p. 293). Some sources discuss enuresis as occurring at age 5 or older (von Gontard, Freitag, Seifen, Pukrop, & Rohling, 2006; El-Radhi & Board, 2003) and other sources put the limit at age 6 and older (Dunn, 2004). This condition may be due to the neuromotor (neurological and musculoskeletal) development in children varying substantially, so that some children achieve bladder control earlier than others. The incidence is approximately 1% of the population internationally, and it is more common in boys than in girls.

Nursing Insight— Other issues associated with enuresis

Enuresis may carry a genetic etiology. If one or both parents have suffered from enuresis, there is a higher likelihood their offspring may suffer too. Developmental delays in other areas, such as speech, motor, and growth, may accompany enuresis issues. One study found that the brainstem may be immature in children with enuresis problems (von Gontard et al., 2006).

There are different types of enuresis; primary nocturnal enuresis (PNE) as well as primary and secondary enuresis. PNE is bedwetting during the night. Primary

enuresis occurs when children have never been able to gain urinary control. Robson, Leung, & Van Howe (2005) found that constipation can be a major issue in primary enuresis. Secondary enuresis refers to the presence of enuresis after a child has achieved dryness for 6 to 12 months. Children who experience secondary enuresis may be the victims of sexual abuse or have other issues such as school phobias, parental divorce, or other medical problems requiring significant care. Family neglect may have also diminished a positive toileting experience. ADHD is associated with an increase incidence of secondary enuresis possibly because children with attention deficits ignore nocturnal bladder warnings and cannot sit still long enough while toileting to void.

Ethnocultural Considerations— Enuresis

Toileting patterns and expectations vary among different cultural and ethnic groups. Enuresis may be considered more problematic for some cultures than for others, and expectations of bladder and bowel control vary among parents, teachers, health care professionals, and daycare providers as well.

SIGNS AND SYMPTOMS. Children who have nocturnal enuresis are thought to suffer from problems awakening at night in response to a full bladder, smaller nocturnal bladder capacity, or an abundance of nocturnal urine production. Children with secondary enuresis are thought to suffer more from UTIs, constipation, diabetes mellitus, obstructive sleep apnea, psychological stress, and urge syndrome with dysfunctional voiding.

DIAGNOSIS. Diagnosis is based on patient history and physical examination to rule out other medical conditions as the cause of enuresis.

NURSING CARE. The nurse understands that medication administration is the most effective care measure. Many children are embarrassed by this problem, and school functions, camp, and sleepovers become problematic. Some parents use medication only as needed for these special occasions.

The most commonly prescribed medication to treat enuresis is desmopressin (DDAVP), a synthetic analogue of the antidiuretic hormone (ADH). This medication, administered orally or via a nasal spray, acts to lower nocturnal urinary production. The spray is given intranasally at doses of 1 to 40 mcg (1 to 4 sprays) each night, beginning with the lowest effective dose. If given orally, desmopressin (DDAVP) is available in 0.2 mg tablets given in dosages of 0.2 mg to 0.6 mg per night. Success rates range from 10% to 65%, but unfortunately, relapse rates are high, at 80%, when the drug is discontinued. Although there is a slight risk of water intoxication, the drug overall appears safe and efficacious (National Guidelines Clearinghouse, 2004).

Another medication, imipramine (Tofranil), has been used for enuresis, although its significant side effect profile makes it considerably less desirable than desmopressin (DDAVP). Imipramine (Tofranil) may be used in a bedtime dose of 1 to 2.5 mg/kg with up to 60% effectiveness. As imipramine (Tofranil) is a tricyclic antidepressant, it is subject to risk of cardiac arrhythmia and therefore pretreatment EKG is required (National Guidelines Clearinghouse, 2004).

**medication:** ImipramineImipramine (im-**ip**-pra-mean)

Tofranil (brand name)

Pregnancy category: D**Indications:** Depression, enuresis, bulimia, attention deficit disorder in children, obsessive-compulsive disorder, panic disorder**Actions:** Tricyclic antidepressant known to increase the effect of nor-epinephrine and serotonin in the body. It also possesses anticholinergic side effects.**Contraindications and Precautions:**

- Cardiovascular disease
- Seizure disorder
- Children younger than age 6
- Concomitant use of MAO inhibitors, such as Nardil and Parnate; cannot take Tofranil within 2 weeks of taking an MAO inhibitor drug.
- Recent myocardial infarction

Adverse Reactions and Side Effects:

- Nervousness, anxiety, emotional instability
- Fainting; convulsions
- Constipation, nausea, vomiting
- Fatigue; sleep disorders
- Dry mouth
- Gynecomastia
- Confusion; hallucinations
- High or low blood pressure
- Tremor; numbness

Route and Dosage: Pediatric: short-term only, not for children younger than age 6**Dosing:** maximum 2.5 mg for each 2.2 pounds (or 1 kg) of body weight. Usually begins at 25 mg per day, taken 1 hour before bedtime. If necessary, increase this dose after 1 week to 50 mg per day (ages 6–11) or 75 mg per day (ages 12 and up), taken in one dose at bedtime or divided into two doses, one at mid-afternoon and one at bedtime (PDRhealth, 2007).**Nursing Implications:**

- Risk of potential suicidal ideation during initiation of upward titration of this medication, especially in children and adolescents.
- Toxic and possibly fatal drug interactions can occur with concomitant use of MAO inhibitors (e.g., Nardil, Parnate), SSRI drugs (e.g., Prozac, Paxil), and clonidine (antihypertensive drug also used for ADHD).
- Blood pressure and heart rate should be assessed before treatment, and an initial EKG should be taken. Serial EKGs may be needed with dose adjustments, in order to monitor for prolonged PR and QT intervals and flattened T waves.
- Nurses must assess patients for mood alterations, hallucinations, confusion, and laboratory abnormalities (leukocytes, blood glucose, and renal and hepatic status).
- There is a significant risk of agitation, arrhythmias, hallucinations, fever, dyspnea, seizures, and vomiting in acute overdosage. Treatment consists of gastric lavage, use of charcoal, and a stimulant cathartic. Additional supportive measures are heart monitoring, respiratory status monitoring, and possibly use of antiarrhythmic and anticonvulsant agents.

Data from Deglin, J.H., and Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

Another nursing care measure is education. The nurse can explain to the parents that sometimes enuresis is due to developmental stage of the child or the child is a deep sleeper who does not feel the urge to void. In some cases, this may improve as the child grows, but it should be monitored. Avoidance of fluids close to bedtime, avoidance of diuretic beverages or substances (coffee, tea, chocolate, colas), and use of reward charts are other techniques useful to parents. Many commercial items are available to assist

parents. These include mattress pads with alarms, watches with reminders to void, books on staying dry, and absorbent underwear.

Other complementary care modalities have been developed to assist in the management of enuresis. Nurses should familiarize themselves with these in order to instruct parents and children with this problem. One behavioral treatment that has proven very useful involves conditioning through the use of a battery-operated bed wetting alarm, a device that wakens the child if the bedding becomes wet.

**Complementary Care:** Enuresis

- Four to six sessions of hypnotherapy can train a child to awaken when his or her bladder feels full.
- Not every child with enuresis is suffering psychological problems, but there is an increased incidence of psychological issues in secondary enuresis, including parental divorce, school trauma, hospitalization, and sexual abuse. Acupressure or massage therapy can be useful in some cases of psychological induced enuresis.
- Citrus foods, carbonated or caffeinated drinks, red dyes, and artificially colored candy may contribute to enuresis. Elimination trials can be advised by nurses.

**case study** Enuresis

Tommy is an 8-year-old boy who is brought in for a medical evaluation of enuresis. He lives with his divorced mother and a 4-year-old sister in a suburban community. Tommy is in second grade at the local public school and his grades are mostly Bs. The nurse in the pediatrician's office is responsible for taking Tommy's medical history.

critical thinking questions

1. What questions do you need to ask Tommy?
2. What questions do you need to ask Tommy's mother?
The pediatrician is now ready to see Tommy.
3. What laboratory test(s) should you anticipate will be needed?
The pediatrician does a well-child exam on Tommy. He is in the 50th percentile for height and the 40th percentile for weight. He has a normal exam except for a mild, excoriated pink rash in his antecubital fossae bilaterally. He is at Tanner stage I. The in-office urinalysis is normal.
Tommy's mother is distressed that her son is still wetting the bed at age 8. This happens almost every night, and she is washing linens continuously.
4. What education can you give to Tommy's mother about enuresis?
5. What advice can you give her about tools available to help enuresis?
The pediatrician decides to give Tommy a medication for enuresis. You are the office nurse who needs to instruct Tommy and his parents in the medication.
6. What is the likely medication given?
7. What instructions do you need to give Tommy's mother about this medication?

◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

EXSTROPHY OF THE BLADDER

Exstrophy of the bladder is a congenital defect in which the abdominal and anterior bladder walls do not fuse during fetal development. This results in the anterior surface of the bladder being open on the abdominal wall. The defect has a variety of degrees of severity. There are a number of associated congenital anomalies or other structural alterations (epispadias, cryptorchidism, chordee (downward penis), cleft scrotum or bifid (split in two parts) clitoris, inguinal hernia, rectal prolapse, widely split symphysis pubis, and rotated hips (Stein, 2007).

SIGNS AND SYMPTOMS. The visualization that the bladder is open on the abdominal wall is the main determinant of this condition.

DIAGNOSIS. Ultrasound is the tool used to diagnose exstrophy of the bladder.

NURSING CARE. Surgery is usually necessary within the first 48 hours of the infant's life in this rare disorder. It may need to be delayed due to infant stability or other associated problems. Surgical teams work to preserve the bladder and abdominal wall and to maintain support for the bladder. The bladder may need to be augmented to improve its size and urinary diversion is sometimes required (Kenner et al., 2007).

Nurses must focus on presurgical psychological and medical preparation, as well as postsurgical care. The area must be kept clean because urine on the skin can cause irritation. Diapers should be loose-fitted and changed frequently. The exposed bladder may be covered with Vaseline gauze (Stein, 2007).

Across Care Settings: Bladder exstrophy

Nurses must prepare daycare providers and school nurses to care for infants and children with bladder exstrophy. This may involve proper diapering and hygiene maintenance, education about the congenital anomaly and other associated anomalies and preparation for psychosexual problems that may arise as the child reaches adolescence. Hospital pediatric nurses may need to educate community nurses, who may play a role in educating daycare providers and school nurses.

Now Can You— Discuss functional disorders of the urinary tract?

1. Describe care measures for children who experience enuresis?
2. Explain the importance of nurse's role in community care for children with exstrophy of the bladder?

Reproductive Disorders Affecting Girls

VULVOVAGINITIS

There are various etiologies of vulvovaginitis (inflammation of the vulva and vagina) in prepubertal girls. Candidiasis, a yeast organism, is the most common source of this disorder. Vulvitis (vulvar inflammation) may be isolated or occur with vaginitis, which is vaginal inflammation. The prepubertal girl is sensitive to lack of estrogen, lack of protective hair, and lack of labial fat pads, as well

as the influence of poor hygiene and proximity of the anus to the vulva. Clothing, soaps, and other chemicals may be irritating to vulvar skin. Tight jeans, ballet leotards, nylon tights, underwear, and bathing suits may all contribute to maceration and vulvar infection, especially if the weather is warm and there is associated sweating. It is common for young girls to void with their legs together, which increases the risk of urine refluxing into the vagina. Candidiasis is often associated with bubble baths in young girls, and this may also lead to UTI as well.

Nonspecific vulvovaginitis, without a clear etiology, is found in 25% to 75% of all cases in prepubertal girls. Fecal organisms have been found, and so may be a cause of vulvovaginitis in some cases, due to poor hygiene and possibly wiping back to front, spreading anal organisms. *Candida*, bacteroides, and some other streptococcal species have also been noted. Gram-negative *E. coli* organisms have been cultured from girls with vulvovaginitis, and these may be fecal in origin. Normal flora, including lactobacilli, diphtheroids, and *S. epidermidis*, have been noted on vaginal cultures of vulvovaginitis.

If infections that are sexually transmitted, such as those due to *Neisseria gonorrhoea*, *Chlamydia trachomatis*, *Trichomonas*, herpes simplex, and human papillomavirus are found, there is high suspicion of sexual contact, either voluntary or due to sexual assault.

SIGNS AND SYMPTOMS. Vulvar itching may be the only presenting complaint without a defined etiology. Vaginal candidiasis has notable thick, curdy white discharge and is typically very pruritic. The discharge may also be foul-smelling and brown or green.

DIAGNOSIS. Diagnosis is based on patient history, clinical findings, and pH testing. Pseudohyphae (branching yeast organisms) may be found on microscopy where the pH is < 4.5.

NURSING CARE. If no etiology for vulvovaginitis is determined, the child should be instructed to avoid predisposing factors.

Nursing Insight— Vaginal candidiasis and diabetes mellitus

Recurrent vaginal candidiasis should raise the suspicions of diabetes mellitus.

Treatment of vaginal candidiasis in prepubertal girls is best accomplished with over-the-counter antifungal remedies, such as miconazole (Monistat) and chlortrimazole (Gyne-Lotrimin) creams applied topically, avoiding internal insertion. Nurses should instruct young girls to wipe from the front to the back after voiding in order to avoid contaminating the perineum with stool. Educate patients in the complementary treatments.

Complementary Care: Vaginal candidiasis

- Wear cotton underwear to allow better ventilation.
- Avoid wearing wet clothing, such as bathing suits, for long periods.
- Avoid bubble baths, as well as perfumes or powder near the vaginal area.

Family Teaching Guidelines... Vulvovaginitis

HOW TO:

It may be useful for the nurse to suggest tub baths with clear, warm water one to two times daily for 10 to 15 minutes, followed by washing with a bland soap such as unscented Dove, Basis, Aveeno, or Neutrogena. The soap should not be applied to the vulvar area, and the vulva should never be scrubbed. Avoid shampooing the hair in the bathtub, so the vulva is not exposed to shampoo chemicals. Showering is an option.

After bathing, the nurse should instruct the patient to gently pat dry the vulvar area. Sleeper pajamas are not recommended due to their occlusive nature. Underwear should be all cotton for greater ventilation. They should be washed in mild, unscented detergent without bleach.

Some health care providers recommend a small amount of A+D ointment, Vaseline, or Desitin ointment to be applied to protect the vulvar skin. Loose-fitting clothing is ideal, especially in warm weather.

ESSENTIAL INFORMATION

Persistent discharge is occasionally treated with certain antibiotics in oral form or topical form. Pinworms can be a cause of recurrent vulvovaginitis. Nurses can instruct parents to inspect the anal area of their child at night with a flashlight, or apply a small piece of cellophane tape over the anal area to catch the pinworms (Emans, 2005).

medication: Medications for Candida Vulvovaginitis

Miconazole (Monistat Products)—Antifungal Agent Used Topically in the Vaginal Area

Pregnancy Category: C

- Mechanism: damages fungal cell wall membrane that causes leakage of nutrients
 - Absorption: small amount through vagina
 - Apply topically to external vagina very sparingly once or twice daily in adolescents; can be applied through vaginal applicator in adolescents
- Nystatin (Mycostatin Products)—Antifungal Agent Used Topically in the Vaginal Area

Pregnancy Category: B

Mechanism: Bonds to sterols in fungal cell membrane, causing wall permeability changes

Absorption: Not absorbed through mucous membranes; therefore safer for children and infants

- Gently massage cream or ointment onto skin two to four times per day
- Chlortrimazole (Lotrimin, Mycelex products): Antifungal Agent Used Topically in Vaginal Area

Pregnancy Category: B (topical)

Mechanism of Action: Binds to phospholipids in cell membrane causing cell wall permeability and loss of intracellular contents

Absorption: Negligible through intact skin topically; 3%–10% absorption through intravaginal preparations

- Vaginal cream (Mycelex) 2% bid application external vagina in children older than age 3; vaginal applicator of cream usable in children older than age 12 and adults (Taketomo, Hodding, & Kraus, 2007).

- In menstruating females, avoid using scented sanitary pads or tampons.
- Avoid excessive sugars and simple carbohydrates in the diet.
- Eat yogurt. The natural lactobacilli appears to maintain normal bacterial balance in the GI tract, keeping yeast in check.

Nursing Insight— Vaginal foreign bodies

Insertion of a foreign object, normally by the young girl herself, usually from ages 2 to 9, has been noted to cause vaginal bleeding and/or odiferous and blood-stained vaginal discharge. The problem normally was remedied through removal and a simple Betadine irrigation (Stricker, Navratil, & Sennhauser, 2004). Sexual abuse must be ruled out.

LABIAL ADHESIONS

Labial adhesions are most common in girls from 3 months to 6 years old. This disorder is defined as the fusion of the labia minora, due to inflammation, infection, trauma, and estrogen deficit.

SIGNS AND SYMPTOMS. A thin film develops over the labia, from the posterior aspect to the anterior aspect, and if severe, even the vaginal introitus and urethral meatus are not visible. Any scarring that is not midline or seems very severe and dense should raise the suspicion of child sexual abuse or trauma. Also, intersexed (female and male physical sexual characteristics in the same individual) females may have anatomy that resembles that of labial adhesions.

DIAGNOSIS. Diagnosis is based on signs and symptoms and common associated problems such as dysuria and incontinence if urine is trapped, or dribbling after voiding in toilet-trained girls.

NURSING CARE. The nurse can communicate to the family that the condition may be a spontaneous resolution over time, lysis of adhesions, or treatment with hormone cream, such as Premarin cream 0.625 mg bid for 10 to 14 days. It is also important to inform the family that complications may include UTI due to obstruction of urine flow.

AMENORRHEA

Amenorrhea refers to the absence of menses. Primary amenorrhea is when no menses occur by the age of 17. Secondary amenorrhea implies that menses have been established, but have ceased for a minimum of 3 months. There are several possible causes: corpus luteum cyst, lactation, menopause (premature or normal), hypothyroidism or hyperthyroidism, chemotherapy, polycystic ovarian syndrome (PCOS), diabetes mellitus, stress, excessive exercise, weight loss, and pregnancy (Herban Hill & Sullivan, 2004). Pregnancy must always be considered as a cause of secondary amenorrhea, even if the patient denies sexual contact.

The etiologies of primary amenorrhea include agenesis (no formation) of the uterus, Turner's syndrome (genetic disorder with pectus excavatus, heart murmur, and short stature), imperforate hymen, and constitutional delay.

Certain medications can cause amenorrhea, including chemotherapy and medroxyprogesterone acetate (Depo Provera), which is given as a contraceptive injection.

SIGNS AND SYMPTOMS. In primary amenorrhea, the patient may exhibit abnormalities in body habitus, suggestive of delayed puberty. The Tanner stages of sexual characteristic development may show delays. In cases of secondary amenorrhea, signs and symptoms of pregnancy include mastalgia (breast tenderness); breast enlargement; nausea and possibly vomiting, especially in the early morning; gastrointestinal upset; and urinary frequency. On examination, the uterus may be enlarged and Chadwick's sign (blue or violaceous cervix) may be present, a probable sign of pregnancy that becomes evident about the fourth week of gestation.

In hypothyroidism, the patient may have dry skin, dry hair, fatigue, hoarseness, constipation, and an enlarged thyroid gland. In hyperthyroidism, the patient may exhibit oily skin and hair, diaphoresis, tachycardia, diarrhea, and a goiter (enlarged thyroid gland).

Patients with polycystic ovarian syndrome may have hirsutism (excessive facial and bodily hair) and obesity. Corpus luteum cysts tend to cause pain in the lower quadrants that may be intermittent in nature, as some cysts resolve spontaneously. Other cysts grow and may rupture, causing significant lower quadrant abdominal pain and even peritoneal signs of rebound, guarding, and rigidity.

DIAGNOSIS. In the absence of menses, a number of laboratory tests and other diagnostic tests are often necessary in the diagnostic evaluation of amenorrhea.

diagnostic tools Determining Reason for Amenorrhea

- Genetic testing may be required to determine disorders such as Turner's syndrome.
- Pelvic ultrasound or transvaginal (ultrasound wand in the vaginal canal) is used to test for pregnancy, ovarian cysts, and other gynecological abnormalities. Patients normally are required to drink four 8-ounce glasses of water 1 hour before a pelvic ultrasound to elevate the bladder in order to view the pelvic organs.

Labs: Tests for Amenorrhea

- Urine pregnancy test (urinary HCG): these tests are widely available over-the-counter but more sensitive tests are available in clinical facilities.
- Serum pregnancy test (qualitative or quantitative tests show positive pregnancy and approximate duration of pregnancy, respectively). Considered more accurate than urine pregnancy tests and identify pregnancy earlier.
- Thyroid stimulating hormone (TSH) is a general test for hypothyroidism and hyperthyroidism. This may be accompanied by a free thyroxine (T4) test to specify the disorder more clearly.
- Prolactin level: elevated in hyperprolactinemia, which may be seen with hypothyroidism or with a benign pituitary adenoma. Prolactin is a hormone produced in the pituitary gland and is associated with breastfeeding.
- Levels of follicle stimulating hormone (FSH) may be low in PCOS.
- Levels of luteinizing hormone (LH) may be elevated in PCOS.
- Testosterone levels may be high in PCOS, in addition to dehydroepiandrosterone (DHEA) levels.

NURSING CARE. The nurse must realize that some adolescent girls are unaware that pregnancy is possible with just genital contact. Often pregnant adolescents may be in a state of denial. The nurse should evaluate the patient with amenorrhea for signs and symptoms of pregnancy first, including weight gain, unprotected coitus, fatigue, nausea and vomiting, and mastalgia (tender breasts). A urinary human chorionic gonadotropin (hCG) test may be run and may turn positive within days after a missed menses. In cases of possibly false-negative urine pregnancy tests, it is necessary to administer the serum HCG test to determine pregnancy status. If a parent is present with a girl who may be pregnant, the nurse should attempt to have the parent wait outside in order to speak confidentially to the adolescent girl, by suggesting that at this age, it is common to interview young women alone. Invite the parent or guardian back at the conclusion of the discussion. This sometimes allows the opportunity for a young woman to discuss the possibility of pregnancy or her concerns about contraception and sexually transmitted diseases (STDs).

The nurse can also assist the patient in constructing a calendar depicting her abnormal menstrual pattern. Young girls often need to be educated about variations in menstrual cycles, and why it is essential that they keep track of their cycle days, intervals, and duration. Girls who have eating disorders such as anorexia nervosa or bulimia may incur secondary amenorrhea due to weight loss and associated alterations in estrogen. When body fat significantly decreases, amenorrhea or oligomenorrhea (infrequent menses) may occur. Young girls who exercise heavily (gymnasts or distance runners) may develop menstrual disorders, as well as young girls with eating disorders.

In the circumstance of adolescent females, those with primary amenorrhea may have family members who have experienced the same issue.

Nursing Insight— Imperforate hymen

In cases of imperforate hymen (without opening), a surgical intervention is required. If laboratory testing is normal, many amenorrheic patients are given a trial of medroxyprogesterone acetate (Depo Provera), 5 or 10 mg daily for 5 or 10 days in 1 month, in an attempt to elicit the menses by causing a progesterone withdrawal bleed. Some patients are placed on oral contraceptive agents to regulate the menses and cause a monthly withdrawal bleed (Herban Hill & Sullivan, 2004).

Reproductive Disorders Affecting Boys

VARICOCELE

Varicoceles are defined as abnormal dilations in the testicular veins, normally unilateral and affecting the left testicle. Most arise after age 9, and 16% of adolescents and 15% to 20% of adult males have varicoceles. The etiology of this disorder remains unknown, but it is considered now the most common cause of male infertility that is correctable.

SIGNS AND SYMPTOMS. Frequently, varicoles are said to feel like a “bag of worms,” although while still in the smaller stages, they may only feel like thickened spermatic cords.

assessment tools Valsalva Maneuver

Assessment is made by noting distended veins in the scrotum on standing, accentuation of the veins with the Valsalva maneuver, and decrease in visibility of the varicocele when in the supine position. The testes are often smaller in varicocele.

DIAGNOSIS. Doppler ultrasonography may help to definitively determine the presence of varicocele.

NURSING CARE. Surgical ligation (binding or tying) of the spermatic veins is the curative approach to preserve fertility. This must be considered in adolescent males (Elmore & Kirsch, 2006). Nursing care centers on caring for the postsurgical patient.

CRYPTORCHIDISM

Cryptorchidism is defined as absent, undescended, or ectopic testicles. This is the most common male congenital anomaly, noted in 1% of all newborns. It may result from hormonal, anatomical, or chromosomal variations. Prematurity increases the risk of cryptorchidism. Intersex conditions such as congenital adrenal hyperplasia may be associated. In 80% of the cases, the testicles are palpable but undescended, and the scrotal sac is empty, as well as potentially flat or small. This must be distinguished from retractile testes, which are descended testicles that rise up into the groin area, but can be pushed down into the scrotum. Retractable testes are very common in young males. The remaining 20% of cases are nonpalpable testes, which may actually be in the abdomen or inguinal area, or may not be present at all.

The major risk associated with cryptorchidism is testicular cancer, which remains a lifetime risk even if the child has surgical repair. There is also risk of decreased fertility, testicular torsion, and increased trauma. If the testis does not descend permanently by age 6 months, surgical intervention is needed. All patients with a history of cryptorchidism must be vigilant with testicular self-exam and have annual testicular exams by a health care provider.

SIGNS AND SYMPTOMS. A retractile testis has descended but retracts with exam and physical stimulation. An ectopic testis is outside of the normal pathway (e.g., in the groin, abdominal wall, or perineum). After 1 year of age, it is uncommon for the testes to spontaneously descend. In 85% of affected males, the undescended testicle is unilateral and on the right.

DIAGNOSIS. Diagnosis is based on patient history, physical examination findings, and imaging tests.

NURSING CARE. The surgical repair is termed orchiopexy and is usually done between ages 1 and 2. Gentle compression of the inguinal canals should reveal a palpable nodule in undescended testicles (Fig. 32-7).

Nursing Insight— Cryptorchidism

Observation and occasional use of hCG to stimulate testosterone production may be suggested. The nurse understands that deficient knowledge of the caregiver may exist. It is important to communicate to the caregiver that use of hCG may be alarming, in that penile growth, augmented pigmentation, and pubic hair may result. The nurse also recognizes that the caregiver may have anxiety due to the risk of testicular cancer and decrease fertility.

Figure 32-7 An undescended testis is palpable in various areas and needs to be surgically corrected.

Surgical treatment may involve use of dissolving sutures with a Tegaderm dressing (transparent dressing) over the wound. The nurse should instruct the caregiver to have the child wear loose clothing to increase comfort; use appropriate analgesics as ordered, including acetaminophen (Children's Tylenol); and observe for erythema, purulent discharge, fever, and increased pain at the incision site as potentially indicative of infection. The nurse should instruct the caregiver to change diapers more frequently and to avoid having the older child engage in any sports or straddle riding toys that might injure the surgical site (Kenner et al., 2007).

Nursing Insight— Hydrocele

A hydrocele is a collection of fluid in the scrotal sac, related to a patent processus vaginalis, which is the channel that gives fluid the ability to move from abdomen to groin. Peritoneal abdominal fluid can pass into this patent canal, enlarging the scrotal sack. This canal is patent in up to 80% of all newborns at birth, but by the first month of life, the incidence decreases to 60% and by the age of 18 to 24 months, the incidence decreases to 20% to 30%. While this condition can rarely occur in females, primarily in intersex conditions, it is common enough in males that it must be repaired if it has not resolved by 1 year. If a hernia is found with it, earlier surgical repair is necessary.

HYPOSPADIAS AND EPISPADIAS

Hypospadias and epispadias are possibly genetic congenital conditions that implies an abnormal positioning of the urethral meatus in boys. In hypospadias, the meatus is inferior to its usual position. In epispadias, the meatus is superior to its usual position and a surgical correction with possible penile urethral lengthening may be necessary (Montagnino & Currier, 2005). Hypospadias may cause chordee, which is a bending of the penis that may later present problems with intercourse. Young males with hypospadias may not be able to urinate standing and there may be associated cryptorchidism. Patients need to be referred early to pediatric urologists for surgical repair.

SIGNS AND SYMPTOMS. Signs and symptoms of hypospadias include opening of the urethra below the tip on the bottom side of the penis, incomplete foreskin, curvature of the penis during erection, and abnormal position of the scrotum in relation to the penis. Signs and symptoms of epispadias are opening of the urethra above the tip of the penis, curvature of the penis, and urinary incontinence.

DIAGNOSIS. Diagnosis is based on patient history, physical examination findings, radiography, and ultrasound.

NURSING CARE. Surgery is usually performed before the child is 18 months old and before toilet training. Techniques reconstruct the penis to lengthen the urethra and bring it to the distal penis shaft. The chordee is straightened and often foreskin is used as a graft, so children born with hypospadias cannot be circumcised. The child may have a urethral stent or Foley catheter in place to allow urine drainage due to potential obstruction of voiding from surgical edema. A compression dressing termed a penile wrap may be used. The nurse may need to instruct the caregiver to have the child soak in warm water for 20 minutes before the surgical follow-up appointment in order to loosen the dressing. Potential surgical complications include urethral fistula (an opening that allows urine to leak to the surface), return of the meatus to its original site postsurgically, and strictures at the site of the anastomosis (Kenner et al., 2007).

In patients with hypospadias and epispadias surgical repairs are at risk of acute infection. The penile incision must be monitored for signs of infection (e.g., purulent discharge, fever, erythema). Also watch for evidence of UTI (fever; cloudy, foul urine; and hematuria). These pediatric patients also often suffer acute pain related to bladder spasm, incisional pain, and pain related to infection. Oxybutynin chloride (Ditropan) is an anticholinergic medicine that may relieve bladder spasm. Adverse effects of Ditropan include dry mouth and flushed facies.

Nurses must recognize that parents of these children may be deficient in knowledge about the defects and their repair. The nurse should assess the parent's feelings about having a child with a congenital defect (Kenner et al., 2007).

Nursing Insight—Gynecomastia

Sixty percent of males may have temporary gynecomastia (breast enlargement) during puberty. This often coincides with one side of the scrotum growing faster than the other (Kenner et al., 2007).

Gynecomastia may be one of four types:

- Type I is considered benign and self-limited. It occurs during Tanner stages II and III, and most cases are unilateral. The problem may persist for 2 years.
- Type II is painful gynecomastia without any associated disease.
- Type III is gynecomastia that results from obesity.
- Type IV is related to hypertrophy of the pectoral muscles.

Type I gynecomastia has an uncertain etiology, but is thought to be related to an imbalance in estrogen and testosterone levels, or to increased prolactin levels, or possibly to abnormal serum-binding protein levels. The incidence is between 50% to 60% of all males, normally between the ages of 12 and 14. Commonly, a 1 cm to 3 cm mobile, firm, and round mass is palpable proximal to and beneath the areola. An enlarging mass or a mass that persists more than 2 years requires a diagnostic work-up to consider the differential diagnoses of breast tumor, Klinefelter's syndrome (decreased facial hair, eunuch body, normal or borderline low IQ, and micro-orchidism), drug-induced gynecomastia, and thyroid disease (Herban Hill & Sullivan, 2004).

“What to say” — Gynecomastia

- Teach the patient and parents that gynecomastia is usually a temporary condition.
- If obesity is an issue, the nurse should work with the patient and family members to establish an age-appropriate dietary plan. Referral to a nutritionist may be useful.
- Explain to the family and patient that it may be necessary to have certain blood tests to eliminate any risk of pathological causes of the gynecomastia.
- The nurse can discuss ways the child can respond to hurtful comments from other children.

TESTICULAR TORSION

Testicular torsion is considered an emergency and surgical intervention must occur within a 4- to 8-hour time frame from the onset of symptoms, or the patient risks the need for orchiectomy (testes resection). Loss of one testis through orchiectomy has been documented to decrease sperm counts and reduce fertility. This emergency condition is most common in growing males between the ages of 10 and 19 (Mansback, Forbes, & Peters, 2005).

During the neonatal period, testicular torsion can occur because the processus vaginalis about the spermatic cord and testis can twist, causing partial or complete vascular compromise. In ages above the neonatal period, the etiology of testicular torsion is distinct; the testicle normally is attached to the tunica vaginalis, but periodically, the testicle is not attached and it hangs free to twist around the spermatic cord. This can cause torsion with painful ischemia and loss of the testis. Testicular torsion is the cause of 16% to 27% of all cases of acute scrotal pain, and thus it must be ruled out in all cases (Cole & Vogler, 2004).

SIGNS AND SYMPTOMS. Neonates present distinctly from older males with testicular torsion. In the neonate, the scrotum appears dusky colored, a solid mass is palpated, scrotal edema prevents transillumination (inspect the testis by passing a light through the scrotum), and there is minimal or no pain from testicular motion. Older males normally have severe and persistent pain, although it may begin gradually. Trauma and physical exertion may promote the development of torsion, but it may occur without any etiology. The pain may be severe enough to awaken patients at night and prevent ambulation. It is possible to have intermittent torsion, which resolves itself, but eventually a patient may develop full, emergency torsion. Fever, anorexia, nausea, and vomiting may accompany the condition (Cole & Vogler, 2004).

critical nursing action Testicular Torsion

Essential clinical signs and symptoms the nurse should look for:

- The torted testicle may be lying horizontally or appear higher in the scrotal sack than the opposite testicle.
- Although most commonly, the situation is unilateral, it may be bilateral. Scrotal edema is usually present within 12 hours.
- Especially in the neonate, the testicle may feel quite hard.

- One way to differentiate the diagnosis of testicular torsion is to attempt to elicit the cremasteric reflex, which is normally absent on the torsion side.
- Prehn's sign, which is relief of pain from elevating the testicle, is also usually absent in torsion (Cole & Vogler, 2004).

DIAGNOSIS. Diagnosis is based on patient history, physical examination findings, and Doppler ultrasonography.

diagnostic tools Testicular Torsion

Doppler ultrasonography is the preferred diagnostic test, and it should be ordered immediately. In testicular torsion, the testicle may be enlarged and may reveal decreased or absent blood flow. The Doppler test can also differentiate between ischemia and inflammation, such as that seen in orchitis (inflammation of a testis) and epididymitis (inflammation of the epididymis) often associated with gonorrhea. In the case of possible false-negative results on Doppler ultrasound, a technetium scintigraphy test shows definitive testicular torsion (Ringdahl & Teague, 2006).

NURSING CARE. Manual detorsion (surgery for torsion of a testicle) by the urologist can be done with sedation and local anesthesia to provide immediate mitigation of pain (Ringdahl & Teague, 2006). Surgical consultation is always necessary and if the surgery is not performed within the 4- to 8-hour window, orchiectomy may be required. According to Gaylord and Starr (2004), the rate of saving the testicle drops steadily after 3 hours, and testicular atrophy, abscess, total loss of the testicle from necrosis, and loss of fertility may occur particularly if torsion is present for 24 hours or longer.

Reproductive Disorders Affecting Both Girls and Boys

AMBIGUOUS GENITALIA

Approximately 1 out of 2000 newborns are born in the United States with ambiguous genitalia, which cannot be properly identified as either male or female genitalia. In males, it is more typical to have underdeveloped genitalia and in females, overdeveloped genitalia are more common (Fig. 32-8). The etiology may be related to fetal or maternal hormonal imbalances.

SIGNS AND SYMPTOMS. Signs and symptoms include external reproductive organs that are not easily identified as male or female (Venes, 2009).

DIAGNOSIS. Diagnosis can include a family history of congenital adrenal cortical hyperplasia, amenorrhea and infertility in aunts, or maternal history of prostaglandin, androgen, or danazol (Danocrine, a synthetic androgen used for endometriosis) use. Diagnosis is also based on the fact that the infant has both ovaries and testes. The external genitalia may vary from fully masculine to nearly fully feminine.

NURSING CARE. The nurse may assist the patient's family by suggesting endocrinology and genetic referrals. Some patients with ambiguous genitalia become surgical candidates (Gray & Campbell, 2002).

Figure 32-8 Ambiguous genitalia.

Now Can You— Discuss reproductive disorders in girls and boys?

1. Explain family teaching measures for vulvovaginitis?
2. Describe causes of secondary amenorrhea?
3. Examine care measures for hypospadias and epispadias?
4. Discuss ambiguous genitalia?

summary points

- ◆ Pediatric nurses must be aware of the pathophysiology of the renal system, common and uncommon renal disorders, and also associated reproductive anomalies that can occur in children.
- ◆ Assessment is a priority nursing action when caring for the child with a fluid and/or electrolyte imbalance. The astute nurse must recognize fluid deficit and excess as well as electrolyte imbalance and then provide the proper care.
- ◆ Urinary tract infection is the second most common form of bacterial infection in children, ranking only behind upper respiratory problems. It is thought that 8% of girls and 2% of boys will have a UTI during childhood.
- ◆ The major risk of vesicoureteral reflux (VUR) is the development of acute pyelonephritis, due to the back-flow of urine toward the kidney.
- ◆ The most common etiologies for gross hematuria included hypercalciuria with or without stones, hypertension, and glomerulonephritis. However, it is significant to note that asymptomatic microhematuria had no identifiable cause in the majority of patients.
- ◆ Glomerular disease can be due to primary kidney disease or secondary multisystem diseases that cause damage to the glomerulus. Both primary and secondary diseases are accompanied with histological evidence that captures the glomerular damage and resultant clinical manifestations and needed treatment.
- ◆ Hemolytic uremic syndrome (HUS) is considered the most common cause of acute renal failure (ARF) in children. Hemolytic uremic syndrome (HUS) is most

commonly associated with children ingesting beef contaminated with *Escherichia coli* (*E. coli*).

- ◆ Abnormalities of the urinary tract system ultimately affect the kidneys. The abnormalities may be anatomical, infectious, cellular, inflammatory, functional, or maturational.
- ◆ The most common causes of renal trauma are motor vehicle accidents.
- ◆ Collaboration with the health care team is critical so that acute renal failure complications are reduced or prevented from occurring depending on whether the etiology is prerenal, intrarenal, or postrenal.
- ◆ The goals of nursing care for a patient with chronic renal are mutually established with the patient and family. Collaboration with the health care team is essential so that the quality of life can be extended as long as possible as the renal capacity diminishes and affects all organ systems.
- ◆ Children in need of a renal transplant are placed on a waiting list and are registered with the United Network of Organ Sharing (UNOS), which keeps a computer network to link all organ donation centers and transplant centers.
- ◆ Nurses can assist in helping children with dysfunctional elimination syndrome (DES), by identifying issues, asking the child at various times of day if he or she has voided, and asking if children can hold their urine if a bathroom is not always available. Nurses should assess for any emotional or social problems resulting from a child's embarrassment or shame associated with voiding dysfunction.
- ◆ There are a variety of reproductive disorders in girls such as vulvovaginitis, vaginal foreign bodies, labial adhesions, and amenorrhea.
- ◆ There are a variety of reproductive disorders in both girls and boys such as ambiguous genitalia.
- ◆ There are a variety of reproductive disorders in boys such as varicocele, cryptorchidism, hydrocele, hypospadias and epispadias, gynecomastia, and testicular torsion.

review questions

Multiple Choice (Select all that apply.)

1. The pediatric nurse is providing critical information about a 3-year-old who was admitted to the unit with a urinary tract infection to a group of nursing students. Which of the following classic clinical signs and symptoms of urinary tract infection would be discussed?
 - A. Dysuria
 - B. Frequency
 - C. Urgency
 - D. Abdominal pain
2. The pediatric nurse is writing a comprehensive nursing care plan about chronic renal failure. Which of the following nursing diagnosis(es) would be

essential for the nurse to include in the nursing care plan?

- A. Fluid Volume Deficit related to compromised regulatory mechanism.
 - B. Imbalanced Nutrition Less than Body Requirements related to anorexia.
 - C. Risk for Infection related to lowered body defenses.
 - D. Disturbed Body Image related to growth delays.
3. The pediatric nurse is providing health promotion teaching to a child and family related to the care of a newly acquired arteriovenous fistula for hemodialysis treatment. Which of the following should be included in the teaching?
 - A. Wash the access with soap and warm water each day, and always before dialysis.
 - B. Check the area daily for signs of infection, including warmth and redness.
 - C. Take care to avoid traumatizing the arm; no tight clothes or jewelry on the arm.
 - D. Remind health care providers not to take blood pressure on the access arm.

Case Study

4. A 2-year-old child who weighs 33 lb. (15 kg) is admitted with a kidney infection and is receiving intravenous fluids based on her weight. Which of these infusion rates based on the fluid maintenance calculation would the pediatric nurse follow?
 - A. IV fluids infusing at 47 mL/hr
 - B. IV fluids infusing at 52 mL/hr
 - C. IV fluids infusing at 58 mL/hr
 - D. IV fluids infusing at 73 mL/hr
5. The nurse assesses a 7-year-old and notes petechiae and ecchymosis scattered on the abdomen, arms, and legs. The mother states that the child has become progressively lethargic over time. The nurse also notes that laboratory results of the stool culture are positive for *E. coli*. The nurse suspects that the child has:
 - A. Hemolytic uremic syndrome
 - B. Poststreptococcal glomerulonephritis
 - C. Henoch-Schönlein purpura
 - D. Urinary tract infection

Fill-in-the-Blank

6. The child who is in acute renal failure will have an _____ in the serum potassium level, an _____ in the sodium serum level, a _____ colored urine, and proteinuria. Since hydrogen ions cannot be excreted, a state of _____ will result.
7. In North America, the most common cause of acute renal failure in children is _____ due to the pathogen, _____.
8. _____ can be the cause of recurrent vulvovaginitis. Parents are taught to apply a small piece of _____ over the anal area to detect the _____.

True or False

9. The pediatric nurse is aware that urinary tract infections are the second most common form of bacterial infection in children.
10. Circumcision increases the risk of urinary tract infections in boys.
11. Hematuria is considered the cardinal marker of renal injury in children.
12. When acute renal failure is considered to be permanent and fatal, it is called chronic renal failure.
13. Children whose status is postrenal transplant receive immunosuppressive medications to help prevent them from developing infections.
14. In most cases, children who receive kidney transplants can be on a regular diet once the transplant is accepted.

CONCEPT MAP

Caring for the Child with a Hematological Condition

A Nurse's Wish

To be a nurse requires dedication,
With years of study and preparation.
I pray for guidance and humbly ask,
That I will do well with this chosen task.

When illness strikes or pain demands,
And a life is placed within my hands,
Give me compassion, knowledge and skill
To do the things that comfort and heal.

Suffering makes patients' fear grow worse
And they seek reassurance from their nurse.
Help me see things from their point of view
And always to know what is best to do.

May I have a part, in some small way,
In restoring good health to a child today.
Let my work be all that I want it to be—
I ask the great healer to work through me.

—Author Unknown

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Describe the hematopoietic system.
- ◆ Explain the basic components and functions of the blood.
- ◆ Discuss factors that cause deviations in normal laboratory values.
- ◆ Identify common hematological conditions in children.
- ◆ State the common signs and symptoms associated with hematological conditions, as well as diagnostic criteria.
- ◆ Discuss the nursing care of children with hematological conditions.
- ◆ Review the treatment options for children with hematological illnesses.
- ◆ Discuss blood transfusion therapy, apheresis, and thrombosis.

moving toward evidence-based practice Sickle Cell Patients with Acute Chest Syndrome and the Incidence of Asthma

Bryant, R. (2005). Asthma in the pediatric sickle cell patient with acute chest syndrome. *Journal of Pediatric Health Care, 19*(3), 157–162.

The purpose of this study was to determine whether there was an increased frequency of asthma in children who experienced acute chest syndrome (ACS) as a complication of sickle cell disease (SCD). Previous studies cited in the literature found that ACS accounts for 25% of premature deaths in children with SCD and that ACS is four times more likely to develop in children who also have asthma. ACS can be precipitated by cell sickling, which in turn may be a response to the pathogenesis associated with asthma.

The retrospective study included a descriptive chart review to identify the frequency of asthma in SCD patients admitted with ACS over a 5-year period. The diagnosis of ACS was determined using records from emergency room visits and hospitalizations at a children's hospital and a children's sickle cell clinic. All charts were reviewed for the variables of age, gender, race, length of hospital stay, type of sickle hemoglobinopathy, hemoglobin level, pulmonary function test results, and history of asthma. Children diagnosed with asthma that occurred after the ACS episode were not included. Records from a total of 60 children were included in the study.

Study participant data:

- Ninety-two percent of the children were diagnosed with Hgb SS.
- Five percent of the children were diagnosed with Hgb SC.
- Three percent of the children were diagnosed with Hgb SB thalassemia.
- The vast majority (58) of the children were of African American descent; two were described as being of Hispanic descent.

- The children's ages ranged from 1.5 to 17 years, with a mean age of 8.4 years.
- Fifty-five percent of the participants were females.
- The children's hemoglobin levels ranged from 4.4 to 12.1 g/dL, with a mean of 7.7 g/dL.
- Fifty-three percent of the children with SCD had a diagnosis of asthma or abnormal pulmonary function tests before the diagnosis of ACS
- Children with a previous diagnosis of asthma had a mean Hgb of 7.7 g/dL.
- Children with no prior diagnosis of asthma had a mean Hgb of 7.6 g/dL.
- The mean length of hospital stay for children admitted with ACS with a prior diagnosis of asthma was 6.4 days; for children with no prior diagnosis of asthma, it was 8.6 days.

There were no significant differences in the children's age, gender, Hgb levels, or length of stay. There was no significance difference between male and female children with SCD with or without a prior diagnosis of asthma before the development of ACS.

1. What might be considered as limitations to this study?
2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

A hematological disorder in a child can have various causes, including injury, nutritional deficit, genetic disorder, infection, congenital problem, or any number of blood-related conditions. A thorough history and physical examination are essential in the diagnosis and care of the child with a hematological disorder, as the condition can be insidious in nature. A variety of tests can be performed to determine the functional status of the hematological system and proper care can then be provided for the child. To understand the disorders affecting children that involve the hematological system, it is imperative to comprehend the normal function of the blood and formed elements.

cellular portion consists of the formed elements (red blood cells [RBCs], white blood cells [WBCs], and platelets).

The primary function of the RBCs (erythrocytes) is to transport hemoglobin that carries oxygen from the lungs to the tissues. The life span of a normal RBC is approximately 120 days (Hermiston & Mentzer, 2002).

Leukocytes (WBCs) are mobile units of the body's protective system. Most leukocytes migrate to areas of serious inflammation and provide a rapid defense against any foreign agent. WBCs are also important in immune system mediation. The life span of a leukocyte is specific to the cell type.

Megakaryocytes are cells that give rise to platelets. Platelets are small fragments of megakaryocytes. Platelets are the smallest of all formed blood elements and are not really cells because they do not possess a cellular structure. The primary function of platelets is hemostasis and vascular repair after injury to a vessel wall. Platelets aggregate to form a plug. Their life span is approximately 7–10 days (Nathan, Orkin, Ginsburg, & Look, 2003). Almost a third of all circulatory platelets can be found normally in

AU: Pls provide a title.

A & P review Hematopoietic System

Blood is composed of two parts: the fluid portion called plasma and the cellular portion. The solutes in the plasma include albumin, electrolytes, proteins, clotting factors, fibrinogen, globulins, and circulating antibodies. The

the spleen. In normal circumstances, platelets are removed by the liver and spleen in 10 days if not utilized in a clotting reaction (Turgeon, 2005). ♦

Common Hematological Conditions

Several common hematological conditions can occur in children. Some of these are acute in nature and with proper care can be easily managed. Others can be life-threatening or cause a chronic illness that can permanently impact the lifestyle of the child and his or her family. It is essential that the nurse understand the necessary care and important teaching aspects associated with these conditions.

ANEMIA

One of the most common hematological conditions of infancy and childhood is anemia (a decrease in the number of red blood cells [RBCs]). The reduction in circulating RBCs, decreases the oxygen-carrying capacity of the blood. For the majority of patients, anemia is not a disease, but rather a symptom of other diseases.

Nursing Insight— Causes of anemia

- Decreased production of RBCs such as in bone marrow failure and myelodysplastic syndromes
- Increased destruction of RBCs such as sickle cell anemia or hereditary spherocytosis
- Acute or chronic blood loss

Note: It is important to identify the cause of anemia so that the treatment plan can be tailored to the child's specific needs.

Signs and Symptoms

Anemia may be insidious and the child may be asymptomatic due to compensatory mechanisms. The child with mild anemia may be asymptomatic and not diagnosed until blood work is obtained. The initial signs of anemia vary: fatigue, shortness of breath, headache, difficulty concentrating, dizziness, and pale skin. The child with moderate to severe anemia will have overt signs and symptoms: irritability, fatigue, delayed motor development, tachycardia, shortness of breath, decreased activity level, pale skin, listlessness, systolic heart murmur, hepatomegaly, and/or congestive heart failure (Nathan et al., 2003).

clinical alert

Screening guidelines

According to the recommendations in the American Academy of Pediatrics screening guidelines, hemoglobin and hematocrit should be evaluated once during infancy (6–9 months of age), early childhood (1–5 years of age), late childhood (5–12 years of age), and adolescence (14–20 years of age). This screening schedule should identify children who may benefit from treatment for anemia.

Diagnosis

For the child diagnosed with anemia, a thorough history and physical examination are essential to establish a possible etiology. Complete blood count (CBC) and reticulocyte count are obtained to evaluate the hemoglobin and hematocrit. Anemia exists when the hemoglobin content is less than required to meet the oxygen demands of the body.

Nursing Insight— Hemoglobin and hematocrit

Hemoglobin is the iron-containing pigment of the RBC that carries oxygen from the lungs to the tissues. The hemoglobin level is measured as the amount of hemoglobin per deciliter of whole blood. The average hemoglobin in the blood varies based on the age and gender of the individual.

Normal hemoglobin (Hgb) (g/dL) lab values for children are:

Newborn: 12.7–18.6

2 Months: 9.0–14.0

2 Years: 10.5–12.7

6–12 Years: 11.2–14.8

12–18 Years: 10.7–15.7

The hematocrit is the percent of whole blood that is composed of RBCs. The hematocrit measures both the number and size of the RBCs and is approximately three times greater than the hemoglobin value.

The hematocrit indirectly measures the hemoglobin. The average hematocrit value is between 35% and 45% (Gilbert-Barnes & Barnes, 2003).

A child's CBC measures the formed elements in the blood, including RBCs, WBCs, and platelets, providing valuable information with regard to illnesses and disease processes that may be occurring. In addition to the quantitative analysis, the blood cells of the CBC can also be evaluated for shape, size, and color.

Labs: Blood Values According to Age

The nurse needs to be knowledgeable about the age-specific norms for the child. Based on the child's age, there may be variations in expected ranges (Tables 33-1, 33-2, and 33-3). It is unacceptable to use generic adult values.

Labs: Complete Blood Count, Reticulocyte, and Peripheral Smear Lab Values for Children

When evaluating the presence of anemia, initial laboratory tests should include complete blood count (CBC) and a reticulocyte count. The CBC includes hemoglobin, hematocrit, RBC indices, platelet count, WBC count with a differential, and a peripheral smear to examine the morphology of the RBCs. For the patient with suspected anemia, the peripheral blood smear is imperative to confirm the appropriate diagnosis (Gilbert-Barnes & Barnes, 2003).

Nursing Care

Nursing care for a child with anemia varies based on the etiology. To effectively replenish the RBCs, the underlying cause must be identified. For children with mild anemia, the nurse can provide supportive care through diet or

Table 33-1 Lab Blood Values According to Age

Age/Blood Component	Newborn	2 Months	2 Years	6–12 Years	12–18 Years	Comments
Red blood cells (RBCs)	4.1–5.74	2.7–4.9	3.9–5.03	4.93–5.3	3.7–5.5	Measure of bone marrow function
Hemoglobin (Hgb) (g/dL)	Newborn 12.7–18.6	9.0–14.0	10.5–12.7	11.2–14.8	10.7–15.7	Amount of hemoglobin/dL of whole blood
Hematocrit (Hct) (%)	37.4–56.1	28.0–42.0	31.7–37.7	34.0–43.9	33.0–46.2	Percentage of packed RBC to whole blood, approximately three times the Hgb content
White blood cells (WBCs)	6.8–14.3	5.0–19.5	5.3–11.5	4.5–10.1	4.4–10.2	Differential count is more important than the total number of WBCs
Platelets ($\times 10^3/\text{mm}^3$ [μl])	164–586	164–586	206–459	189–403	175–345	Platelets contribute to blood clotting

Table 33-2 Normal White Blood Cell Differential Count According to Age

Age/White Blood Cell Component	Function	Newborn	2 Months	2 Years	6–12 Years	12–18 Years
Neutrophils (%)	Phagocytosis	19–49	15–35	13–33	32–54	34–64
Eosinophils (%)	Allergic reactions	0–4	0–3	0–3	0–3	0–3
Basophils (%)	Inflammatory reactions	0–1	0–1	0–1	0–1	0–1
Lymphocytes (%) (B cells and T cells)	Humoral immunity (B cell) and cellular immunity (T cell)	38–46	42–72	46–76	27–57	25–45
Monocytes (%) (macrophages)	Phagocytosis and antigen processing	0–9	0–6	0–5	0–5	0–5

Table 33-3 Red Cell Lab Values for Children

Test	Reference Range	Comments
Mean corpuscular volume (MCV)	79–95 μm^3	Average size of a single RBC, expressed as cubic microns (μm^3)
Mean corpuscular hemoglobin (MCH)	25–33 pg/cell	Average weight of the Hgb within a RBC, expressed in picograms (pg)
Mean cell hemoglobin concentration (MCHC)	31%–37% Hgb [g]/dL RBC	Average concentration of Hgb in each RBC
Reticulocyte count	0.5%–1.5%	Measure of the production of mature RBCs by the bone marrow
Peripheral smear	Size, shape and structure of the RBCs, as well as an estimate of the amount of Hgb in the RBCs	Can indicate variations in size and shape of RBCs, microcytic, macrocytic, or normocytic

vitamin supplement. Children with moderate to severe anemia may need a RBC transfusion to restore blood volume. For specific types of anemia such as decreased production of RBCs, the nurse can administer hematopoietic growth factors that may prove beneficial in decreasing the need for blood transfusions.

Proper instructions from the nurse are necessary for children with anemia. The teaching required for a child with a chronic illness is more extensive than for

the child who has an acute self-limiting episode of anemia. The family must be made aware of the clinical signs and symptoms that may indicate anemia. The nurse can teach the family that alterations in daily activities may be necessary such as quiet play, allowing for periods of rest, and a diet high in iron. The child with anemia may also need to have laboratory tests and medical exams periodically to evaluate the status of the anemia.

Nursing Insight—Evaluating a CBC

Blood Elements	Increase	Decrease
RBC (Hgb/Hct)	Polycythemia	Anemia
WBC	Leukocytosis	Leukopenia
Platelets	Thrombocytosis	Thrombocytopenia

IRON-DEFICIENCY ANEMIA

The most prevalent nutritional disorder worldwide is iron-deficiency anemia. Iron-deficiency anemia is defined as a microcytic, hypochromic anemia caused by an inadequate supply of iron (Nathan et al., 2003). Iron is essential for the production of hemoglobin. When iron stores are inadequate, the production of hemoglobin is diminished. As a result of the decrease in hemoglobin, there is a decreased oxygen-carrying capacity of the blood. Iron-deficiency anemia is more common in infants. Premature infants are at high risk due to their decreased fetal iron supply (Nathan et al., 2003). Approximately 10% to 20% of infants and toddlers have some type of iron-deficiency anemia, with a greater incidence in children at or below poverty level.

Across Care Settings: Women Infants and Children (WIC) program

Since the implementation of the Women Infants and Children (WIC) program, the incidence of iron-deficiency anemia has decreased. WIC serves 45% of all infants born in the United States.

The target populations for WIC participants who need nutritional counseling are low-income women with nutritionally at risk children:

- Pregnant women (through pregnancy and up to 6 weeks after birth or after pregnancy ends)
- Breastfeeding women (up to infant's 1st birthday)
- Non-breastfeeding postpartum women (up to 6 months after the birth of an infant or after pregnancy ends)
- Infants (up to 1st birthday) and children up to their 5th birthday

It is important for the nurse to recognize the presence of iron-deficiency anemia. Because it has been associated with abnormal infant behavior, growth, and development, it needs to be corrected. Adolescents are also vulnerable to iron-deficiency anemia because of rapid growth and sometimes poor eating habits. The pathophysiology of iron-deficiency anemia can be related to various factors such as a decreased supply of iron, impaired absorption of iron, and increased demand for iron or blood loss (Box 33-1).

Signs and Symptoms

The nurse understands that the signs and symptoms of iron-deficiency anemia vary with the severity of the disorder. If a child has with a mild iron-deficiency anemia, he or she may be asymptomatic. This deficiency may not be apparent until laboratory tests are performed (decreased hemoglobin/hematocrit). For children with moderate to severe iron-deficiency anemia, clinical manifestations that may be present include irritability, fatigue, delayed motor

Box 33-1 Common Causes of Iron-Deficiency Anemia

DECREASED IRON SUPPLY

Inadequate iron supply at birth

Nutrition

- Deficient iron intake
- Excessive milk
- Limited solid foods
- Poor eating habits, vegetarian diet, increased fast foods

INCREASED IRON DEMANDS

Growth

- Low birth weight, twins or multiple births
- Prematurity/infants
- Adolescents
- Pregnancy
- Cyanotic congenital heart diseases (i.e., tetralogy of Fallot)

BLOOD LOSS

Acute

Chronic

Parasite infection

GI tract is the most common site

INABILITY TO FORM HEMOGLOBIN

Lack of vitamin B₁₂ (pernicious anemia)

Folic acid deficiency

IMPAIRED ABSORPTION

Presence of iron inhibitors

- Phytates, phosphates, or oxalates
- Gastric alkalinity
- Malabsorption syndrome (celiac disease, severe prolonged diarrhea, postgastrectomy, inflammatory bowel disease)

ED: NO mention for this box in text?

development, tachycardia, shortness of breath, decreased activity level, pale, conjunctival pallor, listless, systolic heart murmur, hepatomegaly, and congestive heart failure. Pica, the eating of items of non-nutritive value such as starch, clay, ice, or paper (Nathan et al., 2003), may also be associated with iron-deficiency anemia. Iron deficiency, alone or with anemia, may result in impairment of cognitive skills that may not be reversible.

Diagnosis

Diagnosis of iron-deficiency anemia is based on patient history and physical examination findings. Laboratory tests that are frequently performed include those that quantify or describe hemoglobin, iron concentration, and morphological changes in the RBC.

Nursing Care

The nurse understands that early identification and recognition of iron-deficiency anemia is essential. The nurse can stress to the parents that the primary goal of iron deficiency anemia is prevention. Many instances of iron-deficiency anemia can be avoided with the appropriate food selections. The nurse or dietitian can provide nutritional counseling and assist with obtaining recommended iron-fortified formula and cereal.

“What to say” — Nutritional counseling

- “Feed your infant breast milk or commercial infant formula recommended for the first 12 months of life.”
- “Be sure to use iron-fortified cereal from 6 to 12 months of age.”
- “Do not feed your infant cow’s milk before 12 months of age. After 12 months of age limit the amount of cow’s milk to 18 to 24 ounces per day.”
- “Offering solids before bottle once solids are introduced helps prevent iron deficiency.”
- “To meet recommended dietary allowances and to avoid iron-deficiency anemia, it is important for adolescents on a vegetarian diet or weight reduction diet to understand proper dietary alternatives.”
- “Red meats, beans, whole grains, nuts, and iron-fortified cereals are good sources of iron.”

The nurse can teach the parents how to administer oral iron supplements. The recommended dosage of elemental iron is 3 mg/kg per day based on body weight in one to two divided doses. The severity of the anemia dictates the monitoring frequency of laboratory testing and follow-up with the health care provider. Several days after initiating iron replacement therapy, the family can expect a rise in the reticulocyte count, which is an indicator of RBC production. Adequate iron replacement therapy should result in a peak reticulocyte count in 7 to 10 days (Gilbert-Barness & Barness, 2003). It is important for the nurse to communicate to the parents that this time frame is a good opportunity for the child to return to the health care provider for follow-up.

critical nursing action Education About Oral Iron

Educating parents on the proper administration of oral iron is a vital nursing responsibility. The iron supplement needs to be taken between meals because absorption is improved in an acidic environment. Administering this medication with a glass of orange juice may also enhance absorption. Iron supplements should not be taken with tea because it may adversely affect the absorption process.

- Inform parents that liquid iron preparations may stain teeth so it is important to administer the medication with a dropper or drink it through a straw. Encourage the child to rinse his or her mouth after taking this liquid medication.
- Make parents aware that iron can be constipating and it is necessary to increase the fiber and water intake to prevent this possible complication.
- Possible side effects of iron therapy include gastric upset, nausea, vomiting, and constipation. Black tarry stools are a common finding and are normal for children taking iron supplements. Encourage parents to keep no more than a 1-month supply in the home and to store it out of reach of small children because ingestion of excessive quantities may be toxic or even fatal.

case study Iron-Deficiency Anemia

Johnny is a 7-month-old infant visiting the Head Start clinic for a check-up. During the child’s initial history, the 18-year-old mother reports that she missed her last few appointments to the clinic because she does not have any transportation. The nursing assessment reveals that the infant is pale and listless. Johnny’s weight is plotted at 110% on the growth chart. The mother reports that Johnny “drinks lots of milk.” “I give him milk whenever he cries.” She also informs you that she has had “no money for formula but that he likes whole milk just as well.” After a blood draw the nurse notes that his laboratory results are: hemoglobin = 8.8 hematocrit, 26.3. Johnny’s vital signs include: axillary temperature, 97.6°F (36.4°C); heart rate, 166 beats per minute; respiratory rate, 32 breaths per minute; blood pressure, 92/45.

critical thinking questions

1. From a nursing perspective what is your primary concern?
2. What community resource can you suggest to Johnny’s mother?

◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

clinical alert

An overweight child diagnosed with iron-deficiency anemia

The clinic nurse can be vigilant for overweight infants who may have iron-deficiency anemia. While most infants diagnosed with iron-deficiency anemia are underweight, do not be misled. Infants who are overweight may also have this disorder. Many of these infants are overweight because of excessive milk ingestion, known as “milk baby.” These infants are chunky, pale, and have a “porcelain-like” appearance. Other clinical features of these “milk babies” include poor muscle development and they are susceptible to infections. It is essential to obtain a comprehensive nutritional history from the parents.

EPISTAXIS

Epistaxis (nosebleeds) are common in children. Most cases are clinically benign events. The greatest concern occurs when family members or caretakers become upset at the site of blood, which may appear excessive even from a small nosebleed. Nosebleeds are related to the increased vascularity of nasal mucosa.

Signs and Symptoms

The septum of the child’s nose is especially vulnerable to bleeding as a result of direct trauma, foreign body insertion, nasal gastric tube insertion, nasal intubation, nose picking, violent sneezing, inhaled drug use (e.g., cocaine), and related effects (nasal crusting), and chronic infections of the nasal tissue. Other external factors or disease states such as alterations in platelet count, hypertension, or prolonged use of acetylsalicylic acid. (Children’s Aspirin) or aspirin-containing products may precipitate epistaxis.

Diagnosis

To determine the cause of bleeding from the nares, the nurse can perform a thorough history and physical. The majority of the time, bleeding is an independent occurrence. If bleeding is controlled and infrequent, the nurse can identify the causative factor. The nurse should ask the parents about nose picking or foreign body aspiration. In children with reoccurring and prolonged epistaxis, a further diagnostic workup is warranted.

Nursing Care

Nursing care for a child with epistaxis focuses mainly on prevention. The nurse can tell children not to pick the nose, vigorously blow the nose, or engage in strenuous activity that is known to cause a nosebleed. Teach children to sneeze with the mouth open and gently blow the nose if needed. Inform parents to avoid giving the child acetylsalicylic acid. (Children’s Aspirin) or nonsteroidal anti-inflammatory drugs (NSAIDs). Cool mist humidification may also be recommended as a preventive measure. When a nosebleed occurs, the nurse can provide simple first aid measures that may assist in stopping the bleeding (Fig. 33-1).

Figure 33-1 When a nosebleed occurs, the nurse can provide simple first aid measures that may assist in stopping the bleeding.

critical nursing action Controlling Epistaxis (Nosebleeds)

Don gloves and place the child in a sitting position, leaning forward. Apply direct pressure to the anterior nasal septum for 10–15 minutes. Remind the child to breathe through the mouth, so he or she does not become anxious. Applying ice to the nose area is beneficial. If a large amount of blood loss occurs, the nurse must monitor vital signs. In cases with severe nose bleeding that persists beyond 10–15 minutes, nasal packing may be required, as well as topical epinephrine. When an infection is present, antibiotics may be ordered (Kucik & Clenney, 2005). It is essential that the nurse keep the child and family quiet and calm by providing support and reassurance. It is important that families are able to demonstrate first aid measures necessary to control an occurrence of epistaxis.

Labs: Epistaxis Diagnostic Workup

Laboratory tests can potentially diagnose an underlying bleeding disorder. Recommended blood tests include a CBC with differential, prothrombin time, partial thromboplastin time, and coagulation profile, if a bleeding disorder is suspected (Table 33-4).

Now Can You— Provide nursing care to children with iron-deficiency anemia and epistaxis (nosebleeds)?

1. Discuss the cause of iron-deficiency anemia.
2. List nursing interventions for children experiencing iron-deficiency anemia.
3. Discuss the cause of epistaxis (nosebleeds).
4. List nursing interventions for children experiencing epistaxis (nosebleeds).

SICKLE CELL DISEASE

One of the most common genetic hematological conditions present in children is sickle cell disease (SCD). This disorder is transmitted via an autosomal recessive pattern of inheritance. Both parents of the child must have the sickle cell gene in order for the child to have sickle cell disease (Fig. 33-2).

Ethnocultural Considerations— Sickle cell disease

Approximately 8% of the African American population in the United States is a carrier of sickle cell trait (Turgeon, 2005). Children affected by this condition are usually of African American or Mediterranean descent. Although rare, this genetic disorder may be seen in other populations such as Hispanic, Caucasians, and Italians due to the intermarriages that have occurred throughout the world.

Patients with sickle cell *trait* have the heterozygous form of the disease. They usually are asymptomatic since they possess one sickle and one normal gene. The child with *trait*

Table 33-4 Laboratory Tests to Diagnosis Bleeding Disorder

Test	Range	Significance
Prothrombin time (PT)	11–14 seconds	Measures the extrinsic pathway for bleeding, requires fibrinogen, prothrombin, and factors V, VII, and X. Prolonged times may indicate deficiencies of vitamin K liver factors, malabsorption, and liver disease.
Partial thromboplastin time (PTT)	25–38 seconds	Measures the intrinsic pathway for bleeding, requires factors V, VIII, IX, X, XI, and XII and fibrinogen and prothrombin. Prolonged times may indicate a bleeding disorder.

Source: Hillman, R.S., Ault, K.A., & Rinder, H.M. (2005). Hmeatology in clinical practice: A guide to diagnosis and management. New York: McGraw-Hill

Figure 33-2 Pattern of inheritance of sickle cell disease.

may be affected only in certain situations such as high altitudes, periods of extreme stress such as dehydration, and females later in life during pregnancy. Children with sickle cell disease, have the homozygous form of the disorder, indicating that both genes are abnormal (Turgeon, 2005).

Nursing Insight— Inheritance

Consistent with the genetic pattern of inheritance, hemoglobin genes come from both parents. If one parent has sickle cell disease and the other parent does not, the child has only the sickle cell trait. If one parent has sickle cell disease and the other has sickle cell trait, there is a 50% probability (1 out of 2) that the child will have either the sickle cell disease or the sickle cell trait. When both parents have sickle cell trait, they have a 25% probability (1 out of 4) of having a child with sickle cell disease or who will become a carrier of the disease.

The primary defect in this type of genetic disease is that the globin chain in normal hemoglobin A (HbA) is partially or completely replaced by hemoglobin S (HbS). Hemoglobin S has a substitution of the amino acid valine for glutamine which is more sensitive to the changes in the oxygen concentration in the blood. When a patient has a large amount of hemoglobin S and a decrease in oxygen levels, these abnormal hemoglobins clump together within the cell and change the shape from donut-like to a sickled shape (Fixler & Styles, 2002) (Fig. 33-3). The two most significant pathophysiological features of this disease include tissue ischemia as a result of the occlusions and the inherited fragility of the sickled cells. Once RBCs sickle, they are more fragile and easily destroyed. The surfaces of these sickled cells are also sticky and adhere to the blood

vessel walls. The shape of the sickled cell does not promote good oxygenation or movement throughout the circulatory system and hence clinical symptomatology results. If the RBCs cannot circulate through the vascular system and there are occlusions, hypoxemia may result that could lead to ischemia, infarcts, and possible tissue death (Gilbert-Barness & Barness, 2003). The average life span of a sickled RBC is approximate 30 to 45 days (Nathan et al., 2003). Owing to the shortened life span of the RBCs, children with sickle cell disease have an increased amount of hemolysis, as evidenced by their chronic anemia.

Signs and Symptoms

Because sickle cell disease is a blood disorder, all organs of the body may be affected. The signs and symptoms that may be evident in a child with sickle cell anemia are largely the result of the vaso-occlusion of the blood vessels from the sickled red blood cells and hemolysis. Other symptoms seen in children with sickle cell disease may include weakness, pallor, fatigue, tissue hypoxia, and jaundice as result of RBC hemolysis.

The most common presenting clinical manifestation is the child with pain (vaso-occlusive crisis). The pain can present anywhere in the body and is the result of the occlusion of the blood vessels.

Diagnosis

Accurate assessment and diagnosis are essential for appropriate treatment. Newborn screening is a standard in all 50 states. Infants can be identified early to elicit the appropriate diagnosis. For toddlers and preschool children who present to the health care provider with nonspecific symptoms with the presence of anemia, a thorough history and physical must be performed. If the etiology of the anemia is undetermined, a screening for sickle cell may be indicated. The definitive test for diagnosis of sickle cell disease or trait is hemoglobin electrophoresis (Gilbert-Barness & Barness, 2003). This assay separates the various types of hemoglobin and quantifies the percentage of various hemoglobins present. Laboratory tests including a CBC and reticulocyte count are necessary. Expected laboratory findings for sickle cell disease are decreased hemoglobin and hematocrit and an elevated reticulocyte count.

© All rights not available.

diagnostic tools Further Testing for Infants Suspected of Having Sickle Cell Disease

If sickle cell disease is suspected, infants require further testing, such as a hemoglobin electrophoresis (Fixler & Styles, 2002). A hemoglobin electrophoresis is a more specific blood test that identifies sickle cell disease versus sickle cell trait in a child (Gilbert-Barness & Barness, 2003).

Nursing Care

The most important nursing care measure in the treatment of sickle cell disease is the early identification and treatment of hypoxic episodes. The nurse can provide supportive and specific care based on the type of crisis present. Nursing care should focus on encouraging rest, hydration, pain control, and adequate oxygenation. When providing nursing care to patients with suspected sickle cell crisis, attempts should be made to coordinate nursing care to allow adequate rest periods and to minimize unnecessary interruptions. Nursing care always includes adequate hydration (oral or intravenous). The fluid requirement recommendations are one and a half times above the child's normal calculated requirements. The nurse understands that adequate hydration promotes dilution and diminishes the possibility of hypoxic episodes. In addition to hydration, pain control is essential to adequately treat painful crisis. Pain control can be pharmacological or nonpharmacological. A combination of both is preferred. A complete nursing history should be obtained to determine what pain measures have worked in the past. Another critical assessment factor is monitoring respiratory status and oxygenation of sickle cell patients. The child with sickle cell crisis may be at risk for an acute pulmonary event that may be a result of the disease itself or the use of opiates. A complete respiratory assessment should include signs and symptoms of respiratory distress, including auscultation of lung sounds to detect decreased and abnormal breath sounds, respiratory effort and quality, continuous monitoring of oxygen saturations, color and perfusion, and any necessary laboratory or radiographic studies. If abnormal findings are present, the nurse must immediately inform the medical team so treatment can begin. For example, if the patient's oxygen saturation consistently is less than 90% on room air, supplemental oxygen may be indicated. The nurse must remember that pneumonia and pulmonary infarcts occur more often in this patient population.

Complementary Care: Nonpharmacological pain interventions

In addition to administering medications for pain control, the use of nonpharmacological interventions has proven to be beneficial for many patients experiencing painful episodes from a sickle cell crisis. This may include distraction, guided imagery, relaxation techniques, music therapy, comfort care, cutaneous stimulation, and play therapy. If available at your institution, a child life specialist or other interdisciplinary team member can be consulted to assist in providing nonpharmacological interventions.

clinical alert

When a child is asplenic

A child with a temperature greater than 101.5°F (38.6°C) requires immediate medical attention, as most children with sickle cell disease are "functionally asplenic". When a child is asplenic, he or she does not have the ability to filter certain encapsulated bacteria. This allows the bacteria to multiply within the bloodstream, causing a low-grade bacterial infection or serious sepsis. Children with sickle cell disease generally are asplenic by the age of 3–5 years. The major cause of death in children with sickle cell disease who are less than 5 years old is overwhelming infection due to *Streptococcus pneumoniae*, *Haemophilus influenzae* type b, and *Neisseria meningitidis* (Nathan et al., 2003). If a child with sickle cell disease has a fever, immediate treatment involves blood cultures and the implementation of parenteral broad-spectrum antibiotics. Children with sickle cell disease often receive prophylactic oral penicillin at home to prevent overwhelming sepsis. The nurse knows that this critical information is necessary for parents to ensure the child receives the pneumococcal and *H. influenzae* type B vaccine and other routine vaccinations.

For the family that seeks medical attention for the child with mild pain, the initial management consists of oral pain medication at home. Oral pain medication may consist of acetaminophen (Children's Tylenol), ibuprofen (Children's Advil), or acetaminophen with codeine (Children's Tylenol-Codeine) for mild to moderate pain. If the child continues to have pain, hospitalization may be required. For the hospitalized child with vaso-occlusive crisis, opioids such as immediate and sustained release morphine (Duramorph), oxycodone (OxyContin), hydromorphone (Dilaudid), or methadone (Methadol) may be administered around the clock. Morphine (Duramorph) is often considered the drug of choice. Morphine (Duramorph) may be administered around the clock or by patient-controlled analgesia (PCA) (Fixler & Styles, 2002). PCA is an appropriate method of pain management for children who are able to manage their own pain relief. Another medication that may be used for painful crises and does not have the common side effects of the opiate drugs is ketorolac (Toradol). Toradol (Ketorolac) is a parenteral anti-inflammatory drug that has been found to be effective in reducing pain associated with a vaso-occlusive crisis. The recommended duration of ketorolac (Toradol) should not exceed 5 days owing to the increase risk of gastritis and gastrointestinal bleeding.

assessment tools Pain Assessment

Pain assessment must be documented for all patients. The use of a standardized pain assessment tool provides a more accurate assessment data. A developmentally appropriate pain assessment tool also must be used for all patients in health care settings. Pain assessment tools should be used to assess the pain on admission, reassess pain, and determine treatment effectiveness. The Joint Commission national patient safety goals recommended pain assessment as the 5th vital sign (for developmentally appropriate pain assessment tools see Chapter 21).

Children who have experienced numerous hospitalizations, cerebral vascular accident (CVA), or acute chest syndromes may be candidates for hypertransfusion therapy. These patients receive blood transfusions every 3 to 4 weeks to increase the amount of hemoglobin A. This

**medication:** Toradol (Ketorolac)

Toradol (tor-ah-dal)

Generic name: Ketorolac (Kee-toe-role-ak)

Pregnancy Category: C (D if used in the 3rd trimester)**Indications:** Short term (<5 days) management of moderate to severe pain, including postoperative pain.**Actions:** Inhibits prostaglandin synthesis by decreasing activity of the enzyme cyclooxygenase, which results in a decrease of prostaglandin precursors.

THERAPEUTIC EFFECTS: pain relief

Pharmacokinetics:

ORAL: Well absorbed; 100%

IM/IV: Rapid and complete

Contraindications and Precautions:

Contraindicated in: Hypersensitivity to Toradol, acetylsalicylic acid (Children's Aspirin), or other NSAIDs; patients with peptic ulcer disease or anyone with bleeding tendencies

Adverse Reactions and Side Effects: Dizziness, headache, rash, diarrhea, GI pain, bleeding, prolonged bleeding times, anaphylaxis, hypersensitivity reactions.**Route and Dosage:** Ketorolac injection is approved for use in pediatric patients only as a single I.M. or I.V. dose in children 2–16 years of age; the use of ketorolac injection in children <2 years of age, the use of multiple doses of the injection in children <16 years of age, and the use of the tablets in children <16 years of age are outside of the manufacturer's recommendations; ophthalmic solutions are approved for use in children ≥3 years of age.

SINGLE-DOSE TREATMENT: Manufacturer's recommendations:

I.M.: 1 mg/kg as a single dose; maximum dose: 30 mg

I.V.: 0.5 mg/kg as a single dose; maximum dose: 15 mg

Nursing Implications:

Instruct the patient and parents on medication administration.

Do not exceed 5 days of total use.

May cause drowsiness and impair ability to perform activities requiring mental alertness.

Additional Information: 30 mg of Toradol (Ketorolac) provides analgesia comparable to 12 mg of morphine or 100 mg of meperidine

Data from Deglin, J.H., & Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

treatment regimen is not without potential risks, which may include the transmission of various infectious diseases, an acute transfusion reaction, or iron overload from multiple blood transfusions. Chelation therapy must be initiated to prevent organ damage from iron accumulation (Fixler & Styles, 2002). An experimental treatment modality for sickle cell patients with numerous complications is a bone marrow transplant.

**Across Care Settings:** Education about sickle cell disease

Children and families affected by sickle cell disease must learn to cope with a lifelong chronic illness. Families must be knowledgeable of the signs and symptoms of sickle cell crisis so they can report them to their primary health care provider. The community-based nurse can educate the family about the goals of ongoing care including the prevention of complications associated with infections, hypoxemia, and vaso-occlusive crisis. Ensure that parents understand that strenuous activities that

may precipitate hypoxia should be avoided. Nurses must teach parents how to avoid a sickle cell crisis by providing rest and adequate hydration. Patients with sickle cell disease are on prophylactic penicillin to prevent overwhelming sepsis and supplemental folic acid to assist with red blood cell production. Adherence to these medications is critical in preventing complications associated with this disease. The nurse can inform the parents about genetic screening and counseling.

In the event a patient experiences a mild sickle cell crisis at home, instruct him or her to stop what he or she is doing, rest, drink fluids, and take the prescribed pain medication. If improvement is not observed, notify the physician and anticipate the need for the patient to see a health care provider or to go to the nearest emergency facility for additional treatment.

Complications related to occlusion of blood vessels include splenic sequestration, functional asplenia, avascular necrosis of the femoral head, leg ulcers, hand-foot syndrome (dactylitis), and chronic organ damage. Additional complications secondary to hemolysis include anemia, cholelithiasis (gallstones), jaundice, retarded growth, and sexual maturation. The most severe complications are the occurrence of acute chest syndrome, priapism (painful and continuous erection of the penis), splenic sequestration (separation), and a CVA. These conditions are medical emergencies and treatment must be obtained immediately to prevent permanent disability or a life-threatening event (Fixler & Styles, 2002).

**nursing diagnoses** Sickle Cell Disease

- Knowledge Deficit related to home care
- Pain related to tissue hypoxia secondary to vaso-occlusive crisis
- Alteration in Tissue Perfusion related to anemia
- Activity Intolerance related to anemia
- Risk for Injury related to anemia
- Altered Family Process related to hospitalization
- Ineffective Coping related to chronic illness
- Fluid Volume Deficit related to decreased fluid intake and the kidney's ability to concentrate urine
- Risk for Infection related to limited splenic filtering abilities

**case study** Sickle Cell Disease

Sammy is a 16-year-old boy with a history of sickle cell disease. He also has a history of numerous admissions to the hospital for pain crisis and blood transfusions. Today, in the emergency room, Sammy complains of pain in his chest and fever. During the physical assessment the nurse notes that his lungs are congested and that he has a moist cough. His oxygen saturation is 87% on room air. Sammy's vital signs are: heart rate, 121 beats per minute; respiratory rate, 28 breaths per minute; temperature, 101.5°F (38.6°C) orally; and blood pressure on the left upper extremity, 139/96.

critical thinking questions

1. In addition to respiratory status, what are the other concerns?
2. What are the priority nursing interventions?
3. What information will the nurse teach the parents?

◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

THALASSEMIA

Beta-thalassemia is the most common inherited genetic disorder in the world (Sapountzi-Krepia et al., 2006). This condition involves a deficiency in the globin chains of the hemoglobin. It is also classified according to which specific globin chains are affected. For example, if the beta-chain is affected, the child is diagnosed as having beta-thalassemia. Beta-thalassemia also has an autosomal recessive pattern of inheritance, which is similar to the pattern of inheritance as sickle cell disease. There are three forms of beta-thalassemia:

- Thalassaemia minor (or thalassaemia trait) is asymptomatic, or a mild microcytic anemia is present.
- Thalassaemia intermedia has signs and symptoms similar to those of splenomegaly (enlarged spleen) with severe anemia.
- Thalassaemia major (the most severe form), also known as Cooley's anemia (Turgeon, 2005). Cooley's anemia was first described by Dr. Thomas Cooley in 1925 (Nathan et al., 2003). Children with thalassaemia major are usually dependent on blood products in order to maintain their hemoglobin, support growth, and prevent extramedullary hematopoiesis (the production of blood cell in tissues other than bone marrow).

In addition to beta-thalassemia, there is alpha-thalassemia, which occurs when the alpha-chain is affected. These patients are sometimes mistakenly diagnosed with iron-deficiency anemia. The severity of alpha-thalassemia is based on the number of alpha genes affected. If the patient has one or two missing alpha genes, he or she is mostly likely asymptomatic or has a mild anemia. A patient missing three alpha genes is classified as having Hgb H disease (Turgeon, 2005), which is characterized by an excess of beta-chains, resulting from minimal production of alpha-chains in the bone marrow and development of hemoglobin H as a result (Turgeon, 2005). Although hemoglobin H has oxygen-carrying capacity, its effectiveness is somewhat decreased and these patients often present with anemia and splenomegaly (enlarged spleen).

Signs and Symptoms

Children with beta-thalassemia who are symptomatic have an enlarged liver and spleen, mild jaundice, growth retardation, and a moderate to severe anemia. Due to the rapid destruction of red blood cells, the body attempts to increase more RBC production to compensate for the anemia that is present (Turgeon, 2005). When the hemoglobin level declines and severe anemia is present, bones that normally do not produce RBCs take on this function. As a result, there may be bony deformities such as frontal bossing or maxillary prominence from the excess cell production. These children also have an increased susceptibility to infection secondary to their nonfunctioning spleen.

Diagnosis

A thorough history and physical examination are necessary for diagnosis. Frequently performed laboratory tests include those that quantify or describe hemoglobin such as a CBC with red cell indices. Laboratory studies often reveal decreased hemoglobin and hematocrit, hypochromia, microcytosis, low mean corpuscular volume (MCV), and increased reticulocyte count (Turgeon, 2005).

Labs: Hemoglobin Electrophoresis

The nurse understands that hemoglobin electrophoresis can distinguish the type and severity of the thalassemia. Electrophoresis separates hemoglobin variants based on molecular charge. Hemoglobins are then described in order of relative abundance, detecting the homozygous and heterozygous forms of the disorder (Gilbert-Barness & Barness, 2003). Based on the results of the hemoglobin electrophoresis, a referral to a hematologist may be warranted for further evaluation.

Nursing Care

The goal of nursing care for children with beta-thalassemia major (Cooley's anemia) is to prevent hypoxia by providing blood transfusion therapy usually every 3–4 weeks for the child's lifetime (Lo & Singer, 2002). These children are dependent on transfusion therapy to maintain their hemoglobin, improve the quality of their lives, prevent extramedullary hematopoiesis, promote growth and development, and reduce infections.

Children with beta-thalassemia may experience numerous complications related to their disease and/or the treatment of their disease. As a result of chronic transfusion therapy, these children are at high risk for developing hemosiderosis.

clinical alert

Accumulation of iron (hemosiderosis)

As a result of the chronic blood transfusion therapy, in which each unit contains approximately 200 mg of iron, iron may accumulate in the body. The body does not have a mechanism to remove the iron. Excess iron is stored in the tissues and organs (hemosiderosis). Hemosiderosis must be treated to prevent toxic levels of iron in the body and possible death. Iron may be removed from the body by using drugs called chelating agents that bind with the iron and allow for excretion through the urine and stool. The main chelating agent is deferoxamine B (Desferal) (Lo & Singer, 2002). This drug is rapidly excreted in the urine. It must be administered intravenously or subcutaneously over 8–10 hours, usually at bedtime, at least 5 days a week. Most parents can be taught how to insert the butterfly catheter and administer the drug via an infusion pump at home without difficulties. The treatment process with deferoxamine B (Desferal) may become burdensome, expensive, and the issue of adherence is quite often a concern for health care professionals. Routine monitoring of iron levels is indicated for patients on chelation therapy to evaluate compliance and effectiveness of treatment. Patients at risk for hemosiderosis should be evaluated for long-term complications. Complications that may occur are a result of iron deposits that may damage vital organs causing hearing loss, diabetes, organ failure, and ultimately death.

Children with beta-thalassemia (Cooley's anemia) may be cured of their disorder with a bone marrow transplant (Martin, Foote, & Carson, 2004). Finding a suitable match is often difficult. Younger children often fare significantly better than older children who are treated with bone marrow transplant, primarily because their organs have not sustained substantial damage from the chronic transfusion therapy that may have caused iron overload.

Patients with this chronic disorder and their families require supportive care by the nurse. The nurse must address the importance of blood transfusion therapy and

chelation to ensure compliance with the treatment regimen. The nurse teaches the family the appropriate technique for administration of the chelation therapy. Other nursing interventions include good hand washing because these children are often asplenic, which increases their susceptibility to infection. The nurse can alert parents to seek medical attention if the child develops a temperature of 101.5°F (38.6°C). If the child has a fever, the nurse can inform the parents that antibiotic prophylaxis may be indicated. Genetic counseling is needed to guide a family on making decisions about having additional children who possibly can be affected with this inherited disorder.

HEREDITARY SPHEROCYTOSIS

Hereditary spherocytosis (HS) is a hemolytic anemia acquired via autosomal-dominant inheritance and is caused by an abnormal RBC membrane. In most cases, there is a defect of the red cell skeletal protein called spectrin or it may also include the proteins involved in the attachment of the spectrin to the membrane (Hillman, Ault, & Rinder, 2005). The severity of the disease is directly contingent on the amount of the spectrin deficiency.

The cellular defect results in an abnormal RBC membrane. The malformed cell membrane has a smaller surface area in relationship to a normal RBC and an alteration in the actual shape of the cell from donut like to that of a spherocyte. The new shape makes it difficult for the RBCs to circulate through the body, particularly to the spleen, which leads to sequestered cells and early destruction (Turgeon, 2005). HS does not involve an abnormality of the hemoglobin. Rather it is an inherited disorder, which actually transforms the configuration of the red cell membrane (Turgeon, 2005).

Signs and Symptoms

Clinical manifestations may include hyperbilirubinemia, anemia, splenomegaly, and a negative Comb's test. In many cases, there is a strong family history. Some children can present later in life with anemia, jaundice, splenomegaly, or with an aplastic crisis often linked to a viral infection. The anemia may range from mild to severe based on the extent of compensation by the body.

Diagnosis

The diagnostic workup for HS includes a thorough history and physical examination. A CBC is frequently performed. Laboratory tests often reveal a low hemoglobin level between 7 and 10 grams per deciliter. The peripheral smear reveals small, dense, round, spherical red cells. The MCV is usually normal and there is increased red cell osmotic fragility, which is a measure of the lysis of spherocytes.

Nursing Care

The nurse understands that mild to moderate cases of HS include folic acid supplementation recommended at 1 mg/day. Children who have less than 80% of normal spectrin content are candidates for a splenectomy. The splenectomy eliminates the anemia and is reserved for children with moderate to severe cases of HS. After a splenectomy, the spherocytosis of the RBCs continues, although the cells no longer become sequestered in the spleen. The red cell survival improves to near normal.

critical nursing action Pneumococcal and *Haemophilus influenzae* Type b (Hib) Vaccine

Children with hereditary spherocytosis (HS) should receive the pneumococcal and *Haemophilus influenzae* type b (Hib) vaccine before the splenectomy to prevent life-threatening bacterial infections. Children should also be given prophylactic penicillin to prevent fatal infections.

The nurse can provide supportive care measures for all children with HS. It is essential to teach parents of children with the milder form of HS about the folic acid supplementation regimen. The nurse must pay careful attention to infection control principles for a child who has undergone a splenectomy. The nurse needs to encourage parents to adhere to a prescribed antibiotic regimen. Promote good hand washing by all care providers because these children have increased susceptibility to infection. Instruct parents on the proper method for taking a temperature. Inform parents to seek medical attention if the child develops a temperature of 101.5°F (38.6°C). The nurse can remind parents that routine visits to their health care provider must be scheduled to evaluate blood counts and the need for immunizations. Provide support to the child and family to help them cope with this lifelong illness.

HEMOPHILIA

Hemophilia is a group of bleeding disorders caused by a congenital X-linked deficiency of either clotting factor VIII or IX (Sevier, 2005).

Ethnocultural Considerations— The royal disease

Hemophilia has been present for centuries throughout the world. Often, members of the royal English family married into royalty of other countries. Hemophilia has been referred to as “the royal disease.” The marriage of England’s Queen Victoria and Prince Albert hallmarked the beginning of hemophilia in the British royal line. Queen Victoria, who had nine children, was a carrier of the hemophilia gene. As a result, hemophilia was transmitted to most of the royal houses of Europe (Stevens, 1999). A specific example of the royal disease is the case of the Czar and Czarina of Russia, Nicholas II and his wife, Alexandra. As a granddaughter of Queen Victoria of England, Alexandra was a carrier of the same genetic mutation that afflicted several of the major European royal houses and passed the disease to her only son, Alexei. Because the family was killed by the Bolsheviks in 1918, it is not known whether any of the couple’s four daughters (Olga, Tatiana, Maria and Anastasia) inherited the gene as carriers as their mother had before them.

Hemophilia is found in all races and is present throughout the world. This disorder is an X-linked recessive disease, males are predominately affected, and females are “carriers” of this genetic illness. In rare instances, a female may be affected with the disease when a man with hemophilia produces an offspring with a woman who is a carrier of this disorder.

In children with hemophilia, the coagulation process cannot be completed, so bleeding is prolonged. A common misconception is that bleeding is faster in these patients, but this is not the case. The prolonged bleeding is what causes the clinical manifestations to be evident. There are two basic types of hemophilia. In hemophilia A (classic hemophilia), there is a deficiency of factor VIII. In hemophilia B (Christmas disease), there is a deficiency of factor IX (Sevier, 2005). The symptoms of these bleeding disorders are clinically similar, but hemophilia A is more common (Sevier, 2005). The severity of these bleeding disorders is directly related to the degree of factor deficiency. The child with a greater degree of factor deficiency experience more bleeding episodes than the child with mild deficiency. Hemophilia A is classified as mild, moderate, or severe based on the degree of deficiency present.

Signs and Symptoms

Often a child with hemophilia is diagnosed after presenting with bleeding or there is a known family history of bleeding disorders. Children with bleeding disorders often experience **hemarthrosis** (a bloody effusion within a joint) and soft tissue bleeding (Sevier, 2005). Children who have hemarthrosis often seek medical attention after a minor injury in which there is swelling, stiffness, tingling, decreased range of motion, or pain in the affected joint.

Most children are free of symptoms until they crawl or walk. In infancy, a bleeding disorder may be discovered at the time of circumcision. In older children, excessive bleeding may occur with a tooth extraction or tooth loss. For the child with hemophilia who experiences frequent bleeds in the joints, there may be long-term consequences including mobility limitations, bony changes, and crippling deformities.

Diagnosis

For the child who experiences moderate to severe bleeding from minor procedures or bleeding into large joints, diagnostic testing is warranted. Common diagnostic tests may include a prothrombin time (PT) and a partial thromboplastin time (PTT) (See Table 33-4). The most important test is the direct assay of plasma factor activity level for hemophilia A and B (Hillman et al., 2005). Based on the type of factor deficiency and the percentage of factor level in the plasma, the diagnosis of the type and the classification of hemophilia is confirmed.

Nursing Care

A collaborative interdisciplinary approach is essential to manage children with hemophilia. The nurse must initiate prompt treatment of bleeding episodes. The identification of the deficient factor is imperative in order to administer the proper replacement factors.

Nursing Insight— Proper replacement factors

Years ago, most factor products were derived from human plasma. This treatment posed severe risks to hemophilia children due to the transmission of viral illnesses. Children who were treated with human factor products may have contracted human immunodeficiency virus (HIV) or hepatitis

(Sevier, 2005). Now recombinant factor products are the main treatment of hemophilia patients (Sevier, 2005). After years of receiving replacement factor products, children may develop inhibitors to the specific coagulation proteins. The development of inhibitors poses a unique treatment challenge to manage these patients. Changes or additions to the treatment regimen may be necessary to provide adequate replacement factors.

The number one nursing priority for all patients with bleeding disorders is always patient safety, prevention of additional complications, and promoting wellness. Depending on the severity of the bleed, patients may require close observation and inpatient hospitalization. The majority of patients with hemophilia can be managed at home by informed and educated family members. Inpatient nursing care focuses on preventing additional bleeding episodes, monitoring laboratory values as indicated, and administering replacement factor products.

For children with severe hemophilia, prophylactic doses of recombinant factor products may be administered in the home setting by caretakers in order to prevent bleeding episodes. The nurse instructs family members how to administer these factor products by intravenous access. Older mature children may assume the responsibility of self-administering factor products at home after teaching has been completed. Proper administration of factor products at home improves the quality of life, decreases hospitalizations, reduces missed days in school, and prevents long-term complications for children with this chronic illness.

nursing diagnoses Bleeding Disorders

- Risk for Injury related to bleeding tendencies
- Pain related to bleeding episodes in joints and muscles
- Knowledge Deficit related to home care
- Potential for Impaired Physical Mobility related to bleeding in the joints and muscles

VON WILLEBRAND'S DISEASE

One of the most common inherited bleeding disorders is von Willebrand's disease (vWD) (Allan & Glader, 2002), first described in 1926 by Eric von Willebrand (Turgeon, 2005). It is transmitted via an autosomal dominant pattern of inheritance, affecting males and females equally (Allan & Glader, 2002). vWD is characterized by a deficiency of von Willebrand factor (vWF) and has variable clinical manifestations. vWF plays an important role in the early phase of hemostasis by enhancing platelet aggregation and adhesion. The vWF assists in forming the "platelet plug" to the damaged endothelium and also acts as a carrier protein for coagulation factor VIII (Allan & Glader, 2002).

Signs and Symptoms

When there is a deficiency of vWF, signs and symptoms of prolonged bleeding times may be present. The most common presenting clinical manifestation is epistaxis, followed by bleeding from the oral cavity (Allan & Glader, 2002). In addition, these children may experience menorrhagia (excessive menstrual bleeding) and easy bruising.

Family Teaching Guidelines... The Child with Hemophilia

HOW TO: Teach the Family How to Care for the Child with Hemophilia

- ◆ Instruct families on what signs and symptoms require prompt medical attention. Most importantly, any trauma to the head or a change in the level of consciousness is a medical emergency.
- ◆ Teach the family about the factor replacement products; including how to obtain the product. Often parents are instructed on how to administer prophylactic doses of factor replacement at home.
- ◆ Ensure that the family is aware that safety is of utmost importance. Injury prevention should be reviewed at all stages of development as risk factors change based on the child's age. Contact sports are highly discouraged. The child should be fitted for a safety helmet to prevent head injury when bike riding.
- ◆ The nurse communicates to the family that an interdisciplinary team meeting reviews home environmental factors that can affect the treatment plan, such as safety concerns (e.g., bunk beds, difficulty in obtaining or paying for medications, mobility issues).
- ◆ The nurse also informs the family that for children who have experienced bleeding into the joints, physical therapy may be necessary to preserve and maintain functional status. The physical therapist is a key member in the collaboration with the family to provide comprehensive care.
- ◆ The child should wear a medical alert bracelet in the event that a medical emergency occurs outside the home when his or her caretaker or parent is not present.
- ◆ The nurse can reinforce to the family that genetic counseling is recommended since this is an inherited disorder (Lea & Williams, 2002).
- ◆ Collaboration with the social worker is essential to assist with insurance issues, obtaining medications and supplies, rehabilitation services, home nursing, and other concerns. The social worker is also available for emotional and psychosocial support.
- ◆ Numerous resources are available at comprehensive hemophilia centers and also online by the National Hemophilia Foundation at www.hemophilia.org.

ESSENTIAL INFORMATION

As there is no known cure for hemophilia, the interdisciplinary team members, including physicians, nurses, rehabilitative services, social workers, child life specialist, and school personnel, are instrumental in teaching the family about how to care for their child with hemophilia.

Recommendations are to seek health care at a facility with a comprehensive hemophilia care center. If the treatment regimen is followed, these children can live long and productive lives. It is essential that the health care team members teach the family about the prevention of bleeding to avoid complications. If a bleeding episode occurs,

the family should be instructed on the proper interventions to take. In the instance that the child has a soft tissue injury or bleeding into a joint, before seeking medical attention, the family should initiate supportive measures (i.e., application of pressure to bleeding site, ice, elevation, and rest) (Sevier, 2005).

Diagnosis

Often children are diagnosed with von Willebrand disease when excessive bleeding is present with a simple tooth loss or a minor procedure such as circumcision. A comprehensive family history is essential. The family history reveals similar bleeding manifestations in other family members since vWD is an inherited bleeding disorder. A complete physical examination is essential to detect clinical abnormalities for bleeding tendencies such as multiple sites of bruising. For a child who is experiencing moderate to severe bleeding, a thorough diagnostic evaluation is warranted. The nurse obtains blood samples for PT, PTT, fibrinogen, thrombin time, platelet function assay, CBC, vWF, and vWF antigen.

Nursing Care

Treatment for this disorder includes the administration of desmopressin (DDAVP), a synthetic analog of the antidiuretic hormone vasopressin. This hormone increases the plasma vWF and factor VIII after the administration by releasing vWF from its endothelial cell storage to produce an immediate increase in the plasma levels. This improves the platelet function and shortens the bleeding time. This treatment method may be effective in correcting the bleeding defect of vWD. In addition to the primary function of desmopressin (DDAVP), there may be secondary stabilization of additional factor VIII. Other treatment modalities of vWD include the intravenous administration of Humate-P and/or the administration of cryoprecipitate or fresh frozen plasma (FFP) (Hillman et al., 2005).

For the child identified with an inherited bleeding disorder such as hemophilia or vWD, the nurse should recommend that a medial alert bracelet be worn to appropriately alert health care personnel of the condition. Nursing care includes instructing parents about common sites of bleeding such as nosebleeds, gums, and internal bleeding. Even the smallest nosebleed can be upsetting to a child and parent. Education can also be focused on controlling the bleeding by applying pressure, applying ice, and seeking medical attention. Educate adolescent females on what constitutes excessively heavy menses. The nurse's teaching should also include tips to avoid an embarrassing moment during periods of heavy menstrual flow, such as wearing two maxi pads and not wearing light-colored pants or skirts. Small children can be instructed to avoid nose picking, vigorous nose blowing, and strenuous activity that may cause a nosebleed. Teach children to sneeze with their mouth open and gently blow nose if needed. Avoid the use of acetylsalicylic acid) (Children's Aspirin) or NSAIDs, which may promote bleeding episodes. For the child prone to epistaxis, cool mist humidification may also be recommended as a preventive measure.

IDIOPATHIC THROMBOCYTOPENIA PURPURA

Idiopathic (immune) thrombocytopenia purpura (ITP) is the most frequently occurring thrombocytopenia of childhood. The cause of this hemorrhagic disorder is unknown although it may be an autoimmune response to a disease-related antigens (Di Paola & Buchanan, 2002). The characteristic features include thrombocytopenia (an excessive destruction of platelets) and purpura (discoloration caused by petechia beneath the skin). The peak incidence occurs in children 2 to 10 years of age.

There are two types of ITP: acute and chronic. The more common type is acute. Acute ITP is often benign, self-limiting, and often occurs in children younger than 10 years after an upper respiratory infection; after the childhood diseases such as measles, rubella, mumps, and chickenpox; it may also occur after an infection with parvovirus B19 (Turgeon, 2005). Acute ITP is characterized by a normal platelet count within 6 months of diagnosis with no evidence of relapse. Approximately 80% to 90% of children diagnosed with acute ITP achieve complete remission; the remaining 10% to 20% continue with symptoms and are classified as having chronic ITP (Turgeon, 2005). Chronic ITP is most common in adults. A small percentage of children have this chronic condition. Chronic ITP is defined as the persistence of thrombocytopenia (usually less than 150,000) that lasts longer than 6 months (Nathan et al., 2003). In some chronic ITP cases there seems to be a strong correlation with the development of systemic erythematosus lupus.

ITP is a disorder of increased platelet destruction caused by antiplatelet antibodies. These antiplatelet antibodies attach to the child's own platelets and the body's immune system eliminates the platelets, erroneously identifying them as bacteria. The antibodies usually responsible for this response are glycoprotein anti-IIb and IIIa. Antibodies can be identified in many children diagnosed with ITP (Di Paola & Buchanan, 2002).

Signs and Symptoms

The clinical presentation of ITP is generally a previously healthy child who may have had a recent viral infection and then presents with petechiae, bruising, mucocutaneous bleeding, and epistaxis (Sevier & Houston, 2005). Rarely does internal bleeding, such as intracranial hemorrhage, occur (Sevier & Houston, 2005). An adolescent female's chief complaint may be menorrhagia.

Diagnosis

A thorough history and physical examination are essential. Most of these patients appear healthy, with the exception of bruising and bleeding.

“What to say” — Diagnosing idiopathic (immune) thrombocytopenia purpura

The nurse can communicate to the family about how ITP is diagnosed. It is essential that the nurse tell the family that there are no definitive tests to establish the diagnosis. Explain that other disorders such as lupus, leukemia, and lymphoma must be ruled out (Sevier & Houston, 2005). Numerous tests are required to confirm the diagnosis of ITP, including CBC and peripheral

smear examination, coagulation analysis, and possible bone marrow aspirate if steroid therapy is implemented. A bone marrow aspirate may be performed to rule out an underlying malignancy. The CBC often shows isolated and usually severe thrombocytopenia, usually a platelet count of less than 20,000 (normal platelet count is 150,000 to 400,000). The peripheral smear is often normal with the exception of thrombocytopenia with normal size to large platelets (Di Paola & Buchanan, 2002).

Nursing Insight— Accurately diagnosing idiopathic (immune) thrombocytopenia purpura

Often the child who presents to the emergency department with ITP may be erroneously identified as a child abuse victim. An accurate history and physical and evaluation of CBC should assist the health care team in determining the actual cause of the observed bruising/bleeding. ITP and child abuse may be easily confused. An accurate history is essential to elicit the appropriate diagnosis.

Nursing Care

The majority of patients with acute ITP may have spontaneous resolution of the disorder with no treatment (Sevier & Houston, 2005). The treatment for ITP among pediatric hematologists is not consistent, although recommendations from the American Society of Hematology have been established. General guidelines recommend that children who have a platelet count greater than 20,000 and are asymptomatic do not require treatment, and platelet counts should be monitored. Small toddlers and active children with bruising and petechia with platelet counts less than 20,000 are treated aggressively to avoid the most serious complication of a life-threatening intracranial bleed. Unless severe life-threatening bleeding is present, transfusion of platelets is not recommended to treat acute ITP because the antibodies attach to the infused platelets and destroy the new platelets in a similar fashion to the destruction of the patient's own platelets.

The nurse must recognize that first-line treatment strategies may include steroid administration, intravenous immune gamma globulin (IVIG) administration, or Anti-D antibody (WhinRho) administration. Children with exceptionally low platelet counts and acute bleeding require inpatient hospitalization with close observation. These children may also receive a 2- to 3-day course of IVIG intravenously. The mechanism of action of IVIG is to prevent antibody attachment to the platelets, thereby preventing platelet destruction in the spleen. A vast majority of patients who receive IVIG experience a substantial rise in platelet count within 48 hours.

clinical alert

The administration of intravenous anti-D antibody

The newest treatment modality for acute ITP patients with an Rh+ blood type is the administration of intravenous anti-D antibody. The mechanism of action of anti-D antibody is to bind to the RBCs,

which are selectively destroyed in the spleen instead of platelets. The anti-D antibody coats the Rh+ RBCs with antibody, only for Rh+ patients. The anti-D-coated cells saturate the capacity of the spleen receptors, and the platelets are spared. A common side effect of anti-D antibody is a transient hemolytic anemia that often resolves as the IgG disperses. It is important that the nurse communicate to the family the other possible side effects of anti-D antibody (e.g., fever, chills, or headache after infusion). A paramount nursing action is close observation and monitoring of the child's vital signs.

Nursing Insight— Splenectomy

In selected children in whom medical treatment has failed and there have been acute life-threatening bleeding episodes, a treatment modality may include a splenectomy. These patients must be older than 5 years of age and have low platelet counts that impact their activities of daily living (Sevier & Houston, 2005). However, advancements in medical treatment for ITP have diminished the need for the major surgical procedure of a splenectomy.

Be sure to— Understand institutional guidelines related to intravenous immune gamma globulin (IVIG)

The nurse must understand that intravenous immune gamma globulin (IVIG) is a blood product and that blood product consent may be necessary based on institutional guidelines. Administration of this product requires frequent measurement of vital signs to monitor for possible side effects, which may include fever, chills, hypotension, nausea, and headache. It is important for the nurse to check product specific information for administration guidelines (Di Paola & Buchanan, 2002).

The nurse must teach the family the most important information related to this condition: safety. Advise parents to restrict activities such as contact sports and high-risk activities such as bicycle riding, roller skating, and riding motor scooters. Parents must be instructed on how to manage a bleeding episode in the home. Most common sites of bleeding would be minor cuts and scrapes and nosebleeds. Instruct parents to apply pressure to the injury site. If the bleeding is from the nose, the nurse can instruct the caretaker to have the child lean down and forward, pinch the bridge of the nose, and if possible apply ice. For severe bleeding that does not stop with manual pressure, the caregiver must seek medical attention. Other important teaching strategies include avoiding the use of acetylsalicylic acid (Children's Aspirin) or other aspirin-containing products, injections, the use of straight-edge razors, the use of tampons, or inserting a thermometer or suppository into the rectum. The nurse should instruct caregivers to report signs or symptoms of bleeding immediately, provide a safe environment to prevent trauma such as padding a crib and using a nail file as opposed to clippers for nail grooming. It is essential that the nurse recommends to parents of a child with chronic ITP that a medical alert bracelet be worn (Fig. 33-4).

Figure 33-4 Any child who has idiopathic (immune) thrombocytopenia purpura (ITP) should wear a medical alert bracelet.

clinical alert

Intracranial bleeding

The nurse must ensure that caretakers are knowledgeable about identifying the most serious complication of ITP, an intracranial bleed. Parents must report any changes in level of consciousness or behavior, severe headaches, vision changes, ataxia, slurred speech, complaints of weakness or numbness, and severe vomiting not associated with nausea.

case study Idiopathic (Immune) Thrombocytopenia Purpura

Kelly is a 4-year-old child who has just had a respiratory infection last week. When she woke up this morning to go to daycare she had bruises and petechia. She did not have a fever. The parents immediately phoned the pediatrician and were told to bring the child to the emergency department. Her physical examination was unremarkable except for her bruising, petechia, and a platelet count of 6000. All of Kelly's other labs were within normal limits. She was admitted to the hematology oncology unit.

critical thinking questions

1. What is the goal of Kelly's treatment?
2. What would you expect Kelly's treatment to consist of?

◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation (DIC) is a hematological illness that is secondary to an underlying disease (Turgeon, 2005). Some disease states in which children may develop DIC include sepsis (usually gram-negative bacteria), hypoxemia, major trauma with severe tissue

injury, malignancy, thrombotic thrombocytopenic purpura (TTP), hemolytic uremic syndrome (HUS), extensive burns, and severe viral infections (Hillman et al., 2005).

In children with DIC, there is an abnormal coagulation process. This process is characterized by an excessive stimulation of normal coagulation that results in microthrombi. These microthrombi are released and as a result more coagulation factors and platelets are consumed and produced. When the process occurs, there is a destruction of platelets and coagulation factors resulting in hemorrhaging and thrombosis. When this clinical diagnosis of DIC is evident, there is accompanying decreased platelet count, increased prothrombin, decreased fibrinogen, and a buildup of fibrin degradation products that may develop into DIC and tissue ischemia.

Signs and Symptoms

The clinical symptomatology of excessive bleeding from orifices or due to minor procedures may lead the clinician to suspect the patient has DIC. Other pertinent assessment findings include the presence of an underlying primary illness that may place the child at high risk for developing DIC. A nursing assessment may also include the presence of petechia; purpura; hypotension; and, as the child's condition progresses, the possibility of multiorgan failure due to numerous infarctions and ischemia.

Diagnosis

There is no single test that confirms the diagnosis of DIC. The diagnosis is based on the combination of the child's clinical condition and laboratory tests pertinent to coagulopathies (Turgeon, 2005). For a child with DIC, suspicious findings include thrombocytopenia, prolonged prothrombin time (PT), prolonged partial thromboplastin (PTT), decreased fibrinogen, and increased D-dimer.

Nursing Care

When caring for a child with DIC, the nurse's primary intervention is to assess the child and provide supportive care for the symptomatology. Children with DIC are critically ill and may require management in the intensive care unit. The administration of blood and factor products is often necessary. More importantly, the underlying cause must be identified and treated. Important nursing responsibilities include early identification of risk factors that predispose patients to develop DIC. The nurse must monitor for signs of hemorrhage, bleeding (Procedure 33-1), petechiae, cutaneous oozing, dyspnea, lethargy, pallor, increased heart rate, decreased blood pressure, headache, dizziness, muscle weakness, and restlessness. If the child is bleeding, it is important that the nurse does not disturb clots, uses pressure, and applies ice to control bleeding, and measures blood loss. The nurse must monitor for internal bleeding by checking both the urine and stool for occult blood. The nurse can also obtain necessary laboratory tests and administer supportive treatments such as blood and factor products per physician orders (Hillman et al., 2005). Prognosis for DIC has improved significantly over the last two decades due to advances in supportive care such as improved antibiotics, antifibrinolytic therapy, and improvement in transfusion therapy.

When a child is critically ill and has the diagnosis of DIC, parents must be informed about the plan of care and the course of treatment. In the intensive care unit

the nurse can orient families to the unit procedures, equipment, and treatments. The possibility of excessive bleeding from multiple sites may occur and could be upsetting to family members. The nurse must communicate to families about the occurrence of excessive bleeding to help decrease anxiety. Identifying areas of knowledge deficits and ensuring consistent caregivers during this time of crisis are important nursing interventions. Provide families with honest answers in clear and concise terms (see Chapters 11, 14, and 16 for further discussion).

APLASTIC ANEMIA

Aplastic anemia is rare but is one of the most serious hematological conditions that generally afflicts adolescents and young adults. It is characterized by **pancytopenia** (a reduction in all cellular elements of the blood) caused by bone marrow hematopoiesis failure (Hillman et al., 2005). Patchy brown melanin-like pigmentation of the skin (café-au-lait spots), short stature, microcephaly, mental retardation, strabismus, and other musculoskeletal and genitourinary anomalies are also associated with aplastic anemia (Turgeon, 2005).

Nursing Insight—Pancytopenia

Pancytopenia is a common finding in aplastic anemia. In pancytopenia all formed elements of the blood are depressed at the same time. A patient with pancytopenia has neutropenia, decreased white blood cell count, anemia, decreased hemoglobin count and thrombocytopenia.

The body's cells arise from a universal/pluripotent "mother" cell called the stem cell (Nathan et al., 2003). In aplastic anemia, hematopoietic precursor cells are absent in the bone marrow, with the resultant space replaced by fat. This effect results in a decrease in all cell lines. Aplastic anemia can be congenital or an acquired illness.

Hereditary aplastic anemia is a congenital disorder that is relatively rare but it can occur with diseases such as Fanconi's anemia. Fanconi's anemia is inherited as an autosomal recessive trait. Fanconi's anemia accounts for 25-30% of cases of childhood aplastic anemia (Turgeon, 2005). Children with congenital aplastic anemia have chromosomal breakages and structural abnormalities that increase the incidence of various malignancies such as leukemia.

The majority of aplastic anemia cases are considered to be idiopathic and the specific cause is never determined (Box 33-2). Other forms of aplastic anemia are considered secondary to etiological agents that are usually associated with various environmental factors and physical conditions.

Signs and Symptoms

The presenting signs and symptoms of a child with aplastic anemia vary by severity of bone marrow suppression. The clinical course may be acute and may progress to severe bone marrow suppression with the possibility of rapid deterioration leading to death. The condition could also have an insidious onset and chronic course (Turgeon, 2005). Classification can range from moderate aplastic anemia to very severe aplastic anemia.

Procedure 33-1 Obtaining a Fecal Occult Blood Test Sample

Purpose

A fecal occult blood test (FOBT) is performed to detect hidden (occult) blood in the stool.

Equipment

Hematest cards
Gloves
Sterile tongue blade
Chemical reagent

Steps

1. Wash hands and don gloves.
RATIONALE: Prevents the spread of bacteria.
2. Verify the identity of the patient.
RATIONALE: Accurate patient identification is necessary in the delivery of safe care.
3. Check the manufacturer's instructions for specific Hematest cards.
RATIONALE: Following the correct instructions ensure proper administration of the test as well as accurate results.
4. Keep the Hematest cards at room temperature.
RATIONALE: Extreme temperatures may damage the Hematest cards.
5. Use a sterile tongue blade to remove a sample of stool from the diaper.
RATIONALE: A sterile tongue blade helps to prevent contamination of the collected specimen.
6. Place a smear of stool on both windows of the Hematest card as indicated on the instructions.
RATIONALE: Collecting an adequate amount of stool is necessary to complete the test.

7. Cover the windows with the paper flaps and wait the correct amount of time before reading the results.

RATIONALE: It is important to follow the manufacturer's instructions.

8. Apply the recommended drops of developing solution to the Hematest card.

RATIONALE: It is important to follow the manufacturer's instructions.

9. Read the back flap of the sample card within the recommended time of application of developing solution.

RATIONALE: Reading the card within the recommended time is essential to performing the test accurately.

10. The Hematest card should change color to indicate the test results.

RATIONALE: A change in color may indicate occult blood in the stool.

Clinical Alert When the nurse records results, it is important to notify the health care provider of any abnormal findings. In addition, the nurse should check the expiration date on the developing solution.

Teach Parents

It is important to teach the parents the rationale for the test.

Documentation

5/20/10 1300 Stool Hematest negative.

-D. Salani, RN

Nursing Insight— Signs and symptoms of aplastic anemia

The child's symptoms are related to the degree of pancytopenia. Anemia, pallor, dizziness, and fatigue may be present because of a decreased RBC count. Increased bleeding and bruising, petechia, and epistaxis may be attributed to a low platelet count. Increased susceptibility to infections and oral ulcerations that do not respond well to antibiotics are related to a low WBC count. The most common presenting symptom is bleeding, usually from the nose, mouth, and gastrointestinal tract. The nurse must be aware that the child with aplastic anemia characteristically does not have the clinical finding of hepatosplenomegaly or lymphadenopathy. The child with this clinical finding is usually diagnosed with leukemia.

Diagnosis

To confirm the diagnosis of aplastic anemia and rule out other hematopoietic diseases, a bone marrow aspirate and biopsy must be performed. Children who are suspected to have aplastic anemia require a thorough history and

physical and laboratory tests, including a CBC with differential. The findings of the CBC usually are consistent with all cell lines depressed. To confirm a diagnosis of aplastic anemia, a bone marrow aspiration must be performed. The results of the bone marrow aspiration generally reveal a fatty marrow with few developing blood cells.

Nursing Care

Nursing care for children with aplastic anemia varies based on the severity of illness and determination of causative factors. If the causative factor of the aplastic anemia has been identified, immediate removal of the agent is necessary. Some patients may respond to medical treatment and support. In these cases, a hematopoietic stem cell transplant may not be warranted. If there is no identified cause of the severe aplastic anemia and a suitable stem cell donor is identified, the treatment of choice is a hematopoietic stem cell transplant (HSCT). For best outcomes and long-term survival, every effort must be made to proceed to transplant as soon as possible. Following the stem cell transplant, nursing care consists of supportive care, immunosuppressive therapy, or the administration of hematopoietic growth factors.

Box 33-2 Causative Factors of Acquired Aplastic Anemia

- High dose radiation
- Autoimmune disorders
- Pregnancy
- Infectious processes
 - Hepatitis
 - Epstein–Barr virus
 - HIV
 - CMV
 - Infectious mononucleosis
- Nonpharmacological agents
 - Benzene
 - Lindane (insecticide)
 - Kerosene
 - Heavy metals
- Pharmacological agents
 - Chemotherapy
 - Chloramphenicol
 - Selected antiepileptics (carbamazepine)
 - Sulfonamides
 - Penicillamine
 - Nonsteroidal anti-inflammatory drugs (NSAIDs)
 - Antithyroid drugs
 - Psychotropics (clozapine)
 - Certain cardiovascular drugs
 - Penicillamine
 - Antithyroid drugs
 - Psychotropics (Clozapine)
 - Certain cardiovascular drugs

All patients diagnosed with aplastic anemia are extremely susceptible to infectious agents. These patients may not exhibit the “classic signs of infection.”

**critical nursing action** Supportive Care

For all patients with aplastic anemia, and especially those who are preparing for hematopoietic stem cell transplant (HSCT), the nursing care plan often consists of supportive care including transfusions of RBCs and platelets. Transfusions are used cautiously to prevent development of antibodies (alloimmunization) and possible graft versus host disease (GVHD) if this patient proceeds on to transplant. Antibiotics are often given to treat infections but are generally not recommended prophylactically.

**where research and practice meet:**
Single Stem Cell Research

The first theory about a single pluripotent stem cell to repopulate was first documented in the early 1960s by Till and McCulloch. Their early research involved injecting bone marrow cells into mice. Till and McCulloch observed “small raised lumps” that grew on the spleen of the mice related to the amount of marrow cells injected. Through this experiment, the theory of a “single stem cell” was discovered (Becker, McCulloch, & Till, 1963).

The nurse understands that drug therapy may be the first line of therapy while searching for a potential bone marrow donor. The two most common immunosuppressive drugs used in treating aplastic anemia include antithymocyte globulin (ATG) and high-dose cyclosporine (Neoral, Gengraf). Antithymocyte globulin (ATG) is a horse serum containing polyclonal antibodies against human T cells, and cyclosporine is also a T-cell-suppressing agent. Immunosuppressive therapies work with the child’s immune system. The mechanism of action is to stimulate the bone marrow to produce cells or to reduce the patient’s immune response, thereby allowing the bone marrow to work. Combined ATG and cyclosporine is the gold standard for first-line immunosuppressive therapy. There is usually a 75% to 85% response rate (Turgeon, 2005).

Another treatment modality includes the administration of hematopoietic growth factors. These growth factors are copies of substances that occur naturally in the body and attempt to stimulate the bone. Sometimes combinations of these growth factors are used to treat aplastic anemia.

**clinical alert****Anaphylactic reaction in children who receive antithymocyte globulin (ATG)**

Children with aplastic anemia who receive antithymocyte globulin (ATG) require specific nursing care related to the administration of this medication. Although rare, a severe anaphylactic reaction may occur (hypotension, tachycardia, shortness of breath, chest pain). Since there is a potential risk for anaphylaxis, an antithymocyte globulin (ATG) test dose is often administered to determine if there is a potential for an adverse reaction to this medication. The child may have no adverse reaction to the test dose, but still may have a reaction to antithymocyte globulin (ATG). If the child has been identified as being “allergic” to antithymocyte globulin (ATG), administration of this medication can still take place after a desensitization process or administration of premedications such as antihistamine and steroids.

This special population of pediatric hematology patients requires diligent nursing assessments secondary to their pancytopenia. These children may experience numerous complications from neutropenia, anemia, or thrombocytopenia. When caring for children who are neutropenic, the nurse does not traditionally see the hallmark signs of infections such as redness, swelling, and pus, since these patients do not have the neutrophils to provoke such a response. The nursing care plan can be used to monitor the subjective responses of the child.

**medication:** Hematopoietic Growth Factors

Granulocyte colony-stimulating factors (G-CSF), also known as Neupogen, are one example of a hematopoietic growth factor. G-CSF stimulates the WBC lines. Growth factors for the WBCs are given to prevent profound neutropenia and decrease susceptibility to life-threatening infections. In the home setting, this medication is given by subcutaneous injection once daily by the child’s caregiver. Possible side effects include fever, bone pain, headache, and local reaction at the injection site.

Nursing Care Plan The Child with Aplastic Anemia

Nursing Diagnosis: Risk for Infection related to decreased white blood cell count

Measurable Short-term Goal: Patient will be afebrile within 24 hours of initiation of antibiotic therapy

Measurable Long-term Goal: Patient will have a decrease in the incidence of infections

NOC Outcome:

Immune Status (0702) Natural and acquired appropriately targeted resistance to internal and external antigens

NIC Interventions:

Infection Protection (6550)
Medication Administration (2300)

Nursing Interventions:

1. Monitor temperature, blood pressure, pulse, and respirations (specify frequency).
RATIONALE: Allows recognition and treatment of fever, tachycardia, tachypnea, or hypotension or other signs of sepsis allows early intervention.
2. Administer antibiotics and acetaminophen per physician orders (specify drug, dose, route, and times).
RATIONALE: Antibiotics are used promptly to treat suspected infections in the neutropenic patient. Acetaminophen is the preferred antipyretic because acetylsalicylic acid (Children's Aspirin) or NSAIDs may increase bleeding.
3. Reinforce strict hand washing and the use of antimicrobial hand gels/foams.
RATIONALE: Hand washing is the number one method to reduce the spread of infections
4. Maintain protective isolation as per institution guidelines (specify).
RATIONALE: Individualized isolation precautions avoid contact with infectious agents.
5. Provide or assist family member to provide meticulous oral and skin hygiene.
RATIONALE: Reduce the portals of entry for infections.
6. Instruct family and visitors that no fresh fruits, vegetables, flowers, or plants are allowed in the child's room.
RATIONALE: Some fresh fruits, vegetables, flowers, and plants may harbor bacteria or viruses.

Owing to the variations in severity of aplastic anemia, the nurse's teaching plan must correlate with the child's clinical condition. The nurse can provide reassurance and support to families, including basic explanations of the disease process and recommended treatment plan. It is important for the nurse to review the child's prescribed drugs and discuss possible adverse reactions. Children who do not require hospitalizations can continue a normal lifestyle with some restrictions. The nurse can communicate to the family that monitoring the child's CBC is imperative so changes in condition from mild to moderate aplastic anemia are noted. Children and their families must be aware of signs and symptoms of pancytopenia. Patients with moderate to severe aplastic anemia should be encouraged to schedule regular rest periods, avoid contacts with crowds, and avoid sources of infections (sick contacts, soil, standing water). Injury prevention may include using a soft toothbrush for oral hygiene, ensuring a safe play environment, and avoiding the use of tampons for adolescent girls. The nurse can stress the importance of meticulous oral hygiene and diligent hand washing. For additional education materials and resources for family teaching, the nurse can refer families to the Aplastic Anemia and MDS International Foundation at www.aamds.org. New therapies are being tested and developed with the hope of developing a cure of this chronic disease.

NEUTROPENIA

Neutropenia occurs when an absolute neutrophil count is less than 1000/ μL in infants younger than 1 year of age and 1500/ μL for those older than 1 year of age.

Nursing Insight— Absolute neutrophil count (ANC)

The absolute neutrophil count (ANC) is the total number of white blood cells multiplied by the percentage of neutrophils (segs and bands) to determine the ANC.

The National Cancer Institute neutropenia grading system classifies slight neutropenia as grade 1 with ANC of less than 2000, minimal neutropenia grade 2 with ANC of less than 1500, and moderate neutropenia grade 3 with ANC less than 1000. The most severe neutropenia is grade 4 with an ANC of less than 500. When caring for children with neutropenia, the nursing plan of care is based on the severity of neutropenia present.

Neutropenia is further classified as an acquired or congenital illness. Acquired neutropenia is more common than the congenital form. Viral infections (e.g., HIV, EBV, hepatitis A and B, RSV) are often a common cause of acquired neutropenia (Turgeon, 2005). Acquired neutropenia is often referred to as secondary neutropenia due to

the fact that it occurs as a result of an illness or of treatment of the illness (e.g., chemotherapy, radiation therapy, immunosuppressive agents, specific medications, and malignancies). It can also result as part of the normal aging process. Congenital neutropenia (also known as primary neutropenia) is usually caused by a genetic abnormality that results in profound neutropenia. Some examples include severe combined immunodeficiency syndrome (SCIDs), Wiskott–Aldrich syndrome, and Kostmann's syndrome. Often these congenital neutropenia disorders are associated with the future development of more serious illnesses such as myelodysplastic syndromes or acute myelogenous leukemia.

Signs and Symptoms

Signs and symptoms of neutropenia include lymphadenopathy, organomegaly, pallor, bruising, petechia, and other abnormalities in appearance. The nurse observes the child for any underlying infection, especially the mouth, skin, ears, and perianal area. A fever may be the only clinical sign that an infection is present. Often the child with neutropenia may not have the classic signs of an underlying infection, so the nurse must pay close attention to the subtle signs that may be present. The reason these children do not display the classic signs and symptoms is that they do not possess the cells (i.e., neutrophils) to evoke such a response, such as redness, swelling, or pus.

Diagnosis

The child diagnosed with neutropenia requires a meticulous history and physical examination. The child's height and weight can be plotted on the growth chart to evaluate for any underlying genetic illness or deviations from the norm. The child's laboratory work up is based on the findings from the history and physical. In most cases a CBC with differential and a peripheral smear will be performed. It is important to focus on the absolute neutrophil count (ANC) as opposed to the total WBC count. If the child has other clinical findings such as anemia, thrombocytopenia, or high MCV with normal B₁₂, a bone marrow aspirate may be indicated. The bone marrow aspirate is helpful in ascertaining the cause and treatment regimen for the neutropenia. Usually the child with congenital neutropenia has a normal cellularity with absence of mature neutrophils in the bone marrow sample. If a bone marrow aspirate cannot be obtained, a bone marrow biopsy may be required. Additional diagnostic tests may include cytogenetics (identification of chromosomes), including flow cytometry (laser device is used for the counting and measuring cells in specialized laboratories).

Nursing Care

The initial determination of the cause of the neutropenia is relevant to the plan of care. For the patient with acquired neutropenia, the etiology must be evaluated. For patients with congenital neutropenia, the nursing plan of care is based on the degree of neutropenia and physical findings. Treatment may range from supportive measures to the administration of colony-stimulating factors and in most severe cases to bone marrow transplant if necessary.

The administration of granulocyte colony-stimulating factor such as GCSF (Neupogen) stimulates the bone marrow to produce more neutrophils.

One of the most important aspects of nursing care for neutropenic patients includes monitoring for infections such as fever, absolute neutrophil count evaluation, and physical exam. In the event an infection is suspected, treatment of a documented infection in the neutropenic patient is dependent on the organism that is isolated. Empiric therapy, usually with a broad-spectrum antibiotic, is usually implemented during the period of time in which culture results are pending. Once culture results are obtained, antibiotic therapy should be evaluated for sensitivities and adjusted accordingly. The child, who has neutropenia, whether it is congenital or acquired, needs specific teaching on management. Families must be instructed on when and how to appropriately wash their hands. Hands should be washed with soap and water for at least 10 to 15 seconds using a circular motion. Friction (rubbing) is the most important aspect of hand washing as it assists in removing germs from the hands. The nurse can teach parents how to appropriately check the child's temperature. Remind them to never check a temperature rectally because this route may cause a tear in the rectal mucosa, promoting an entrance for bacteria. Parents need to seek medical attention if the child develops a temperature of 101.5°F (38.6°C). Teaching the family about meticulous oral hygiene is also important. To prevent bacteria in the mouth, the child can use a soft toothbrush and rinse well after brushing. Good skin care is essential to prevent infections or breaks in the skin. The nurse can instruct caregivers to keep the neutropenic child away from anyone who is sick or recently received live vaccines. Instruct parents of a child who has had an exposure to chickenpox (i.e., any type of varicella illness) to immediately contact a health care provider. Administering the varicella zoster vaccine may be helpful to the neutropenic child who might be exposed to an outbreak of chickenpox.

critical nursing action The Neutropenic Child

Families and children with neutropenia can be taught the following measures to reduce the incidence of infection:

- Always be aware when routine visits are scheduled.
- Be aware of the signs and symptoms of infections such as fever (greater than 101.5°F [38.6°C]).
- Avoid large crowds, or anyone who may be sick with a cold, flu, etc.
- Keep the child's body clean by bathing every day, and brush teeth after meals and before bedtime.
- Avoid hot tubs.
- Always be sure to wash the child's hands before eating or touching her face, eyes, nose, and mouth.
- Avoid constipation and straining to have a bowel movement by drinking two quarts of fluids each day such as water and use a stool softener.
- Avoid putting anything in the child's rectum, including thermometers and suppositories.
- Avoid exposure to fresh flowers or live plants.
- Avoid exposure to stool droppings from pets and cleaning bird cages, as well as cleaning cat litter boxes.

- Do not share bath towels or drinking glasses with others, including family members.
- Avoid eating the following items:
 - Raw milk or milk products; any milk product that has not been pasteurized, including cheese and yogurt made from unpasteurized milk.
 - Raw or uncooked meat, fish, chicken, eggs, tofu
 - Foods that contain mold (e.g., blue cheese)
 - Raw honey (honey that has not been pasteurized)
 - Uncooked fresh fruit or vegetables
 - Outdated foods or foods left at room temperature for more than 2 hours
- Adolescents should not use tampons, vaginal suppositories, or douche.
- Adolescents should avoid manicures, pedicures, acrylic nails, or nail tips.
- Adolescents should use an electric shaver instead of a razor.

Blood Transfusion Therapy

With recent advances in health care and more children living with chronic illnesses, blood transfusion therapy may be required as part of the nursing care plan. Illnesses such as hematological, oncological, and other chronic conditions often necessitate the use of blood products. Nurses must be knowledgeable about blood transfusion products and specific indications for each blood product (Table 33-5). Administration of blood may vary based on institution policy and procedures and the actual product being administered.

BLOOD PRODUCT ADMINISTRATION

Most blood transfusions are delivered in the hospital. The first responsibility of the nurse who is administering a blood transfusion to a child is to review the plan of care with the family and explain in detail the indications and process of a blood transfusion. The nurse must obtain signed consent from the parent or guardian to administer blood to the child.

Be sure to— Obtain transfusion consent

Transfusion consent must be obtained before the transfusion of all blood products. Transfusion consent must include the description of procedure for transfusion, risks and benefits, treatment alternatives, and appropriate signatures including those of the health care provider, the patient if 18 years or older, the parent or other legal representative and witness (American Association of Blood Banks [AABB], 2004). Provide the opportunity for the family to ask questions. The family has the right to revoke the consent if they wish.

After the consent process is complete, obtain the required blood samples from the patient. For example, if a child requires a packed red blood cell transfusion, a type and crossmatch is indicated in order to determine the ABO and Rh factor and to reserve the donated red blood cells for this specific child.

clinical alert

Blood transfusion safety measure

During the collection of a blood sample for crossmatch, a blood bracelet with the specific identifying numbers is placed on the child's extremity. This safety measure is to ensure that the child receives the correct blood product crossmatched specifically for his or her blood type in order to prevent a fatality. Fatalities have occurred when these safety steps are not adhered to.

The only instance in which the nurse may transfuse a blood product in which a type and crossmatch are not obtained is in a severe emergency situation. In this situation, O negative blood (the universal donor for all blood products) is rapidly infused in order to save the child's life. In most emergency departments that treat trauma patients, a "rapid infuser" is the best method to warm and infuse the blood in a more efficient manner.

Optimizing Outcomes— Type and screen and type and crossmatch

The best outcome exists for the child when the nurse understand the difference between the type and screen and type and crossmatch

Type and Screen

- Obtained in anticipation that a child may need blood
- ABO group and Rh type of patient identified
- Does not remove blood from inventory

Type and Crossmatch

- Obtained if almost certain child will require blood
- ABO/Rh compatible donor red cells combined
- Cross match is good for 72 hours. (Hillman et al., 2005)

Blood is administered to the child after verifying that the correct blood product is available and that the child's clinical condition is stable (i.e., vital signs within parameters to safely administer blood). The nurse must complete the pre-assessment process for blood administration. The nurse must be aware that there are several clinical conditions that may delay the administration of a blood product:

- Fever greater than 101°F (38.3°C)
- Lack of intravenous access
- Child is unable to be closely monitored by nursing staff

Nursing Insight— Understanding blood type

When the clinical criterion is met, the nurse may proceed and obtain the product to be infused from the institution's blood bank or pharmacy. Understand that blood type is essential information for the nurse (Box 33-3).

Table 33-5 Transfusion Products

Transfusion Product	Indications	Critical Nursing Actions
Red Blood Cells	<p>Hemoglobin <8 grams on a stable patient with a chronic anemia</p> <p>Hypovolemia due to acute blood loss</p> <p>Evidence of impending heart failure secondary to severe anemia</p> <p>Patients on hyper transfusion regimen for sickle cell disease and history of:</p> <ul style="list-style-type: none"> • Cerebral vascular accident • Splenic sequestration • Acute chest syndrome • Recurrent priapism • Preoperative preparation for surgery with general anesthesia • Hypoxia <p>Children requiring increased oxygen-carrying capacity (i.e., complex congenital heart, intracardiac shunting, severe pulmonary disease—ARDS):</p> <ul style="list-style-type: none"> • Shock states (decrease B.P., increased peripheral vasoconstriction pallor, cyanosis, diaphoretic, clamminess, mottled, increased oxygen requirement, decreased urinary output • Cardiac failure • Respiratory failure requiring significant ventilatory support • Postoperative anemia 	<p>Observe for clinical signs and symptoms of anemia:</p> <ul style="list-style-type: none"> • Fatigue • Syncope • Pallor • Tachycardia • Diaphoretic • Shortness of breath • Inability to perform activities of daily living <p>Don appropriate PPE (personal protective equipment) for all blood product transfusions</p> <p>Monitor vital signs per hospital policy and procedure</p> <p>Monitor hemoglobin and hematocrit.</p> <p>During blood product infusions, observe for adverse reactions</p> <p>Blood can be stored only in a designated blood refrigerator</p> <p>Generally 10–15 mL/kg of packed red blood cells are transfused (Khilnani, 2005).</p>
Autologous Blood (self-donated blood product)	<p>For general scheduled surgical procedures in which there are clinical indications that a blood transfusion may be necessary during the intraoperative or postoperative period the patient may elect to self-donate. Check with blood bank facilities for time criteria for this type of donation.</p> <p>For general surgical procedures, the recommended hemoglobin is 10 grams or greater and for orthopedic surgery recommendations is hemoglobin of 11.5 or greater.</p>	<p>Verify with parents that self-donation has occurred</p> <p>Patient identification and administration process is the same as for all other blood products.</p>
Whole blood or Packed red blood cells (PRBC) reconstituted with Fresh frozen plasma (FFP)	<p>Hypovolemia due to acute blood loss non-responsive to crystalloids</p> <ul style="list-style-type: none"> • Hct <35% • Hypovolemia due to acute massive blood loss (i.e., major trauma) • History of blood loss at delivery or large amount of blood drawn for lab studies (10% blood volume) • Cardiac patients Hct <40% (structural heart disease, cyanosis, or congestive heart failure). • Drop in Hgb to below 10 grams intraoperatively • Exchange transfusion 	<p>Same nursing actions applicable to red blood cell infusions</p> <p>In major trauma situations, patient may be transfused with O negative blood, the universal donor</p> <p>Use blood warmer and rapid infuser if available.</p>

clinical alert

The administration process for blood products

The nurse must understand the administration process for blood products.

Pretransfusion

- Do not call for the blood product until it is needed.
- Verify the physician's orders, including the appropriate product and volume to be infused. For packed red blood cell infusions, the appropriate volume is 10–13 cc/kg. Check with institution policies and procedures. The transfusion must be started within 30 minutes after the blood has left the blood bank.
- The maximum time for the infusion is 4 hours. Transfusion needs to start immediately due to the risk of bacterial contamination and cell lysis. Most blood banks do not accept blood back after 30 minutes.

- Follow institutional policy for obtaining, verifying, and transporting blood products obtained from the blood bank.
- Complete appropriate forms and ensure accurate patient identification.
- Indicate product type and check for any special orders such as CMV safe, irradiated.
- Always check to see if any premedications were ordered before administration.
- Use personal protective equipment. Be sure to wear goggles and gloves.
- All blood products must be checked at the patient's bedside by two appropriate health care team members as per the institution's policy.
- Remember the two patient identifiers: matching the number on the blood product and the wrist band.

Initiation of the Transfusion

- Obtain baseline vital signs.
- Start the infusion slowly for the first 15 minutes.
- Designate a nurse to remain with the patient for the first 15 minutes of transfusion in the event of an adverse reaction.

During the Transfusion

- Do not infuse any other solutions simultaneously with blood through the same intravenous line. The only exception to this is normal saline (AABB guidelines, 2004).
- Never add any medications to blood.
- Monitor vital signs per the institution's policy and procedures.
- All identification information that is attached to the blood product must remain attached until the transfusion is completed.

- Monitor for signs and symptoms of adverse reactions (*see section on adverse reactions.*)

Posttransfusion

- Save the transfusion bag for at least 1 hour after the transfusion has ended.
- The blood slip must be completely filled out with the institution's required information.
- As per the American Association of Blood Bank guidelines, information to be included in the child's medical record must include the transfusion order, the type of blood product, the donor unit number, date and time of transfusion, pre- and post-vital signs, the volume infused, required signatures, and if applicable any transfusion adverse events (2004).
- Place the chart copy and blood bank copy of blood slip in an appropriate area to be kept on file as per policy and procedure.

SENSITIVITY TO CULTURAL AND RELIGIOUS BELIEFS

The nurse must be sensitive to cultural and religious beliefs in order to provide the most culturally competent care to patients and their families. In most cases, the nurse is the primary health care provider at the bedside and may experience some personal conflict when providing the necessary medical care. The nurse must be knowledgeable about various belief systems that impact care and be aware of what resources are available to assist in these situations.

Ethnocultural Considerations—Jehovah Witness

People of the Jehovah Witness faith are adamantly opposed to receiving blood and blood products. This belief is based on the literal interpretation of the Bible that states that to be transfused with blood is equivalent to eating it and therefore prohibited by scripture as cited in Leviticus 17:10-14; Acts 15:19, 20, 28, 29 and Genesis 9:3, 4. Although the Jehovah Witnesses believe it necessary to “abstain from ... blood,” they have the high standards of receiving all medical treatment including advanced technology. Jehovah Witnesses feel strongly that if blood is removed from the body, it cannot be reinfused (e.g., cell saver technology that could be used in the operating room). Self-donation is also prohibited based on this premise.

When caring for a child from a Jehovah Witness family, there may be an ethical and medical dilemma to provide quality medical care. The health care team should explore all alternative methods of treatment in order to respect the family's beliefs. In some circumstances when the child's life is severely threatened, the courts may be called upon. A court order may be required to proceed with the necessary medical treatment. The involvement of the court system relinquishes the family from making the decision for their child to have a blood transfusion. This transfer of responsibility may diminish the disgrace that the family might experience from other members of this religious group when this medical treatment is necessary to save the child's life (Linnard-Palmar & Kools, 2004).

TRANSFUSION REACTIONS

Most transfusion reactions occur during the initiation of a transfusion, but a reaction can occur at any time during this process (AABB, 2004). These reactions can vary from a mild reaction, such as mild fever, to the most severe complication of death. Children who have received multiple transfusions are at higher risk for developing a transfusion reaction (Knippen, 2006).

critical nursing action The Administration of Blood

Strict observance to the institutional policy regarding the administration of blood products cannot be stressed enough. The accuracy of patient verification is a critical nursing action that can help prevent a transfusion reaction.

FEBRILE REACTION

The most common blood transfusion reaction is a nonhemolytic **febrile reaction** in which the child develops a fever greater than 1.8°F from the baseline temperature. These reactions generally occur on initiation of the transfusion, but have been known to occur up to 12 hours posttransfusion.

Signs and Symptoms

Signs and symptoms that may be present during a transfusion reaction include fever and chills, which then may progress to more serious complications such as tachycardia, tachypnea, and hypotension.

Nursing Care

With the increased use of leukocyte-depleted blood products, this type of reaction has diminished. Premedication with acetaminophen (Children's Tylenol) sometimes can prevent this type of adverse reaction. An important nursing care measure includes monitoring the child's temperature to recognize febrile reactions early and prevent progression. If the child is having a febrile response, the nurse must immediately stop the transfusion, monitor vital signs closely, and notify the physician.

ALLERGIC REACTION

Another type of nonhemolytic reaction is an allergic reaction. This reaction occurs during a transfusion in which the child has had a previous exposure to a particular allergen in the blood product. The exposure to this allergen stimulates an antibody response and an allergic transfusion reaction is then evident. An allergic reaction may occur on the second or subsequent transfusions.

Signs and Symptoms

Signs and symptoms may include rash, hives, pruritus, swelling of the lips, wheezing, and anxiety.

Nursing Care

If the nurse suspects an allergic reaction, stop the transfusion immediately, monitor vital signs closely, and notify the physician. In most cases, the administration of an antihistamine such as diphenhydramine (Benadryl) resolves

an allergic response. An histamine blocker such as ranitidine (Zantac) may be administered to aid in relieving the symptoms of a reaction. In severe allergic reactions, the child may require the administration of steroids such as hydrocortisone (Solu-Cortef) and possibly adrenaline (epinephrine). For future transfusions for this child, prophylaxis care may be required with diphenhydramine (Benadryl) and hydrocortisone (Solu-Cortef).

BACTERIAL CONTAMINATION

Bacterial contamination is a rare nonhemolytic reaction that generally occurs during the initiation of the infusion. The actual contamination of the blood product can occur anywhere during the process of collection, storage, and administration. Guidelines from the AABB (2004) require strict adherence to the completion of all transfusions in 4 hours or less to prevent this from happening. There are strict guidelines for blood collection centers on screening of potential donors, collection, and storage of blood products.

Signs and Symptoms

Signs and symptoms that may occur during a transfusion of blood that is contaminated are shaking chills, fever, vomiting, diffuse erythema, and the onset of hypotension that may progress to shock. In severe cases hemoglobinuria, actual renal failure, and DIC may develop.

Nursing Care

If any of the signs and symptoms are identified the nurse must stop the transfusion immediately, monitor vital signs closely, start a normal saline infusion, notify the physician, and prepare emergency care (support oxygenation and ventilation, antibiotics, and vasopressors may be ordered). Nursing responsibilities include obtaining blood samples for culture and sensitivity and sending the blood product with tubing to the blood bank also to be cultured.

CIRCULATORY OVERLOAD

Circulatory overload is a rare occurrence. This reaction occurs when the infusion is given too rapidly or an excessive quantity of blood is given.

Signs and Symptoms

Signs and symptoms may include dry cough, dyspnea, rales, distended neck veins, hypertension/hypotension, bradycardia/tachycardia, clammy skin, and cyanosis of the extremities.

Nursing Care

The nurse understands the importance of accurate verification of physician orders, double-checking the volume to be infused, and the use of an intravenous pump. The nurse must be aware of children on fluid restriction and the accuracy of intake and output. If any of the signs and symptoms are identified, the nurse must immediately stop the transfusion, monitor vital signs closely, place the child upright with feet in a dependent position to increase venous resistance, notify physician, and prepare emergency care (support oxygenation and ventilation as well as diuretics may be ordered).

ACUTE HEMOLYTIC TRANSFUSION REACTION

Acute hemolytic transfusion reaction is rare but it is the most severe type of reaction. It occurs when the donor RBCs and the recipient plasma are incompatible, and there is an ABO mismatch. Acute hemolytic transfusion reactions occur upon initiation after exposure to a small amount of blood (Hillman et al., 2005).

Signs and Symptoms

Symptoms may include fever, shaking chills, pain at the intravenous site, tightness of the chest, difficulties breathing, impending sense of doom, pallor, jaundice, nausea/vomiting, red or black urine, flank pain, and progressive signs of shock such as tachycardia and hypotension.

Nursing Care

If any of the signs and symptoms are identified, the nurse must immediately stop the transfusion, monitor vital signs closely, start a normal saline infusion, verify patient identification, notify the physician, and prepare emergency care (support oxygenation and ventilation, antihistamines, fluids, diuretics, and vasopressors may be ordered). Other nursing responsibilities include obtaining blood and urine samples and sending them to the laboratory to analyze for the presence of hemoglobin, which indicates intravascular hemolysis. Insert a urinary catheter to monitor the child's output more accurately.

Nursing Insight— Teaching parents

For children receiving blood transfusions, thorough teaching by the nurse to the child and parents is essential to ease anxiety. The first transfusion of a blood product may be frightening for the child. If available, the use of a child life therapist to provide developmentally appropriate medical play could assist the child in understanding this required treatment. The nurse must alert parents to be aware of the signs and symptoms of an adverse reaction and to report any possible reaction signs and symptoms immediately. Teaching by the nurse is tailored specifically to the type of blood product being administered.

Be sure to— Transfusion reaction procedure and documentation

For any transfusion reaction, the nurse must be aware of the appropriate procedure and documentation required by the institution when an adverse reaction occurs. The nurse can check specific institutional policies and procedures about transfusion reactions. Documentation may include completing a blood transfusion reaction form and submitting an incident report.

clinical alert

Transfusion-related acute lung injury

A 2001 letter from the Food and Drug Administration (FDA) issued an alert to clinicians about transfusion-related acute lung injury (TRALI) (U.S. Food and Drug Administration, 2002). In 2003, TRALI was the most frequent cause of transfusion related deaths

(FDA Patient Safety, 2004). This complication occurs when there is an antigen–antibody reaction. This is not characterized as the typical allergic reaction. The causes of TRALI reactions are the antibodies that are found in the donated blood. These are antibodies to human leukocytes. The donor antibodies are infused to the patient and begin to attach to the patient's white blood cells and form microaggregates. These microaggregates often end up in the lungs, which may result in a vascular permeability, pulmonary edema, and life-threatening events (Knippen, 2006).

The child who is experiencing TRALI may develop respiratory distress such as shortness of breath, hypoxia, hypotension, fever, and abnormal breath sounds. The reaction typically occurs within 1–2 hours after the transfusion has started and full-blown acute respiratory distress may occur within 6 hours (Knippen, 2006).

Based on the severity of symptoms, respiratory support with a ventilator may be indicated. For mild cases of TRALI, supportive care is indicated. If this complication is suspected, it is reportable to the FDA (U.S. Food and Drug Administration, 2002).

Bone Marrow Transplantation

Hematopoietic stem cell transplant (HSCT) is the treatment for some types of oncological illnesses and hematological diseases. There are several types of hematological diseases in which hematopoietic stem cell transplant (HSCT) may be a treatment option. For instance, a child newly diagnosed with severe aplastic anemia who has an HLA-matched sibling donor may proceed immediately to transplant as curative treatment. Children with other hematological disorders who have severe sequela, such as sickle cell disease with multiple complications such as cerebral vascular accidents (CVA) and acute chest syndromes may also be candidates to undergo a HSCT. Children who require chronic transfusion therapy may also have the indications for HSCT such as beta-thalassemia and Diamond Blackfan anemia. Some genetic and autoimmune diseases are now being treated with hematopoietic stem cell transplant.

In these conditions a large volume of actual bone marrow, a bone marrow transplantation (BMT) is performed. The preparative BMT regimen consists of the administration of “near lethal” doses of chemotherapy and/or radiation to ablate the diseased bone marrow. This preparative regimen results in severe myelosuppression and places the child at grave risk for infection.

After the preparative regimen the bone marrow is surgically obtained and then infused through a central line. On the day of the transplant, also known as day “0,” the child is given an intravenous infusion of stem cells as a “rescue” and the waiting for engraftment (when the donated cells start to grow and make new blood cells). This treatment is not without potential risks, including death. Proceeding with this type of therapy may have life-long consequences for the patient and his or her family.

Nursing Insight— Hematopoietic stem cell transplants (HSCT)

There are three types of hematopoietic stem cell transplants.

In an **autologous transplant**, the ill child is his or her own donor of stem cells. These donor stem cells are obtained by harvesting the child's cells through peripheral access or

directly from the bone marrow cavity. This method is not used in hematological diseases because hematological illnesses originate in the bone marrow.

In an **allogeneic transplant**, the recipient's human leukocyte antigens (HLAs) are matched to a compatible donor, usually a sibling. The sibling must be tested by a thorough genetic investigation to determine if he or she is a carrier of the same hematological illness as the patient or is a compatible match before the transplant can occur. In other cases, the allogeneic donor is an unrelated donor but is someone who has been identified from the National Marrow Donor Program. Umbilical cord blood stem cell transplant is another allogeneic type of transplant. These rich stem cells are obtained from the childbirth process immediately after delivery of the infant. The ability to obtain stem cells in this manner is a viable alternative that recently became available.

In a **syngeneic transplant**, the donor of the bone marrow is an identical sibling.

Nursing Insight— Hematological diseases cured by hematopoietic stem cell transplant (HSCT)

- Severe aplastic anemia
- Beta-thalassemia
- Sickle cell disease
- Fanconi anemia
- Kostmann's disease
- Diamond Blackfan anemia

The child with a hematological illness who receives a HSCT must be prepared to live with potential complications. The majority of these children receive the HSCT from an unrelated donor. This carries a greater risk of long-term complications such as acute and chronic graft versus host disease (GVHD). Other complications that may occur can be a result of the preparative regimen from the chemotherapy or radiation. Additional complications may result from infections, immunosuppression, organ dysfunction, and psychosocial impact.

Apheresis

Some children with hematological diseases may require apheresis as part of their treatment plan. The name of the apheresis procedure is identified according to a specific blood component that is extracted. This process usually takes place in the hospital setting with specially trained staff. In most institutions, children must be greater than 11 lbs. (5 kg).

The process of apheresis is the selective removal of a specific blood component from a donor or child while retransfusing the remaining components. The ultimate goal in using apheresis therapy is to deplete or collect a circulating cell or substance. Blood is removed from the child, pumped through a special cell separator in the apheresis machine that removes the specific desired component by centrifugal force, and then is returned to the patient. The mechanics of the apheresis machine are comparable to those of a dialysis machine and require two large-bore lines, one line to draw from and another to return the blood.

 **Nursing Insight—Pheresis**

There are three types of pheresis.

Plasmapheresis is removal of plasma containing harmful components such as circulating complexes, antibodies (IgM, IgG), cholesterol, and toxins. Plasma alone is depleted from the child's blood and replaced by donor plasma or a plasma substitute that is reinfused along with the child's own RBCs, WBCs, and platelets. Critically ill patients who have conditions such as thrombotic thrombocytopenic purpura (TTP), meningococemia, toxic ingestion, hemolytic uremic syndrome, Guillain-Barré syndrome, and systemic lupus erythematosus may require a plasmapheresis.

Erythrocytapheresis (Red Cell Exchange)

In erythrocytapheresis (red cell exchange), RBCs are removed from the patient's blood and replaced by leukocyte depleted donor red blood cells which are reinfused to the patient along with the patient's own plasma, WBCs, and platelets. Sick cell anemia with acute chest syndrome, CVA, or severe priapism may require red cell exchange.

Leukapheresis (Stem Cell Collection or Leukodepletion)

The purpose of stem cell collection is to harvest an adequate amount of stem cells/mononuclear cells as noted by a countable marker on the white cell called a CD34 antigen. Based on the disease or reason for collecting, there may be multiple sessions in order to collect sufficient targeted cells. These mononuclear cells (monocytes) are involved in the body's immune responses. The collected stem cells are processed by the blood service and are cryopreserved in liquid nitrogen for future use. These stem cells are reinfused at a later specific date after the preparative regimen has ablated the bone marrow. Patients with solid tumors are the usual candidates to have their own stem cells removed, treated, and reinfused. Another procedure that may be used to remove excess white blood cells is leukodepletion. Leukodepletion is primarily used for patients with high white blood cell counts such as patients newly diagnosed with acute or chronic leukemia, or at risk for acute tumor lysis syndrome. Complications may develop during the apheresis process (Table 33-6).

Table 33-6 Complications of Apheresis

Complication	Critical Nursing Actions
Hypocalcemia	<p>Obtain ionized calcium levels before treatment. Correct all abnormal levels before initiating treatment.</p> <p>For apheresis lasting longer than one hour, ionized calcium levels should be monitored every hour until the end of the procedure.</p> <p>Consider calcium drip if needed:</p> <ul style="list-style-type: none"> • Calcium chloride: 20–25 mg/kg per dose used for acute hypocalcemia • Calcium gluconate: 100–500 mg/kg per day <p>(Robertson & Shilkofski, 2005)</p>
Hypotension	<p>Hypotension may occur with onset of treatment. Be sure to have fluid readily available at the bedside. Patients receiving inotropic support may need an increase in the rate of administration.</p>
Risk for Bleeding	<p>Prothrombin time (PT), partial thromboplastin time (PTT), fibrinogen level, platelet count, Hct, and activated clotting time (ACT) are measured before and after apheresis.</p> <p>ACT should be measured at the bedside at regular intervals, and citrate and/or heparin doses adjusted accordingly.</p> <p>Platelet or other blood products such as clotting factors may be required during the procedure.</p>
Hypothermia	<p>Hypothermia may result from the blood being circulated in the extracorporeal circuit outside the body.</p> <ul style="list-style-type: none"> • Utilize blood warmer on pheresis machine. • Monitor frequent temperatures to avoid hypothermia. • Assess patient for other signs of hypothermia such as bradycardia, and shivering. • Keep child warm with blankets and/or external warmer. • Increase ambient room temperature.
Transfusion Reaction	<p>Utilize leukodepleted blood.</p> <p>Monitor for transfusion reactions from the replacement products. Follow the transfusion reaction protocol if this occurs.</p> <p>Consider administration of an antihistamine for patients receiving multiple treatments.</p>
Infection	<p>Maintain strict sterile technique with all intravenous lines.</p>
Air Embolism	<p>Monitor tubing and connection sites. Check that all are secured properly.</p>
Thrombus	<p>Obtain platelet count before catheter placement and be aware when possible transfusion of platelets are necessary.</p> <p>Flush vigorously with adequate volumes of normal saline as per institutional policy.</p>

Thrombosis

A possible hematological complication for patients with chronic illness includes the development of a thrombosis (blood clot). A thrombosis is an abnormal formation of blood constituents within the vascular system. Thrombi can be caused by a variety of factors such as prolonged immobility, disease states, major surgery or trauma, hypercoagulability, venous access devices, obesity, medications, and hereditary factors. Additional complications of thrombi include stroke, deep vein thrombosis, and pulmonary emboli. Certain disease states promote a higher incidence of thrombi, such as sickle cell anemia, malignancies, and diseases of coagulation.

Signs and Symptoms

A blood clot in the lungs causes a sudden pain in the side of the chest, shortness of breath, lightheaded or increased heart rate. If blood appears in the urine there may be a blood clot in the kidneys. In the skin, small hemorrhagic spots may appear. If there is a blood clot in a large artery of an extremities (arm or leg), an obstruction occurs and the extremity becomes cold, pale, blue, and the pulse disappears below the obstructed site (Venes, 2009).

Diagnosis

Diagnosis is based on a nursing assessment of the lungs, urine, skin or red, swollen, or tender extremity. A venogram (an x-ray test that shows the blood flow through the veins) is used as well as a Doppler ultrasound exam of a limb. A D-dimer blood test is also drawn.

Nursing Care

Nursing care for children with hematological diseases include obtaining a thorough assessment of the child's risk factors for developing a thrombus. When caring for a child at risk for thrombosis a prophylactic plan of care should be individualized for each child's condition and interventions should be reviewed daily for effectiveness. All children on prolonged bed rest and those at high risk should have prophylaxis care which may include compression stockings, intermittent pneumatic compression devices, and passive range of motion. Compression stockings and intermittent pneumatic compression devices are usually used on the lower extremities. These assistive devices may promote increased venous flow and decreased venous pooling and stasis. These devices can be discontinued when the patient is ambulatory. Nursing assessment must also include a thorough skin assessment under the stocking and compression device to evaluate for redness or skin breakdown. Implementing early ambulation when appropriate is an additional preventive measure. Some children may benefit from the administration of low molecular weight heparin therapy (Vedantham, 2006).

The most serious complication associated with thrombi is the possibility of developing pulmonary emboli (sudden blockage) that can result in a life-threatening event. Deep venous thrombosis (DVT) occurs less often in children than in adults, but when it does, it has the same potential for pulmonary embolization and death (Koschel, 2004). Institutions should implement formal protocols to identify children at risk for thrombotic events and implement preventive measures.

summary points

- ◆ Blood is composed of two parts, the fluid portion called plasma and the cellular portion. The solutes include albumin, electrolytes, proteins, clotting factors, fibrinogen, globulins, and circulating antibodies. The cellular portion consists of the formed elements: red blood cells, white blood cells, and platelets.
- ◆ Several common hematological conditions occur in children. Some of these conditions can be acute in nature and with proper care can be easily eliminated. However, others can be life-threatening or cause a chronic illness that can permanently impact the lifestyle of the child and his or her family.
- ◆ The nurse can stress to the parents that the primary goal with regard to iron-deficiency anemia is prevention. Nursing care consists of nutritional counseling, assistance with obtaining recommended iron-fortified formula/cereal, and the administration of oral iron supplements.
- ◆ Children and families affected by sickle cell disease must learn to cope with lifelong chronic illness. The community-based nurse can educate the family about the goals of ongoing care including the prevention of complications associated with infections, hypoxemia, and vaso-occlusive crisis.
- ◆ Since there is no known cure for hemophilia the nurse can teach the family about how to care for the child with hemophilia. If the treatment regimen is followed, these children can live long and productive lives.
- ◆ Aplastic anemia is rare but one of the most serious hematological conditions that generally afflicts adolescents and young adults. This clinical syndrome is characterized by pancytopenia (a reduction in all cellular elements of the blood) caused by bone marrow hematopoiesis failure.
- ◆ The child who has neutropenia, whether it is congenital or acquired, will need specific teaching on management. First and foremost, the nurse can teach the importance of hand washing.
- ◆ The first responsibility of the nurse who is administering a blood transfusion to a child is to review the plan of care with the family, explain in detail the indications and process of a blood transfusion, and then obtain blood consent from the appropriate individual.
- ◆ During every transfusion the importance of strict observance to the institutional policy regarding the administration of blood products cannot be stressed enough. In addition, the accuracy of patient verification is a critical nursing action that prevents this type of acute hemolytic transfusion reaction.
- ◆ Some children with hematological diseases may require apheresis as part of their treatment plan. The process of apheresis is the selective removal of a specific blood component from a donor or child while retransfusing the remaining components.
- ◆ A possible hematological complication for patients with chronic illness includes the development of a thrombosis. A thrombosis is an abnormal formation of blood constituents within the vascular system.

review questions

Multiple Choice

- During an assessment, the pediatric nurse finds the child to be short of breath, tachycardic, pale, and irritable. The mother reports the child also has been easily fatigued. When examining the child's complete blood count, the nurse notes:
 - An increase in red blood cells
 - An increase in platelets
 - A decrease in red blood cells
 - A decrease in white blood cells
- After a sickle cell crisis, the family requires health promotion teaching before discharge. The pediatric nurse should include which of the following in the teaching plan about sickle cell crisis? (*Select all that apply.*)
 - Call the pediatrician when the child has a fever above 101.5°F (38.6°C).
 - Increase the child's fluid intake during a sickle cell crisis.
 - Administer acetaminophen (Children's Tylenol) for pain.
 - Encourage the child to rest during a sickle cell crisis.
- The pediatric nurse teaches the parents of a newly diagnosed child with hemophilia important health promotion aspects. (*Select all that apply.*)
 - Apply pressure to a bleeding injury.
 - Administer acetylsalicylic acid (Children's Aspirin) for pain and swelling.
 - Apply ice to the injury and elevate an extremity.
 - Encourage the child to return to normal activities.
- The pediatric nurse who works in a clinic with adolescents realizes that there is knowledge deficit when a 16-year-old girl says:
 - "I take my iron supplements every night with a cup of hot tea."
 - "Since I have become a vegetarian, I must eat whole grains and nuts."
 - "I take my iron pill with a glass of orange juice every morning."
 - "Since I have been taking iron pills, I've noticed that my stools are dark in color."
- When planning care for a child with aplastic anemia, the pediatric nurse is aware of which of the following? (*Select all that apply.*)
 - The child is at risk for bleeding due to thrombocytopenia.
 - Invasive procedures such as taking a rectal temperature should be avoided.
 - When the child is feeling well, it is important for the child to play.
 - Anaphylactic precautions are set up before the administration of antithymocyte globulin.

True or False

- The symptoms associated with idiopathic or immune thrombocytopenia purpura can be mistaken for signs of child abuse.
- Children with sickle cell anemia have increased hemoglobin S.

- Children with hereditary spherocytosis should receive the Hib vaccine (*Haemophilus influenzae* type b) and the pneumococcal vaccine following a splenectomy in order to prevent life-threatening bacterial infections.
- When a child has a blood disorder, a signed consent from parents is not necessary before administering blood products.

Fill-in-the-Blank

- A rise in the _____ is an indicator of red blood cell production.
- An accumulation of iron, termed _____, can be treated with a _____ agent.

Matching

Match the term with the correct definition.

- | | |
|---------------------------|---|
| 12. Purpura | a. Bloody effusion within a joint |
| 13. Thrombocytopenia | b. Painful and continuous penile erection |
| 14. Hemarthrosis | c. "Mother cell" which gives rise to all other cell lines |
| 15. Splenomegaly | d. Hand-foot syndrome |
| 16. Priapism | e. Discoloration beneath the skin caused by petechiae |
| 17. Dactylitis | f. Decrease in the number of the platelets |
| 18. Pluripotent stem cell | g. Enlarged spleen |

CONCEPT MAP

chapter 34

Caring for the Child with Cancer

Once you choose hope, anything is possible.

—Christopher Reeve

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Identify the common pediatric cancers.
- ◆ Understand the incidence and etiology of pediatric cancers.
- ◆ Describe the signs and symptoms of pediatric cancers.
- ◆ Explain diagnostic criteria for pediatric cancers.
- ◆ Explore nursing care for the pediatric cancer patient.
- ◆ Discuss the negative and long-term effects of chemotherapy for the pediatric cancer patient.
- ◆ Describe medical emergencies for the pediatric cancer patient.
- ◆ Examine the psychological impact of pediatric cancer.

moving toward evidence-based practice Quality of Life in Children with Cancer

Yeh, C.H., Chang, C.W., & Chang, P.C. (2005). Evaluating the quality of life in children with cancer using children's self-reports and parent-proxy reports. *Nursing Research, 54*(5), 354–362.

Major advances in cancer treatment outcomes and improved survival rates make the assessment of quality of life an important concern for parents and nurses. Literature cited in this study supports the belief that proxy reports tend to have greater validity with measures of objective assessments (i.e., physical findings) than with subjective assessments such as depression and anxiety.

The purpose of the study was to explore the level of agreement about quality of life measures as self-reported by children and parent-proxy reports at two specified points in time: initially and at a 6-month follow-up.

The longitudinal study included 126 children ages 7–18 (75 children; 51 adolescents) previously diagnosed with cancer and at least one parent. The Quality of Life for Children with Cancer (QOLCC), an instrument that consists of 34 items, measures the following constructs: (1) disease state and physical

symptoms; (2) physical function; (3) psychological function; (4) social function; (5) cognitive function; and (6) communication and understanding.

According to the study findings, a better quality of life for the child was reported by parents more often than by the children at both the initial and the 6-month measurement.

The investigators concluded that the parent-proxy report is not a valid tool for determining the child's perceived quality of life when the child is unable to self-report.

1. Based on the above synopsis, what additional data could be collected to expand the scope of this study?
2. How is this information useful to clinical nursing practice? See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

Cancer is a group of diseases in which there is out of control growth and spread of abnormal cells (anaplasia). Anaplastic cells resist normal growth controls. This abnormal cellular growth is also known as a neoplasm and is caused by one or a combination of three factors: (1) external stimuli or environment, (2) viruses that can alter the immune system and let the cancer grow, and (3) chromosomal and gene abnormalities.

Nursing Insight— Cell division

Normal cells divide in an orderly fashion through the four phases of cell division. Normal cells have a control mechanism that stops division when it is complete. Cancer cells have no control mechanism as they keep dividing and replicating unchecked without stopping.

Nursing Insight— Oncogenes

An oncogene is a gene found in a virus that has the ability to encourage a cell to become malignant (Venes, 2009).

A tumor is a mass of abnormally growing cells that is either benign (not cancerous), with slow and limited non-invasive growth, or malignant (cancerous), a progressively virulent growth. Cancerous growths are divided further into solid tumors (i.e., a brain tumor) and systemic cancers such as leukemia. Cancer is second only to accidents as the leading cause of death among children. It is important for the nurse to understand the terms associated with cancer (Box 34-1).

Box 34-1 Terms Associated with the Cancer Patient

Roadmap—protocol or treatment plan that is “mapped out” to guide staff and families through the treatment course.

Protocol—complete explanation of a treatment plan, includes background, drug dosages and timing, protocol requirements like tests and laboratory specimens.

Clinical trials—medical research studies conducted with volunteers. Each study is designed to answer scientific questions and to find new ways to treat cancer.

Remission—the partial or complete disappearance of signs and symptoms of disease. This does not mean “cancer free.” There could still be cancer cells that are undetectable in the body. Treatment will continue during this time.

Extravasation—leaking of potentially tissue damaging medications surrounding the injection site. May cause blistering, blanching, or excoriation that may lead to ulcer and deep skin sloughing.

Induction—chemotherapy given to achieve remission

Consolidation—chemotherapy given after induction to control microscopic disease

Maintenance—chemotherapy given on a long-term basis to maintain remission

Palliative care—treatment given to relieve rather than cure symptoms caused by cancer. Supportive care services are usually involved. The patient may still receive chemotherapy or radiation.

A & P review Pattern of Tumor Progression

A tumor originates as a single transformed cell somewhere in the body. That cell must undergo a long process of growth and development before it can form a tumor. The cell also undergoes countless divisions to form a mass that may be made up of a billion cells at the time of diagnosis. Tumor cells have very stringent constraints placed upon them as they grow. Each of the newly created cells must have a steady supply of nutrients to keep growing. While the tumor may not be directly next to a capillary, it may be close enough so that oxygen and nutrients can diffuse through tissue to tumor cells. If the tumor receives a continuous supply of nutrients and blood, it grows and invades surrounding tissue. Once a tumor grows past its critical phase it induces growth of new blood vessels into the tumor mass. It can then grow much more rapidly and produce a clinically detectable tumor. If a tumor does not receive adequate blood supply and nutrients it can die. A tumor lacking a sufficient blood supply can also remain dormant for years and not grow beyond a certain size. ♦

Nursing Insight— Gene therapy

The use of gene therapy is complex and in the early stages of usage for cancer patients. Gene therapy is used to understand and treat the genetic mutations that cause disease. The goal of gene therapy is to correct a genetic defect by inserting healthy copies of missing or altered genes into the defective gene (Alcoaster & Rodgers, 2003). Exploring the potential benefits of gene therapy for cancer patients is proceeding cautiously.

Differences Between Childhood and Adult Cancers

Anatomically and physiologically, cancers in children differ greatly from the types of cancer occurring in adults. In children many common malignancies arise from primitive embryonic tissue where there has been a strong environmental link related to the development of cancer.

where research and practice meet: Epstein-Barr Virus and Nasopharyngeal Carcinoma

Nasopharyngeal carcinoma primarily involves the lining of the nasal cavity and pharynx. It is an infrequent cause of childhood cancer. In the United States, the incidence of this tumor is approximately one in 100,000 persons younger than the age of 20, but there is a higher frequency of the tumor in North Africa and Southeast Asia. Nasopharyngeal carcinoma occurs in association with Epstein-Barr virus (EBV) infection. The virus can be detected in biopsy specimens of nasopharyngeal carcinoma, and tumor cells may have EBV antigens on their cell surface. Research is ongoing. A study by Ozyar et al. in 2004 examined 166 patients. The researchers were unable to prove a prognostically significant role of the presence of the EBV latent protein-1 and interleukin-10 expression in patients with nasopharyngeal carcinoma.

The cure rate for childhood cancers is better than for adults. The 5-year survival rate for children is 79% for those diagnosed from 1995 to 2000 as compared to 56% for children diagnosed in 1974 to 1976. The 5-year survival rate for adults has increased to 64% for all types of cancer (Jemal et al., 2005). Children tend to get cancers that affect stem cells. Adults primarily get cancers of epithelial cells, highly differentiated cells that line body cavities or cover the body surface. Pediatric cancers tend to be more aggressive and faster growing than adult cancers. They also respond more readily to chemotherapy and radiation, which target dividing cells. In comparison with adults, sometimes children with cancer are not treated locally but are referred to major cancer centers in the United States that are more familiar with research study protocols and treatment regimens. Children are also generally more resilient than adults and can tolerate more aggressive therapy. Many adults have other physiological problems that can complicate treatment.

Now Can You— Discuss cancer in children?

1. Describe the pattern of tumor progression?
2. Differentiate the differences between childhood and adult cancers?

Common Childhood Cancers

LEUKEMIA

The term leukemia refers to the cancers of the blood-forming cells or hematopoiesis. There are two types of blood-forming cells: myeloid and lymphoid. Myeloid cells differentiate and form into red blood cells, monocytes, granulocytes, and platelets (Fig. 34-1). Lymphoid cells differentiate and form into B cells and T cells. In leukemia, normal hematopoiesis (production and development of blood cells) is altered. Immature blood cells multiply at the expense of normal blood cells. These immature blood cells also have a growth advantage over normal cellular elements because of an increased rate of proliferation, a decreased rate of spontaneous apoptosis (cell death), or both (Behrman, Kliegman, &

Jenson, 2004). The immature cells are known as blast cells. Normal bone marrow elements are replaced by large amounts of these immature lymphocytes (blast cells), which causes a “crowding out” of normal red blood cells, platelets, and white blood cells, resulting in pancytopenia (a marked reduction in the number of red blood cells [RBCs], white blood cells [WBCs], and platelets) and immunosuppression. Leukemia can develop at any point during the stages of normal lymphoid or myeloid differentiation in the bone marrow and can spread to the blood, lymph nodes, spleen, liver, central nervous system, or other organs (Colby-Graham & Chordas, 2003).

Classification of leukemia is based on the predominant cell line affected and the level of cellular differentiation. The terms myeloid and lymphoid denote the cell line involved. Both myeloid and lymphoid cell lines can proliferate into acute or chronic forms of leukemia. Acute leukemia is a rapidly progressing disease that affects mostly immature, undifferentiated cells that are not able to perform their normal functions. Chronic leukemia is a less rapidly progressing disease allowing for the production of mature, more differentiated cells. These cells can maintain some of their normal function. The three major classifications of childhood leukemia are acute lymphocytic leukemia, acute myelogenous leukemia, and chronic lymphocytic leukemia (Figs. 34-2 and 34-3). Chronic lymphocytic leukemia is rarely reported in children (Colby-Graham & Chordas, 2003). Juvenile chronic myelogenous leukemia (JCML) is also rare.

Figure 34-2 Dark-stained lymphoblast cells seen in acute lymphocytic leukemia (ALL), the most common type of childhood leukemia.

Figure 34-1 Myeloid cells differentiate and form into red blood cells, monocytes, granulocytes, and platelets.

Figure 34-3 Acute myelocytic leukemic cells (AML).

Acute Lymphocytic Leukemia

Acute lymphocytic leukemia (ALL) is the most common type of cancer in children. ALL accounts for 75% to 80% of all childhood leukemias and for approximately one-third of all childhood cancers. Approximately 2800 children are diagnosed with ALL in the United States annually (Behrman et al., 2004). The peak incidence is between 2 and 5 years of age. During infancy, boys are more likely than girls to develop ALL. The leukemic cells usually are acquired versus inherited. However, there is an increased risk among children with certain genetic disorders such as Down syndrome. A variety of factors have been implicated that might predispose children to developing leukemia (Table 34-1).

SIGNS AND SYMPTOMS. The presenting symptoms of ALL vary widely, depending on the degree of infiltration of the bone marrow and other organs by leukemic cells. Most cases have an acute onset, while in others symptoms appear slowly. Fever occurs in approximately 50% of the cases. Fatigue and lethargy are also present. ALL patients have anemia and are therefore pale. Anorexia is also usually present. In more than one-third of children with ALL, especially the younger ones, bone or joint pain is present. Parents may notice a limp or the child may refuse to walk. Less common symptoms include headache, vomiting, difficulty in breathing, and low urine output. Bleeding under the skin, in the mouth, or sometimes in the eyes may be present. Petechiae can also be noted. Abdominal distention caused by an enlarged spleen as well as enlarged lymph nodes are present in more than half of the patients. Hepatomegaly may also be present.

DIAGNOSIS. A bone marrow aspirate is required to make the diagnosis of ALL. A finding of more than 25% abnormal lymphoblasts in the bone marrow is diagnostic. Other samples in the bone marrow are sent for further testing that can show chromosomal changes and better identify the specifics of the leukemia. The child's WBC count and age at diagnosis are the most important prognostic signs in ALL. The best prognosis is associated with a WBC count less than 5000/mm³ and an age of 2 to 9 years. The worst prognosis is associated with an initial WBC count of 50,000/mm³ and an age older than 10 years. Infants younger than 1 year of age at the time of diagnosis also have a very poor prognosis.

Table 34-1 Factors Predisposing to Childhood Leukemia

Genetic Conditions	Environmental Factors
Down syndrome	Ionizing radiation
Fanconi syndrome	Drugs
Bloom syndrome	Alkylating agents
Shwachman syndrome	Nitrosourea
Klinefelter syndrome	Epipodophyllotoxin
Turner syndrome	Benzene exposure
Neurofibromatosis	Advanced maternal age
Li–Fraumeni syndrome	
Severe combined immune deficiency	

Infants and patients who present with specific chromosomal abnormalities have a higher risk of relapse despite intensive therapy (Behrman et al., 2004). Lumbar puncture is performed to assess for the presence of central nervous system (CNS) disease and staging of leukemia. A chest radiograph is obtained to detect a mediastinal mass. Laboratory findings show liver or kidney involvement.

Nursing Insight— Staging

Staging describes the severity of the patient's *cancer*. It is the process of classifying tumors in relation to the degree of differentiation, possibility of responding to therapy, and prognosis (Venes, 2009).

Stage 0 indicates early cancer that is present only in the layer of cells in which it began.

Stage I, Stage II, and Stage III indicate more extensive disease, greater tumor size, and/or spread of the cancer to nearby lymph nodes or adjacent organs.

Stage IV indicates that the cancer has spread to another organ(s).

NURSING CARE. Without effective therapy and nursing care, ALL is fatal. Leukemia is treated with chemotherapy and includes three phases: remission-induction, consolidation, and maintenance. In the remission-induction phase, the tumor burden is reduced to an undetectable level. Ninety-five percent of children with ALL achieve remission during induction, which usually lasts 4 weeks. Once remission is achieved, most children relapse within a few months if treatment is stopped.

Chemotherapy agents used for remission-induction are vincristine (Oncovorin), L-asparaginase (Elspar), and prednisone (Deltasone) or dexamethasone (Decadron). Children who have a poorer prognosis are also given an anthracycline drug (chemotherapy drug that is known to affect and damage the heart, such as doxorubicin [Adriamycin]). Children with ALL also receive CNS prophylaxis. The prophylactic chemotherapy agent is injected intrathecally (in the spinal canal) into the cerebrospinal fluid (CSF) space during a lumbar puncture. Once the child is stable, the chemotherapy can be given in an outpatient setting.

diagnostic tools Lumbar Puncture

A lumbar puncture (LP), also known as a “spinal tap,” is the introduction of a needle into the subarachnoid space of the lumbar spinal cord. The needle is inserted with a stylet into the interspace between the third and fourth lumbar vertebrae under strict sterile technique (Fig. 34-4). This test is usually done to remove a sample of CSF to test it for infection. For cancer patients this procedure is also used to introduce chemotherapeutic agents into the CSF space. Since some medications cannot cross the blood–brain barrier without difficulty, physicians have obtained better results by introducing chemotherapeutic agents into the CSF space to kill cancer cells so they cannot “hide” behind the blood–brain barrier.

Complementary Care: Visualization and distraction

The child may experience anticipatory anxiety before a procedure. The use of visualization and distraction can be helpful in these situations.

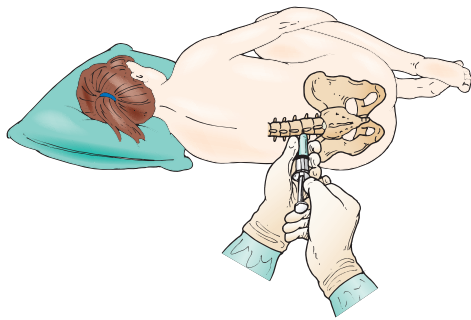

Figure 34-4 Lumbar puncture.

When using visualization, be creative. Help the child imagine a trip to his or her favorite place. Have the child close his or her eyes while the nurse plays tour guide. Ask the child questions about the favorite place and encourage the child to be part of the story or trip.

The nurse can also use distraction depending on the child's developmental level. Blowing bubbles, performing a magical light show, or simply reading a story can distract the child from the procedure.

The goal of the second phase, consolidation, is to destroy any residual leukemic cells. This phase starts immediately after remission is achieved and lasts about 6 months. Chemotherapy in this phase is frequently administered in high doses. Children are not usually hospitalized for this phase unless a complication arises. This phase may also require radiation.

The maintenance phase controls the leukemia. It can last for 2 to 3 years after diagnosis. Today, remission can be induced in 95% of children, and 5-year survival rates are nearly 80%.

Nursing Insight— Philadelphia chromosome

A small number of patients with particularly poor prognostic features, principally those with a translocation known as the Philadelphia chromosome, may undergo bone marrow transplantation during the first remission. In ALL, this chromosome is similar but not identical to the Philadelphia chromosome of chronic myelogenous leukemia (CML) (Behrman et al., 2004).

Once the maintenance phase is completed, the caregivers and the children look forward to the return of a “normal life.” Unfortunately, a number of the children do relapse. Relapse occurs in 15% to 20% of children with ALL (Behrman et al., 2004). Children who relapse while on therapy or within 6 months have a poor prognosis. This is especially true if relapse occurs shortly after completion of therapy.

Nursing Insight— Bone Marrow Transplant

Bone marrow transplant is the treatment option for children who have a second remission after relapse. This treatment involves giving the child high doses of chemotherapy and/or radiation to eradicate disease or cancer and then rescuing the patient with a source of stem cells that allows for recovery of healthy bone marrow.

There are two basic types of bone marrow transplants: autologous and allogeneic. In an autologous transplant, the patient's own peripheral blood or bone marrow is given back. An allogeneic transplant can be from a matched sibling, a relative, or an unrelated donor accessed through the National Marrow Donor Program.

Acute Myelogenous Leukemia

Acute myelogenous leukemia (AML) is the second most common type of leukemia seen in children. In the United States, it comprises 11% of the cases of childhood leukemia, with approximately 380 children diagnosed annually (Behrman et al., 2004). AML is equally distributed among ethnic groups. Males and females are affected equally. Unlike ALL, the incidence of AML is constant from birth to 10 years of age, with a slight peak in adolescence. However, a neonate is more likely to have AML than ALL. The principal defect in AML appears to be an arrest in the differentiation pathway of myeloid progenitors or precursors rather than abnormal growth kinetics. The molecular mechanism that leads to a block in differentiation is mostly unknown (Colby-Graham & Chordas, 2003). AML can affect all three types of blood cells. Accordingly, a standard classification system called the French–American–British (FAB) system is used that differentiates AML into eight main types.

SIGNS AND SYMPTOMS. Children with AML may present with vague symptoms resembling the flu. Since blast cells replace the normal blood cells in the bone marrow, children with AML often present with abnormal blood counts. A decreased number of RBCs may result in anemia that may lead to decreased oxygen delivery to the blood cells and tissue. Pallor, fatigue, headache, or dizziness may result. As a result of a decreased number of platelets, thrombocytopenia, petechiae, easy bruising, nosebleeds, or bleeding gums may be present. Fever and infection may be present as a result of decreased WBCs. Bone pain and arthralgias are less common complaints in childhood. Massive hepatosplenomegaly is uncommon except in infants with AML (Colby-Graham & Chordas, 2003). Patients with AML present with signs and symptoms that infrequently occur with ALL, including subcutaneous nodules or “blueberry muffin” lesions, infiltration of the gingiva, signs and laboratory findings of disseminated intravascular coagulation (DIC), and discrete masses known as chloromas or granulocytic sarcomas that may occur in the absence of apparent bone marrow involvement (Behrman et al., 2004).

DIAGNOSIS. A bone marrow aspiration and analysis is required for a diagnosis of AML. The biopsy typically reveals a hypercellular marrow consisting of a pattern of cells with features that permit a subclassification of disease (Behrman et al., 2004). The diagnosis is typically made when there are more than 25% malignant myeloid blast cells.

NURSING CARE. Once diagnosis is made, treatment begins promptly, especially to control any copresenting symptomatology. Induction treatment includes the combination of cytarabine (Ara-C) and daunorubicin (Daunomycin). Commonly used pediatric induction therapy regimens use

Nursing Care Plan Child with Acute Lymphocytic Leukemia

Nursing Diagnosis: Risk for Infection related to neutropenia from the disease process and treatment regimen

Measurable Short-term Goal: The child will be afebrile

Measurable Long-term Goal: The child will not experience an infection during neutropenic episode

NOC Outcome:

Immune Status (0702) Natural and acquired appropriately targeted resistance to internal and external antigens

NIC Interventions:

Infection Protection (6550)
Laboratory Data Interpretation (7690)
Surveillance (6650)

Nursing Interventions:

1. Monitor vital signs (specify frequency). Report a temperature 101.2°F (38.5°C) in a 24-hour period or 100.4°F (38.0°C) three times in a 24-hour period, or decrease in blood pressure to the physician.
RATIONALE: Increased temperature, heart rate, and respiratory rate are signs of infection. A drop in blood pressure may be a late sign of septic shock.
2. Assess the child for signs of potential infection, such as mucosal ulcerations, breaks in the skin, or localized signs of infection such as pain, redness, or swelling.
RATIONALE: The skin and mucous membranes are the first line of defense against infection, and openings in this protective barrier could be a portal for microbial entry. The child with neutropenia has diminished defense against infection, and sepsis may develop quickly.
3. Monitor laboratory values as obtained and report abnormal values to the physician.
RATIONALE: Neutropenia from the disease process and chemotherapy increase the risk for infection. An elevated WBC count indicates an infectious process.
4. Wash hands thoroughly before and after providing care and teach the child and family when and how to wash their hands. Implement isolation precautions as ordered (specify).
RATIONALE: Good hand hygiene is an effective and simple way to prevent transmission of infective microorganisms. Isolation precautions help protect the child from microorganisms in the hospital environment.
5. Instruct the family and visitors that no flowers, plants, fresh fruits, or vegetables should be brought into the child's room.
RATIONALE: Promotes a safe environment for the child. Fresh plants and foods may carry infectious microorganisms that could be dangerous for the neutropenic child.
6. Flag the child's chart and alert all caregivers that the child should not use a drinking straw, have a rectal temperature taken, or receive rectal suppositories.
RATIONALE: Protects the fragile mucous membranes of the mouth and rectum from mechanical injury, which could lead to infection.
7. Administer antibiotic and antifungal medications as ordered in a timely fashion (specify drug, dose, route, and times), and monitor for expected and adverse effects (specify).
RATIONALE: Antibiotic therapy may be started in a child with a fever and who is neutropenic with an absolute neutrophil count (ANC) of less than 500.

cytarabine (Ara-C) and anthracyclines in combination with other agents such as etoposide (VP-16) and/or thioguanine (6-TG). The anthracycline that has been used most often in induction regimens for children with AML is daunorubicin (Daunomycin). Idarubicin (Idamycin) has also been used. Studies show no difference in efficaciousness between the drugs (Colby-Graham & Chordas, 2003).

Treatment has improved significantly since the first effective therapies were introduced in the 1970's. Five-year survival rates have increased from less than 5% in 1970 to 43% today as a result of treatment intensification, the incorporation of hematopoietic stem cell transplant into primary therapy, and enhanced supportive care. Aggressive multiagent chemotherapy is successful in inducing remission in about 80% of patients. Up to 10% of patients

die of either infection or bleeding before a remission can be achieved (Behrman et al., 2004). Matched-sibling bone marrow or stem cell transplantation after remission has been shown to achieve long-term disease-free survival in 60% to 70% of patients (Behrman et al., 2004).

Now Can You— Discuss leukemia?

1. Describe the two main types of leukemia?
2. Describe the signs and symptoms of acute lymphocytic leukemia?
3. Describe three phases of acute lymphocytic leukemia chemotherapy treatment (remission-induction, consolidation, and maintenance)?
4. Discuss the purpose of a lumbar puncture?

Chronic Myelogenous Leukemia

Chronic myelogenous leukemia (CML) is a clonal disorder of the hematopoietic tissue (formation of blood cells) that accounts for 2% to 3% of all cases of childhood leukemia. About 99% of the cases are characterized by a specific translocation known as the Philadelphia chromosome. This disease has been associated with exposure to ionizing radiation, but very few children have a history of such exposure.

SIGNS AND SYMPTOMS. The presenting signs and symptoms of CML are nonspecific. They may include fever, fatigue, weight loss, and anorexia (Behrman et al., 2004).

CML is also characterized clinically by an initial chronic phase in which the malignant clone (cancerous alteration) produces an elevated leukocyte (WBC) count with increased numbers of immature granulocytes. In addition to leukocytosis, the blood counts may reveal mild anemia and thrombocytosis (increased number of platelets) (Behrman et al., 2004). The spleen is often greatly enlarged, resulting in pain in the left upper quadrant of the abdomen.

The chronic phase typically ends 3 to 4 years after onset when the CML moves into an accelerated or “blast crisis” phase. At this point, the blood counts rise dramatically and cannot be controlled with drugs. Additional manifestations may occur, including hyperuricemia and neurological symptoms, which are related to increased blood viscosity with decreased CNS perfusion (Behrman et al., 2004).

DIAGNOSIS. A diagnosis is suggested by increased numbers of myeloid cells with differentiation to mature forms in the peripheral blood smear and bone marrow. Cytogenetic studies yield the presence of the characteristic Philadelphia chromosome (Behrman et al., 2004).

NURSING CARE. Treatment of the signs and symptoms in the chronic phase can be controlled with hydroxyurea (Droxia, Hydrea), which gradually returns the leukocyte count to normal. This treatment is not definitive and does not eliminate the abnormal clone or prevent the progression of the disease. Therapy with interferon- α can produce a hematological remission in up to 70% of patients and cytogenetic remission in about 20% of patients. Combination chemotherapy has been successful in achieving remission in a small proportion of patients with CML. The optimum therapy is allogeneic bone marrow or stem cell transplantation from a matched sibling, which is curative in up to 80% of children (Behrman et al., 2004).

Nursing Insight— Juvenile chronic myelogenous leukemia (JCML)

Juvenile chronic myelogenous leukemia (JCML), also known as juvenile myelomonocytic leukemia, is a clonal proliferation of hematopoietic stem cells that typically affects children younger than 2 years of age. Patients with this disease do not have the Philadelphia chromosome that is characteristic of CML. JCML is rare and accounts for fewer than 2% of all cases of childhood leukemia (Behrman et al., 2004).

SOLID TUMORS

Solid tumors in children differ significantly from those in adults. There are some solid tumors that children acquire that never develop in adults, or if they do, are quite rare such as neuroblastoma, Wilms’ tumor, rhabdomyosarcoma, and osteosarcoma (Kline & Sevier, 2003). The most common types of solid tumors found in children are discussed here. Solid tumors are named for the type of cells of which they are composed:

- Sarcoma is a cancer arising from connective or supporting tissues (e.g., bone or muscle).
- Carcinoma is cancer arising from the body’s glandular cells and epithelial cells
- Lymphomas are cancers of the lymphoid organs such as the lymph nodes, spleen, and thymus that produce and store infection-fighting cells. These cells also occur in almost all tissues of the body; therefore, lymphomas may develop in a wide variety of organs.

Brain Tumors

Tumors of the brain or CNS are the second most common cancer in children after leukemia. Brain tumors in children differ greatly from those seen in adults. Virtually all childhood brain tumors are primary tumors, meaning that they originate in the brain. In contrast, in adults brain tumors are primarily metastatic, originating from another site and then spreading to the brain. The mortality rate among children and adolescents with brain tumors approaches 45% (Behrman et al., 2004).

Nursing Insight— Glial tumors

Glial cells are the major supportive and structural cells of the CNS, as they form a framework supporting and nourishing nerve cells. The most common type of primary brain tumors in children are glial tumors. An example of this tumor comprises the primitive neuroectodermal tumors (PNETs), which arise almost exclusively in children. This tumor often resembles the early and undeveloped cells in an embryo and may be referred to as embryonal tumors. The most common site for this tumor is in the cerebellum.

Brain tumors are also divided into two types: supratentorial and intratentorial. Supratentorial tumors occur in the anterior two-thirds of the brain above the tentorium (dura matter located between the cerebrum and cerebellum, supporting the occipital lobes), primarily in the cerebrum. Infratentorial tumors are located in the posterior third of the brain, primarily in the cerebellum and brain stem and below the tentorium.

Nursing Insight— Age-related differences in primary location of the tumor

There are age-related differences in primary location of the tumor:

Within the first year of life, supratentorial tumors predominate and include, most commonly, choroid plexus complex tumors and teratomas.

From 1 to 10 years of age, infratentorial tumors predominate, owing to the high incidence of juvenile pilocytic astrocytoma (tumor of the brain or spinal cord composed of astrocytes) and medulloblastoma (an infiltrating malignant tumor of the roof of the fourth ventricle and cerebellum) (Venes, 2009).

After 10 years of age, supratentorial tumors predominate (Behrman et al., 2004).

SIGNS AND SYMPTOMS. Clinical manifestations of patients with brain tumors depend on the tumor location, tumor type, and the age of the child. Classic signs and symptoms are related to the tumor causing obstruction of CSF drainage paths, leading to increased intracranial pressure (ICP).

Because their cranial sutures are open, infants may exhibit lethargy, irritability, and macrocephaly. They may also have a raised or tense fontanel. Projectile vomiting is often seen in the morning with little warning, or a headache may be noted.

In young children, the diagnosis of a brain tumor may be delayed because the symptoms are often similar to those of a typical gastrointestinal illness (Behrman et al., 2004). Subtle changes in personality, mentation, and/or speech may precede the classic signs and symptoms of brain tumors. Brain stem tumors are associated with cranial nerve abnormalities such as hemiparesis, a weakness on one side of the body, or a spastic gait. Older children may fall or stumble.

DIAGNOSIS. Any child who displays signs of increased ICP or other neurological signs such as ataxia, visual disturbances (if able to ascertain), or hemiparesis needs to be referred for a complete neurological exam. The diagnostic workup may include magnetic resonance imaging (MRI) or a computerized tomography (CT) scan. CT takes less time (5 to 10 minutes) and may be more appropriate if the child is able to lie still without sedation. An endocrine workup may be required for tumors that occur in the pituitary area.

Nursing Insight— *Performing the neurological exam*

The main focus of a physical assessment of a child with a brain tumor should be the neurological exam. A patient's baseline assessment is important to detect any subtle changes. This exam includes vital signs; pupil size, equality, and response to light; level of consciousness; strength and equality of grip of hands; and movement of the legs. Head circumference and the assessment of the anterior fontanel is extremely important in assessing an infant's intracranial pressure. Parents may first notice behavioral changes. The nurse should perform frequent neurological exams to determine early changes in a child's condition. Detecting subtle changes in the neurological exam can be of great value in managing a child's condition and eventual prognosis. It is important for the nurse to remember that the neurological exam can change rapidly. Timely responses to neurological changes are of vital importance for the child with a brain tumor.

NURSING CARE. First the tumor is staged. Tumor tissue is needed for the pathologist to determine the histologic

diagnosis so that proper treatment can be determined. Treatment may include surgical resection, radiation therapy, chemotherapy, and or a combination of these. In addition good communication is essential because children diagnosed with a brain tumor may die.

clinical alert

Surgical resection

The extent of surgical resection (cutting off) of the tumor correlates with the prognosis. Radical resections are particularly important in children younger than 2 years of age because cranial radiation can be deferred in these patients. Because many of the brain tumors infiltrate into surrounding normal brain, often complete resection is not possible.

After resection, postoperative care includes intravenous steroids such as dexamethasone (Decadron) to prevent edema within the brain. Anticonvulsants are indicated for the child with a supratentorial tumor where seizures are possible. Other nursing care measures include frequent neurological assessments, airway and fluid maintenance, prevention of infection, pain management, adequate nutrition and promotion of normal growth and development.

The goal of radiation therapy is to destroy the tumor while sparing normal brain tissue in the developing brain. Early use of radiation is used sparingly, related to the desire to preserve intellectual growth and decrease the possibility of growth impairment. When radiation must be used, the dose is usually high and the toxicity (poisonous) can be severe. Radiation therapy to large areas of the brain can sometimes cause changes in brain function (Venes, 2009).

In the last decade, chemotherapy has emerged as the standard care in the treatment of certain pediatric brain tumors, especially for children younger than 3 years of age. Several rounds of high-dose chemotherapy with stem cell rescue is now being offered for metastatic medulloblastoma as well as some other incurable brain tumors.

Good communication with the care delivery team is vital. Parents and the child need much emotional support and accurate information. Nurses are the pivotal coordinators of the care in this difficult situation. The nurse needs to demonstrate a positive attitude and be reassuring to parents during difficult treatments in order to build a trusting relationship with the family.

“What to say” — *When a child is diagnosed with a brain tumor*

A 4-year-old child has just been diagnosed with a brain tumor. The pediatric nurse must realize that the family is probably in a state of shock. The family or the child does not understand the exact nature or future implications of a brain tumor. While caring for the child, the nurse must treat him or her as normally as possible. It is acceptable to communicate with the child and family while the child plays. It is also important that the nurse support the parents or caregivers and allow them time to “absorb” the diagnosis.

What would the pediatric nurse say to the family?

- “It is important for you to verbalize and express your feelings.”
- “You may find it helpful to talk with others who have had the same experience as you. I have contact information for a support group. Would you like me to make a call for you?”
- “I know this is a very difficult time for you. Let’s take this a day at a time and make your child’s daily routine as normal as possible.”

Neuroblastoma

Neuroblastoma is the third most common pediatric cancer after leukemia and brain tumors (Behrman et al., 2004). Neuroblastoma is a tumor originating from neural crest cells, which are embryological precursors of the adrenal medulla and sympathetic nervous system. These cells are present in tissues of the brain, adrenal medulla, pelvis, mediastinum, and sympathetic ganglia. A neuroblastoma tumor may occur at any of these sites.

Neuroblastoma accounts for about 8% of all childhood cancers (Behrman et al., 2004). Neuroblastoma is the most common diagnosed neoplasm in infants. The median age at diagnosis is 2 years of age. Ninety percent of all cases are diagnosed in children younger than 5 years. The incidence is slightly higher in males and in white non-Hispanic children (Kline & Sevier, 2003).

The etiology of neuroblastoma remains unknown. The most common site of a primary tumor is the abdomen. In about 25% of patients, the tumor arises in the adrenal gland. The next most common site is the chest, followed by the neck. Sometimes a primary tumor site cannot be identified.

Neuroblastoma is staged into low, average, and high-risk groups, as well as into a I through IV classifications using the International Neuroblastoma Staging System (INSS) (Kline & Sevier, 2003). The prognosis can be determined by the age of the child, the stage of the tumor, and the histology of the tumor. The prognosis for children who have abdominal masses is poorer than for those with cervical, mediastinal, or pelvic tumors.

SIGNS AND SYMPTOMS. Children with neuroblastoma can present with a wide variety of initial symptoms depending on the primary site of the tumor. Most commonly the tumor is detected by palpation. On palpation the nurse notes that neuroblastoma crosses the midline. The tumor is noted as a hard, painless mass in the neck or abdomen. Masses of the thorax can be seen on radiographs and are usually an incidental finding on a film done to rule out pneumonia. If large enough, the tumor can produce edema of the lower extremities related to vascular compression. Unfortunately, at the time of diagnosis, 75% of patients with neuroblastoma have a tumor that has already spread or metastasized to another site. Nearly one-half of the patients have widespread metastasis to the bone that causes bone pain. The bones of the skull and orbit are also frequently affected, so swelling and bruising around the eyes are common.

DIAGNOSIS. Imaging studies such as MRI and CT scan may indicate the presence of a mass. A clear diagnosis of neuroblastoma can be made only by biopsy. Bone marrow aspiration may also be performed. Laboratory studies may

be ordered, as 95% of neuroblastomas secrete catecholamines. These are secreted in the urine, so vanillylmandelic acid (VMA) and homovanillic acid (HVA) tests are used to measure the level of catecholamines or catecholamine metabolites (breakdown products) in the urine.

NURSING CARE. Treatment for neuroblastoma is determined by the stage of the disease and the age of the child. Initially surgical resection is performed followed by chemotherapy. In advanced stage disease, a complete surgical resection is sometimes not possible and chemotherapy is initiated. Neuroblastoma is radiosensitive, but radiation alone is not curative. Radiation is used for tumor control in conjunction with chemotherapy and autologous or allogeneic bone marrow transplant.

During the treatment phase a complete nursing assessment is vital to ensure that the child does not have an infection and their condition remains stable. Place emphasis on the child’s comfort and alleviating pain. Supporting the child and the family during the diagnosis and treatment phase is most important. Encourage both the child and caregivers to share their feelings about the disease process and related treatments. Providing accurate information and education for the family is also important.

Wilms’ Tumor

Wilms’ tumor (nephroblastoma) is a tumor that originates in the kidney. It is named after the German doctor, Max Wilms, first described it in 1899. Ninety percent of all kidney tumors are Wilms’ tumors. Wilms’ tumor is the fourth most common cancer in children.

Wilms’ tumor accounts for 6% of all childhood cancers. The average age at diagnosis is between 2 and 5 years (Behrman et al., 2004). The disease occasionally affects older children and adults. Girls and boys are equally affected. The majority of Wilms tumors cases are sporadic, although 1% to 2% of patients have a family history. One Wilms’ tumor gene has been located at 11p13, but only 20% of all Wilms’ tumors carry that mutation (Behrman et al., 2004). The actual cause of Wilms’ tumor is unknown.

SIGNS AND SYMPTOMS. Children with Wilms’ tumor present with an abdominal mass that is usually painless. Hematuria, hypertension, and pain occur infrequently. The tumor is usually discovered on a routine physical exam, or is felt or seen by a family member during bathing or routine care. Unlike neuroblastoma, the mass frequently presents on one side and seldom crosses the midline as does a neuroblastoma. Other symptoms may be aniridia (absence of the iris, colored part of the eye), hemihypertrophy (an increased size of one half of the body), or urinary defects such as cryptorchidism and hypospadias. The tumor may be in one kidney or both kidneys (Behrman et al., 2004).

DIAGNOSIS. A child presenting with an abdominal mass needs a timely diagnostic workup. An abdominal ultrasound is often the first test ordered. An abdominal CT scan or MRI may more definitively identify other structural involvement. A complete blood count (CBC), urinalysis, and electrolyte analysis should also be ordered.

NURSING CARE. Nursing care for Wilms’ tumor consists of a thorough health and history and nursing assessment. The nurse can explain to the parents that laboratory and

diagnostic testing may include urinalysis, drawing blood for a complete blood count, a renal or abdominal ultrasound or CT scan, or MRI of the abdomen. If metastasis is suspected a chest x-ray exam may also be ordered. A surgical removal of the mass, which usually involves taking the entire kidney, and biopsy are performed.

Nursing care also centers on the administration of chemotherapy and post-radiation care. The first-line chemotherapeutic agents for Wilms' tumor are vincristine (Oncovorin), dactinomycin (Cosmegen) doxorubicin (Adriamycin), and cyclophosphamide (Cytoxan). More than 85% of children diagnosed with Wilms' tumor are cured with current treatment (Kline & Sevier, 2003).

After surgical resection for a Wilms' tumor postoperative care is similar to care for children undergoing other abdominal surgeries. A critical postoperative assessment of the remaining kidney is necessary to ensure its function.

Foods high in calories and protein are important. If a child is unable to eat or meet basic caloric requirements for growth and development, dietary supplements, allowing the child food choices, and ensuring that food textures can facilitate eating might help. Enteral or parental feeding may be provided if necessary.

critical nursing action Palpitation of the Abdomen in a Child with Wilms' Tumor

Once a child has been diagnosed with Wilms' tumor, never palpate the abdomen or allow anyone else to do so. Palpating this kind of encapsulated tumor can cause it to rupture or lead to further metastasis.

Place a warning sign on the child's hospital room door that says, "No abdominal palpation."

case study Wilms' Tumor

A mother brings her 3-year-old to the pediatrician's office. She states that while giving her daughter a bath, she noticed a "lump" on her abdomen. The mother also says the child shows no abnormal behavior. She is sleeping and playing normally. However, the mother does state she is a picky eater, but assumes that is normal for a preschooler. The mother is concerned about a "hernia or something." On physical examination by the pediatrician, a small mass in the abdominal cavity is discovered. The pediatrician sends the child for an abdominal CT scan. The CT confirms there is a mass on the left kidney. It is classified as a stage II Wilms' tumor.

critical thinking questions

1. What is the course of treatment for this child?
2. What information does the parent need to know about nutrition?

◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

Rhabdomyosarcoma

Rhabdosarcoma is the most common pediatric soft-tissue sarcoma (Behrman et al., 2004) and accounts for 5% to 8% of all childhood cancers. Overall, two-thirds of children

diagnosed with rhabdomyosarcoma will become long-term survivors. Children with distant metastatic disease at diagnosis have a poor prognosis, with only 30% surviving 5 years.

Rhabdosarcoma arises from mesenchymal cells that are normally committed to skeletal muscle formation, but can also arise from smooth muscle cells (Kline & Sevier, 2003). These tumors occur at virtually any anatomical site but are most often found in the head and neck, genitourinary tract, extremities, and trunk.

Rhabdomyosarcoma occurs with an increased frequency of patients with neurofibromatosis (Behrman et al., 2004). There are four recognizable types of rhabdomyosarcoma based on subtypes.

Nursing Insight—Rhabdomyosarcoma subtypes

The embryonal type (resembling an embryo) accounts for about 60% of all cases and has an intermediate prognosis. The botryoid type resembles a 'bunch of grapes' and accounts for 6% of cases. It is most often found in the vagina, uterus, bladder, nasopharynx, and middle ear. The alveolar type accounts for about 15% of cases. The tumor cells in this type tend to grow in cores that often have cleft like spaces resembling alveoli. Alveolar tumors occur most often in the trunk and extremities and carry the poorest prognosis. The pleomorphic type (having many shapes) is rare in childhood (1% of cases).

Note: About 20% of rhabdomyosarcomas are considered to be undifferentiated (an alteration in cell character toward a malignant state) sarcomas (Venes, 2009).

SIGNS AND SYMPTOMS. Signs and symptoms of rhabdomyosarcoma depend on the location of the primary tumor and metastasis. In the head and neck, orbital or eyelid tumors may cause proptosis (a downward displacement of the eyeball) and may impair vision (Venes, 2009). Tumors in the nasopharynx may cause sinus obstruction or result in continual sinus drainage. If the tumor erodes through the bone to the brain, signs and symptoms of increased intracranial pressure (headache, vomiting, etc.) may be present. In the genitourinary tract, the bladder and prostate are the most common sites, and hematuria or urinary obstruction may result. Extremity sarcomas are diagnosed as the affected area begins to swell. Erythema and tenderness may occur. Other sites can be any skeletal or smooth muscle and the intrathoracic, retroperitoneal, perineal, and perianal regions (Kline & Sevier, 2003).

DIAGNOSIS. Definitive diagnosis is established by biopsy. Investigating a lesion may help with diagnosis. Paratesticular lesions may be ignored for a long time by adolescents (Behrman et al., 2004). A lesion in an extremity may be mistaken for a hematoma or hemangioma. Physical examination should also include attention to the lymph nodes. Radiographic studies should include x-rays exams, CT scan, and MRI.

NURSING CARE. Treatment is based on the primary tumor and disease stage (Behrman et al., 2004). Patients with complete surgical resected tumors have the best prognosis. Unfortunately, most rhabdomyosarcomas are not completely resectable. Chemotherapy is the standard treatment. Radiation may also be added (Kline & Sevier, 2003).

Retinoblastoma

Retinoblastoma is a malignant tumor that arises from the retina at the back of the eye during fetal life or early childhood. A retinoblastoma can grow rapidly or slowly. It may produce multiple tumors that can affect one or both eyes. It is sometimes recognized at birth. It affects mainly very young children. There is no racial or gender predominance, but there is a familial predisposition in about a third of patients. Retinoblastoma can often be seen by looking at a young person's eyes or by observing a photograph taken of the individual.

Overall, 60% of cases are unilateral and nonhereditary. Bilateral involvement is found in 42% of those presenting when younger than 1 year of age and is even less common at older ages. Close to 95% of retinoblastomas are cured (Behrman et al., 2004).

SIGNS AND SYMPTOMS. Usually retinoblastoma is detected by the caregiver, who notices a whitish glow in the pupil known as leukocoria (cat's eye reflex). This is seen instead of the red eye reflex typically seen in photographs and is the most common manifestation. Other signs include strabismus, red painful eyes, and blindness (late sign). Other less common evidence of tumor is an inward or outward turning of the eye, visual impairment, or an abnormal appearance of the eye. This abnormal appearance consists of a change in color of the iris, pupils of unequal size, or increased pressure inside the eye.

DIAGNOSIS. Retinoblastoma is usually diagnosed via an examination under anesthesia using an ophthalmoscope. Orbital ultrasound and CT or MRI may be used to evaluate the extent of intraocular disease and extraocular spread.

NURSING CARE. Treatment depends on the size and location of the tumor (or tumors), with the primary goal being cure and a secondary goal of preserving vision. Primary enucleation (removal of the eye) is usually performed if there is no potential for useful vision (Behrman et al., 2004).

An important care measure before surgery includes showing parents a photograph of another child who has had this type of surgery. Parents will then understand that the child's facial appearance will be near normal. It is also important to inform parents that after surgery the eyelid is usually closed and their child will be wearing a patch over the operative eye. It is important to keep the operative site clean and dry. Postoperative medical orders may include eye socket irrigation and the application of an antibiotic ointment. Traditional postoperative measures such as airway and fluid maintenance, vital signs, pain management, and nutrition are also important.

The child is usually discharged in 3–4 days after the surgery. The nurse can teach parents about care of the eye socket by showing them gentle irrigation of the area (with the prescribed solution) and then applying a thin coating of the prescribed antibiotic ointment. Eye gauze pads are applied until the wound has completely healed. Enforce good hand washing for the entire family. In about 3 weeks the child is fitted for a prosthetic eye and the child's facial appearance appears near normal. Through the entire process the nurse can offer support to the child and family and encourage follow-up care.

Nursing Insight— Additional treatment modalities

Cryotherapy (freezing of the tumor) and photocoagulation (laser light treatment of the tumor) is used to treat small primary tumors.

BONE TUMORS

Malignant bone tumors account for approximately 5% of all childhood cancers. The two most common bone tumors are osteogenic sarcoma and Ewing's sarcoma.

Osteosarcoma

Osteogenic sarcoma or osteosarcoma is a tumor of bone that usually occurs in the metaphysis (the growing portion of a bone) (Fig. 34-5). The long bones are more frequently affected than the flat bones such as the pelvis or skull. The leg is the most common site, with the femur (upper leg) being the most commonly affected bone, followed by the tibia (lower leg) and the humerus (upper arm). The high-risk period of developing osteosarcoma is during adolescent growth spurts. Often a traumatic event leads to the discovery of osteosarcoma as a secondary finding.

Osteosarcoma can also occur as a complication of treatment for another tumor, especially at a site of prior radiation for a tumor such as retinoblastoma. These secondary radiation-associated osteosarcomas can occur 7 to 15 years after successful treatment of the primary tumor.

Nursing Insight— Osteosarcoma

The cause of osteosarcoma is unknown. Certain genetic or acquired conditions may predispose children to the development of osteosarcoma. Children with hereditary retinoblastoma have a significantly increased risk of developing osteosarcoma (Behrman et al., 2004). The annual incidence of

Figure 34-5 Osteosarcoma.

osteosarcoma in the United States is 5.6 cases per million children younger than 15 years of age. There is a slightly lower incidence in black children. Boys are usually more often affected than are girls.

Nursing Insight— Osteosarcoma prognosis

Patients with nonmetastatic extremity osteosarcoma are cured with current multiagent treatment protocols 75% of the time. Patients with pelvic tumors do not have as good a prognosis as those with extremity tumors. From 20% to 30% of patients who have limited numbers of pulmonary metastases can also be cured with aggressive chemotherapy and resection of lung nodules. Patients with bone metastasis and those with widespread lung metastasis have an extremely poor prognosis (Behrman et al., 2004).

SIGNS AND SYMPTOMS. Pain and swelling are the most common presenting symptoms. The pain increases with activity and weight bearing and may cause the child to limp. It is common for a child to have a dull aching pain for several months before diagnosis. Palpation at the site of disease often reveals tenderness, swelling, warmth, and erythema (Kline & Sevier, 2003).

DIAGNOSIS. An x-ray film may include a sunburst pattern of the affected bone. An accompanying chest x-ray exam should be performed to check for metastasis. A MRI of the entire bone should be performed to evaluate the extent of the tumor.

A nuclear medicine scan or bone scan may also be done to determine the extent of involvement in the bone (Behrman et al., 2004). Nuclear tracer isotopes such as technetium-99m or thallium-201, which are radioactive materials, show an increased uptake of radioactive material in the areas of primary tumor as well as any area of metastasis. The most common site of distant metastatic spread of osteosarcoma is to the lung.

Certain laboratory tests, such as elevated blood serum levels of serum alkaline phosphatase or lactic acid dehydrogenase, can help make the diagnosis of osteosarcoma. Although the diagnosis of osteosarcoma may be very strongly suspected after diagnostic studies, only a biopsy with microscopic examination provides final confirmation of osteosarcoma.

NURSING CARE. The primary treatment goal is total eradication of the tumor. Children with osteosarcoma receive chemotherapy first to shrink the size of the tumor. Surgical resection of the affected bone is then performed.

Nursing Insight— Amputation

Amputation was the surgical treatment used almost exclusively in the past. Today a limb-saving procedure is available. Limb-sparing surgery uses cadaver bone, grafted into place to replace the section of bone that must be resected with tumor (or where the affected part of the bone is removed) and then replaced with a metal prosthesis. In the most severe cases, total limb amputation must be used. Various types of amputation can be done, including removal of the joint (disarticulation)

or across-the-bone (transosseous) amputation. The decision as to which type is chosen must take into consideration the patient's lifestyle.

Ewing's Sarcoma

Ewing's sarcoma is the second most common type of bone tumor in children and young adults. Ewing's sarcoma is a highly malignant bone tumor with a histologic appearance that is different from that of osteosarcoma. Ewing's sarcoma tumors can occur anywhere in the body but is typically found in bones other than the long bones of the arms and legs. The most common sites are the pelvis, the arms and legs, and the ribs (Fig. 34-6). In the United States, the incidence of Ewing's sarcoma is 2.1 cases per million children. It is extremely rare among African American children (Behrman et al., 2004) and in Asian Americans. It is more often seen in young males than in females. Ewing's sarcoma commonly affects patients between 10 and 20 years of age.

There are two different types of tumors. The first type, Ewing's sarcoma family of tumors, refers to a group of small round cell undifferentiated tumors thought to be of neural crest origin that generally carry the same chromosomal translocation. The second type is called peripheral primitive neuroectodermal tumor (PPNET). Both of these tumor types can arise in long bone or in soft tissue (Behrman et al., 2004).

SIGNS AND SYMPTOMS. Clinical symptoms of Ewing's sarcoma are similar to those of osteosarcoma. Pain or tenderness and swelling at the site of the tumor are the usual presenting symptoms. The bone pain or swelling may be attributed to a sports injury and caregivers may delay seeking care (Behrman et al., 2004).

When the tumor is present in the chest wall, Askin tumor, the child may present with respiratory distress. The child with paraspinal or vertebrospinal tumors may present with symptoms of spinal cord compression. There may be systemic manifestations such as fever, or weight loss.

Figure 34-6 Ewing's sarcoma.

DIAGNOSIS. Diagnosis is made via biopsy of the bone lesion. A complete staging procedure must be performed. A CT scan, MRI, or radionuclide bone scan is helpful in determining the primary site. Location of the primary tumor is important, especially with pelvic and sacral lesions, since those tumors are not resectable.

Nursing Insight—Metastasis

Ten to thirty percent of patients have metastatic disease at the time of diagnosis. The lung, other bones, and the bone marrow are the most common sites of metastasis. Widespread metastasis to other bones and the bone marrow may have a poor prognosis.

NURSING CARE. Multiagent chemotherapy is important because it can rapidly shrink the tumor. Surgical resection is preferred if possible. Radiation treatment is also performed but it is associated with the risk of radiation-induced secondary tumors, especially osteosarcoma, as well as failure of bone growth in skeletally immature patients.

Patients with small, nonmetastatic, distally located extremity tumors have the best prognosis, with up to a 75% cure rate. Long-term follow-up is needed related to the chance of developing secondary malignancies. Late relapses even 10 years after initial diagnosis have been reported (Behrman et al., 2004).

LYMPHOMAS

Lymphatic tissue is present throughout the entire body. A lymphoma is a malignancy that arises from the lymphatic system.

Hodgkin's Disease

Two types of lymphomas are seen in children: Hodgkin's disease (HD) and non-Hodgkin's lymphoma (NHL). Hodgkin's disease was first described in 1832 by the English physician Thomas Hodgkin. The major difference between the two is that HD tends to involve the lymph nodes (those near the surface of the body) and NHL is frequently a disease of the tissues, especially the bowel, particularly in the region adjacent to the appendix, and in the upper mid-section of the chest (National Cancer Institute, 2008).

In the United States, HD accounts for about 5% of childhood malignancies. HD is rare in children younger than 5 years of age. There are three main age groups affected by Hodgkin's disease:

- Childhood form (younger than 14 years of age)
- Young adult form (15 to 34 years of age)
- Older adult form (55 to 74 years of age)

There is a male predominance in patients younger than 10 years of age, with an equal gender distribution in adolescence. People with a preexisting immunodeficiency, either congenital or acquired, have an increased risk of developing HD. The role of the Epstein–Barr virus is being studied in relation to HD. The Reed–Sternberg cell, a large cell with multiple or multilobulated nuclei, is considered the hallmark of HD, although similar cells are seen in mononucleosis (Behrman et al., 2004).

SIGNS AND SYMPTOMS. The onset of HD is commonly not acute in nature. The child may have symptoms for a long time before telling anyone or seeking care. The disease is usually localized when patients present at the time of diagnosis.

Painless, firm, cervical, or supraclavicular lymphadenopathy is the most common presenting sign. Inguinal or axillary sites are uncommon areas of presentation of lymphadenopathy. These lymph nodes are different than those associated with infection in that they are hard and not painful since they are filled with cancer cells. An anterior mediastinal mass is often present and can rapidly disappear with therapy. Systemic symptoms considered important in staging are unexplained fever, weight loss, or drenching night sweats. Less common symptoms are lethargy, anorexia, pruritus, and hepatomegaly, or splenomegaly (Behrman et al., 2004).

DIAGNOSIS. The only way to confirm HD is with a biopsy or removal of the enlarged lymph node. After biopsy confirms HD, several tests and scans are performed to determine the extent of spread: chest x-ray exam, CT scan, lymphangiogram to show abnormal nodes, MRI, bone scan, bone marrow biopsy, and blood tests.

NURSING CARE. Chemotherapy and/or radiation therapy may be used depending on the clinical stage at the time of diagnosis (Fig. 34-7).

Non-Hodgkin's Lymphoma

Malignant lymphoma is a cancer of lymphoid tissue. NHL is different from HD in that there is no single focal origin (the malignant cells are rarely localized). NHL has a rapid onset and presents with widespread involvement. NHL results from malignant clonal proliferation of lymphocytes of T or B or indeterminate cell origin. There are three histologic types of NHL:

- Small noncleaved cell lymphoma, with Burkitt and non-Burkitt subtypes, is a malignancy of B-cells.
- Lymphoblastic lymphoma is a malignancy of T cells.
- Large B-cell lymphoma with diffuse and anaplastic subtypes is a heterogeneous group of tumors characterized by cells that tend to be larger than cells seen in the other two subtypes of NHL.

Figure 34-7 A child receiving chemotherapy.

Among children younger than 15 years of age, 60% of lymphomas are NHL. NHL is seen from infancy through adolescence, with a peak between the ages of 7 and 11. Boys are affected more often than girls are. The cause is unknown, although viral, genetic, immunological, and environmental factors have been implicated.

SIGNS AND SYMPTOMS. The presenting symptom of NHL is usually pain or swelling dependent on the initial site of involvement and the extent of disease spread. The most frequent sites of involvement are the abdomen, chest, and the head or neck region. These lymphomas grow rapidly, and most children present with advanced-stage disease. Spread into the CNS may result in weakness of the facial muscles. Spread to the bone marrow may be associated with pale skin or bruising.

DIAGNOSIS. Prompt tissue diagnosis and staging is important because of the rapid growth of lymphomas. Elevated levels of serum lactic dehydrogenase (greater than 500 U/L) correlate with tumor mass and are useful in deciding on therapy intensity. Other laboratory findings vary with the site or organs involved. A CT scan or MRI of the chest or abdomen or both may assist in determining disease extent.

NURSING CARE. Aggressive multi-agent chemotherapy is started as soon as possible once the diagnosis is made and tumor staging is complete. Intrathecal chemotherapy is given for CNS prophylaxis. Children with limited disease have a good prognosis, 90% cure rate. Seventy to ninety percent of those with extensive disease who receive good supportive care can expect to be cured.

clinical alert

Discarding chemotherapy drugs

When handling equipment or material that has contained chemotherapy drugs, discard it in a designated container that is properly labeled (Fig. 34-8). Chemotherapy drugs are considered hazardous waste material.

Figure 34-8 Chemotherapy waste receptacle.

OTHER CANCERS

Liver Cancer

In the United States, primary malignant liver tumors are the tenth most frequent pediatric malignancy. However, many other kinds of cancers can spread or metastasize to the liver. The two primary types of liver cancer are hepatoblastoma and hepatocellular carcinoma.

SIGNS AND SYMPTOMS. The first sign of liver cancer is a mass in the abdomen discovered by a family member or physician during a routine exam. It is usually located in the upper right side of the abdomen. Other symptoms the child might experience are a vague feeling of abdominal fullness, pain, vomiting, diarrhea, fever, abnormal weight loss, jaundice (yellow appearance of skin or sclera), or general itching. It is not uncommon for these symptoms to be present for months before a diagnosis is made. Occasionally the liver may produce hormones that cause platelets to increase and the child has a very high platelet count.

DIAGNOSIS. X-ray, ultrasound, CT scan, and MRI are used to diagnose liver cancer. These tests enable the physician to determine the severity and metastasis. The most common areas of metastasis are to other parts of the liver, the lungs, lymph nodes in the abdomen, and rarely to the brain or bones. Biopsy of the liver cells confirms the diagnosis.

NURSING CARE. Chemotherapy may be used first to shrink the size of the tumor. The best chance of curing liver cancer is surgical removal of the tumor. More than three-fourths of the liver can be removed without any problems because the liver can regenerate or regrow. Hepatoblastoma responds very well to chemotherapy, but hepatocellular carcinoma does not respond well to any known chemotherapy. It is important to remember that new drugs are being investigated all the time.

Nursing Insight— Alpha-fetoprotein (AFP)

An interesting note is that both hepatoblastoma and hepatocellular carcinoma can produce a protein called alpha-fetoprotein (AFP), which can be detected in the blood via a simple blood test. If AFP levels fall, it indicates that treatment is working. If AFP levels rise, it means the tumor is not responding.

Nursing Insight— Extragonadal germ cell cancer (EGC)

Extragonadal germ cell cancer (EGC) are tumors that originate in the sperm forming cells in the testicles (male gonads) or egg producing cells in the ovary (female gonads). This type of cancer is located on the midline from the pineal gland to the coccyx. EGC can be either benign or malignant. Most of the benign tumors occur in children. Surgical treatment can result in high rates of long-term survival and cure. Note: Undescended testes are associated with an increased risk of testicular cancer (Behrman et al., 2004).

Nursing Care of the Child with Cancer

Tailored nursing care of the child with cancer is important. After diagnosis/staging and during the ongoing treatment a thorough nursing assessment is crucial in order to maintain realistic optimal health and prevent complications. The nurse assesses for signs and symptoms of infection and bleeding. Additionally, the nurse monitors skin integrity (including mucous membranes), heart, kidney, bowel, lung, musculoskeletal and sensory function. Assessing the child's nutritional and pain status as well as evaluating the child's ability to meet normal growth and developmental milestones is also important.

There are several areas of nursing care for the child with cancer: maintaining nutrition, preventing infection, administering chemotherapy, addressing radiation side effects, understanding the use of surgery and related nursing diagnosis, pain control, offering psychosocial support, managing negative and long-term effects of cancer treatments and preventing medical emergencies. Understanding the psychological impact of pediatric cancer is also an important element of care.

NUTRITION

Good nutrition is essential for the child with cancer to promote realistic optimal health as well as maintain normal growth and development (Fig. 34-9). For the child with cancer, the demands of the illness and subsequent treatment can cause certain challenges. Malnutrition has been reported to occur in 8% to 32% of pediatric oncology patients (Bryant, 2003).

Parents frequently have anxiety about proper nutrition because the child can respond differently to treatment(s) and their desire and ability to eat and drink often times changes. Some children are able to eat enough food to have strength and energy to enjoy a normal level of activity; others are not. Poor nutrition can lead to tiredness or irritability, greater susceptibility to infections, and reduction of growth and developmental patterns.

The side effects of cancer therapy (nausea and vomiting, mouth sores, diarrhea, or constipation) can also make achieving adequate nutrition a challenge too. Chemotherapy

Figure 34-9 Good nutrition is essential for the growing child to maintain normal growth and development.

and radiation may interfere with the ability to chew and swallow. The child's sense of taste may change and their appetite may be poor.

A healthy immune system is a critical foundation of treatment. The immune system needs good nutrition for proper function. Proper immune function is possible only if the child obtains enough fluid intake and a high-calorie balanced diet, emphasizing proteins, fatty acids, vitamins, and minerals. The nurse can offer suggestions to maintain good nutrition (Box 34-2). Encourage a diet that includes foods from all four food groups.

The nurse tries simple care measures first, such as offering small frequent feedings, allowing the child food choices, choosing food textures that are appealing and providing the child adequate time to eat. If the patient is unable to maintain good nutritional status, the nurse considers enteral tube feedings. If the gastrointestinal tract is not functioning well, total parenteral nutrition (TPN) via the intravenous route may be the only option. Communicate to the child and his or her parents that tube feedings or (TPN) may be temporary and that he or she may be able to eat independently again.

Collaboration in Caring— *The role of a nutritionist*

Consultation with the dietician is essential to achieve the child's best nutritional outcome. If a child is unable to eat or meet basic caloric requirements for growth and development, the dietician can recommend protein shakes and nutritional supplements. The dietitian can also teach the child and family what foods would be best tolerated for certain conditions such as oral ulcerations or difficulty in swallowing.

INFECTION

A priority nursing action is preventing infection. It is essential that the nurse monitor for systemic and localized signs of infection every 2–4 hours (take the child's temperature every 4 hours). Report a single temperature greater than 101.2°F (38.5°C) in a 24-hour period or 100.4°F (38.0°C) three times in a 24-hour period.

The nurse provides meticulous skin care and uses good hand washing. Instruct visitors to wash hands on entering and leaving the patient's room. Universal precautions and designated isolation precautions as instituted. Monitor and report laboratory values as ordered, such as absolute granulocyte count, WBC count, complete blood count (CBC) with differential, serum protein, serum albumin, and cultures. Encourage rest and sleep by providing a quiet environment.

Teaching the child and parents about the principles of prophylactic antibiotics as well as on the signs and symptoms of infection in order to promote the best possible health for the child is important.

CHEMOTHERAPY

Chemotherapy is the primary treatment modality for many pediatric cancers. The nurse administers chemotherapy using a variety of drugs to destroy or kill cancer cells. The goal of chemotherapy is to reduce the primary size of the tumor by destroying cancer cells and to prevent

Box 34-2 Suggestions for Nutrition**NAUSEA/VOMITING**

- Offer plain, bland foods such as cereal, canned or fresh fruit, rice, pasta, toast, mashed potatoes, soup, crackers, or plain meat.
- Avoid spicy, heavy, or fatty foods.
- If food smells bother the child, choose cold or room-temperature foods, use a cup with a lid.
- Do not offer solid food and liquid at the same time, as this can induce nausea by making the child feel too full; give liquids 30–60 minutes after solid food.

DIARRHEA

- Offer plenty of liquids.
- Try bananas, rice, applesauce, toast, and tea.
- Cut back on fiber in the diet.

CONSTIPATION

- Provide extra liquids; offer beverages that contain caffeine, like coffee, tea, and cola.
- Increase fiber in the diet.
- Encourage the child to increase activity level.

POOR APPETITE

- Offer small amounts of food four or more times a day.
- Offer liquids between meals.
- Make every bite count by offering “power packed foods.”
- Start with small portions, then gradually increase them.
- Allow the child to have foods and beverages that he or she especially likes.

SORE THROAT AND MOUTH

- Offer soft foods such as pudding, Jell-o®, macaroni and cheese, apple sauce, bananas, ice cream, Italian ice, popsicles.
- Avoid acidic foods like oranges and tomatoes, spicy foods, or foods that require a lot of chewing.
- Encourage good oral hygiene.

HEARTBURN OR REFLUX

- Do not give the child high-fat, spicy foods, caffeine, citrus juices, cinnamon, peppermint, or pepper.
- Keep the child upright for at least 1 hour after eating.

DIFFICULTY CHEWING OR SWALLOWING/DRY MOUTH

- Give the child soft, moist foods.
- Encourage sips of liquids while eating.
- Avoid hard foods that require a lot of chewing.
- Cut the food into small pieces.
- Use extra butter, sauces, or gravies.
- Offer hard candy to suck on.

BELCHING, INTESTINAL GAS, OR CRAMPS

- Avoid gas-forming foods such as cabbage, broccoli, cauliflower, cucumbers, beans, and carbonated beverages.
- Encourage the child to eat or drink slowly.
- Do not allow the child to chew gum.

Family Teaching Guidelines... Signs and Symptoms of Infection

HOW TO: Teach the Family How to Recognize Signs and Symptoms of Infection

The family needs to understand that any of these signs and symptoms or a combination of them must be reported to the physician immediately.

Fever

Decrease in temperature

Runny nose (or other respiratory illness)

Sore throat

Childhood disease such as chickenpox

Lethargy

Pale or ashen color

Chills

Diaphoresis

Poor appetite

Poor fluid intake

Nausea, vomiting, or diarrhea

Decreased urination

Foul smelling urine, or pain or burning upon urination

ESSENTIAL INFORMATION

The rectal mucosa is very vascular and an area of potential injury or a source of infection. Never take a rectal temperature, administer any rectal suppository or an enema.

those cells from spreading or metastasizing (Alcoser & Rodgers, 2003).

Chemotherapy destroys and stop these rapidly dividing and mutating cancer cells by interfering with cell division (Alcoser & Rodgers, 2003) (Table 34-2). A variety of venous access devices are available to administer chemotherapy (Table 34-3).

RADIATION

Radiation therapy is using ionizing radiation to break apart the bonds within a cell, damaging it and causing it to die. This treatment has evolved over the years with respect to children. Today with the use of CT scan and MRI scans, it is possible to more precisely deliver radiation therapy to very specific targeted areas. External beam accounts for the majority of radiation treatments in children. The amount of radiation used is determined by the patient's age, tumor site, tumor size, tumor radiosensitivity, coexisting disease, and the use of other treatment modalities. The lowest effective dose of radiation is calculated and then delivered over a 3- to 6-week period. Treatment lasts just a few minutes. It is very important for the child to remain still and not move during treatment. Sometimes it may be necessary to sedate the child (Alcoser & Rodgers, 2003). Radiation is used with some hesitancy in children younger than 3 years of age because it can cause severe damage to healthy cells and restrict growth and fertility in the future. Nursing care includes measures that address the radiation side effects.

Table 34-2 Chemotherapeutic Agents and Common Cancer Drugs

Agent	Indications	Route	Side Effects
Asparaginase (Elspar, Kidrolase) Classification: Antineoplastic Pharmacological action: Enzyme	Acute lymphoblastic leukemia (ALL)	IM and IV	Seizures, hyperglycemia Nausea/vomiting, rashes, coagulation abnormalities, hepatotoxic, pancreatitis, anaphylaxis (have emergency medications available)
Bleomycin (Blenoxane) Classification: Antineoplastic Pharmacological: Antitumor antibiotics	Hodgkin's disease (HD) Osteosarcoma Testicular embryonal cell carcinoma	IM, IV, and SQ	Pulmonary fibrosis Pneumonitis, hypotension, nausea/vomiting, anorexia, hyperpigmentation, rashes. Anaphylaxis: fever, chills
Carboplatin (Paraplatin, Paraplatin AQ) Classification: Antineoplastic Pharmacological: Alkylating agent	Brain tumors Soft tissue sarcoma Osteosarcoma Retinoblastoma Neuroblastoma	IV	Ototoxicity, nausea/vomiting, constipation, diarrhea, stomatitis, renal and liver toxicity, hypocalcemia, hypokalemia, hyponatremia, hypomagnesemia Anaphylactic-like reactions
Corticosteroid (Dexamethasone, Decadron, Hydrocortisone, Prednisone) Classification: corticosteroid Pharmacological: Systemic corticosteroids, anti-inflammatory	ALL Non-Hodgkin's lymphoma (NHL) HD Cerebral edema	PO, IV, and IT	Immunosuppression Weight gain, hypertension, anorexia, nausea/vomiting, acne, delayed wound healing, hirsutism, petechiae, osteoporosis, growth delay Cushingoid appearance
Cyclophosphamide (Cytosan, Neosar, Procytox) Classification: Antineoplastic, Immunosuppressant Pharmacological: Alkylating agent	NHL HD ALL Neuroblastoma Wilms' tumor Bone and soft tissue sarcoma Retinoblastoma	PO and IV	Myelosuppression Nausea, vomiting, anorexia, diarrhea, pulmonary & myocardial fibrosis, hemorrhagic cystitis, leukopenia, hematuria, alopecia, sterility, SIADH May cause second neoplasm
Daunorubicin (Daunomycin, Cerubidine) Classification: Antineoplastic Pharmacological: Anthracyclines	ALL AML Osteosarcoma Soft tissue sarcoma	IV	Blistering, myelosuppression, Cardiotoxic: arrhythmias, acute cardiac myopathy—delayed Nausea/vomiting, stomatitis, potentiation of radiation, alopecia, rash, hyperpigmentation of nails
Doxorubicin (Adriamycin, Adria, DOX, Rubex) Classification: Antineoplastic Pharmacological: Anthracyclines	ALL AML Osteosarcoma Soft tissue sarcoma Neuroblastoma	IV	Blistering, nausea/vomiting, stomatitis, esophagitis, diarrhea, red urine, anemia, hypersensitivity reaction, sterility. Cardiotoxic: arrhythmias, acute cardiomyopathy—delayed, potentiation of radiation hyperpigmentation of nails, seizures, hypertension, edema, nausea/vomiting, diarrhea, cough, shortness of breath, rash, thrombotic events
Epoetin/Erythropoietin (Epoen, EPO, Procrit) Classification: Biological Response Modifier Pharmacological: Hormone	Anemia	IV and SQ	Pulmonary edema, CHF, MI, hypotension, nausea/vomiting, anaphylaxis

Table 34-2 Chemotherapeutic Agents and Common Cancer Drugs—cont'd

Agent	Indications	Route	Side Effects
Etoposide (VP-16, VePesid) Classification: Antineoplastic Pharmacological: Podophyllotoxin derivative	AML, ALL NHL HD Bone and soft tissue sarcoma Wilms' tumor Brain tumor Neuroblastoma Retinoblastoma	IV	Excessive leukocytosis, pain, and redness at subcutaneous site.
Filgrastim (G-CSF—granulocyte colony stimulating factor) (Neupogen) Classification: colony-stimulating factor Pharmacological: Hematopoietic progenitor mobilizer	Recovery drug for neutropenia	IV and SQ	Medullary bone pain
Fluorouracil (5-FU, Adrucil) Classification: Antineoplastic Pharmacological: Antimetabolite	Brain tumors Germ cell tumors Osteosarcoma Soft tissue sarcoma NHL ALL	IV	Myelosuppression, nausea/vomiting (mild), mucositis (severe), hyperpigmentation of nails, nail loss, dermatitis, phototoxicity, myelosuppression, nausea/vomiting, diarrhea, neurotoxicity (encephalopathy, hallucinations), hepatotoxicity, hemorrhagic cystitis, alopecia, sterility, may cause second neoplasm.
Ifosfamide (Ifex) Classification: Antineoplastic Pharmacological: Alkylating agent	Stops methotrexate from harming the cells when given in high doses	IV	Allergic reactions: rash, urticaria, wheezing
Leucovorin (Citrovorum factor, folinic acid, Wellcovorin) Classification: Antidote (for methotrexate), vitamins Pharmacological: Folic acid analog	Recovery drug to prevent hemorrhagic cystitis from ifosfamide and cyclophosphamide	IV PO	*Dose dependent on methotrexate level *Given 24 hours after first methotrexate level has begun
Mesna (Mesnex, Uromitexan) Classification: Antidote Pharmacological: Ifosfamide detoxifying agent	Prevention of ifosfamide-induced hemorrhagic cystitis	IV, PO, IM, and IT	Dizziness, drowsiness, headache, anorexia, diarrhea, nausea/vomiting, unpleasant taste, flushing, flu-like symptoms
Methotrexate (MTX, Amethopterin) Classification: Antineoplastic Immunosuppressant Pharmacological: Antimetabolite	ALL Osteosarcoma NHL	IV	Myelosuppression, nausea/vomiting/stomatitis, alopecia, hepatotoxicity, neurotoxicity, photosensitivity, rash, pulmonary fibrosis, aplastic anemia.
Ondansetron (Zofran) Classification: Antiemetic Pharmacological: 5-HT ₃ antagonist	Prevention of nausea/vomiting associated with chemotherapy	IV and PO	Headache, diarrhea, constipation, dry mouth, extrapyramidal reactions
PEG-L-asparaginase (pegasparagase) (Oncospar) Classification: Antineoplastic Pharmacological: Enzymes	ALL HD	IM and IV	Seizures, pancreatitis, lip edema, headache, nausea/vomiting, diarrhea, DIC, hemolytic anemia, pancytopenia, chills, night sweats
Vincristine (Oncovorin, Vincasar PFS) Classification: Antineoplastic Pharmacological: Vinca alkaloids	Wilms' tumor Ewing's sarcoma Brain tumor	IV	Altered LOC, blistering, peripheral neuropathy, alopecia, constipation, SIADH, seizure, nausea/vomiting

IV = intravenous; IM = intramuscular; SQ = subcutaneous; PO = by mouth; IT = intrathecal.

Data from Deglin, J.H., & Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

Table 34- 3 Venous Access Devices

Name	Description	Advantage	Nursing Care
Central Implanted Ports such as Infus-a-port, Mediport, port-a-cath, or Norport	A saucer-shaped plastic device with a self-sealing injection port that can be accessed from the top or side. Requires placement in operating room.	Decreased risk of infection Placed under the skin; reducing the chance of becoming dislodged or pulled out Limited noticeably (small bump under the skin) Patency is maintained by administering heparin after access Little maintenance or care: child can participate in regular activities	Cleanse skin with warm water and soap prior to use Administer topical anesthetic such as EMLA (lidocaine and prilocaine) before accessing the port Use a Huber needle to access the port Observe child during medication administration for dislodgment of needle When treatment complete the port must be surgically removed
Central Groshong catheter	A silicone, flexible and clear catheter. At the proximal end, there is a closed-tip two-way valve. Requires placement in operating room.	Easy for self-administered medications and fluids No heparin required No clamping needed due to two-way valve Minimal backflow Decrease possibility of air embolism	Weekly irrigation with normal saline Parents can learn catheter care (site must be kept clean and dry) Teaching includes; (1) strenuous activity and water sports are restricted (2) safety as the catheter protrudes from body and may be pulled out Offer support based on body image disturbance
Central tunneled catheter such as Broviac or Hickman	An open-ended silicone, flexible, radiopaque catheter. Requires placement in operating room	Easy for self-administered medications and fluids Decrease risk of infection	Daily heparin flushes Parents can learn catheter care (site must be kept clean and dry) When not in use must be clamped Teaching includes; (1) strenuous activity and water sports are restricted (2) safety as the catheter protrudes from body and may be pulled out
Peripherally inserted central catheters	Catheter made of silastic or polyurethane material Single or double lumen available Inserted into antecubital fossa passing through the cephalic or basilica vein entering the superior vena cava	Does not require placement in operating room Pediatric nurse practitioners can insert the line using a small lumen needle Decrease risk of infection	Flushed with saline using 5 to 10-mL syringe Not suitable for rapid fluid replacement (small lumen needle) Sometimes can be difficult to remove because of resistance

clinical alert

Radiation side effects

- Nausea
- Alopecia
- Fatigue and malaise
- Low WBC
- Skin desquamation
- Mucous membrane inflammation and irritation

SURGERY

Before the development of chemotherapy and radiation, surgery was the principle treatment of children with solid tumors. Now surgery is used as an adjunct to both chemo-

therapy and radiation. Tumors are usually treated with chemotherapy and radiation first to reduce the size before surgical resection. The use of surgery varies widely depending on the child's diagnosis. Surgery is also an important role in the diagnosis of a tumor via biopsy. The biopsy sample may be obtained through a fine-needle aspiration or an open biopsy procedure.

Nursing Insight— Insertion of central venous catheters

The insertion of central venous catheters is one of the most frequent surgical procedures performed (Fig. 34-10). These long-term central venous access devices make it safer to administer chemotherapy and total parenteral nutrition, and are also used in administering of antibiotics and obtaining blood specimens (Alcoser & Rodgers, 2003).

Figure 34-10 The insertion of a central venous catheter helps in administering chemotherapy and is one of the most frequent surgical procedures performed on children with cancer.

The child may have cancer-related medical conditions before surgery; therefore the nurse understands that care measures are tailored to the child's pre- and postoperative nursing diagnoses.

nursing diagnoses Children with Cancer

- Ineffective Airway Clearance
- Risk of Injury (bleeding) related to thrombocytopenia
- Risk for Fluid Volume Deficit related to vomiting and decreased oral intake
- Risk for Infection related to neutropenia
- Pain related to diagnosis, disease process, and treatment
- Fatigue related to anemia
- Impaired Oral Mucosa related to oral ulcerations from cancer treatment
- Imbalanced Nutrition: Less than Body Requirements related to loss of appetite, nausea, vomiting, and mucositis
- Caregiver Role Strain related to disease process and frequent hospitalizations
- Ineffective Coping related to diagnosis
- Altered Family Process related to hospitalization

PAIN CONTROL

Controlling the child's pain is an essential nursing intervention. Pain associated with cancer can be acute or chronic. Four common types of pain found in children with cancer are tumor-related pain, impingement of tumor on nervous tissue, treatment-related pain, and post-lumbar puncture headaches. Postoperative pain is also a concern after tumor resection, biopsy, amputation, or central line placement. The most effective pain management strategies reported by children with cancer are use of effective pain medications combined with adequate rest and sleep, massage, heat, distraction, and social support.

Nursing Insight— Topical anesthetics

Use topical anesthetics when possible for procedure-related pain such as EMLA (Astra Zeneca) cream, which is a lidocaine/prilocaine 1:1 mixture. The nurse applies a thin coating of ointment to the projected insertion site(s) and covers the site(s) with a hydrocolloid dressing (such as DuoDERM). It is important to keep the cream on for at least 1 hour (sometimes longer) prior to the procedure (Bryant, 2003).

Ethnocultural Considerations— Caring for a Hispanic child with cancer

People in the Hispanic culture may approach pain with stoicism. The lack of verbal or other expression of pain does not necessarily mean that the child is pain free. Hispanics have a belief in folk health care practices and nondrug interventions. Some Hispanics do not understand the instructions for pain management. When caring for the Hispanic patient, it is important to respect his or her values and incorporate Hispanic folk practices when possible. More importantly, the nurse must provide written instruction for the child and parents in Spanish so that they understand the treatment plan. Do a thorough pain assessment and do not rely on verbal or observational cues. Explore the parents' or caregivers' and child's beliefs to achieve optimal pain control (Juarez, Ferrell, & Borneman, 1998).

PSYCHOSOCIAL SUPPORT

Psychosocial support is essential in providing holistic nursing care. Encourage 24 hour stay with parents and other family members or friends. Involve the child life specialist who can use therapeutic play or encourage arts and crafts. Video games, computers, hand-held devices or other technological equipment can be helpful when offering psychosocial support. Encourage visits to the playroom (if appropriate for the child's condition) while the child is in the hospital. Being present or simply listening can be powerful in the care of children with cancer. The nurse can also provide the family with community resources, reliable internet sources or information about support groups.

Nursing Insight— Taking care of children with cancer

The pediatric nurse understands that children with cancer still want to be loved and treated like other children. Be sure to encourage these children to play and be involved in self-care activities as their condition allows. Encourage them to talk about their dreams, feelings, and fears. The pediatric nurse realizes that it is a privilege to share in the lives of these brave children.

Negative Effects of Chemotherapy

Chemotherapy has several associated negative effects. The nurse must recognize and provide proper nursing care to promote the best health for the child during his or her treatment.

critical nursing action Recognizing Negative Effects of Chemotherapy

Chemotherapy is toxic to the body because it kills not only cancer cells but healthy cells as well. It is important that as soon as chemotherapy is administered the nurse ensures that the child is also well hydrated so that the chemotherapeutic agent (or toxin) is flushed out of the system. A way to ensure proper hydration is to measure the specific gravity of the urine. The urine specific gravity should be or 1.012 or below. If it rises above this, IV fluid boluses are required.

NAUSEA AND VOMITING

Nausea and vomiting is a major negative effect of chemotherapy and the nurse understands that the nausea may persist for weeks. Acute nausea begins 2 to 3 hours after chemotherapy starts, peaks at 4 to 10 hours, and lasts for 12 to 24 hours. Delayed nausea begins 1 to 5 days after chemotherapy, peaks 48 to 72 hours, and is less severe than acute nausea. Anticipatory nausea is psychological and the nurse understands that it is important to medicate the child if he or she complains about nausea.

It is also important for the nurse to be knowledgeable about medications (antiemetics) that can prevent or lessen nausea and vomiting in children (Fig. 34-11).

ALOPECIA

Hair loss (alopecia) is another negative effect associated with cancer treatment (Fig. 34-12). Not all children undergoing chemotherapy lose their hair. When it does occur, it may be devastating to the child and the family. Providing a wig or a hat and helping the child present a positive body image and peer acceptance is crucial. There are agencies (i.e., <http://www.locksoflove.org/>) that assist with providing the child with a wig.

Figure 34-11 It is important for the nurse to be knowledgeable of medications (antiemetics) that can prevent or lessen nausea and vomiting in children receiving chemotherapy.

medication: Common Antiemetics

Odansetron (Zofran)

0.15 mg/kg every 8 hours

Duration:

IV: 24 hours

PO: 8 hours

Not as effective as a prn

Not as effective if vomiting has begun

While the child is receiving chemotherapy, give 30 minutes before chemotherapy, then every 6–8 hours for 24 hours

Diphenhydramine (Benadryl)

1 mg/kg per dose every 6 hours

PO/IV immediate onset

Duration 4–7 hours

SIDE EFFECTS: sedation, dry mouth, blurred vision

Lorazepam (Ativan)

IV: 0.4 mg/kg/dose every 6 hours

IV duration: 4–6 hours

Often used for anticipatory nausea/vomiting

Side effects: sedation, euphoria

“What to say” — *If I lose my hair will it grow back?*

Many children who start chemotherapy have many questions, especially wanting to know “if my hair falls out, will it grow back”? Children worry about their appearance to an extent that depends on their age. The nurse should explain that the hair will probably start to fall out 10 days to 2 weeks after chemotherapy begins and that it may fall out in sections. The nurse can assure the child that once the chemotherapy has been completed, their hair will grow back. Try to make this experience as positive as possible by emphasizing there are wigs available as well as scarfs, and “cool” hats and

Figure 34-12 Alopecia is a negative effect associated with cancer treatment that can make the child feel very self-conscious.

caps to cover the child's head. Encourage the child to speak with others his or her age who have been through this experience. It is important for the nurse to emphasize the fact that just because his or her hair falls out, it does not change the person the child is inside. The child is the same person, who just looks a little different for a little while. The nurse can make this a special event by arranging for a first "cool hat" purchase before the child leaves the hospital.

EXTRAVASATION

Chemotherapeutic drugs must be handled carefully to avoid extravasation (accidental leakage of drug into the subcutaneous tissues surrounding the injection site/IV site). This is caused by known vesicants or a chemotherapy agent that can produce a blister or tissue destruction (Box 34-3). It is also important to handle chemotherapy agents safely (Box 34-4). For central lines it is important to make sure there is a blood return in the line to ensure patency before administering any chemotherapeutic agents by this route.

clinical alert

Monitor closely the intravenous (IV) site

Before administering a known "vesicant," a chemotherapy agent that can result in tissue necroses and even potentially the loss of a limb, make sure the peripheral IV or central line is patent. This involves more than flushing the IV site. Some institutions require a return blood flow, which is important to ensure the peripheral line is patent because the infiltration of a known vesicant can result in blistering, tissue sloughing, and severe cellulites. In rare cases, this can cause cellulitis that turns into a more severe infection. It is important that the nurse infusing these agents be specially trained and certified in the administration of chemotherapy agents. Through this training, the nurse learns that vigilant monitoring is paramount.

Box 34-3 Agents Known to Cause Extravasation

TPN and other hyperosmolar fluids
 Dilantin
 Chemotherapeutic agents (Doxorubicin, Daunorubicin, Mitomycin C, Vincristine, Vinblastine, VP-16, Dacarbazine)

Box 34-4 Safe Handling of Chemotherapeutic Agents

- Use disposable gloves and gowns when handling or preparing chemotherapy medications to prevent contact with medication.
- Use aseptic technique when administering medications.
- Prepare drugs in a well ventilated room.
- Dispose all medications, contaminated needles, syringes, intravenous tubing, gloves, and gowns in an appropriate leakproof, puncture-resistant container.

Source: Alcoser, P., & Rodgers, C. (2003). Treatment strategies in childhood cancer. *Journal of Pediatric Nursing*, 18(2), 103–112.

MUCOSITIS

Mucositis is a diffuse inflammation of the mucosa of the mouth, a change in the integrity of the mucous membranes characterized by soreness, redness, and swelling. Lesions on the mucous membranes allow bacteria to attach themselves to the affected areas and are a source of localized and systemic infection. Mucositis is caused by chemotherapy and radiation to the head and neck. It is essential to keep the oral cavity clean by rinsing the mouth with a solution (e.g., Peridex, sodium bicarbonate swish and spit, Nystatin swish and swallow, a "magic mouthwash" consisting of milk of magnesia and Carafate, and others variable by institution).

DIARRHEA AND CONSTIPATION

Diarrhea may occur with chemotherapy. The nurse must assess the rectal mucosa to prevent infection. Gently cleaning the skin around the anus with a soft cloth and warm water is important. Applying a barrier cream (such as Desitin) and allowing the irritated skin to be exposed to open air as much as possible may be necessary. Have the child drink plenty of clear fluids (based on 24-hour intake) and eat small amounts of soft bland low fiber foods such as bananas, rice, noodles, white bread, or skinned chicken. Avoiding greasy, fatty, spicy, or fried foods as well raw vegetables/fruits and whole grains breads (cereals, nuts, and popcorn) can help. It is also important to discourage gas-forming foods (beans, cabbage, and carbonated beverages) and limiting beverages with caffeine. The nurse communicates to parents that they can contact the health care provider about an over-the-counter medication for diarrhea such as Loperamide (Imodium) or a prescription medication like Diphenoxylate (Lomotil).

If the child becomes constipated, the nurse can suggest foods high in fiber (fruits and vegetables) and drink plenty of fluid such as water and juices. Normal activity and playing if approved by the health care provider can help. The nurse can instruct parents to ask their health care provider for medications that will help with the constipation. The health care provider may prescribe medications such as Docusate sodium (Colace) or Bisacodyl (Dulcolax).

ANEMIA

Anemia can also be acquired during chemotherapy. Bone marrow suppression, nutritional deficiencies, and blood loss may all lead to anemia below 8 g/dL. While the cancerous cells are being killed, sometimes healthy cells such as RBCs are killed also.

Some signs of anemia are severe fatigue, headache, irritability, or tachycardia (Bryant, 2003). For children with mild anemia, the nurse can provide supportive care guidelines for improving the anemia through diet or vitamin supplementation. Children with moderate to severe anemia may need a RBC transfusion to restore blood volume. For specific types of anemia such as decreased production of RBCs, the nurse can administer hematopoietic growth factors (filgrastim [Neupogen]) that may prove beneficial in decreasing the need for blood transfusions.

THROMBOCYTOPENIA

Like RBCs, platelets can also be destroyed. Platelets are important for the clotting of the blood. Thrombocytopenia is a decreased number of platelets (less than 100,000 μL) (Bryant, 2003). Thrombocytopenia develops as a result of increased destruction, decreased production, or loss of platelets. A platelet transfusion should be given if platelet counts drop to less than 50,000 μL , if the patient has spontaneous bleeding, or if an invasive procedure is scheduled (Behrman et al., 2004).

NEUTROPENIA

Neutropenic children have few WBCs and often do not show signs of infection, such as swelling, redness, or drainage. The only sign may be fever. A fever in an oncology patient is 101.2°F (38.5°C) in a 24-hour period or 100.4°F (38.0°C) three times in a 24-hour period. Take only axillary or oral temperature.

A severe neutropenic patient has an absolute neutrophil count (ANC) of less than 500. An ANC of 500 to 1000 is considered moderately neutropenic, and an ANC greater than 1000 is considered mildly neutropenic. When a child undergoing chemotherapy develops a fever, it is considered an emergency.

diagnostic tools Calculating the Absolute Neutrophil Count (ANC)

Formula: $(\text{WBC} \times 10) \times (\text{Bands} + \text{Neutrophils})$

Example: $\text{WBC} = 8.8$, $\text{Neutrophils} = 82$, $\text{Bands} = 5$

$\text{ANC} = (8.8 \times 10) \times (82 + 5)$

$\text{ANC} = (88) \times (87)$

$\text{ANC} = 7656$

Two sets of blood cultures are required for the neutropenic patient before the start of antibiotics. Antibiotics should be started as soon as possible, no later than 1 hour after admission. The nurse must monitor vital signs very closely when administering antibiotics due to the release of endotoxin that may occur. Left unchecked, this condition may lead to septic shock.

Optimizing Outcomes— Neutropenic patient admitted to a pediatric unit

A 2-year-old neutropenic oncology patient is admitted to the in-patient pediatric unit. The unit is full and bed space is limited. It is the middle of winter and there are several patients with respiratory syncytial virus and rotavirus on the floor. In what type of room should the child be placed?

Best Outcome: To ensure the best outcome for the child place the child in a private room by him or herself. If a private room is not available, assigning the child to a room with a noninfectious child such as a fractured femur is acceptable.

LONG-TERM EFFECTS OF CANCER TREATMENTS

Now that children with cancer are surviving longer, researchers are just beginning to understand the long-term effects of cancer treatments. Children undergoing cancer treatments are assessed for acute effects at the time

but also need follow-up care in adulthood to assess for potential long-term effects. A long-term survivor of any cancer is considered a child who has been in remission for 5 years or who has been off cancer therapy for 2 years.

For example, high-tone hearing loss may be a side effect of cisplatin (Platinol). Other chemotherapeutic agents can cause loss of speech, impairment in depth perception, and increased response time can be a problem for the adolescent who wishes to drive. Lung problems can be caused by scarring of lung tissue or a reduction in lung elasticity during breathing. Shortness of breath and a reduced capacity to exercise can significantly impact the child. Kidney problems include bleeding, damage to the tubules that affects electrolyte exchange and salt balance, and protein wasting. Musculoskeletal defects involving the bones or soft tissue and teeth have been reported. Functional and/or mobility deficits may persist if an amputation was performed. Hormonal abnormalities that are often treatable may also exist. Cancer treatment can sometimes produce sterility. Hearing, skin problems and cardiac dysfunction are some of the late side effects that children are left to deal with later in life.

Children who had radiation to the brain may show growth retardation, cognitive impairment, and/or learning disabilities. Damage to the hypothalamus may cause an irreversible disorder called diabetes insipidus (DI). A type of nerve damage called peripheral neuropathy can lead to decreased reflexes and weakness. The thyroid gland is also sensitive to radiation and may pose problems later in life.

Medical Emergencies

Due to his or her altered state of health, a child with cancer is prone to various conditions that may constitute a medical emergency, including accidents, infections, allergic reactions, or common childhood diseases. If one or more of these conditions is negatively affecting the child, the pediatric nurse must act quickly and notify the physician or oncologist caring for the child in order to prevent a life-threatening condition or further complications.

HEMORRHAGIC CYSTITIS

When caring for an oncology patient who is undergoing chemotherapy, using certain chemotherapy agents such as cyclophosphamide (Cytosan) or ifosfamide (Ifex), can cause hemorrhagic cystitis (bloody or painful urination). Radiation may also cause hemorrhagic cystitis. This condition can range from mild dysuria (painful urination) with urinary frequency to severe hemorrhage with significant enough to damage to the epithelial lining of the bladder. Patients also have leukocytes, erythrocytes, and clots in the urine. The best way to treat hemorrhagic cystitis is to prevent it with adequate hydration before and during the administration of chemotherapy. Be sure to test the urine for blood, pH and specific gravity. The specific gravity should be less than 1.010. If it is not, a bolus of IV fluid is required (Box 34-5 and Procedure 34-1). If the urine is positive for blood, send an immediate urinalysis sample to the lab and notify the physician immediately. Monitoring of intake and output is vital as well as a daily blood urea nitrogen (BUN) and creatinine. Mesna (Mesnex, Uromitexan) is a drug given to prevent hemorrhagic cystitis by helping to protect the lining of the bladder.

Procedure 34-1 Checking Urine Specific Gravity

Purpose

The purpose of checking the specific gravity of urine is to measure the concentration of the particles in the urine.

Equipment

- Refractometer
- 3- or 5-mL syringe (needleless)

Steps

1. Have the child urinate into a urine collection receptacle.

RATIONALE: *The urine collection receptacle is not a sterile container.*

2. Using a 3- or 5-mL syringe, draw up 0.5 mL of urine into the syringe

3. Place the syringe into a universal precaution container.

RATIONALE: *Promotes a safe environment.*

4. Take the urine specimen to the testing area.

RATIONALE: *A specific testing area promotes a safe environment.*

5. Open the refractometer.

6. Place one drop of urine in the center of the square opening.

7. Close the lid.

8. Look through the focused eyepiece to see the horizontal line clearly.

RATIONALE: *Ensures accurate measurement of specific gravity.*

9. Note where the blue horizontal line crosses the markings (see picture below).

RATIONALE: *The blue horizontal line that crosses the markings is the specific gravity reading.*

Clinical Alert If the institution does not have a refractometer, it is acceptable to use a urine dipstick, with the realization that this is not as detailed. The specific gravity markings on a urine dipstick are in increments of 0.005. On a refractometer, the markings are in increments of 0.001.

Teach Parents

The nurse can teach the parents about the purpose of a specific gravity measurement.

Documentation

Specific gravity done at 1300 h. Specific gravity = 1.010.
-M. Godshall, RN

Box 34-5 Checking Urine Specific Gravity

SPECIFIC GRAVITY

- Check urine specific gravity for patients receiving Cytosan, ifosfamide, cisplatin, high-dose carboplatin, high-dose methotrexate
- Specific gravity must be less than or equal to 1.010 before the start of chemotherapy and then for at least 24 hours after its completion.
- If at any time the specific gravity rises above 1.010, the patient should receive a fluid bolus (extra fluid). DO NOT turn off the main IV. The bolus is in addition to the main IVF.
- If giving more than two or three fluid boluses, notify the oncologist on call.

URINE pH

- Monitor when the patient is receiving methotrexate.
- Urine pH must be higher than 7.0 before starting methotrexate, and must be maintained at that level until the methotrexate serum blood level is <0.1 mg/dl.
- Before receiving high-dose methotrexate, patients are hydrated with IVF of D5½ with 40 mEq/L of NaHCO₃. The NaHCO₃ is needed to keep the urine alkalinized.

TUMOR LYSIS SYNDROME

Tumor lysis syndrome is a life-threatening condition that may develop in children with cancer. Tumors with high growth rates, large volume, or that are widely disseminated such as Burkitt's lymphoma, lymphoblastic lymphoma, T-cell, and ALL are associated with this disorder. Tumor lysis syndrome may result from cell death related to a chemotherapy agent or the malignancy itself.

SIGNS AND SYMPTOMS. Children develop lethargy, nausea and vomiting, oliguria, flank pain, pruritus, tetany, and altered level of consciousness. Renal failure can also occur.

DIAGNOSIS. After the cell dies, there is a rapid (12 to 72 hours after treatment starts) release of intracellular contents (metabolites) that lead to hyperuricemia, hypocalcemia, hyperphosphatemia, and hyperkalemia. An astute nursing assessment and immediate laboratory results can help diagnosis this condition.

NURSING CARE. It is important to keep the urine alkalinized and maintain a low-phosphate diet. Administration of allopurinol (Aloprim) to reduce uric acid formation and promote excretion of byproducts of purine metabolism is

essential. Maintaining adequate hydration is also paramount. Monitoring electrolytes such as calcium, magnesium, phosphorus, potassium, as well as kidney function with measurements such as BUN and creatinine is very important. Sometimes dialysis or exchange transfusions are necessary to decrease the metabolic consequence that causes an even more severe effect on the child.

SEPTIC SHOCK

The patient who is neutropenic and has a fever is at great risk for septic shock. Septic shock happens in a child who is undergoing or has just finished chemotherapy and/or radiation. The level of the WBCs that fight infection and invading organisms is extremely low (neutropenia).

When the child is admitted to the hospital with a fever, he or she is given an antibiotic regimen to cover both gram-positive and gram-negative bacteria within a 1-hour window of the patient arriving on the inpatient unit. As the antibiotic destroys the cell wall of the bacteria, endotoxin is released from the cell wall. This endotoxin starts a cascade and overwhelms the compromised body's ability to deal with the endotoxin.

SIGNS AND SYMPTOMS. Signs can include confusion, fever, increased respirations (tachypnea), decreased urinary output, and cold, clammy skin. The patient becomes pale and the heart rate increases in an attempt to compensate, and then suddenly the patient's blood pressure plummets (late sign). Laboratory studies reveal acidosis and sometimes renal failure (Venes, 2009).

Nursing Insight—Hypotension

Pediatric patients compensate for shock by increasing the heart rate. When that is no longer effective, the blood pressure falls rapidly.

DIAGNOSIS. Vigilant monitoring of signs and symptoms by the nurse who is giving antibiotics to a neutropenic patient is crucial in diagnosing this condition.

clinical alert

Septic shock

It is important to remember that this septic shock response can occur immediately or up to 48 to 72 hours later.

NURSING CARE. By the time the blood pressure drops, the situation is ominous.

critical nursing action Nursing Care for Septic Shock

For a child who is neutropenic and is admitted for a fever, and is being given antibiotics, the nurse must take vital signs every 10 to 15 minutes during the antibiotic administration to recognize signs of septic shock. Recognizing the other signs is also crucial. Remember that a drop in blood pressure is a late sign. Be ready to administer large amounts (1-L bags) of an isotonic fluid, such as normal saline

(20 mL/kg) rapidly to prevent circulatory collapse and possibly death. Be sure to check peripheral pulses and capillary refill to monitor perfusion (whether the blood is reaching the extremities). In an emergency remember the ABCs and other emergent care measures:

Airway

Breathing

Circulation

Fluid resuscitation

Evaluation of etiology (CBC, electrolytes, DIC panel, blood cultures, liver and renal functions)

Blood products

Antibiotics

Vasopressors

clinical alert

Other emergencies

- Superior vena cava syndrome—obstruction or thrombus in the superior vena cava, superior mediastinum syndrome—tracheal compression
- Pericardial effusion—fluid in the pericardial cavity, between the visceral and the parietal pericardium. This condition may produce symptoms of cardiac tamponade, such as difficulty in breathing (Venes, 2009).
- Pleural effusion—fluid in the thoracic cavity between the visceral and parietal pleura. It may be seen on a chest radiograph if the fluid exceeds 300 mL (Venes, 2009).
- Abdominal emergencies—esophagitis, gastric hemorrhage, perirectal abscess, hemorrhagic pancreatitis, massive acute hepatomegaly, bowel obstruction
- Neurological conditions—stroke, seizure, spinal cord compression
- Shock—hypovolemic, cardiogenic, distributive
- Hyperleukocytosis—WBC count greater than 100,000 mm³

The Psychological Impact of Pediatric Cancer

The psychological impact that cancer has on the entire family is enormous. The feelings of shock, denial, confusion, and fear strike everyone. Families may feel someone or something is to blame for their child's illness. Adding to the stress is the feeling of having absolutely no control over any part of the situation. Feelings of any kind during this situation are normal as everyone reacts differently.

Sometimes one of the best sources of support for the parents are other parents who have gone through the experience of their child having cancer. It is important to encourage families to develop support systems whether they are family, friends, or other people who may be able to help in some way.

Many parents maintain a bedside vigil, which is understandable because they want to be there for their child. As this can be very wearing and tiring (Fig. 34-13), the nurse can communicate to the parents that it is important that they get adequate rest and nutrition to avoid becoming sick themselves.

Figure 34-13 Many parents maintain a bedside vigil to support their child during treatment for cancer.

Depending on his or her level of understanding, it is important for the parents and health care team to be honest with the child. A multidisciplinary approach is necessary and the goal of the team is to communicate enough information so that the child can make sense of the situation without becoming overwhelmed. Information must be tailored to each child's developmental stage. The nurse must keep the lines of communication open.

Families may ask questions such as, Why did this happen? Why does my child suffer? What did I do wrong? These are normal feelings for families when a child is diagnosed with cancer. Steen and Mirro (2000) stated, "faith is like a lens through which you experience all of life. During this process grief comes into play. When grief and faith meet, a crisis of faith occurs" (p. 283). The nurse understands that it is important to offer spiritual support when the child and family are ready. The child may feel a sense of spirituality through the nurse. The nurse can ask the hospital Chaplain or Faith Community Nurse to visit on a regular basis, use prayer or meditation if requested or read from a spiritual/inspirational text. Be sure to allow the child and family quiet time during the day to be alone and meditate if they choose.

Help the child and family express his or her feelings. Being present and giving reassurance that he or she is not being punished is important. Through the nurse's care the child will know that he or she is loved. Many parents tell the nurse how they were touched deeply knowing that the nurse really cared for their child (Fig. 34-14).

“What to say” — To siblings of an ill child

While children with cancer are undergoing many stressful events, as a pediatric nurse do not forget about the sibling(s) of the children with cancer. Visiting a sick sibling is stressful for both the ill child and the sibling. The nurse can help make the sibling's day special by telling them a story, or giving them a sticker or a coloring book and crayons. Encourage the ill child to color a picture for their sibling and hang it in the room.

A sincere demeanor and common pleasantries such as saying hello or calling the sibling by their name can make the visit special and less stressful.

case study Family Dilemma

An 18-year-old adolescent named Joe who is dying from liver cancer is admitted to your pediatric unit. His parents are divorced. He lives with his father. He has a sister who lives with the mother. The mother is remarried and therefore Joe has a stepfather as well. You are the nurse caring for this family. No one but Joe wants to talk about the fact that he is dying. The father tries to keep Joe's spirits up with jokes. The mother appears to be in denial and will not accept the possibility that Joe is dying. He is receiving antibiotic therapy and continued chemotherapy, which at this point is palliative. One day when you are caring for Joe, he says to you that he is tired of being in pain and just wants to die. He says "I know I am dying, but my family refuses to accept it." He is a mature young man, and you listen as he tells you of the dreams he had to go to a state college. He tells you that he has spoken to his oncologist who has agreed to stop chemotherapy for him. He is 18 and legally an adult. His mother now refuses to visit him because she feels everyone has given up on him. Joe is the only one who is realistic about his future and disease progression.

critical thinking question

1. As Joe's nurse, how would you help him and his family so that he can experience a peaceful death?

Note: This is a true story and Joe died peacefully with his father and nurse at his bedside.

- ◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

Figure 34-14 Through the nurse's care the child will know that he or she is loved.

summary points

- ◆ Cancer is a group of diseases in which there is out-of-control growth and spread of abnormal cells known as anaplasia (loss of the normal pattern of growth of cells).
- ◆ In children many common malignancies arise from primitive embryonic tissue where there has been a strong environmental link related to the development of cancer.
- ◆ Acute leukemia is a rapidly progressing disease that affects mostly immature, undifferentiated cells. Chronic leukemia is a less rapidly progressing disease allowing for the production of mature, more differentiated cells.
- ◆ The most common types of solid tumors in children include brain tumors, neuroblastoma, rhabdomyosarcoma, retinoblastoma and nephroblastoma (Wilms' tumor).
- ◆ The two most common bone tumors are osteogenic sarcoma and Ewing's sarcoma.
- ◆ Lymphoma is a malignancy that arises from the lymphatic system. Two types of lymphomas are seen in children: Hodgkin's disease (HD) and non-Hodgkin's lymphoma (NHL).
- ◆ Liver and extragonadal germ cell cancer are other types of cancer seen in children.
- ◆ Nursing care for a child with cancer: maintaining nutrition, preventing infection, administering chemotherapy, addressing radiation side effects, understanding the use of surgery and related nursing diagnosis, pain control, offering psychosocial support, managing negative and long-term effects of cancer treatments and preventing medical emergencies.
- ◆ Understanding the psychological impact of pediatric cancer is also an important element of care.

review questions

Multiple Choice

1. A 3-year-old girl is admitted to your unit with acute lymphocytic leukemia. She received chemotherapy treatment 10 days ago and her neutrophil count is low. The nurse utilizes critical thinking and assigns her in a room with
 - A. A 3-year-old admitted with bronchiolitis
 - B. A 5-year-old with a fractured femur
 - C. A 4-year-old admitted with a streptococcal infection
 - D. A 3-year-old with a history of diarrhea
2. The pediatric nurse provides health promotion teaching to the parents of a 6-year-old boy who has been discharged after chemotherapy. The nurse should instruct them:
 - A. "Do not allow your child to play with any children in the few days."
 - B. "Be sure to encourage your child to brush his teeth vigorously every day."
 - C. "If your child feels warm, be sure to take his temperature rectally."
 - D. "If your child has a temperature of 101.2°F (38.5°C) bring him to the emergency room immediately."

True or False

3. The pediatric nurse who is assessing a child with a decreased number of platelets (thrombocytopenia) is aware that this child may present with clinical manifestations such as bleeding gums, nosebleeds, and easy bruising.
4. The pediatric nurse recognizes that a child with acute myelogenous leukemia has "blueberry muffin" lesions.
5. Sarcomas are solid tumors that may develop in lymphoid organs such as the thymus, spleen, and lymph nodes.
6. During nursing rounds, the pediatric nurse discusses that leukemia is the first most common pediatric cancer, brain tumors are second, and neuroblastoma is the third most common pediatric cancer.
7. The pediatric nurse recognizes that children with leukemia who relapse while on chemotherapy or within 6 months after cessation of chemotherapy have a poor prognosis.
8. During the physical assessment, the pediatric nurse carefully palpates the scrotum to confirm that both testicles are present since a child with undescended testes has an increased risk of developing testicular cancer.

Fill-in-the-Blank

9. Ninety-five percent of children with acute lymphocytic leukemia will achieve remission during the _____ of chemotherapy treatment. If treatment is stopped during this phase, _____ cells will reappear. This is why _____ treatment is crucial. Because leukemic cells can cross the _____ and most chemotherapy does not, central nervous system prophylaxis treatment is necessary. This medication is injected _____ into the cerebrospinal fluid space during a lumbar puncture.
10. The second phase of chemotherapy treatment is called the _____ phase. The goal of this phase is to eliminate any residual leukemic cells. _____ is also required during this phase of treatment.
11. The _____ phase maintains control of leukemia. This phase can last for _____ to _____ years after diagnosis.
12. Children with cancer should be encouraged to play in the playroom as long as their _____ are within normal. Allowing the child to continue with recreational activities helps to promote a sense of normalcy.

Case Study

13. Johnny, a 5-year-old boy, is admitted to the pediatric unit to rule out a brain tumor. The nurse performs a neurological exam. Which of the following does the nurse note to be indicative of increasing intracranial pressure?
 - A. A bulging fontanel with irritability
 - B. Speech disturbance with vomiting

- C. A blood pressure of 98/58 with an apical pulse of 90
- D. Hyperactivity with a temperature of 101.2°F (38.5°C)

- 14.** The diagnosis is confirmed that Johnny has a brain tumor. The parents are very upset and say to the nurse, “I can’t believe my son is going to die. What am I going to do”? The most therapeutic response that the nurse can say is:
- A. “Your son is not going to die. We will take good care of him.”
 - B. “I will call the hospital minister to come and speak with you.”
 - C. “I can understand how upset you must be feeling, but we need to take this one day at a time.”
 - D. “I will be here every day to help your son. Would you like me to introduce you to another family with a child who has the same illness?”

CONCEPT MAP

Caring for the Child with a Chronic Condition or the Dying Child

We don't have to wait until we are very sick and know this might be "it." We can get support from the day we learn something could happen.

—Mattie Stepanek

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Define what is meant by a chronic condition.
- ◆ Explore chronic conditions and the role of technology in their management.
- ◆ Discuss the impact of a chronic condition for children of all ages.
- ◆ Recognize the emotional responses to a chronic condition.
- ◆ Explain important aspects of a chronic condition such as establishing a therapeutic relationship, growth and development, education, and cultural issues.
- ◆ Explore the aspects of the dying process and related nursing care.
- ◆ Describe palliative, hospice, and end-of-life care for the dying child.
- ◆ Explore grief and saying good-bye.
- ◆ Describe additional nursing aspects related to the death of a child such as preparing a remembrance packet, organ tissue donation and funerals.
- ◆ Explore what it means to care as a professional caregiver.

moving toward evidence-based practice Quality of Life in Chronically Ill Children

Svavarsdóttir, E.K. & Örylgisdóttir, B. (2006). Comparison of health-related quality of life among 10 to 12 year old children with chronic illnesses and healthy children: The parents' perspective. *The Journal of School Nursing*, 22(3), 178–185.

The purpose of this study was to compare mothers' and fathers' perceptions of the health-related quality of life of well children and those with chronic illness. The study was conducted as part of a larger cross-sectional study; the Health-Related Quality of Life (HRQOL) among 10- to 12-year-old school children.

Twelve randomly selected public elementary schools from one city were selected for this study. Data were collected over a 3-month period.

Participants in the study were recruited from a total population of 1079 children in the 5th and 6th grades and their parents. From the total population, 480 children (209 boys and 271 girls) and 912 parents (519 mothers and 402 fathers) agreed to participate in the study. A majority of the children (70.2%) lived in a household where both parents were present,

8.1% lived with one biological parent or a stepparent, and 21% lived with only one parent.

Information collected included:

- Demographic data (collected from parents and children) that included information about health status and the presence of chronic conditions or illnesses in the child
- Children's experiences with bullying either as a victim or a perpetrator (reported by children)
- Children's visits to the school nurse over a 1-week period and their level of involvement in after-school activities (reported by children)
- Parents' ratings of the child's complaints of various symptoms such as headaches, stomachaches, dizziness, and difficulty sleeping

(continued)

moving toward evidence-based practice (continued)

- Parents' reports of the child's chronic physical conditions or illnesses including allergies/eczema, migraines, asthma, seizures/epilepsy, diabetes and "other"
- Parents' reports of the child's chronic psychiatric conditions or illnesses including learning disabilities, hyperactivity/attention-deficit disorder, dyslexia, developmental delay, autism, and "other."

Study Tools

The Health Promotion Scale-Parents' Proxy Report was used to measure the parents' perception of the children's level of health promotion. This tool contained 21 items and 5 subscales: social-support, life-appreciation, health-responsibility, stress-management, and nutrition behavior. The tool was a modification of a previously tested measure. Parents were asked to rate items on a 5-point Likert-type scale with 1 = never to 5 = always. The total score could range from 0 to 84.

A 23-item Pediatric Quality of Life Inventory scale was also used. This tool contained four subscales: physical functioning, emotional functioning, social functioning, and school functioning. Parents were asked to rate each item based on how they perceived problems in each area over the previous month from "never a problem" to "almost always a problem."

Data analysis revealed the following findings:

- 84.8% of the mothers had technical institution or university level education.
- 88% of the fathers had technical institution or university level education.
- 81.5% of mothers were married or cohabiting with their partner.

- 95.2% of fathers were married or cohabiting with their partner.
- 87.4% of the mothers were working outside the home.
- 98.9% of the fathers were working outside the home.
- 27% of the children were diagnosed with chronic health conditions or illnesses (56% of those were physical conditions or illnesses; 47% were considered psychiatric conditions or learning disabilities, hyperactivity, or dyslexia).
- 299 students were involved in after-school activities.
- 21 children identified being bullied by other children.
- 48 children engaged in school nurse visits during the past month.

Overall Findings

- The fathers' evaluation of the girl's quality of life (77.91) was significantly higher than the evaluation of the boy's quality of life (74.87).
- There was no significant difference between the mothers' and fathers' quality of life scores.
- Parents of children with chronic health conditions perceive their child to have a low quality of life, as compared with parents of children without chronic health conditions.

1. Given the synopsis provided above, what additional information might help the reader to gain a better understanding about the variations between the fathers' and mothers' perception of their children's quality of life and school functioning?
2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

A chronic condition is a health situation that persists over time, usually longer than 3 months, or one in which recovery progresses slowly. A chronic condition is a physical, psychological, or cognitive impairment that places limitations on the child's daily activities and requires ongoing care. The condition may require that the child and family rely on another individual's assistance in carrying out the activities of daily living. A chronic condition can be a congenital defect or a problem that occurs during fetal development. At birth, a chronic condition can arise from sepsis, prematurity, or intraventricular hemorrhage. It can also develop from a genetic predisposition. The chronic condition can be acquired sometime during the child's life as a result of an illness, accident, or injury. Either a chronic (or acute) condition can lead to a child's death.

Nursing Insight—Chronic Conditions

Brain: Cerebral palsy (CP) or a seizure disorder

Heart: Congenital or acquired heart disease

Lungs: Cystic fibrosis, bronchopulmonary dysplasia (BPD), or asthma

Muscular or skeletal: Muscular dystrophy or skeletal malformations

Abdominal organs: Kidneys (renal failure), liver (cirrhosis), or intestine (short bowel syndrome)

Skin: Eczema, dermatitis, or conditions such as Lyme disease that can cause chronic arthritis

Psychological: Depression, bipolar disorder, or autism

Cognitive: Down syndrome, developmental or learning disabilities

Conditions such as diabetes, cancer, and human immunodeficiency virus (HIV) are considered chronic. The condition may also have been acquired through an acute medical condition such as an infection or from a trauma such as near drowning, motor vehicle crash, head injury, or shaken baby syndrome (SBS). Whatever the reason for the chronic condition, it becomes a lifelong situation for the child and family. The impact and adaptation to the condition depend on its severity, the age at which the insult occurred, the overall effect on the growth and developmental aspects, and the child's and family's responses to the condition.

The child with the chronic condition may require the use of adaptive devices (e.g., wheelchairs, walkers, braces,

crutches) that help to overcome environmental barriers (Schmitke & Scholmann, 2002) (Fig. 35-1). The nurse must remember that when caring for the child with a chronic condition, the child may feel more like his or her unaffected peers than different from them.

Nursing Insight— Other terms associated with a chronic condition

There are other terms used to describe a child who is unable to actively participate in daily activities and needs ongoing care.

Disability is similar to a chronic condition in that it also refers to the limitations that prevent or interfere with a child's ability to perform daily activities.

Handicap is the inability to carry out tasks or access certain aspects of the environment due to one or more impairments. The terms “activity limitation” or “participation restriction” are preferred by many specialists in physical, occupational, and speech therapy as well as those in related fields (Venes, 2009).

A Chronic Condition and Its Relationship to Technology

In the United States today, the increase in chronic conditions may be partially attributed to technological life-saving and life-sustaining measures or technological devices that can now diagnose and treat diseases that previously were either undiagnosed or untreatable. For instance, the use of a refined diagnostic tool such as a level 2 ultrasound has enabled health care providers to find

Figure 35-1 Some children who have a chronic condition require an adaptive device to help with mobility.

where research and practice meet: Where Do Children with a Chronic Condition Die?

Feudtner, Silveira, and Christakis (2002) researched where children with chronic conditions die. Their study found 52% of deaths occurred in the hospital, 17.2% occurred at home, 8.5% occurred in the emergency department, and 21.7% were classified as other. Infants (younger than 1 year of age) with chronic illness died predominantly in the hospital (88.4%–99.6%). Beyond the first year of life, the incidence of children with a chronic condition who died at home increased from 21% in 1980 to 43% by 1998.

developmental problems while the infant is still in the mother's womb. Once the condition is diagnosed, health care professionals can begin to develop a plan of care. The child who is born prematurely benefits from medical technology such as a ventilator that enables the infant to live. While technology has many benefits and has enabled some children to live, it has also caused them to be dependent on technology for survival. **Technology dependent** means the child is reliant on some type of medical device to compensate for the loss of normal use of a vital body function. The Technology Related Assistance for Individuals with Disabilities Act Amendments of 1994 provide for programs that support the development, acquisition, or application of assistive technology devices or equipment to assist the child living with limitations (Venes, 2009). The child may also require substantial skilled nursing care to avert death and further disability.

Be sure to — Understand the type of technological equipment required

Technology dependent children are grouped according to the type of equipment required. According to a United States Congress report, the groups are designated from the most complex equipment to the least complex equipment required:

- Group 1—Children who require a ventilator
- Group 2—Children who require devices for total parenteral nutrition
- Group 3—Children who have a daily dependence on some other device for respiratory or nutritional support (e.g., tracheostomy, oxygen support, tube feeding)
- Group 4—Children who require an apnea monitor, peritoneal dialysis or hemodialysis or other devices, such as catheters and colostomy bags
- The infants and children who fall into groups 1 and 3 are further defined as needing high-technology care; medically fragile (Judson, 2004).

Impact of a Chronic Condition

A chronic condition affects the child and family differently depending on the age at diagnosis. It can create a threat of the unknown, loss of control, and long-term effects yet to be discovered. Depending on the degree of illness, frequent hospitalizations or clinic visits may be

needed. Frequent visits to the hospital can create stress because normal home routines are disrupted and more demands are placed on the caregivers, who now must balance time between the sick child in the hospital and other responsibilities at home and work. This lack of control and sense of powerlessness may lead some parents to become controlling and overprotective (Melnyk, Feinstein, Moldenhouer, & Small, 2001).

The child may also have to cope with unfamiliar people, places, and medical treatments. The family, depending on the coping mechanisms, may become overwhelmed and unable to deal or cope with the condition and related treatments. Because the condition is life long, the family may experience social, financial, and psychological strain as a result.

The nurse can assist the family in developing an ongoing plan of care to meet the child's physical, emotional, and spiritual needs. The nurse can offer ongoing support and supply resources to help ensure successful coping. The nurse caring for the family must remember that uncertainty and fear about the future is a constant worry for the parents of a chronically ill child (Melnyk et al., 2001).

IMPACT OF A CHRONIC CONDITION ON THE INFANT

In infancy, the developmental task is to achieve an emotional attachment or a bond with the primary caregiver. The need for necessary treatments or hospitalizations may require a separation from the caregiver that can interfere with the bonding process. Pain due to invasive procedures and forced changes in diet and sleep may alter normal growth and developmental milestones (Armstrong-Dailey & Zarbock, 2001).

Nursing Care

Priority nursing interventions include rocking, holding, comforting, and using a soothing voice. It is also important to provide visual and auditory stimulation. Brightly colored mobiles, calming music, low lighting, grouping nursing cares, and protecting nap time can assist in the healing process. The crib or nursery area must be maintained as a safe place where invasive procedures are not performed. The nurse must also encourage parents to hold the infant whenever possible, regardless of the amount of wires and equipment to which the infant is attached (Fig. 35-2). Siblings can be encouraged to visit and participate in simple care taking measures or create pictures to hang up in the room (Armstrong-Dailey & Zarbock, 2001).

case study An Infant with a Chronic Condition

Cindy, a mother at 24 weeks' gestation with twins, developed HELLP syndrome (a condition characterized by hemolysis, elevated liver enzymes, and low platelets; a serious complication of preeclampsia) and went into premature labor. The birth was further complicated when the first baby died from a heart defect and the second baby experienced significant medical conditions. The living infant was placed on a ventilator and subsequently developed the chronic lung condition bronchopulmonary dysplasia (BPD). After 3 months in the intensive care unit, the infant was transferred to a rehabilitation facility closer to the parents'

Figure 35-2 It is important for parents to hold and care for their chronically ill child.

home. As the days turned into months, the infant developed sepsis, pneumonia, and had one episode of cardiopulmonary arrest. With the decline in health, one nurse at the rehabilitation facility felt that the nursing care was no longer helpful and was actually causing pain. However, another nurse believed that the infant could eventually go home. As time progressed, the infant's condition continued to deteriorate, and during this time the infant received extreme care that included oscillatory ventilation, numerous medications and other painfully invasive procedures. The parents voiced that everything possible be done for the infant. Later, the infant died at the rehabilitation facility at the age of 14 months.

critical thinking questions

1. The infant had several chronic conditions. How can the care given to the infant be viewed by the nurse?
2. What are extreme care measures?
3. What happens when the nurse feels that the treatments have become more of a burden than a benefit?
4. Does the nurse suffer?
5. What if the nurse's beliefs about care differ from those of the institution?

◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

IMPACT OF A CHRONIC CONDITION ON THE TODDLER

For the toddler, the major developmental task is initiating autonomy or self-control. When the child has a chronic condition, accomplishing this task is in jeopardy. The

most frightening aspects of illness and hospitalization for the toddler are pain, anxiety, and separation from parents. The toddler is also sensitive to bodily harm (Armstrong-Dailey & Zarbock, 2001).

The child's chronic condition can hinder both gross and fine motor development. Frequent or repeated hospitalizations cause the toddler stress. The toddler has a tremendous capacity to withstand the stress provided that the relationship (attachment) to the parents is maintained. It is important for the nurse to encourage parents to stay with the child by giving 24-hour unlimited visitation and proper sleeping accommodations.

The most common coping method employed by the chronically ill toddler is regression.

Nursing Insight—Regression

Regression is an abnormal return to an earlier reaction, characterized by emotions or behaviors that are inappropriate for the current age and may include the loss of recently acquired skills (Venes, 2009). Regression can be both physical and emotional. For example physical regression occurs when a toddler refuses to continue bowel or bladder training. Regression can be considered emotional when a child refuses to talk, withdraws, or becomes easily irritated.

Nursing Care

Priority nursing interventions for the toddler with a chronic condition include maintaining the bond between the parents and child, promoting realistic developmental skills, and not reacting negatively to regression. Praise the child for all attempts at self-care. The nurse can also give parents instructions about realistic methods of discipline. Parents may be reluctant to enforce rules for the chronically ill child based on feelings and concerns about the child's condition. In turn, the child may react emotionally (naughtily) to inconsistent discipline patterns. Without consistent limitations, the toddler may feel insecure and unable to complete developmental tasks essential to the promotion of autonomy.

Pain management includes medication and other traditional nursing comfort measures such as clean sheets, good hygiene measures, oral care, and skin care.

Because the toddler needs a set routine, the nurse can also encourage parents to maintain the child's normal home schedule as much as possible. The nurse can allow the child to express feelings through play and artwork. Sometimes the toddler uses a toy to project personal feelings (Armstrong-Dailey & Zarbock, 2001).

IMPACT OF A CHRONIC CONDITION ON THE PRESCHOOLER

The developmental task of a preschooler is to create a sense of initiative. A painful treatment, isolation, separation from a parent, or loss of autonomy or mobility can be associated with chronic illness and the preschooler is likely to interpret this experience as punishment for real or imagined wrongdoing (Armstrong-Dailey & Zarbock, 2001).

The preschooler with a chronic condition may react aggressively to the impact of illness by throwing toys, biting, and hitting other people. The preschooler may also

regress, withdraw from others, wet the bed, have difficulty sleeping, or refuse to cooperate (Armstrong-Dailey & Zarbock, 2001). The nurse must remember that young children accept the literal meanings of words. If death is associated with "going to sleep" the child may fear going to sleep. The child also may have nightmares that symbolize fears.

Nursing Care

Priority nursing interventions include providing the preschooler with the opportunity to express fears and frustrations. At this age, storytelling and reading books about the illness may be helpful in providing a nonthreatening approach to the topic. The preschooler can express concerns through dramatic play. The nurse can ask the child life specialist for assistance with methods of expression. It is essential that the nurse communicate to the parents that the preschooler's sense of security is derived from schedules and rules. Parents can be encouraged to maintain as normal a home schedule as possible and enforce consistent limits. The nurse can also teach the parents that the child needs constant reassurance that nothing the child has done has caused the illness. The nurse caring for the preschooler must remember that honesty is important when explaining and preparing for procedures. The preschooler has a limited concept of time, so general terms like after lunch, after your nap, or at bedtime when describing time-related events is important (Armstrong-Dailey & Zarbock, 2001).

IMPACT OF A CHRONIC CONDITION ON THE SCHOOL-AGE CHILD

During the school-age period, the child who had achieved a certain degree of autonomy and independence strives to develop a sense of industry. The school-age child takes pride in the ability to assume some new responsibility. Peer relationships become extremely important at this age. Separation from the peer group is often a difficult consequence of a chronic condition. The school-age child who experiences interrupted independence coupled with little peer interaction may show anger by refusing to comply with treatments or compliance with a special diet. The school-age child can listen attentively but sometimes does not completely comprehend all of the information. He or she may be reluctant to ask questions or admit that she does not know the answer. It is easy for the child to misinterpret medical information (Armstrong-Dailey & Zarbock, 2001). The nurse must remember that the school-age child has an increased awareness about the significance of illness and may understand the lifelong consequences of the chronic condition.

Nursing Care

Priority nursing interventions for the school-age child include pain assessment. The nurse can use the FLACC pain scale (see Table 21-8), the Wong-Baker FACES pain scale, or the numeric pain scale (see Fig. 21-14). The child needs to be reassured that his or her personal behavior has not caused the illness. It is important for the nurse to answer questions about treatment, procedures, and medications honestly and at a level the school-age child can understand. Play can be used as an outlet or a temporary escape

from the illness. Allowing for unstructured play may enhance feelings of control and predictability during hospitalization or clinic visits (Armstrong-Dailey & Zarbock, 2001). Include peers as much as possible. The nurse can teach parents how to help the child attain realistic independence by allowing him or her to play with friends, attend school, choose activities, and enjoy private time. The nurse can communicate to the family that the school-age child is acutely aware of nonverbal cues and often understands more information than parents and caregivers realize. For this reason, it is important to encourage the child to maintain open and honest dialog with family and caregivers (Armstrong-Dailey & Zarbock, 2001).

Collaboration in Caring— *Child life specialist*

Whenever a child is diagnosed with a chronic condition, it is important to involve the child life specialist. Because the child with a chronic condition often spends significant amounts of time in the hospital, the days can be long and boring. The child life specialist is an expert in child development and therapeutic play. She can assist in diversion activities during procedures, arrange for therapeutic play, or simply let the child take time to play (Fig. 35-3).

IMPACT OF A CHRONIC CONDITION ON THE ADOLESCENT

Adolescence is a time of increasing independence, autonomy, and vulnerability. It is a time to ask, “who am I?” and a time when self-esteem is closely related with peer acceptance. To complicate matters, during a chronic illness the adolescent may be placed on a pediatric ward or on an adult floor. Neither situation seems to be the right fit (Armstrong-Dailey & Zarbock, 2001). Previously independent, the adolescent is now faced with a chronic condition

Figure 35-3 The child life specialist is called upon to work with a child who has been diagnosed with a chronic condition.

and may be required to accept help from others. Dependence on caregivers and family for physical care, coupled with a lack of privacy, can crush the adolescent’s sense of autonomy. Based on this loss of independence, the adolescent may exhibit maladaptive coping behaviors such as hostility, aggression, and even refusal of treatment. Sometimes when presented with frequent medications, tests, appointments, and other procedures, the adolescent is easily overwhelmed and may show regression in behavior. Besides worrying about the condition, self-esteem, and identity, the adolescent may show concern about the burdens and strains the family may now face.

Nursing Care

Priority nursing interventions for the adolescent with a chronic condition include providing solitary time to help the adolescent regain control. The nurse understands that it is important to give the adolescent realistic choices to enhance control when possible. Realistic choices include when to bathe, sleep, eat, and visit with friends. They should be included in medical-related matters when possible. The nurse must remember that peers can be a strong source of support for each other, so peer interaction is important. The adolescent can be encouraged to expand networks of social support through peer groups and other community programs when possible. A support group may help normalize the adolescent’s crisis and give him or her a new source of strength and hope (Armstrong-Dailey & Zarbock, 2001).

IMPACT OF A CHRONIC CONDITION ON THE SIBLING

It is important for the nurse to understand that a chronic condition also has an effect on siblings. The sibling may be affected in ways such as experiencing decreased self-esteem, receiving less support from parents, exhibiting mood swings, lacking an understanding about the condition, and displaying a negative attitude toward the ill sibling’s condition (Williams et al., 2002). The sibling may also have feelings of jealousy, embarrassment, resentment, loneliness, and isolation (Beckman, 2002). For some siblings the chronic condition means the loss of a playmate. A young child, who has a vivid imagination, may believe he or she caused the condition or may fear that he or she might acquire the same condition as the sibling (Beckman, 2002).

Nursing Care

Priority nursing interventions include instructing the parents to maintain familiar home routines as much as possible for the sibling. In addition, the nurse can help the parents include the sibling in simple care. Remind the parents that providing information about the ill child may decrease stress reactions in the sibling.

Optimizing Outcomes— *The sibling*

How does the nurse handle “acting out” in the sibling?

Best outcome: The sibling has time to regain control and can express feelings. To convey genuine understanding the nurse might say, “You seem very angry today (reflection). It is all right to be angry about your sister’s condition and about the situation (validating the sibling’s feelings). It must

be difficult for you to have your sister in the hospital (empathizing and understanding).” The nurse can then help the sibling find a positive outlet for the anger such as art therapy (channeling). The nurse can encourage the sibling to tell an adult when the anger returns (providing an outlet).

The Child Living with a Chronic Condition

Judson (2004) suggests that 15% to 18% of children in the United States have a chronic health condition. Each year about 50,000 children acquire a permanent disability as a result of injury or illness. Asthma is the leading chronic condition in the United States, affecting about 6 million children. Other chronic conditions are sickle cell disease (SDS), bronchopulmonary dysplasia (BPD), congenital heart disease (CHD), cystic fibrosis (CF), type 1 and type 2 diabetes mellitus, epilepsy, and chronic renal failure.

Nursing Insight— Children living with chronic conditions

According to Judson (2004), children living with a chronic condition experience one or more of these symptoms:

- Limitation in bodily functions appropriate for age and development
- Disfigurement
- Dependence on medical technology
- Dependence on medication or special diet to ensure normal functioning or control of the condition
- Ongoing need for medical care or related services compared to other children of the same age
- Special ongoing treatments at home or at school

A child living with a chronic condition requires day-to-day care and can become a source of stress for parents and other caregivers. Melnyk et al. (2001) describes day-to-day care as “chronic burden of care.”

Nursing Insight— Caregiver burden

Caregiver burden, as described by Kuster, Badr, Chang, Wuerker, and Benjamin (2004), is the unrelenting pressure and anxiety in providing daily care to a child with disabilities while meeting other family needs and can be a major source of stress.

Balancing the demands of the child’s chronic condition and the parent’s personal and family responsibilities can be challenging and exhausting. Many daily health care regimens for the ill child are time consuming, rigorous, and unrelenting, which prove taxing to both the parents and child. The complex schedule of care for the ill child and combined with family responsibilities such as shopping, preparing meals, doing laundry, cleaning, spending time with the other children and getting them to school, paying bills as well as finding personal time for self and marriage can be overwhelming even with the best

of support systems and help in place. Parents of a child living with a chronic condition frequently experience role and marital strain as well as higher levels of psychological distress such as depression and anxiety compared to parents of healthy children (Melnyk et al., 2001).

The financial burden of ongoing care is also a concern. Continuous health care is expensive. Other costs related to housing, lifestyle modifications, special equipment, and special services for the child are also expensive. Some of these costs may not be reimbursed by private health care insurance plans (Melnyk et al., 2001).

Nursing Care

The nurse must communicate to the family that overwhelming feelings can be discussed with a health care professional and that respite care is available.

Across Care Settings: Respite care

Respite care is short-term care offered to families living with a child who has a chronic condition. The main goal of respite care is to provide relief for family members of the burden and stress of sustained care giving (Venes, 2009). Parents can also use respite care in situations in which someone besides them can accompany the child to a doctor’s appointment. The availability of respite care varies in every community (Orloff, Quance, Perszyk, Flowers, & Veale, 2004). It is important to note that respite care is not always paid for by private insurance. Sometimes state agencies or national programs can reimburse the family for respite care.

case study The Frequently Hospitalized Child and His Family

Jack is a 7-year-old boy who is admitted to the inpatient unit at the local children’s hospital with a diagnosis of cerebral palsy, apnea, and seizure disorder. He has been admitted to the hospital numerous times in the past. Soon after he was admitted, Jack’s mother leaves the hospital and goes home to tend to another child who is 4 years old. When Jack is at home, the mother has difficulty getting anyone to watch Jack because of his apnea spells that can happen several times a day. The father refuses to stay alone with Jack for fear that “something might happen to Jack when he is alone with him.” Some of the nurses on the unit talk despairingly about the mother because they think that the mother does not care about Jack, as evidenced by “dropping him off and leaving him alone.” A few of the nurses fail to understand the complexity of the total situation. However, one nurse notices that the mother visits Jack every day at lunchtime, staying at Jack’s bedside for about 1 hour.

critical thinking questions

1. As a nurse supervisor, what can be said to the staff nurses when making judgments about the mother?
2. What kind of support systems does Jack’s mother have in place at home? What can be done to increase support in the home?
3. Do you think this mother is suffering from “caregiver burden” and may be in need of respite care?

◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

Emotional Responses to a Chronic Condition

When a child is diagnosed with a chronic condition, the family equilibrium is disrupted and emotional responses follow. The family is faced with multiple, powerful stresses related to the medical diagnosis, treatment, and the course of the disease that may include a fatal outcome. At the time of initial diagnosis, it is not possible for the family to comprehend the diagnosis and the impact it may have on family life. Initially, the emotional response is shock and chaos. Family members may experience anger, fear, disbelief, anxiety, pain, stress, and feelings described as an “emotional roller coaster” (Gibbons, 2001).

The nurse must understand that there is no typical response and must be prepared to expect a wide range of responses from the family. The nurse must also remember that the emotional reaction may also differ depending on the specific diagnosis and whether there is a chance for the child to be cured. If a child has been ill for a period, some parents may express relief at finally having an answer to the child’s illness. The parental reaction to the diagnosis of asthma will be different than the reaction to a diagnosis of cancer in their child.

Nursing Care

The priority nursing intervention for the family’s emotional responses to a chronic condition is communication. The nurse can communicate to the family that the child can continue to live a good life and not just merely exist. The nurse can help the family understand that the child needs to participate in normal childhood activities (when possible) such as remaining involved in the family’s typical lifestyle, going to school, playing with friends as well as expecting to be disciplined and acting in a responsible manner. Sometimes simple childhood activities sustain the foundation for the child to embrace life. It is important to remember that regular daily activities must not be lost in the frantic endeavor to treat the condition. The family can be taught that the child needs to incorporate the condition and treatment into a new daily routine (Gibbons, 2001).

The nurse can also communicate important information to the family related to treatment, procedures, medicine, and visits to the hospital or clinic. Potts and Mandelco (2002) found that children who do not focus on the positive aspects of the condition may blame themselves or others and display negativity and irritability.

Because parents are grieving, they may have difficulty in understanding how their family life can return to normal. Parents may blame themselves for not having been able to prevent the condition, especially if the condition is a congenital defect. Based on a myriad of emotions, one parent may blame the other parent. In addition, a parent may not be able to bond with the child. Sometimes, as a defense mechanism, a parent may be fearful of bonding with the child in case the child dies. The nurse can listen carefully to the family’s concerns and communicate the importance of bonding, spending quality time with the ill child and promoting as normal life as possible.

Parents of a child with a chronic condition may also report episodes of recurrent sorrow, particularly at times of important transitions in the child’s life that remind

them that the child is not the same as other healthy children. The period of episodic grieving interspersed by periods of denial is called **chronic sorrow**. Episodic grieving is a coping mechanism allowing parents to adjust to the situation while permitting them to carry on with daily life and other responsibilities (Melnik et al., 2001). The nurse can discuss the importance of the parent’s continued involvement in the care of the child through these recurrent sorrowful periods. The nurse can also give parents information about community resources and help them sort through the details of medical care.

“What to say” — Talking about the chronic condition

When talking about the child’s chronic condition with the family, the nurse must be sure to use the child’s name and personalize the discussion. It is important that the nurse avoid labeling the child by, for example, saying “CF kids.” Instead, the nurse can say, “Timmy will need ongoing care for his cystic fibrosis.” This kind of communication places the emphasis on the child and not on the condition. It is also important to listen to the family so that home routines can be continued during hospitalization.

Important Aspects When Caring for a Child with a Chronic Condition

ESTABLISHING A THERAPEUTIC RELATIONSHIP

The nurse understands the importance of establishing a therapeutic relationship with the child and his or her family who are living with a chronic condition. This therapeutic relationship is vital when providing family-centered care because the family has a tremendous amount of responsibility in the care of the child.

Nursing Care

Care may be technical as well as emotional in nature. For the nurse to build a successful therapeutic relationship with the family, the nurse must first establish trust.

critical nursing action Establishing Trust with the Family

Godshall (2003) suggests that the nurse take the following actions when establishing trust:

- Consider the needs of the entire family; do not forget the siblings.
- Familiarize yourself with the child’s condition and know about the disease process.
- Be open and honest.
- Show the family that the burden of care is understood. Burden of care includes the combination of physical, psychological, social, and financial burdens the family may face.
- Take time to listen to the child and to the caregiver.
- Include parents in the plan of care. Some parents like to participate in the child’s care while the child is hospitalized. It is also important to maintain home rituals as much as possible while the child is hospitalized.

- Treat each child as an individual. It is essential that the nurse not label the child according to the disease process.
- Allow the child to make decisions about the care when possible. Decision making is especially important for the adolescent.
- Maintain confidentiality.
- Do not prematurely judge the parents. Some parents cannot stay with the child in the hospital based on personal needs and responsibilities.
- Arrange for continuity of nursing care.
- Assess the family's support systems and resources.

GROWTH AND DEVELOPMENT

The child with a chronic condition may experience negative physical growth (growth failure) and developmental aspects. **General growth failure** means that the child grows more slowly and that the height and weight is in a lower percentile on the growth charts than for children of the same age. It may result from the condition itself or from related treatments and medications. Conditions such as cystic fibrosis or end-stage renal disease may significantly alter the growth process.

The pathophysiology of the condition may affect the child's growth. For example, if the child has a severe hypoxia problem, the tissues may simply not receive the needed oxygen required to promote normal growth. Treatment protocols associated with chemotherapeutic agents may hinder growth or damage usual organ functioning.

The child with altered growth may be delayed developmentally as well. The child may achieve developmental milestones much later than do peers or not at all. The nurse must be aware that the parents may positively or negatively affect the child's development. For instance, a parent, teacher, or guardian who is fearful of consequences of a child's condition may unduly restrict a child's opportunity for interaction and subsequently hinder development (e.g., parents of a child with autism do not allow him or her to play with peers). Conversely, some parents can embrace the child's condition and help the child attain the most realistic potential. The child's personality, temperament, and motivation may help or hinder developmental attainment.

Nursing Care

An important nursing care measure related to growth is carefully plotting their growth using charts from the National Center for Health Statistics (NCHS) <http://www.cdc.gov/nchs/about/major/nhanes/growthcharts/charts.htm>. When a child is unable to take adequate nutrition by mouth, an alternate feeding method is used to maintain and promote growth in the child. The type of feeding method selected depends on the child's medical condition.

The nurse can encourage parents to maintain realistic developmental milestones. Helping the child interact with children of his or her own age (when possible) and creating a social network consisting of family, friends and others in the community can help maintain development. Finding appropriate social activities also positively affect the child's development.

EDUCATION

By federal law, all children, including those with a chronic condition, are entitled to a free education that is matched to the developmental and functional capabilities of the child. School personnel must be informed about any chronic condition. Today's educators need to receive special training to prepare them for ongoing monitoring and care of the child. Along with adequate training, resource allocation is needed to support the child and can help make entry into the school less challenging (Kliebenstein & Broome, 2000).

Nursing Care

The nurse can discuss home schooling as an educational alternative. Helping the family understand laws about educational services is important.

Be sure to— Observe federal laws providing educational services for children

Education for All Handicapped Children Amendments, PL 99-457 of 1986 expanded the scope of PL 94-142 to include appropriate services for infants and toddlers with disabilities and the families.

Individuals with Disabilities Education Act (IDEA), PL 105-17 of 1997 ensures that all children with disabilities have available to them a free appropriate public education that emphasizes special education and related services designed to meet their unique needs and prepare them for employment and independent living. Every child with a disability must have a written individualized education plan (IEP), and parents have the right to question placement decisions and due process when settling differences.

Rehabilitation Act, PL 93-112 of 1973, prohibits discrimination against people with a disability. Section 504 specifies that each student who has a disability be entitled to accommodations needed to attend school and participate as fully as possible in school activities.

The Education for All Handicapped Children Act, PL 94-142 of 1975, mandated that all children, even those with handicaps, be provided with public education and related services.

CULTURAL ISSUES

Understanding ethnocultural aspects of the child who has a chronic condition is paramount. Ethnocultural considerations emphasize cultural sensitivity in both the hospital and community settings.

Nursing Care

Field and Berman (2003) state that the nurse should assess the language and nonverbal cues being used by the child and family. The nurse must also try to determine the locus of control and where the decision-making process lies (with the parents exclusively or if it involves a larger social unit of the family). The nurse must consider the relevance of religious beliefs and spiritual practices, particularly about death, the existence of an afterlife, and the belief in miracles. The nurse can evaluate whether expressions of pain and related aspects are allowable in the culture or looked at as signs of weakness. Assessing how hope

for future recovery is negotiated within the family is also important.

In working with a family dealing with a chronic condition, the nurse must assess how the members express grief. Some families feel that grief is a private matter and tend to suppress feelings until they are alone. Other families outwardly express sorrow by crying or moaning. It is important to recognize those beliefs and culture influence the family's reactions to grief and death.

The Dying Child

Dying is the total cessation of life. Death is difficult to comprehend and might be considered mysterious, ambiguous or confusing for the child and family. The dying process is unique and the exact time or date of death is unpredictable. When the child enters the dying process the body begins to shut down physically as well as emotionally and spiritually. This failure might happen slowly or rapidly depending on the circumstance.

critical nursing action Do Not Resuscitate

The Do Not Resuscitate (DNR) request means withholding life-sustaining treatment and requires that no attempt be made to revive a child who has clinically died. Withholding life-sustaining medical treatment includes decisions to withhold, withdraw, or limit medical treatment. Some medical ethicists feel that there is no difference between withholding and withdrawing treatment if the treatment is no longer beneficial to the child.

When making recommendations to withhold, withdraw, or limit medical treatment, the benefits of treatment must be weighed against the burden of continuing treatment for the child. The nurse understands that a do-not-resuscitate (DNR) order means that no lifesaving measures will be initiated in the event of cardiac or respiratory arrest. This decision also can mean removing medical equipment such as a ventilator or monitor, dialysis machine, feeding tube used for artificial nutrition, and intravenous fluids for hydration. Aggressive treatments such as chemotherapy or radiation therapy are also terminated.

Wiegand (2006) states that the child and family participating in the process of withdrawal of life-sustaining therapy need consistency among health care providers and the delivery of consistent messages. All members of the interdisciplinary team need to communicate effectively with each other so that families receive ongoing and reliable information.

PERCEPTIONS OF DEATH

Perceptions of death vary across the age continuum. The nurse needs to prioritize nursing actions and assist the child according to the appropriate developmental level to

help make the transition to death fearless, peaceful, and painless.

Death for the infant is undefined yet related to the level of cognitive development. The infant's perception of death is based on the degree of discomfort and the reactions of the parent and others in the environment. The nurse can ensure that the infant's basic physiological needs are met and that the child is able to build trust with caregivers.

Toddlers have a more developed perception of death and can sense by the way that the parents react that something is wrong. The toddler is unable to distinguish fact from fantasy, which inhibits a true comprehension of death. Death for the toddler may mean separation from parents or disruption in routine. The dying toddler responds with fear and sadness. It is important for the nurse to encourage parents to stay with the child by giving 24-hour unlimited visitation, ensure their needs are met and comfort is maintained.

The preschool child seems to comprehend death more than can be verbalized. The preschooler is able to see the body changing and can understand that something is wrong. Fear of death may be present as early as 3 years of age and nurses can discuss death simply and honestly in response to the child's questions. It is important for the nurse to keep answers short. The nurse remembers that the preschooler is a magical thinker and may view illness or injury as punishment for bad behavior. Reinforce that their condition is not caused by bad behavior. Because preschoolers are concrete thinkers, death should not be described as "going to sleep." A child of this age takes this response literally and fears going to sleep so the nurse must never equate sleep with death.

The school-age child often has a realistic understanding about the seriousness of the condition, but the understanding of death is not precise until he or she can understand the concept of time. Kübler-Ross (1983) found that after the age of 8 or 9 children understand the permanence of death. The school-age child is aware of nonverbal cues and often understands more of what is overheard than parents and nurses realize. Attempts to shield the school-age child from death can be perceived as distrust. The nurse must include children of this age in discussions about their care, condition, treatment or non-treatment, prognosis, and death.

The adolescent has the capacity to understand death at the adult level, but has difficulty accepting it as reality and often thinks that death can be defied. The adolescent thinks that the body is invincible, hence some of the risk-taking behaviors among this group. Adolescence is a difficult time to deal with death because establishing identity and independence is important. The adolescent has a fear of becoming dependent on parents. The nurse can help the family realize that even though the cognitive ability to understand death is present the emotional maturity to face death is absent.

The nurse and family can include the adolescent in decision making. The adolescent might wish to write a final poem or message as well as say good-bye to friends. It is important to allow the adolescent to talk about feelings and disappointments about goals and experiences never to be attained.

where research and practice meet: Causes of Death

Anderson and Smith (2005) studied the various causes of death among children ages birth to 19. Currently, in infants, the main cause of death is prematurity, congenital defects and infections. Death in toddlers and children is a result of accidents and injuries. School-age children die from cancers and unintentional injuries. The leading causes of death in adolescents are homicide, suicide, and cancer.

BEFORE THE CHILD DIES

Before the child dies the nurse completes the institution's checklist to ensure that all of the necessary institutional policies and procedures are followed. The nurse can contact the bereavement team before the death so they are ready to offer support when the death occurs. The nurse can also create a file that includes community resources that the family may need after the death to receive ongoing support.

A ledger may be created as a follow-up for acknowledging important times in the child's life (e.g., on the child's birthday or another special day). Later on, the nurse can send a "thinking of you" card to let the family know that the child is still remembered on these occasions. The nurse can also make note of the child's death date in order to make a follow-up phone call that can allow parents to ask unanswered questions or express feelings.

Signs and Symptoms

The nurse recognizes physical signs of impending death. Knowing the normal physical processes may help the family through the experience.

assessment tools Recognition of Physical Signs of Impending Death

- Loss of sensation
- Loss of ability of body to maintain thermoregulation: skin may feel cool
- Loss of bowel and bladder function
- Loss of awareness, consciousness and slurring of speech
- Alteration in respiratory status
- Cheyne–Stokes respirations (a waxing and waning of respiration in the depth of breathing with regular periods of apnea)
- Noisy chest or respirations with the accumulation of fluid in the lungs or in the posterior pharynx
- Decreased, weak, or slow pulse rate and drop in blood pressure

Nursing Care

Once medical treatment is halted and the family has determined that death is inevitable, the focus of nursing care is about allowing the child to die. Ward (2006) finds that the nurse can shift from the curative technological approach to providing care that enables the child to move toward death accessing his or her own inner resources.

To help the child have a peaceful death comfort measures are essential which can help create a positive outcome at the time of the child's death as well as later on for the family. The nurse must be aware of family needs and communicate genuine feelings of kindness and sympathy to the family.

Nursing Insight— Presence

The nurse may wonder how to respond to the family at the time of the child's death. The death of a child is a sorrowful time for the family. One primary intervention for the nurse is to be present. Presence includes a receptive, nonverbal posture that signals to the family that the nurse is willing to sit quietly and listen. Being present may reduce the family's feelings of isolation. It is important to remember that the family may not need the nurse to say profound words. They may simply want the nurse's support and willingness to remain in the room.

where research and practice meet: Facilitators and Barriers to Providing a "Good Death" Experience in the ICU

A study by Beckstrund, Callister, and Kirchoff (2006) listed facilitators and barriers to providing a "good death" experience in the ICU.

Facilitators

- Make environmental changes to facilitate dying with dignity.
- Communicate challenges.
- Manage pain and discomfort.
- Follow child and family wishes for end-of-life care.
- Promote early cessation of treatments if requested.
- Eliminate aggressive treatments, especially when they would be futile.
- Ensure effective communication among the total health care team.

Barriers

- Staffing patterns and nursing shortage
- Treatments based on medical regimens rather than on child and family needs

Mays (2005) noted that relationships are extremely important during the dying process and that physical contact is a major source of comfort to both the child and family. A simple touch from the nurse's hand, gentle stroking the child's head, or the placement of the child's favorite toy next to the child shows the family that the nurse truly cares about the child. When a nurse offers touch, the family members may lean in toward the nurse and respond positively. The nurse must also be sensitive to a family who is not comfortable with being touched, who may respond with stiffening or drawing back. In this situation, the nurse can quietly remove the hand and perhaps take a step back. The nurse must also have the insight to realize that this is not the time to share personal stories about loss. It is important for the nurse to keep the focus on the family.

It is important that the nurse give the family choices about what is possible during the dying process. The nurse can ask the family members if holding the child is desired. If death is imminent, the nurse must be sure to tell the family that death could occur while holding the child. Sometimes parents request to get into the bed with the child. This behavior is acceptable during the death of a child.

The nurse must assess the situation and accurately determine the proper environment. Sometimes it is appropriate for the nurse to give the family short periods to be alone with the child or the family may want a health care professional in the room at all times. When the nurse presents these choices, if the family does not respond, ask the family again, a few moments later, as sometimes the family member cannot absorb everything that is occurring.

Across Care Settings: Care of the dying child

Heller and Solomon (2005) found that slightly more than half of the parents recalled that their child was cared for in more than one setting near the end of life (either one or more hospital units or in different hospitals, or moved between the hospital, home, or long-term care setting).

Most parents felt that care was well coordinated. Parents who felt differently stated that there was inadequate discharge planning and poor preparation related to home care, disjointed outpatient care, inadequate staffing levels to provide sufficient care, poor organization of care, and staff who were unprepared to care for gravely ill children, as well as the staff not knowing the child and family. These factors were frustrating for parents. When a gravely ill child will be cared for in the home it is essential to begin discharge planning early and have a discharge family meeting to ensure that all aspects related to the child's care are covered before the parents are expected to provide the care independently (Fig. 35-4).

PALLIATIVE CARE, HOSPICE CARE AND END-OF-LIFE CARE

Care of the dying child also includes holistic nursing interventions that address the physical, emotional, and spiritual aspects of the child and family. Care of the dying child can be addressed in three ways: palliative care, hospice care and end-of-life care. These three ways are similar yet different from one another.

Palliative Care. With technological advances, nurses and other health care professionals are faced with decisions as to when to stop treatment once it is initiated. **Palliative care** is a term that has drawn much attention in health care today.

Nursing Insight— Palliative care

The American Academy of Pediatrics (AAP, 2002) describes palliative care in a policy statement entitled Palliative Care for Children. In this policy statement palliative care is described as enhancing quality of life in the face of an ultimately terminal condition.

In 2008, The World Health Organization discussed palliative care as providing physical, emotional, and spiritual care of the child and family. Palliative care refers to the type of care that the child receives at the end of life after it becomes obvious that no cure is possible.

Figure 35-4 The health care team is of tremendous support to parents and family of a chronically ill or dying child.

The main aspect of palliative care is that it follows a medical model of care through the hospital and follows the hospital's rules. Hain, Weinstein, Oleske, Orloff, & Cohen (2004) state that sound scientific principles should govern care. Important nursing interventions of palliative care include relief from pain, dyspnea, and other distressing symptoms. Emotional and spiritual aspects are essential care measures that help the child and family function as actively as possible until the child's death. Palliative care addresses conditions such as loneliness that cause distress and detract from the child's enjoyment of life. In addition, the nurse can provide a support system to help the child and family members cope during the illness and bereavement process.

Palliative care measures neither hasten nor postpone death. For a child receiving sometimes rigorous medical treatments, the nurse must consider that the benefit of the treatment outweighs the burden of care. For example, a child who has already been diagnosed with metastatic bone cancer should not have to undergo further painful and invasive procedures like injection of radioisotopes to prove something that is already known. This type of care is considered an unnecessary burden to the child.

With palliative care measures, dying at home care is not always possible. Some institutions have implemented Palliative Care Units (PCUs). In some institutions, a PCU works well; in others a PCU may not be a good choice for the child because the environment has a medical focus.

Complementary Care: Complementary and alternative medicine

Complementary and alternative medicine (CAM) therapy has become increasingly popular in palliative care. Neuhauser, Patterson, Schwartz, Hedderson, Bowen, & Standish, 2001, state that 66% of children with cancer use some form of CAM. This includes self-care practices such as relaxation, aromatherapy, acupuncture, or other therapies performed by a licensed practitioner. Other therapies, including dietary supplements and herbal remedies, are unregulated. A study by Pitetti, Singh, Hornyak, Garcia, & Herr, 2001, found that CAM therapies are frequently used to treat children. Many of the parents of children using CAM therapy use it themselves. A large proportion of children taking herbal medications are also taking over-the-counter medications. Sanders et al. (2003) found that the use of CAM therapy in children with special needs is common. The frequency and type of CAM are dependent on the child's condition and prognosis. This study also found that the use of spiritual blessings and prayers was beneficial to various types of chronic conditions.

Advantages of CAM

- Easy to understand
- Familiar methods
- Many are noninvasive
- Many have fewer side effects compared to medical treatments
- Help improve the overall quality of life
- Help maintain current state of health
- More holistic and in balance with nature (Suzuki, 2004).

Disadvantages of CAM

- Some treatments are complex.
- They have not undergone adequate testing of effectiveness.
- Many herbal preparations and remedies lack FDA approval.
- Many not covered by third-party reimbursement.

What makes CAM controversial?

One of the main controversies is that many of the therapies have not been tested through research. CAM therapies have not been proven effective 100% of the time. Some health care providers find that it is through pure belief that these measures work, similar to a placebo effect and that people who are drawn to CAM are desperate and “will try anything.” In addition, some health care providers are concerned that some patients may refuse traditional medicine based on belief in CAM.

Hospice Care. Hospice care refers to a program that focuses on quality of life for dying persons. It is a method of treating a serious illness when cure or meaningful improvement is no longer possible, and end-of-life care describes a certain time frame wherein care is given during the final 6 months of life (AAP, 2000). According to Children’s Hospice International (2005), the focus of hospice care for the child is on life and living, improving the quality of the life for the child and the ongoing lives of the family. In 1967, Dr. Cicely Saunders established the first hospice, St. Christopher’s Hospice in London.

The main aspect of hospice care is that it uses a variety of services (medical equipment, diagnostics, and therapeutic interventions) provided by a multidisciplinary group consisting of physicians; nurses; and other personnel, such as chaplains, health aides, and bereavement counselors

Hospice care also provides respite care that allows family members to “take a break” or “time off” to reenergize before returning to the role of primary caregiver. In addition to the actual care of the dying child, hospice care also offers professional support after the death of the child.

“What to say” — Children’s Hospice International, 2005

Children’s Hospice International, 2005 states that it is important to give clear answers to children who are dying. Evasive answers may confuse the child. The nurse must remember that the child may be at a developmental level at which he or she may take conversations literally. When the nurse is talking to the child, it is important to remember:

- Do not tell the child that death is sleeping peacefully. The child may fear going to sleep.
- Do not tell the child abstract concepts like, “It is God’s will” or “you are such a good boy that God wants you to be with him.” He or she may start to misbehave so as not to die.
- Approach the child with compassion, honesty, support, and love.

(Adapted from Children’s Hospice International, 2005).

End-of-Life Care. After it has been determined that the end of life is near (about 6 months) for the child, care measures can be initiated to help the child die peacefully and without pain. End-of-life care recognizes that each child and family has unique needs at this time.

End-of-life care should be accessible to the child and the family in their desired setting (the home, inpatient hospice, or intensive care unit). The home is usually the preferred site (Children’s International Project on Palliative/Hospice Services [ChIPPS]. Compendium of Pediatric Palliative Care. Alexandria, VA: National Hospice and Palliative Care Organization, 2003).

The main aspect of end-of-life nursing care is to provide the best quality of life possible for the child and family. End-of-life care is a holistic approach to care that includes physical, emotional, social, spiritual interventions, and complementary care. Quality of life can be enhanced by offering support to the bereaving child and family, relieving distressing symptoms, and providing respite.

critical nursing action The hospice approach

- Family-centered care is essential.
- A comprehensive, holistic approach can meet the child’s physical, emotional, social, and spiritual needs.
- Effective symptom control and pain management is paramount.
- Care is provided by an interdisciplinary team.
- The child can be cared for at home or in a homelike environment.
- Coordination and continuity of care is a priority.
- In addition to regularly scheduled home care visits, services are available on a 24-hour, 7 days-a-week, on-call basis.
- The focus of care is on improving the quality of remaining life; that is, on palliative, not curative, measures.

Bereavement follow-up services are offered to family members in the year after the death of the loved one (Lattanzi-Licht & Connor, 1995).

Once hospice care is initiated, the nurse can help the family determine the best place for the child to spend the final days. Most children prefer to die at home surrounded by family. The concept of children’s home hospice care is a growing alternative to in-patient hospital care for the dying child. Holistic care measures can be implemented easily in the home. The child who is cared for in the home receives nursing care that includes visits, treatments, medications, supplies, and equipment offered by the home care agency. At home, the child is exposed to normal daily activities and surrounded by family members as death draws near. When the child is at home, he or she may be able to continue to play with other children and “feel normal” for as long as possible.

The nurse understands that remaining in the home environment may not always be possible. Assuming care for a dying child can be an overwhelming duty. Some parents simply have too much grief to care for the dying child and other children along with household responsibilities.

critical nursing action Holistic Care for the Dying Child

Comfort Measures	Emotional Support	Spiritual Interventions	Complementary Care
Pain management	Active listening and showing empathy	Offering presence	Art therapy
Good hygiene	Distraction	Meditation	Energy-based therapy (healing touch, therapeutic touch, Reiki)
Repositioning	Encourage positive coping	Music	Relaxation
Nutrition and diet management	Encourage verbalization and ventilation of feelings	Prayer	Guided imagery

Physical or occupational therapy	Psychotherapy referral	Read from spiritual text or poetry	Acupuncture
Help the family create new rituals when the old ones no longer work due to the disease process	Suggest support groups	Allow for sacrament	Reasonable exercise
	Discuss topics about grief, loss, isolation, fear, guilt, and relationships	Contact the family's religious or spiritual community	Aromatherapy
	Discuss concerns about life after the child's death that relate to family, friends, and others	Discuss God/Higher Power, or spiritual source	

Providing end-of-life nursing care means addressing pain in the dying child. This can be difficult, as pain is a subjective experience. Some children can clearly describe the pain while others cannot. Dying children who are nonverbal have the most difficulty in conveying pain. The nurse can communicate to the family the necessity of pain management.

Clinical alert

Principles of pain medication administration

- Give pain medications orally for as long as possible.
- Alternate routes for pain medication administration include intravenous, subcutaneous, transcutaneous, transmucosal, rectal, nasal, epidural, and intrathecal. The enteral route (or through a gastrostomy tube) is the preferred route for children in the dying process.
- Consider using an appropriate adjuvant (a drug added to a prescription to hasten or increase the action of a principal ingredient in the medication).
- Adjuvants offer analgesia in certain situations, and include anti-convulsants, antidepressants, or muscle relaxants. (Hain et al., 2004).

Questions and concerns raised about the end of life can be discussed with the nurse as they arise. When a child is dying, parents tend to want to protect him or her from death by avoiding the subject or not talking about death. Some parents feel that if they discuss death with the child, the child may lose hope (Mazanec & Tyler, 2003). The nurse can help the family understand that the child may want to talk about death. The nurse can communicate to the family that the child does not want to be left alone. The child may be more afraid of being abandoned. The nurse can also inform the family about other good resources.

Across Care Settings: National Cancer Institute

The National Cancer Institute (NCI) has resources available by calling the Cancer Information Service (CIS) Toll-free: 1-800-4-CANCER (1-800-422-6237) TTY (for deaf and hard of hearing callers): 1-800-332-8615.

The NCI's Web sites are located at <http://www.cancer.gov> or http://www.cancer.gov/cancer_information/coping/ (click on the title under "End-of-Life Issues.") Cancer information specialists offer online assistance through the *LiveHelp* link on the NCI's Web site.

Facts Sheets

- The NCI fact sheet about hospice care includes contact information for hospice organizations.
- The NCI Advance Directives fact sheet discusses a patient's rights regarding medical treatment.
- The NCI fact sheet on Home Care for Cancer Patients provides information and resources related to home care services.
- The NCI booklet *Advanced Cancer: Living Each Day* provides support to cancer patients, families, and friends.

Ethnocultural Considerations— Cultural practices

The nurse must be knowledgeable of cultural practices of the child and family. It is important for the nurse to include the right support person to facilitate the cultural care of the dying child. By including cultural rituals or customs, nursing care can ease the death process for the child and family. Special ceremonies or rites may be requested by the family and should be accommodated whenever possible. Other cultural care measures may include use of spiritual texts and symbols, prayer or meditation, chanting, offering music, lighting a candle, listening in silence, being present in the moment, or including other methods of care as deemed appropriate by the culture.

AFTER THE CHILD DIES

If the family arrives at the unit after the child has died, the nurse must take the time to prepare the family about the child's appearance and description of the death. The nurse can describe the child's dress, hairstyle, if the child's eyes are open or closed, any noticeable injuries, positioning of the child, and what occurred at the moment of death. It is essential that the nurse give the family the choice of seeing the child alone or having the nurse to accompany them into the room. If the family chooses to be alone, the nurse must stay close by in case the family has questions or needs.

Nursing Insight— Handling the child's belongings

When handling the belongings of a child who has died, the nurse must treat them gently and with respect. The nurse can give the belongings to the family in a special container or package, not simply placing them in a plastic bag, as this action may appear insensitive. The nurse must remember that these items are the final possessions of the child.

Collaboration in Caring— A father's story

One father tells about a personal precious moment after the death of a child. The father said that as he held his adolescent daughter as she was dying, he felt her heart stop beating next to his chest. This was the actual moment when

the daughter's heart took its last beat. The father treasures this moment. The nurse caring for the child was privileged to hear this father's story and collaborate with him in caring for his child during her death. The compassionate nurse is honored to be present for these moments in time, holding dear, and striving to make the tragedy of the death of a child special, positive, and memorable for the family.

nursing diagnoses The Dying Child

- Pain related to frequent invasive procedures
- Alteration in Family Process related to frequent hospitalization
- Anxiety related to separation from caregivers
- Alteration in Nutrition: Less than Body Requirements related to decreased appetite from disease process
- Anticipatory Grieving by family related to prognosis of disease process and imminent death of child
- Social Isolation related to frequent hospitalizations
- Depression related to the potential for death
- Fear related to the child's understanding of the disease process and the unknown
- Altered Coping Mechanism related to parental anxiety and stress from imminent death of the child
- Knowledge Deficit related to the disease process, unknown outcome, and possible experimental treatment

Grieving

From the moment that a family has been informed about the child's fatal condition the family's life changes direction and grieving begins (Fig. 35-5).

Nursing Insight— Grief

Grief is a normal and appropriate emotional response to loss. Grief is unique to every individual and there is no timetable in which grief is complete. The stages of grief may come and go. Feelings of grief can return when least expected. Parents may not realize that grief begins the moment the child's diagnosis is communicated (Steen & Mirro, 2000).

Figure 35-5 The hospital chaplain or another religious figure can offer spiritual support to the child and his or her family.

Signs and Symptoms

Grief can be an emotional response as well as a physical response to death.

Nursing Insight— Somatic Grief Response

Somatic grief response can be described as:

- Somatic distress that includes feelings of tightness in the throat or chest, sighing
- Weakness or shortness of breath
- Preoccupation with the image of the deceased (e.g., hearing or seeing the person who died)
- Inability to focus on anything other than the loved one who died
- Emotionally distancing self from others
- Feelings of guilt
- Feeling responsible for the loved one's death.
- Searching for what could have been done differently, thinking in terms of "if only had done..."
- Hostile reactions that include feelings and expressions of anger
- Inability to complete daily tasks

Nursing Care

A nursing plan of care is essential when caring for the grieving family.

The nurse can also offer ongoing emotional support to help family understand the situation.

"What to say" — Helping the family understand the situation

After the child's initial diagnosis, the family may ask the nurse questions such as, What did I do to deserve this? Did I do something wrong? Am I being punished? The nurse can listen empathetically to the family and encourage them to "take it one day and sometimes one moment at a time". The nurse can help the family understand that there may be "good days" and that inevitably there will be "bad days." The nurse can give the family hope that over time the emotional pain may dissipate and that they can better understand the experience of their child's death.

GRIEF THEORIES

It is important for the nurse to understand grieving from well known theories in order to provide proper support (Steen & Mirro, 2000).

Kübler-Ross's Stages of Grief

Elisabeth Kübler-Ross (1983) described five stages of grieving.

DENIAL AND ISOLATION. This stage includes feelings of numbness, disbelief, and shock. Denial is a way of protecting the family and child from the emotional pain that may be too severe to handle all at once. The numbness can also help the family or the child by creating emotional distance from the pain, thereby allowing continuation of daily responsibilities.

Nursing Care Plan The Grieving Family

Nursing Diagnosis: Anticipatory grieving related to poor medical prognosis for child

Measurable Short-term Goal: Family will explore their beliefs and feelings about the medical prognosis

Measurable Long-term Goal: Family will begin the grieving process, using resources and positive coping mechanisms.

NOC Outcomes:

- Family Coping (2600) Family actions to manage stressors that tax family reserves
- Grief Resolution (1304) Adjustment to actual or impending loss

NIC Interventions:

- Anticipatory Guidance (5210)
- Family Integrity Promotion (7100)
- Grief Work Facilitation (5290)
- Sibling Support (7280)

Nursing Interventions:

1. Develop a trusting relationship with child and family by spending time with them, using active listening techniques, and providing consistency in assignment of nurses to care for the child.
RATIONALE: Enhances family comfort and enables the family to build trust with the nursing staff.
2. Assess the family's understanding, beliefs, and feelings about the child's prognosis.
RATIONALE: Assists the family to organize and verbalize their concerns while allowing for correction of misunderstandings.
3. Provide ongoing information about the child's condition and what to expect next. Allow time for questions and reassurance.
RATIONALE: Allows the family to understand what is happening and to prepare themselves for the next stage in a supportive environment.
4. Provide the child and family with a quiet space and protect their private time together from unnecessary interruptions.
RATIONALE: Ensures privacy for family to freely experience and show feelings without worrying about strangers and interruptions.
5. Encourage the family to participate in the child's care as much as possible, if desired.
RATIONALE: Care provided by a familiar person may ease the child's anxiety and allows the family to demonstrate their love for the child.
6. Refer the family and child for spiritual care and/or professional support as needed (specify, e.g., pastoral care, family spiritual advisor, social services, grief counseling, or grief support groups).
RATIONALE: Support systems can offer the family and child a constant source of support during the dying process and after the death of the child.

Nursing Insight— Denial and isolation

The nurse can acknowledge these feelings of numbness and remind the family to slow down, “take it easy,” and pay attention to safety measures and retain healthy habits.

ANGER. Anger can be one of the most difficult stages. At this point, the family and child have developed awareness about the reality of the diagnosis. The feelings of anger, fear, and guilt can be an overwhelming but a normal response to the impending death. Both the family and child may become angry with God or experience a spiritual crisis.

Nursing Insight— Anger

The nurse can give spiritual care by calling upon a hospital chaplain or the family's personal clergy to provide support. The nurse can use prayer, meditation, reading from a spiritual text or just being present with the family. The nurse can also

encourage the family to find a positive outlet for the emotions. Positive outlets can include talking with other family members or friends, nurses, and families at the hospital, or expressing feelings in a support group. Physical exercise is another positive way to release anger. Family members can be encouraged to write in a journal or draw to express emotions. The child can express anger through therapeutic play or art therapy.

BARGAINING. It is common for the family members to ask, “What did I do to make this happen?” It is normal for the family to try to bargain with either self or with ‘God’ in hopes that the child's life will be spared. The family may express guilt at times for disciplining the child on occasion. The family may also feel punishment for personal life circumstances. Specifically, a mother might wonder if she caused the illness or injury during pregnancy. During this stage, it is natural for the family to make vows of personal improvement if the child is cured.

Nursing Insight— Bargaining

It is important for the nurse to talk to the family about bargaining and reinforce that the child's illness is not anyone's fault.

DEPRESSION. When the illness can no longer be denied or bargained away, the family and child may begin to feel a profound sadness.

Nursing Insight— Depression

The nurse understands that this sadness or depression is to be expected.

There are some warning signs that the nurse must be aware of that indicate extra help is needed during this period of depression (e.g., insomnia or excessive sleeping, nightmares, weight gain or weight loss, loss of concentration that interferes with the ability to function normally, overwhelming anger, and constant fear or worry about the physical wellness of other family members). If the nurse assesses that any of these signs are present, it is imperative to talk to the hospital social worker, physician or a professional counselor to obtain help.

ACCEPTANCE. Accepting a child's illness and possible death means that the family or child has made an emotional adjustment to the illness. Although the family and child may still feel as if they are on an emotional roller coaster, the difficulties will become more predictable and manageable. At this phase, many family members find strength and joy in everyday living. Family members begin looking for meaning and a reason about why this happened to the child and what impact this experience may have on the future.

Nursing Insight— Acceptance

The nurse can remain present with the family and continue to offer support and encouragement. The nurse can provide community resources for the family to help them continue in the grieving process.

Nursing Insight— Miles and Perry's Stages of Grief

Miles and Perry (1985), two other well known grief theorists, identify three phases of parental grief.

Phase 1

Phase 1 is a state of numbness and shock. The parents may seem to be in a trance and display no emotion. Some parents may try to comfort others, yet show no emotion themselves.

Phase 2

Phase 2 is a period of intense grief. The parents may cry. Some parents express grief loudly with outbursts, while others cry quietly. Some parents display inappropriate silliness or euphoria. It is a mistake for the nurse to judge a parent as unaffected or uncaring because of the type of emotional reactions at the time of death.

Phase 3

Phase 3 is a period of reorganization. Initially the parents are in a state of emotional shock and forget important information. Later parents can remember verbatim the information that was given at the time of the child's death.

Epperson's Theory of Grieving

It is important for the nurse to remember that no two families go through the grieving process at the same time or at the same pace. A family who experiences a sudden or catastrophic loss appears to go through a slightly altered grief process. Epperson's theory about catastrophic grief may be helpful in the emergency department setting. With the absolute loss of a child already evident, bargaining is absent and depression is replaced with remorse. According to Morroni-Leash (1994), Epperson's theory of the grieving process includes six phases.

HIGH ANXIETY. High anxiety is described as a time of great stress, with many physical manifestations of emotional upheaval.

Nursing Insight— High anxiety

A nursing assessment of the family member finds agitation, rapid respiration and increased heart rate, irritability, muscular tension, and fainting, along with digestive or bowel changes that may result in nausea and diarrhea. It is important to refer the family member to a health care provider.

DENIAL. Denial is a protective emotional reaction to postpone the realization of the loss until sufficient psychological preparation has been made.

Nursing Insight— Denial

The nurse understands that this phase should not be hurried and a period of acute denial is normal. However, the denial should not persist beyond the viewing of the child's body and after the family has departed the hospital. If denial continues the nurse needs to refer the family member to a health care provider or a professional counselor.

ANGER. Anger is a common emotional response and can be directed inwardly, toward another family member, or toward others. Usually the anger is a diffuse kind that lashes out at society or life in general, with the feeling that the loss was somehow "allowed" to occur. Many times, the anger may be an attempt to affix blame. The anger is usually brief.

Nursing Insight— Anger

During an assessment, if the nurse sees that the anger persists, a complex underlying cause such as fear needs to be addressed further by a mental health specialist.

REMORSE. Remorse includes feelings of both guilt and sorrow. The family regrets that the accident or illness occurred and feels responsible that it could not be prevented.

Nursing Insight— Remorse

The nurse understands that this is the “if only.....” stage. Nursing care includes giving the family repeated reassurance that personal actions were reasonable. In situations of true culpability, the responsible family member needs intensive support and counseling in order to come to terms with personal liability.

GRIEF. Grief is an intense period of overwhelming sadness. The duration and intensity of the grief depend on factors such as the medical condition of the child, existing support systems, and culpability in the disease or injury scenario.

Nursing Insight— Grief

The nurse can provide emotional support and genuine caring during this phase.

RECONCILIATION. Reconciliation is described as the final phase to be experienced and may be an end-point to the acute family crisis.

Nursing Insight— Reconciliation

The nurse can tell the family that reconciliation is a time when the family begins to adapt to the existing circumstances and begins to move on with life (see Chapter 3 for further discussion).

Ethnocultural Considerations— The Hispanic culture and grief

Hispanics (Latinos) are persons of Mexican, Cuban, Puerto Rican, Central or South American, or other Spanish origins. As a result of this diversity, grieving behaviors surrounding the death of a child might take different forms. One example is a Hispanic family who is of the Catholic faith and who has a close extended family network within the social structure. Based on their culture and way of grieving, their infant child who has died is viewed as an angel who has returned to heaven. This belief brings comfort to the parents and the extended family, particularly the grandparents, and allows them to move on through the grieving process. To honor the deceased child, pictures are displayed in the home as a tribute, keeping the memory alive. There is a specified grieving time called *luto*. When this family is in *luto*, few celebratory activities take place, and usually no parties are attended and music is not played in the home. Outward expressions of happiness are discouraged for usually a year. In some instances, the relatives may wear black clothing to signify that they remember the loved one. If these traditions are not observed, there may be criticism from others. Any criticism is of the utmost concern to the family.

Coping Patterns

Grief reactions can differ. Certain behaviors by the family directly after a notification of illness or impending death

tend to be magnifications of their predominant stress-coping behaviors in times of duress. In times of stress, the child and parents may revert backwards to familiar ways of coping. It is important to note that if there is too much damage to a familiar lifestyle or family structure, the child or parents may become unable to cope.

NURSING CARE. The nurse must recognize the exhibited coping patterns and find ways to support the family directly or indirectly. The nurse can listen, sit silently, refer a pastoral care person, offer spiritual care such as prayer, or encourage journal writing or reading from a spiritual text. If the nurse notices that the behavior is destructive to self or others it is necessary to call in a physician or a professional counselor. The nurse should not alter the coping pattern completely because alteration could strip the child and family completely of protective buffers and leave them exposed to more pain than bearable.

Pathological Grief

On occasion, personal support systems do not adequately allow the individual to cope and the family members may experience dysfunction or pathological grief. Intense grief feelings or a dysfunctional personality may easily bring on **pathological grief** (deviation from a healthy or normal grief) such as violence, addictions, or poor decision making.

Nursing Insight— Subtle indicators of grief

These subtle signs are warning signs and may not necessarily indicate a severe problem. It is the intensity and duration of these behaviors that are the deciding factors indicating the need for professional help.

- Absence of grief such as showing little or no emotion
- Persistent blame or guilt
- Anxiety
- Aggressive and destructive outburst
- Depression and suicidal thoughts or actions
- Unwillingness to speak about the deceased
- Expressing only positive or only negative feelings about the deceased
- Prolonged dysfunction in school
- Always assuming a caregiver role
- Stealing or other illegal acts
- Signs of addictive behavior; drugs, food, certain activities

TYPES OF PATHOLOGICAL GRIEF. Another type of pathological condition is suicidal ideation and can occur when an individual is notified about the death of a child. The individual may feel intense hopelessness, helplessness, and loss of love. It is very important that the nurse recognize these feelings and listen carefully to the individual who may be expressing suicidal ideas. The nurse must immediately obtain professional psychiatric help for the individual.

The sudden loss of a child may be perceived like an emotional assault and an assertion of vulnerability. Therefore, sometimes an individual becomes violent when experiencing this significant loss in control. When the behavior of the individual escalates beyond the realm of verbal interchange, pathology is present. The nurse must try to understand the cause of the violent behavior. If the nurse notices that a family member displays a violent

reaction, steps must be taken for other family members to avoid any confrontation with the individual. The nurse can attempt to quietly remove the person to a private area away from others. It is essential that the nurse not be placed in a situation of personal risk. If the violent individual threatens the nurse or others, it is important to obtain help quickly and activate the facilities emergent care system.

Homicidal ideation must never be ignored. The nurse understands that homicidal threats can occur when a child dies due to negligence (whether real or perceived, such as drunken driving or intentional violence). Sometimes after a cooling-down period, the individual regains a calm demeanor and the potential for the violence may diminish. Most often, the violent individual is able to regain self-control and stabilize him- or herself. If this is not the case, the nurse must call for the hospital security guard or the local police to deal with the individual.

Grief that is influenced by drugs and alcohol dramatically alters the individual's ability to work through the grieving process. Illegal narcotic or alcoholic substances cause emotional responses to be exaggerated and uncontrolled. The ability of family members to unite in support of each other can be greatly reduced in this situation. An important nursing management strategy is to call in other family members, friends, or professional counselors to provide immediate help and extended support for the individual under the influence of drugs or alcohol.

Extreme denial is another abnormal response to grief. Most often grief reaches its peak within 3 or 4 months after the bereavement. However, when this does not happen, psychosomatic, psychoneurotic, and psychotic reactions can occur with increased frequency. If an individual is unable to start accepting what has happened beyond the viewing of the child's body or extends grieving into months after the child's death, the nurse needs to be aware of a pathological denial response. The nurse can help the family member find an appropriate community resource or support group.

Now Can You— Discuss the dying child?

1. Discuss nursing care for the dying child?
2. List three nursing diagnosis related to the dying child?
3. Assist the child and family through the grieving process?
4. Recognize pathological grief?

Saying Good-bye

At the time of death, the parents of a dying child can be in extreme grief, and saying good-bye to the child is an important process.

Nursing Care

The nurse can facilitate the saying good-bye process in several ways. It is important for the nurse to remember that the process of saying good-bye should not be rushed. It is paramount that throughout the process the nurse calls the child by name, which helps parents and family members feel that the nurse genuinely cares and that the child is special.

“What to say” — *Comforting a family*

The nurse understands that it is important to avoid platitudes such as “time heals all wounds,” “you wouldn't want him to live like that,” “you're lucky; it could have been much worse,” “you can always have another child.” These phrases minimize the loss and have little comforting effect. They may be upsetting to the family and make them feel that somehow this child's life has limited value. It is better to say nothing if you do not know what to say. Some appropriate responses are:

“I'm sorry.”

“This must be terribly hard for you.”

“Is there anyone I can call for you?”

“Would you like me to stay with you for a while?”

During the good-bye, the nurse keeps the child covered up and as warm as possible. The parents may want to assist in the immediate postmortem care as a way of saying good-bye. Parents can give the child their last bath, comb the hair, wash the face, or dress the child in a clean set of clothing. Allowing parents to hold the child one more time as the final good-bye is said is an act of compassion. Extended family members, friends, and others may come to say good-bye as well. The nurse can encourage the parents and others to talk about memories of the child. Crying is common for the parents, family, friends, and the nurse. If the nurse cannot keep personal emotional control, another nurse should offer relief.

The nurse's role after the child's death is to be supportive and allow the family to dictate the “good-bye” time line. If an extended time frame is needed to say good-bye, the nurse can contact pastoral care services to coordinate a private viewing time in the chapel. After the good-bye, it is important that the nurse ensure that the parents and others have departed from the hospital before transporting the child to the morgue.

THE SIBLING SAYS GOOD-BYE

The sibling relationship is sometimes one of the most consistent and ongoing relationships for a child. It can involve many feelings and experiences, including disharmony. In a sibling relationship, the child may experience love, caring, sharing, comforting, playing, jealousy, envy, fighting, and blaming. To the child, the sibling is not only a brother or sister, but also many times a playmate, friend, or support system. The child and sibling have learned and grown with each other and now the relationship is lost.

When a child dies, the surviving sibling may be mistakenly overlooked. Sometimes overlooking another child is unintentional as the focus is placed on the child who died or on the parents. Sometimes there is a perception that the sibling will “be all right.” The child may have been sent away to a grandparent or neighbor while the brother or sister was dying in the hospital. Sending the sibling away must not be viewed as negative behavior by the parent because the parent may be too overcome with personal emotions to care properly for the other child. When a child dies, the surviving sibling loses not only a brother or sister but sometimes also the grieving parents because they may be unable to attend his or her needs. It is also important to remember that the sibling may experience guilt feelings, thinking he or

she may have done “something” to make the child sick, or has done something wrong and is now being punished.

Nursing Care

The nurse must encourage the family to include the sibling when saying good-bye.

critical nursing action The Sibling

The nurse’s role in relation to the sibling consists of a variety of nursing interventions:

- Listen and help the sibling express his or her feelings.
- Model to the family about how to acknowledge the sibling’s presence during this difficult time (initiate a simple conversation, turn on cartoons, offer a drink or snack, or show the sibling how to touch the dying child).
- Explain the situation to the sibling and relate appropriate information in terms understandable for the sibling’s age.
- Allow visitation during appropriate times.
- Help the sibling understand that he or she is not responsible for the death.
- Contact a child life specialist who can assist the sibling with art therapy.
- Encourage simple ways to be involved in the care such as making a final gift for the sibling to keep at the bedside.
- Remind the family that the sibling is also experiencing a loss.
- Give siblings the chance to say good-bye.

REMEMBRANCE PACKET

After the death of a child, ongoing nursing care includes creating a remembrance packet to give to the family. When creating this memory packet, the nurse must gain permission from the parents to include personal aspects. If a camera is available, the nurse can take pictures of the

child. Taking pictures can be especially important in the death of an infant if parents have not yet taken pictures. Sometimes the nurse may want to make a plaster impression of the child’s hand or footprints. A lock of hair from the back of the child’s head can be included in the remembrance packet. The nurse can suggest to the parents that baptismal certificates or candles can also be incorporated into the remembrance packet.

The nurse understands that in the death of a young infant and, especially with young parents, the gathered items may be refused. If permission is granted to collect the items, it is important to place them in an envelope or box and keep them for a later date. Some parents are in a state of shock but may ask for them later. After the child’s death, the nurse can mail a sympathy card to the parents that may also become a part of the remembrance packet.

ORGAN TISSUE DONATION

In many states, a discussion soon after death about organ tissue donation is required by law. Organ tissue donation may be a sensitive issue for the nurse. The bereavement team or nurse must understand when it is appropriate to approach the family. The bereavement team is a group of trained professionals who know how to approach the topic of organ tissue donation while maintaining dignity and respect for the deceased child. In some circumstances, the family may approach the nurse about organ tissue donation. Sometimes, the physician provides information about organ tissue donation.

Certain criteria must be met for the child to be an organ or tissue donor. Depending on the type of illness, criteria may not be met for organ tissue donation. Nurses should be aware of common questions that the family may ask about organ tissue donation in order to help the family make an informed decision. Sometimes after the organ tissue donation, the family of the child gains comfort in knowing that the death of the child enabled another child to live.

Family Teaching Guidelines... The Sibling Needs to Say Good-Bye

HOW TO: Teach the Family to Help the Sibling say good-bye:

- ◆ Teach the family that it is important that the sibling be included in the grieving process and have the opportunity to say good-bye.
- ◆ Instruct families to bring the sibling for short visits when possible
- ◆ During visitation encourage the family to have another support person with the sibling such as a friend or grandparent
- ◆ Tell the family that the sibling can write letters or draw pictures for the child as a way of saying good-bye.

ESSENTIAL INFORMATION

Kübler-Ross (1983) states that the child who has been included in the death and mourning process with the family is able to let go in a healthy way.

FUNERALS

The nurse may be asked by families to attend the funeral of the child. The presence of the nurse at the funeral is meaningful to the child’s family and may bring the family comfort and convey a sense of caring for the deceased child. Attending the funeral is a personal decision for the nurse. While attending the funeral, the service may be difficult and bring up emotions for the nurse or it may assist the nurse in the grieving process and promote closure. Attending the service may be a meaningful way for the nurse to express feelings for the child and the family. If the nurse cannot attend the funeral, sending a card is sign of caring about the child and family.

Caring for the Professional Caregiver

Caring for the dying child and family can be one of the greatest challenges presented to the nurse. A nurse caring for the dying child can experience personal emotions. One emotion is attachment and it can vary from close contact with the child and family to distancing him- or herself from the situation. The nurse may also feel a sense of

helplessness about not being able to alter the outcome of death, especially in an acute death situation. In caring for a child with a chronic condition, the nurse has time to prepare for the child's death. Either way, the death of a child may not be easy for the nurse.

Caring for the child who is dying requires specialized knowledge and skill, sustaining an ongoing and special relationship with families, and at times advocacy. In addition, caring for a seriously ill or dying child requires compassion, sympathy, and empathy. This type of care can require enormous physical, emotional, and spiritual energy. Often the nurse is able to do this effortlessly. However, it is important to realize that the nurse can become depleted based on constant demands from the dying child and family. When the demands of care exceed personal energy, the nurse's personal energy may be threatened. The nurse may begin to wonder what personal threshold can be endured. Health care professionals are not expected to deliver high-quality care when personal emotions have been shattered (Rushton, 2004).

Nursing Insight— Burnout, compassion fatigue syndrome, and moral distress

The nurse must understand the concepts of burnout, compassion fatigue syndrome, and moral distress.

- Burnout is a state of physical, emotional, and mental exhaustion caused by long-term involvement in emotionally demanding situations. It emerges gradually and is a result of emotional exhaustion and job stress.
- Compassion fatigue syndrome is characterized by a sense of helplessness, confusion, and isolation from supporters and can have a more rapid onset and resolution than burnout.
- Moral distress occurs when the nurse is unable to translate personal moral choices into action. The nurse acts in a manner contrary to personal or professional values which undermines integrity. During moral distress, the nurse experiences feelings of frustration, anger and anxiety.

It is important for the nurse to recognize that simple actions can help relieve burnout, compassion fatigue syndrome, and moral distress. Sharing grief with the child's family after death can help both the nurse and family deal with feelings about the loss of the child. Most institutions have grief counselors and support services available to the nurse. Debriefing sessions with professional grief counselors after the child's death have proven to be helpful. Journal writing is an avenue many nurses explore. The nurse must remember to ask for personal support as well as to be supportive to other nurses. The nurse can also consider organized support sessions after the death of a child. It may be helpful for the nurse to talk with the physician or professional counselor for reassurance that a change in the nursing care would not have changed the outcome.

Another aspect is personal suffering. Suffering is multifaceted. Suffering happens when the nurse feels little control over the practice environment. Even though caring for the dying child and family is a privilege that offers personal rewards, the nurse must recognize that personal suffering is possible (Rushton, 2004). A good way to address the nurse's suffering is to attend a forum specifically for discussion, reflection, and shared understandings about

suffering. During the forum, the nurse can express personal feelings, frustrations, and disappointments. The nurse can also use strategies in the work setting such as journal writing, quiet time, prayer, or meditation that acknowledges and allows the nurse to process the grief and loss. The nurse should accept compassion and care from others. Self-care practices away from the workplace such as exercise, leisure activities with friends and family, and solitary time for reflection and renewal have great value. It is important for the nurse to create healthy boundaries, setting proper limits for compassion and self-sacrifice with the child and his family as well as oneself.

Nursing Insight— Paying attention to personal needs

The nurse can pay attention to personal needs by asking:

- How do I feel?
- Am I comfortable caring for a child who is dying?
- Can I cope with the needs of the family as well?
- Am I becoming overwhelmed or attached when caring for this child and family?

If the nurse feels uncomfortable with any of these questions, it is time for reflection and self-care. The nurse understands that these feelings are normal and are a part of the human experience. The nurse must know when the situation becomes too great to bear. It is difficult to help the patient and the family if the nurse is not coping. Remember there are employee assistance programs or forums at most institutions to assist the nurse with coping.

summary points

- ◆ A chronic condition is a physical, psychological, or cognitive condition that places limitations on daily activities or functions usually for longer than 3 months and may require relying on another individual to assist in daily care.
- ◆ A chronic condition may affect each developmental phase and the family's social, financial, and psychological resources.
- ◆ Technological advances now save premature infants, and infants and children who are very ill leading to an increase in the number of children who are dependent on technology.
- ◆ Chronic sorrow is a coping mechanism that permits parents to carry on with life and daily responsibilities.
- ◆ The nurse caring for the child and family with a chronic condition must establish a therapeutic relationship.
- ◆ Death is difficult to comprehend and might be considered mysterious, ambiguous or confusing for the child and family. The dying process is unique and the exact time or date of death is unpredictable.
- ◆ Perceptions of death vary across the age continuum.
- ◆ To help the child have a peaceful death comfort measures are essential which can help create a positive outcome at the time of the child's death as well as later on for the family.

- ◆ Care of the dying child also includes holistic nursing interventions that address the physical, emotional, and spiritual care of the child and family.
- ◆ A nursing plan of care is essential when caring for the grieving family as well as recognizing pathological grief.
- ◆ At the time of death, the parents and sibling of a dying child can be in extreme grief, and saying good-bye to the child is an important process.
- ◆ There are additional nursing aspects related to the death of a child such as a remembrance packet, organ tissue donation and funerals.
- ◆ Caring for the dying child and family can be one of the greatest challenges presented to the nurse.

review questions

Multiple Choice

1. The pediatric nurse enters the room of an infant newly diagnosed with cerebral palsy and finds the mother tearful, looking over her baby's crib. The nurse places her hand on the mother's shoulder and the mother cries, "I wish my son was normal!" The nurse's best therapeutic response is:
 - A. "I know what you mean. This is very difficult".
 - B. "Sit down and let's talk about how you're feeling."
 - C. "I am here to help you." "I will come back later?"
 - D. "Where is your husband? Can he help you now?"
2. The pediatric nurse working in an acute inpatient unit understands that a Do Not Resuscitate order includes which of the following measures?
 - A. Administering radiation therapy in an attempt to eradicate the disease
 - B. Administering antibiotic therapy as scheduled by the physician
 - C. Administering no lifesaving measures in the event of a respiratory arrest
 - D. Administering feeding via an orogastric tube for artificial nutrition

Select All that Apply

3. A chronic illness can have a direct effect on the family as a whole. The pediatric nurse is aware that the impact of the chronic illness depends on the:
 - A. Severity of the illness
 - B. Growth and developmental age when the insult occurred
 - C. Hospital and community resources available to the family
 - D. Family's coping mechanisms
 - E. Child's response to the condition
4. When assessing the chronically ill toddler, the pediatric nurse notes signs of impending death. The nurse recognizes the importance of supporting this family through this difficult experience and reviews which of the following as signs of impending death with the family members?
 - A. Skin is cool to the touch
 - B. Quiet, easy respirations
 - C. Rapid regular pulse
 - D. Noisy, irregular respirations
 - E. Sleeping for long periods of time
 - F. Difficult to arouse

True or False

5. The child who is chronically ill always has physical involvement.
6. A priority nursing intervention for the adolescent with a chronic condition includes providing group therapy to help the adolescent to regain control.
7. During the time of death, the nurse should leave the family alone to grieve privately.
8. Palliative nursing care can provide relief of pain and other distressing symptoms but cannot postpone death.
9. According to developmental specialists, the preschool age group is a period of concrete thinking and so, death should be described as "going to sleep".

Fill-in-the-Blank

10. The pediatric nurse is aware that the leading cause of death in the school age group is _____.
11. It is important for the pediatric nurse to understand that according to normal growth and development the preschooler is a _____ and may view illness as a punishment for bad behavior.
12. The _____ is unable to distinguish fear from fantasy which inhibits a true comprehension of death.
13. The _____ seems to comprehend death more than can be verbalized.
14. The _____ has difficulty accepting death as a reality and therefore thinks the body is invincible and engages in _____ behaviors.
15. According to Kübler Ross, children after the ages of _____ to _____ understand the permanence of death. This age group understands more of what is overheard than parents and nurses realize. Attempts to shield this age group from death can often be perceived as _____.

Short Answer

16. The parent of the dying child asks the nurse if he/she can hold the child. What action is appropriate for the nurse to take?

A & P (anatomy and physiology) review

blood components, 1072–1073
endocrine system, 887
epidural space, 419–420, 419f
fetal circulation, 604–605
fetal lungs, 604
fetal skull, 359, 361, 361b, 361f
gastrointestinal system, 786
heart, 854–856, 856f
immune system, 820–821
kidneys, 1034–1035, 1035f
lactation-related breast changes, 473
menstrual cycle, 125, 125f
musculoskeletal system, 964
nervous system, 922
oogenesis, 117, 117f
placental hormone, 194–195
primary germ layers, 176
respiratory function, 542
respiratory system, 751
skin, 996, 997f
spermatogenesis, 132, 133f
tumor progression, 1105

Abarelix, in infertility, 157t

Abdomen

auscultation of, in child assessment, 679
in child assessment, 679–680, 679f
distention of, in neonate, 584
examination of, in prenatal assessment, 236
pain in. *See* Abdominal pain
palpation of
in child assessment, 680
contraindication to, 1113
in neonate, 583–584
quadrants of, 679, 679f
trauma to, 814, 815t

Abdominal pain

in children, 787
in constipation, 804
in intussusception, 791, 791f
in malrotation, 791–792
during pregnancy, 279–280

ABO isoimmunization, 328

Abortion

clinical, 153–154
complications of, 145, 154
dilation and evacuation for, 145
elective, 153
methotrexate for, 154
mifepristone for, 154
therapeutic, 153
vacuum aspiration for, 153–154
spontaneous, 280, 295–296
alcohol use and, 261
history of, 225

Abruptio placentae, 280, 299–300, 299b, 299f, 300b, 450, 452

Abscess, brain, 936, 937t

Absolute neutrophil count, 1090, 1126

Abstinence, 144, 246

Acceptance, in grieving, 1149

Accidents. *See also* Trauma
in adolescent, 85
in young children, 31

Acculturation, 66

Accutane, 275

Acetaminophen

in fever, 684
in otitis media, 768

Acetazolamide, with ventricular shunt, 943

Acetylsalicylic acid. *See* Aspirin

ACHES signs, 148

Achondroplasia, 586

Acidosis, 752t
in acute renal failure, 1052t
neonatal, 611, 612t

Acne, 1002–1006
diagnosis of, 1002–1003
neonatal, 575
signs and symptoms of, 1002, 1002f
treatment of, 1003–1004, 1004t–1005t

Acoustic stimulation, in fetal assessment, 342

Acquired immunodeficiency syndrome (AIDS).
See Human immunodeficiency virus (HIV) infection

Acrocyanosis, in newborn, 393, 545

Acromegaly, 890–892

Across care settings. *See* Care settings

Acticoat, for burn wound, 1024

Acupressure

in labor-related pain, 410
in pregnancy-related nausea and vomiting, 297

Acupuncture, in labor-related pain, 410

Acute chest syndrome, in sickle-cell disease, 1072

Acute hemolytic transfusion reaction, 1097–1098

Acute lung injury, transfusion-related, 1097–1098

Acute lymphocytic leukemia, 1106, 1106f, 1107–1108, 1107t, 1109

Acute myelocytic/myelogenous leukemia, 1106, 1106f, 1108–1109

Acyclovir

in chickenpox, 832t
in herpes simplex virus infection, 627, 1009

Adam's position, 983, 984f

Adapalene, in acne, 1004t–1005t

Adaptive devices, in chronic conditions, 1135, 1135f

Addisonian crisis, 901

Addison's disease, 900–902

Adhesive, tissue, 998

Admission procedures, for childbirth, 369–372, 370t

Adnexa, 116, 117f

Adolescent. *See also* Children; Young adulthood

accidents in, 85
