Maternal-Child Nursing Care

Optimizing Outcomes for Mothers, Children, & Families

Contents in Brief

unit one

Foundations in Maternal, Family, and Child Care 1

- 1 *Traditional and Community Nursing Care for Women, Families, and Children* 1
- 2 *Contemporary Issues in Women's, Families', and Children's Health Care* 25
- 3 *The Evolving Family* 46
- 4 *Caring for Women, Families, and Children in Contemporary Society* 71

unit two

The Process of Human Reproduction 111

- 5 *Reproductive Anatomy and Physiology* 113
- 6 *Human Sexuality and Fertility* 137
- 7 *Conception and Development of the Embryo and Fetus* 164

unit three

The Prenatal Journey 191

- 8 *Physiological and Psychosocial Changes During Pregnancy* 193
- 9 *The Prenatal Assessment* 215
- 10 *Promoting a Healthy Pregnancy* 256
- 11 *Caring for the Woman Experiencing Complications During Pregnancy* 291

unit four

The Birth Experience 353

- 12 *The Process of Labor and Birth* 355
- 13 *Promoting Patient Comfort During Labor and Birth* 399
- 14 *Caring for the Woman Experiencing Complications During Labor and Birth* 427

unit five

Care of the New Family 467

- 15 *Caring for the Postpartal Woman and Her Family* 469
- 16 *Caring for the Woman Experiencing Complications During the Postpartal Period* 511

17 *Physiological Transition of the Newborn* 541

18 *Caring for the Normal Newborn* 563

19 *Caring for the Newborn at Risk* 603

unit six

Caring for the Child and Family 639

20 *Caring for the Developing Child* 641

21 *Caring for the Child in the Hospital and in the Community* 664

22 *Caring for the Family Across Care Settings* 701

unit seven

Ongoing Care of the Child in the Hospital and in the Community 715

23 *Caring for the Child with a Psychosocial or Cognitive Condition* 717

24 *Caring for the Child with a Respiratory Condition* 750

25 *Caring for the Child with a Gastrointestinal Condition* 785

26 *Caring for the Child with an Immunological or Infectious Condition* 819

27 *Caring for the Child with a Cardiovascular Condition* 853

28 *Caring for the Child with an Endocrinological or Metabolic Condition* 885

29 *Caring for the Child with a Neurological or Sensory Condition* 921

30 *Caring for the Child with a Musculoskeletal Condition* 962

31 *Caring for the Child with an Integumentary Condition* 995

32 *Caring for the Child with a Renal, Urinary Tract, or Reproductive Condition* 1033

33 *Caring for the Child with a Hematological Condition* 1071

34 *Caring for the Child with Cancer* 1104

35 *Caring for the Child with a Chronic Condition or the Dying Child* 1133

*In loving memory of my mother, Betty A. Tighe, who always said “it’s possible”.
With great love and appreciation to my family, particularly to my intelligent
children Kathleen, Frank, and William.*

*To my co-author, Shelton Hisley, who has amazing fortitude. To faculty,
administration, and staff at Nebraska Methodist College.
To the skilled and caring nurses at Children’s Memorial and Methodist Hospitals.
To my dear friend, Jeanne Snowden.*

Susan Ward

*To my husband, Jack, whose love and encouragement, especially during the dark
days of my cancer diagnosis and treatment, kept me aloft and convinced that I could
achieve this goal.*

*To my parents, Barbara and Hubert McLendon, for a lifetime of love and support.
Also to Susan, my co-author and friend, for whom I hold the greatest admiration
and respect.*

Shelton Hisley

Preface

Maternal–Child Nursing Care: Optimizing Outcomes for Mothers, Children, and Families springs from our passionate commitment to providing the best nursing care possible to mothers and children and our desire to inspire others to make that same commitment. In this all-inclusive source, we provide students with current, comprehensive information about maternal–child nursing in creative, dynamic ways and in a concise, accessible format. Building upon theoretical foundations in basic nursing care, communication skills, and principles of health promotion, the text challenges students to optimize outcomes for their maternal and pediatric patients using critical thinking as they care for them in the hospital and community environments. We focus on aesthetics, cultural sensitivity, and a caring approach. The textbook also serves as an excellent resource for practicing nurses who work with women, children, and families in a variety of settings. We believe that combining essential information about the two specialties into a single textbook supports good educational practice while being economically practical.

Philosophy

The primary objective of this textbook is to identify the myriad of options for holistic, evidence-based practice in maternal and child nursing care in this new millennium, based on a philosophy of physiological and developmental normalcy and stressing safety and optimization of outcomes for mother and child. In addition to comprehensive coverage of maternal and child nursing care in traditional settings, essential elements for providing cost-effective, high-quality, innovative nursing care in community settings are presented. Discussion of health care delivery in community settings is crucial in contemporary nursing education and reflects the present trend for women, families, and children to obtain health care in the diverse settings in which they live, grow, play, work, or go to school.

This book is built upon a framework that views the delivery of nursing care as a continuum spanning the traditional hospital in-patient environment to the community setting. Students are presented with information essential to providing appropriate, culturally sensitive nursing care to women, families, and children. A variety of creative learning aids are used to assist students in subject mastery and prompt the delivery of care that appropriately addresses contemporary needs while incorporating innovative approaches that integrate provider–patient partnerships and alliances with coalitions that serve women, families, and children across the lifespan. Because the traditional hospital experience constitutes an important component of nursing education, content on hospital-based nursing care for women, families, and children examines acute, traumatic, chronic, and terminal conditions. Likewise, content that addresses community-based nursing care for women, families, and children explores strategies and resources for the provision of appropriate care in many

different outpatient settings. With this text, students learn that community-based care can take place in a variety of ways at any time and in any place. It is our hope that the users of this textbook will acquire the essential knowledge for professional nursing practice in the specialties of maternal and child nursing and that they will gain insights about providing nursing care in a myriad of settings and with diverse populations.

Organization

Each chapter opens with a culturally or spiritually oriented story, literary piece, caring element, or quotation that creatively expresses various dimensions of aesthetics in nursing. Because contemporary nursing is a dynamic profession with a rich past, present, and future, we emphasize and promote the importance of innovative, state-of-the-art technology balanced with compassionate, humanistic care. “Learning Targets” offer a guided approach to chapter content and provide a gauge for assessing outcomes.

Chapter introductions provide a preview of content and assist students in identifying essential information and major concepts. Key words appear in boldface print accompanied by brief definitions in the text and are grouped in the glossary for easy, quick reference on the Electronic Study Guide. Color illustrations and photos provide visual cues to enhance understanding. These features facilitate students’ learning and promote an understanding of the relationship between classroom or textbook information and the delivery of nursing care in the clinical setting.

A short review of anatomy, physiology, and pathophysiology is provided in applicable chapters to foster understanding of new applications of concepts previously learned. Eye-catching display boxes draw students’ attention to essential information about medications, critical nursing actions, nursing procedures, related research studies, assessment tools, diagnostic modalities, safety issues, therapeutic communication strategies, and family teaching guidelines.

Each chapter concludes with a concept map that visually summarizes the relationships among the most important concepts presented. The map reinforces students’ learning, promotes mastery of information, and assists students in critical analysis. It is a useful tool for confirming that students have identified the essential chapter elements and for applying classroom information to the clinical setting.

A number of strategies designed to prompt and enhance critical thinking weave through the text. Case studies, nursing care plans, NCLEX-style review questions, and exercises in clinical decision-making assist students in mastering content and in integrating new information. These creative learning activities help students to assimilate and internalize information as they build upon previously learned nursing knowledge and prepare to apply newly introduced concepts in various maternal–child clinical practice areas.

Themes and Key Features

The overarching theme of this comprehensive maternal–child resource focuses on how to provide contemporary nursing care to women, families, and children in the community as well as in the traditional hospital setting. In service to that goal are the broad themes of holistic care, critical thinking, validating practice, and tools for care. We use the following key features throughout the chapters to creatively illustrate and emphasize information essential for the delivery of safe, effective nursing care to diverse populations across care settings, thus ensuring an educational experience rich with critical thinking activities and clinical application opportunities.

HOLISTIC CARE

- Each chapter begins with a culturally or spiritually oriented story, literary piece, caring element or quotation that creatively expresses aesthetics in nursing.
- “Nursing Insight” boxes show students how experienced nurses use their five senses to gain a deeper understanding about the clinical situation or the patient’s condition.
- “Collaboration in Caring” provides guidelines for working with other health care professionals to care for patients and families in in-patient and community-based environments.
- “Ethnocultural Considerations” emphasize cultural humility in both the hospital and community settings.
- “What to Say” helps students develop and enhance their communication skills by providing verbatim examples or helpful hints.
- Nursing Care Plans incorporating NANDA, NOC, and NIC terminology relate classroom and textbook knowledge to clinical practice, while evidence-based rationales for interventions show how research supports practice.
- “Complementary Care” shows students the wide range of complementary options available for integration with conventional approaches to provide safe, timely, and compassionate care.
- “Across Care Settings” foster students’ responsiveness to trends in health care by highlighting holistic health care in acute care and community-based settings in which children and families live, grow, play, work, or go to school. Sensitivity to diverse patient populations is also underscored.
- “Family Teaching Guidelines” help students teach families essential components about caring for themselves and their children and are offered both in English (in the text and on the Electronic Study Guide) and Spanish (on the Electronic Study Guide).

CRITICAL THINKING

- “Learning Targets” offer a guided approach to chapter content and provide a gauge for assessing outcomes.
- Key words appear in boldface type accompanied by brief definitions. Key words are also stored in the glossary for easy, quick reference on the Electronic Study Guide and DavisPlus.
- “Case Studies” facilitate students’ practice in the assimilation of content from various chapters into

actual patient situations. As students work through the various case studies, they are challenged to apply critical thinking and practice clinical decision-making.

- Nursing Diagnoses foster the development of new nursing knowledge where diagnoses are developed based on information obtained during a nursing assessment. A standardized statement about the health of a patient is created for the purpose of providing nursing care. The nursing diagnoses portray patients’ responses to their condition where the nurse can address the problems independently.
- “Clinical Alerts” help students recognize emergent or critical situations and relate classroom or textbook information as they deliver safe, effective nursing care in the hospital and community-based environments.
- “Critical Nursing Actions” prompt students to assimilate and internalize information as they prepare to apply important concepts in the clinical area.
- NCLEX-style review questions located at the end of each chapter prompt and enhance critical thinking and help to prepare students for licensure examination.
- Concept Maps visually summarize the relationships among the most important concepts presented in every chapter. The concept map can be used by students to think critically, to review, and to more clearly see the application of classroom information to the clinical setting.

VALIDATING PRACTICE

- “Moving Toward Evidence-Based Practice” highlights current relevant research and encourages students to incorporate evidence-based findings into their everyday practice.
- “Optimizing Outcomes” enhance critical thinking skills for clinical application and help establish the best possible outcomes and how to obtain them.
- “Where Research and Practice Meet” focus on investigative initiatives that may impact practice in the future, underscoring the value of clinical inquiry in ensuring positive outcomes for patients and their families.
- “Be Sure To...” alert new nurses to important legal issues that impact the clinical environment and help them recognize how to critically analyze potentially litigious situations.
- “Now Can You?” prepares students to assimilate and internalize information presented throughout the chapter and serve as a mini check to ensure mastery of material before proceeding to the next section.
- “Summary Points” bring together the information students should be most careful to comprehend from the chapter.
- References provide current citations that validate practice and support the chapter content.

TOOLS FOR CARE

- “A & P Review” of chapter-specific anatomy, physiology, and pathophysiology foster understanding of new applications of previously learned concepts.
- “Labs” boxes present crucial information about laboratory testing and its relationship to the patient’s overall health status.

- Procedures provide step-by-step instructions for performing common procedures in maternal–child nursing and the rationales for why things are done a particular way. Each procedure includes an example of documentation to emphasize the critical nature of proper, accurate documentation.
- “Medication” boxes present crucial information about commonly prescribed medications and help students in their care of mothers, children, and families.
- “Assessment Tools” facilitate understanding of clinical evaluation and help students make the connection between classroom or textbook knowledge and the clinical setting.
- “Diagnostic Tools” present crucial information about common diagnostic measures and their relationship to various disease entities.

Teaching Ancillaries and Other Related Products

INSTRUCTOR’S RESOURCE DISK

The components on the Instructor’s Resource Disk seamlessly guide faculty through the content and offer innovative strategies for creatively supplementing the text. This complete and easy-to-use collection of teaching aids for maternal–child content includes the following components.

Instructor’s Guide

The course syllabus includes a proposed class schedule for a traditional 15-week semester and for an accelerated 8-week semester along with reading assignments and testing content. The syllabi provide a guide for using the text in the most efficient way.

“Teaching Plans” provide a user-friendly lesson plan for each chapter whether teaching in separate or combined courses. The Teaching Plans integrate teaching tips, PowerPoint presentations, and suggested students assignments.

“Tips for Teaching a Combined Maternal–Child Course” offer suggestions about how to effectively teach these two specialties in one course.

Case Studies

The case studies provided to the instructor are more extensive and detailed than those provided in the text or on the Electronic Study Guide so they can be used for testing as well as post-conference discussions. Answers to the case studies are provided to promote and enhance critical thinking skills and facilitate the application of theoretical concepts into the clinical setting.

Concept Maps

Concept maps are constructed to underscore the relationships among the essential concepts in each chapter. They prompt critical thinking and may be used as a guide for students assigned to create additional maps about other important theoretical elements.

Electronic Test Bank

The electronic test bank is a collection of NCLEX-style questions and rationales to enable students to identify

areas of strength and weakness and prepare for course tests and the national licensure examination.

PowerPoint Presentations

A collection of slides is provided that form the basis for a lecture for each chapter, which can be modified based on the instructor’s preferences.

Media Ancillary

Electronic files of the images from the text are included for use in the classroom, as are audio selections of heart sounds.

ELECTRONIC STUDY GUIDE

A complimentary electronic study guide is included with the text. This is intended to assist and enhance students’ learning and offers creative ways to supplement and reinforce the textbook information. It contains the following:

Interactive Exercises

These provide a creative and enjoyable way to enhance students’ learning and include:

- Hangman
- Quiz Show
- Critical Thinking
- Drag and Drop Bucket
- Fill-in-the-Blank Clue

Case Studies

Thirty-one relevant case studies from selected chapters facilitate students’ practice in the assimilation of content from various chapters into actual patient situations.

Nursing Care Plans

All care plans from the textbook are provided and are printable. There are also twelve expanded care plans that are not included in the text (six for Obstetrics and six for Pediatrics) to provide in-depth information and guidance for planning and providing care to maternity and pediatric patients with commonly encountered normal and pathological conditions.

Family Teaching Guidelines

English and Spanish versions of the Family Teaching Guidelines from the text, as well as additional ones unique to the Electronic Study Guide, can be personalized and printed and used in actual patient care situations.

NCLEX-style Review Questions

A collection of NCLEX-style questions and rationales can help students identify areas of strength and weakness, and prepare for course tests and the national licensure examination.

Sound Collection

Heart sounds depicting various normal and abnormal heart sounds are included to help students recognize when there is a problem.

Podcasts

Podcasts directs students to key chapter concepts and reinforces essential information.

Concept Maps

For students' convenience, all concept maps from the text are included on the Electronic Study Guide.

Clinical Pathways

Clinical pathways display patient goals and corresponding sequence nursing actions to achieve those goals.

DavisPlus Website

In addition to all the Web-suitable content from the Instructor's Resource Disk and the Electronic Study Guide (instructor materials are password protected; students' materials are not), the Web site contains Internet links related to specific content areas presented throughout the book; links to useful Web sites, links to the F.A. Davis Web site and product page, and bonus material, including interactive exercises for pediatric dosage calculations.

CLINICAL POCKET COMPANION TO MATERNAL–CHILD NURSING

The separate, for-sale *Clinical Pocket Companion* contains critical information to facilitate the delivery of safe, effective, compassionate care in maternity and pediatric clinical settings. Information is extracted from the core text and is presented in easy-to-access formats. In addition to nursing skills and procedures, nursing tools and charts, and color illustrations from the parent text, each chapter in the *Clinical Pocket Companion* covers:

- Key Terms
- Focused Assessments
- Clinical Alerts
- Diagnostic Tests
- Medications
- Ethnocultural Considerations
- Teaching the Family
- Additional Information for the Clinical Setting
- Resources

Thank you for choosing *Maternal–Child Nursing Care: Optimizing Outcomes for Mothers, Children, and Families*. It is our sincere hope that this textbook and ancillary package will provide you with the tools needed to convey the essentials of care for the childbearing/child-rearing family.

We believe that providers of contemporary nursing education are challenged to present timely, evidence-based information grounded in a framework of holistic, compassionate care. We appreciate that you will bring your own unique approach as you guide students toward providing competent, sensitive care for mothers, children, and families. We share your passion for maternal–child nursing and hope that this learning package may be instrumental in sparking this same passion in others.

Susan L. Ward

Dedicated Participants

It has taken a village of professionals to bring this project to fruition, and we thank the editors and production staff of the F.A. Davis Company for their expertise and guidance, especially:

- Lisa Deitch, Publisher, Nursing
- Shirley Kuhn, Special Projects Editor
- Darlene Pedersen, Director of Content Development
- Padraic Maroney, Senior Project Editor
- Doris Wray, Executive Editorial Coordinator
- Sam Rondinelli, Assistant Director of Production
- David Orzechowski, Managing Editor
- Julia Reukauf, Marketing Specialist

We are indebted to the following for helping us shoot and collect the photographs used in the text:

Billings Photography, Omaha, Nebraska
Children's Memorial Hospital, Omaha, Nebraska
Methodist Health System, Birth Services, Omaha, Nebraska
Nebraska Methodist College, Omaha, Nebraska
Betsy Toole Media Production Services, St. Luke's Hospital & Health Network, Bethlehem, Pennsylvania
Miami Children's Hospital, The Mary Ann Knight International Institute of Pediatrics, Founded as Variety Children's Hospital, Miami, Florida
Chandra Vig, Ann Harms, and Susan Ward's nursing students, family members, and friends

Many thanks to the following people who helped us supply sketches for the professional illustrator to create many of the line drawings in the text: John C. Hisley, MD, William R. Ward, and Matthew T. Blaszkowski.

Many colleagues and friends assisted the chapter contributors through mentoring, editing and offering content expertise. A special thank you goes to the following individuals:

Nursing Department
Nova Southeastern University
Fort Lauderdale, Florida
Chapter 15

Kelly Tobar, RN, EdD

Associate Professor
California State University Sacramento
Sacramento, California
Chapter 26

Chandra Vig, BSN

Curriculum Developer
Bow Valley College
Calgary, Alberta, Canada
Chapter 20

Susan L. Ward, PhD, RN

Professor of Nursing
Nebraska Methodist College
Omaha, Nebraska
Chapter 18

Nancy Watts, RN, MN, PNC (C)

Clinical Nurse Specialist
London Health Sciences Centre
London, Ontario, Canada
*Maternity NCLEX-style Questions for Text, Electronic
Study Guide, and Instructors Materials*

Ruth A. Wittmann-Price, D.N.Sc., RN, CNS, CNE

Assistant Professor
Drexel University College of Nursing and Health
Professions
Philadelphia, Pennsylvania
Chapter 19

Roseann Mary Zahara-Such, APRN, BC, MSN, CCNS

Assistant Clinical Professor of Nursing
Purdue University
Hammond, Indiana
Chapter 28

Kelly K. Zinn, MSN, RN

Assistant Professor
Nebraska Methodist College
Omaha, Nebraska
Coordinator for certain Ancillary Components

Reviewers

Marie Adorno, APRNC, MN

Assistant Professor of Nursing
Our Lady of Holy Cross College
New Orleans, Louisiana

Rebecca L. Alleen, RN, MNA

Assistant Professor
Clarkson College
Omaha, Nebraska

Anita Dupre Althans, RNC, BSN, MSN

Assistant Professor of Nursing
Our Lady of Holy Cross College
New Orleans, Louisiana

Elaine Andolina, BS, MS

Director of Admissions, School of
Nursing
University of Rochester
Rochester, New York

Bridget Bailey, RN, MSN

Nursing Instructor
Iowa Lakes Community College
Emmetsburg, Iowa

Margaret Batson, RN, MSN

Nursing Instructor
San Joaquin Delta College
Stockton, California

Samantha H. Bishop, MN, RN, CPNP

Assistant Professor of Nursing
Gordon College
Barnesville, Georgia

Linda Boostrom, RN, MSN

Instructor of Nursing Program
Henderson Community College
Henderson, Kentucky

Susan J. Brillhart, MSN, APRN, BC, PNP

Assistant Professor of Nursing
Borough of Manhattan Community
College
New York, New York

Linda A. Browne, MSN, RN

Program Director/Instructor
Southwest Georgia Technical College
Thomasville, Georgia

Tammy Bryant, RN, BSN

Program Director
Southwest Georgia Technical College
Thomasville, Georgia

Gloria Haile Coats, RN, MSN

Professor of Nursing
Modesto Junior College
Modesto, California

Jami-Sue Coleman, MS, RN

Nursing Instructor
Western Nevada Community College
Carson City, Nevada

**Meghan Connelly, MSN, APRN,
CCRN, CPNP-AC**

CNS/NP
Children's Hospital
Omaha, Nebraska

Susan Craig, RN, MSN

Faculty
Butte Community College
Oroville, California

Robin Culbertson, RN, MSN, EdS

Nursing Instructor
Okaloosa Applied Technology Center
Fort Walton Beach, Florida

Lori DuCharme, RN, BSN, MS

Nursing Faculty
Front Range Community College
Westminster, Colorado

Susan Ellison, MSN, RNC

Senior Instructor
The Charles E. Gregory School of
Nursing
Perth Amboy, New Jersey

Marie Esch-Radtke, MN, RN

Nursing Faculty
Highline Community College
Des Moines, Washington

Polly D. Fehler, RN, BSN, MSN

Instructor of Nursing
Tri-County Technical College
Pendleton, South Carolina

Denise M. Fitzpatrick, RNC, MSN

Instructor/Course Coordinator
Dixon School of Nursing
Willow Grove, Pennsylvania

L. Sue Gabriel, MSN, MFS, RN, SANE

Assistant Professor
Bryan LGH College of Health Sciences
Lincoln, Nebraska

Marilyn Johnessee Greer, RN, MS

Associate Professor of Nursing
Rockford College
Rockford, Illinois

Kristin J. Hanak, MS, RN, PNP

Nursing Faculty
Front Range Community College
Westminster, Colorado

Donna Healy, MS, RN

Associate Professor of Nursing
Adirondack Community College
Queensbury, New York

Debra L. Hyde, RN, MSN, CNS

Faculty
Aultman College of Nursing and
Health Sciences
Canton, Ohio

Paula Karnick, PhD, ANP-C, CPNP

Associate Professor
North Park University
Chicago, Illinois

Mary Beth Kempf, BSN, RNC, MSN, OB

Associate Degree Nursing Instructor
Northeast Wisconsin Technical
College
Green Bay, Wisconsin

**Cynthia A. Kildare, RN, MSN,
APRN-BC**

Assistant Professor
Bryan LGH College of Health
Sciences
Lincoln, Nebraska

Karen M. Knowles, RN, MS

Faculty/Specialty Chairperson
Crouse Hospital School of Nursing
Syracuse, New York

**Kathleen Nadler Krov, RN, CNM,
MSN, FACCE**

Assistant Professor
Raritan Valley Community College
Somerville, New Jersey

Barbara Leser, PhD, RN, RM

Doctor
Northwest Nazarene University
Nampa, Idaho

Randee L. Masciola, RN, MS, CNP

Clinical Instructor and Women's
Health Nurse Practitioner
Ohio State University
Columbus, Ohio

Kathleen Matta, MSN, CNS, IBCLC

Visiting Faculty
University of New Mexico
Albuquerque, New Mexico

Sheila Matye, MSN, RNC

Adjunct Assistant Professor
Montana State University
Great Falls, Montana

Trilla Mays, RN, MSN

Nursing Instructor
Midlands Technical College
Columbia, South Carolina

Barbara McClaskey, PhD, MN, RNC, ARNP

Professor, Department of Nursing
Pittsburg State University
Pittsburg, Kansas

Michelle Michitsch, RN, MS, CPNP-PC

Adjunct Nursing Professor
Borough of Manhattan Community
College
New York, New York

Nancy Miller, MSN, RNC, CCM

Nursing Professor
Keiser University
Fort Lauderdale, Florida

Georgia Moore, PhD, MSNed, RN-BC

Consultant/Online educator
Louisville, Kentucky

Julie Moore, RNC, MSN, MPH, WHNP

Associate Professor of Nursing
Hawaii Community College
Hilo, Hawaii

Cindy Morgan, CNM

Instructor
University of Tennessee at
Chattanooga
Chattanooga, Tennessee

Deborah Naccarini, RN, MSN, FNP

Assistant Professor
Carroll Community College
Westminster, Maryland

Debbie Ocedek, RN, BSN, MSN

Professor of Nursing
Mott Community College
Flint, Michigan

Donna Paulsen, RN, MSN

Nursing Faculty
North Carolina Agricultural and
Technical State University
Greensboro, North Carolina

Melissa A. Popovich, RN, MSN

Clinical Faculty
Ohio State College of Nursing
Columbus, Ohio

Karen L. Pulcher, ARNP/CPNP, MSN, RN

Assistant Professor in Nursing
University of Central Missouri
Lee's Summit, Missouri

Jacquelyn Reid, MSN, EdD, CNM, CNE

Associate Professor
Indiana University Southeast
New Albany, Indiana

Jean Rodgers, RN, BSN, MN

Nursing Faculty
Hesston College
Hesston, Kansas

Kathryn Rudd, RNC, MSN

Clinical Educator
MetroHealth Medical Center
Cleveland, Ohio

Christine L. Sayre, MSN, RN

Auxiliary Faculty
Ohio State University
Columbus, Ohio

Gwenneth C. Simmonds, PhDc, CNM, MSN, RN

Clinical Instructor
Ohio State University
Columbus, Ohio

Lisa H. Simmons, RN, MSN

Instructor and Coordinator Child
Health Nursing
University of South Carolina Aiken
Aiken, South Carolina

Cordia A. Starling, BSN, MS, EdD

Division Chair of Nursing
Dalton State University
Dalton, Georgia

Nora F. Steele, DNS, RNC, PNP

Professor
Charity/Delgado Community College
New Orleans, Louisiana

Suzan Stewart, RN, BS

Lab Coordinator
Community College of Denver
Denver, Colorado

Deborah Terrell, RN, MSN, APN, DNSc

Associate Professor
Harry S. Truman College
Chicago, Illinois

Barbara Tewell, RNC, BSN

Perinatal Staff Nurse
Naval Medical Center
San Diego, California

Donna J. Gryctz Thomas, RN, BSN, MSN

Assistant Professor of Nursing
Kent State University
New Philadelphia, Ohio

Joan Thompson, NNP, MSN, RNC

Assistant Professor
University of Hawaii at Hilo
Hilo, Hawaii

Pat Twedt, RN, MS, Med, MS

Associate Professor of Nursing
Dakota Wesleyan University
Mitchell, South Dakota

Becky C. Vicknair, RNBS, APRN, MSN, PNP

Pediatric Instructor
Delgado/Charity School of Nursing
New Orleans, Louisiana

Sherry Warner, RN

Nursing Instructor
Fulton-Montgomery Community
College
Johnstown, New York

Maribeth Wilson, MSN, MSPH

Nursing Faculty
Keiser University
Tallahassee, Florida

Jennifer J. Woods, RN, MSN

Instructor
Delgado/Charity School of Nursing
New Orleans, Louisiana

Detailed Table of Contents

unit one

Foundations in Maternal, Family, and Child Care

1

chapter 1

Traditional and Community Nursing Care for Women, Families, and Children 1

Traditional Nursing Care	4
Historical Perspective	4
Health-Wellness Continuum	5
Changing Demands and Demographics	7
Professional Nursing Roles	7
Contemporary Nursing Care	8
Current Health Care Settings	8
Family Centered Care	10
Combining Modern Technology with the Caring Touch	11
Professional Nursing Roles	13
The Caring Art and Science of Nursing	13
Theories that Frame Caring as the Core of Nursing	14
Essential Characteristics of Caring	14
Professional Nursing Roles	15
Evidence-Based Practice	18
The Nursing Process	19

chapter 2

Contemporary Issues in Women's, Families', and Children's Health Care 25

Framework: The Public Health Intervention Model	26
How the Intervention Wheel Works	27
<i>Healthy People 2010: A Blueprint for Action</i>	28
Overview of Selected Societal Trends	29
Aging Population with More Chronic Illnesses	29
Increased Racial and Ethnic Diversity	29
Disparities in Health Care	30
Childbirth Trends	30
Patterns of Physical Fitness	30
The Intersection of Race, Class, and Health	31
The Current Health Status of the Nation	31
Infants and Young Children	31
Families	33
Women	33
Politics, Socioeconomics, and Culture: Contemporary Influences and Trends	34
Political Influences and Trends	34
Socioeconomic Influences and Trends	35

Personal and Cultural Influences and Trends	37
Health Care for the Nation	38
Delivery Systems	39
Challenges for Nurses in Contemporary Society	39
Contemporary Issues and Nursing Roles	41

chapter 3

The Evolving Family 46

The Evolving Family	47
Viewing the Family in a Nursing Context	47
The <i>Healthy People 2010</i> National Initiative	47
Families Today	47
The Changing Family as Reflected in the Media	48
Stressors on Families Today	49
Family Theories and Models	50
Family Systems Theory	51
Family Developmental Stages and Theory	52
Structural-Functional Theory	53
Communication Theory	53
Group Theory	54
Bowen's Family Systems Theory	54
Nursing Theories	54
Family Assessment	55
The Nursing Role in Family Assessment	55
Tools to Facilitate the Family Assessment	56
Components of the Family Assessment	58
Assessment of Roles and Relationships	59
Assessment of the Family Developmental Stage	59
Assessment of Family Rituals	60
Assessment for Triangulation	60
Assessment for the Presence of Dyads and Other Subsystems	60
Family-Centered Care	61
Nursing Diagnosis: Altered Family Processes	61
Families with Special Needs	62
Hospitalization	62
Chronic Mental Illness	62
Substance Abuse	63
Sexual or Physical Abuse	64
Posttraumatic Stress Disorder	64
Chronic Physical Illness	65
Death of a Family Member	65
Family Cultural Characteristics	66
Acculturation and Assimilation	66
Identity	66
Connectedness	67
Communication Patterns	67
Socioeconomic	67
Holistic Nursing Encompasses a Culturally Sensitive Family Approach	67

chapter 4***Caring for Women, Families, and Children in Contemporary Society 71***

Health Promotion Screening	73
Health Screening Schedule	73
Infant and Child Health	73
Nutritional Guidance	73
Dental Care	76
Sleep and Rest	76
Safety	78
Play	79
Immunizations	80
Sexuality	80
Adolescent Health	80
Nutrition	82
Sleep and Rest	84
Safety	84
Health Promotion	87
Menstrual Disorders	91
Young Adulthood Health	92
Safety	92
Health Promotion	93
Middle Adulthood Health	95
Health Promotion Screening	96
The Climacteric, Menopause, Perimenopause, and Postmenopause	99
Gynecologic Disorders	101
Older Adulthood Health	102
Health Promotion	102
Common Health Problems in Women	103
Prostate Cancer Screening	105
Mental and Emotional Health	106

**unit two****The Process of Human Reproduction****111****chapter 5*****Reproductive Anatomy and Physiology 113***

Sexual Differentiation in the Embryo	114
Male Gender	114
Female Gender	114
Female Reproductive System	115
External Structures (Pudendum Muliebre)	115
Pelvic Floor	116
Internal Structures	116
Accessory Organs	118
Uterine Anatomy	119
Corpus	119
Isthmus	119
Cervix	119

Uterine Support Structures	120
Vagina	121
Ureters, Bladder, and Urethra	121
Bony Pelvis	121
True/False Pelves	121
Pelvic Diameters and Planes	122
Pelvic Types	123
Breasts	123
Parts of the Breast	124
The Interplay of Hormones and Reproduction	124
Hormones Released by the Hypothalamus	124
Hormones Released by the Pituitary Gland	124
Hormones Released by the Gonads	125
Human Chorionic Gonadotropin, Prostaglandins, and Relaxin	126
Sexual Maturation	127
Puberty	127
Female Secondary Sexual Characteristics	127
The Menstrual Cycle and Reproduction	128
Uterine (Endometrial) Cycle	128
Menstrual Phase	128
Proliferative Phase	128
Secretory Phase	128
Ischemic Phase	129
Hypothalamic-Pituitary-Ovarian Cycle	129
Hypothalamic-Pituitary Component	129
Ovarian Component	129
Follicular Phase	129
Luteal Phase	129
Body Changes Related to the Menstrual Cycle and Ovulation	129
Natural Cessation of Menses	130
Climacteric Phase	130
Perimenopausal Phase	130
Menopause	130
Postmenopausal Phase	130
Male Reproductive System	131
External Structures	131
Internal Structures	132
Characteristics of Semen and Sperm	132
Male Hormonal Influences	134
Testosterone	134
Fertility	134
Age-related Development of the Male Reproductive System	134

chapter 6***Human Sexuality and Fertility 137***

Sexuality and Reproductive Health Care	138
The Human Sexual Response	138
Exploring Dimensions of Sexuality	139
A Nursing Framework for Promoting Women's Sexual and Reproductive Health	139
Assessment	139
Nursing Diagnosis for Patients Seeking Contraceptive Care	140

Planning and Implementation of Care	140
Evaluation	142
Toward Achieving the National Goals for Reproductive Life Planning	142
Providing Contraceptive Care: Methods of Contraception	143
Medication-Free Contraception	143
Coitus Interruptus	143
Lactational Amenorrhea Method (Breastfeeding)	143
Abstinence	144
Barrier Methods	144
Hormonal Methods	147
Injectable Hormonal Contraceptive Methods	150
Subdermal Hormonal Implant	151
Intrauterine Devices	151
Sterilization	152
Clinical Termination of Pregnancy	153
Nursing Care Related to Elective Pregnancy Termination	153
Surgical Termination of Pregnancy	153
Medical Termination of Pregnancy	154
The Nurse's Role in Infertility Care	154
The Initial Assessment	154
Later Methods of Assessment	155
Treatment Options for Infertility	156
Medications	156
Surgical Options	157
Therapeutic Insemination	157
Advanced Reproductive Technologies	158
Infertility, ART, and Potential Effects on the Couple's Relationship	159
Lifestyle Choices and Infertility	159
Additional Options for the Infertile Couple	159

chapter 7

Conception and Development of the Embryo and Fetus 164

Basic Concepts of Inheritance	165
The Human Genome Project	165
Chromosomes, DNA, and Genes	165
Inheritance of Disease	167
Multifactorial Inheritance	167
Unifactorial Inheritance	167
Cellular Division	169
The Process of Fertilization	170
The Process of Implantation and Placental Development	171
Development of the Embryo and Fetus	172
The Yolk Sac	172
Origin and Function of the Umbilical Cord	173
The Fetal Circulatory System	173
Fetal Membranes and Amniotic Fluid	174
Human Growth and Development	175
Pre-Embryonic Period	175
Embryonic Period	175
The Fetal Period	176

Factors that May Adversely Affect Embryonic and Fetal Development	178
Chromosomes and Teratogens	178
TORCH Infections	181
The Nurse's Role in Prenatal Evaluation	182
Heredity and Genetics	183
Maternal Age and Chromosomes	184
Multifetal Pregnancy	185
The Nurse's Role in Minimizing Threats to the Developing Embryo and Fetus	186

unit three

The Prenatal Journey

191

chapter 8

Physiological and Psychosocial Changes During Pregnancy 193

Physiological Preparation for Pregnancy	194
Hormonal Influences	194
Reproductive System	195
Integumentary System	197
Neurological System	197
Cardiovascular System	198
Respiratory System	201
Gastrointestinal System	202
Urinary System	202
Endocrine System	203
Musculoskeletal System	204
Nursing Assessment and Health Education	205
Psychosocial Adaptations During Pregnancy	205
Developmental and Family Changes	205
Maternal Tasks and Role Transition	207
Paternal Adaptation to Pregnancy	209
Adaptation of Siblings and Grandparents	210
Maternal Adaptation During Absence of a Significant Other	210
Cultural Influences and Psychosocial Adaptations	210
Hazards of High-Tech Management on Maternal Adaptation	211
Societal and Cultural Influences on Family Adaptation	211
Factors that Interfere with Psychosocial Adaptations During Pregnancy	211
Nursing Assessment of Psychosocial Changes and Prenatal Health Education	211

chapter 9

The Prenatal Assessment 215

A Time of Wonder and Growth...and Ambivalence	216
Concerns over Self-Preservation	216
Navigating the Health Care System	217
CAREing for the Patient	217

Diminishing Stress and Improving Pregnancy Outcomes	218	Constipation	278
Choosing a Pregnancy Care Provider	219	Dental Problems	278
The First Prenatal Visit	220	Leg Cramps	278
The Comprehensive Health History	220	Dependent Edema	278
The Obstetric History	225	Varicosities	278
Establishing the Estimated Date of Birth	226	Dyspareunia	278
The Pregnancy Classification System	227	Nocturia	279
Pregnancy Testing	228	Insomnia	279
The Medical History	229	Round Ligament Pain	279
The Gynecological History	231	Hyperventilation and Shortness of Breath	279
Screening and Diagnostic Tests During Pregnancy	231	Numbness and Tingling in the Fingers	279
Sexually Transmitted Infections	232	Supine Hypotensive Syndrome	279
Cervical Cancer	233	Recognizing Signs and Symptoms of Danger	279
The Prenatal Physical Examination	233	First Trimester	279
Preparing the Patient	233	Second Trimester	280
Performing the General Assessment	233	Third Trimester	280
Performing the General Physical Examination	234	Using a Pregnancy Map to Guide Prenatal Visits	281
The Focused Obstetric Examination	236	Childbirth Education to Promote a Positive Childbearing Experience	281
Subsequent Prenatal Examinations	242	Methods of Childbirth Preparation	281
Assessing Special Populations	243	Finding Information on Childbirth Education	286
The Adolescent	243	Creating a Birth Plan	286
The Pregnant Woman Older Than Age 35	249		

chapter 10

Promoting a Healthy Pregnancy 256

Planning for Pregnancy	258
Preconception Counseling: A Tool to Help Promote a Positive Pregnancy Outcome	258
The Healthy Body	259
The Healthy Mind	263
Nutrition and Weight Gain	264
Important Nutritional Elements	265
Weight Gain During Pregnancy	267
Planning Daily Food Intake	268
Factors Affecting Nutrition During Pregnancy	270
Exercise, Work, and Rest During Pregnancy	271
Exercise and Travel	271
Work	272
Rest	273
Medications	274
Safe versus Teratogenic Medications	274
FDA Classification System for Medications Used During Pregnancy	275
Common Discomforts During Pregnancy	276
Nausea	276
Vomiting	276
Ptyalism	277
Fatigue	277
Nasal Congestion	277
Upper and Lower Backache	277
Leukorrhea	277
Urinary Frequency	277
Dyspepsia	277
Flatulence	278

chapter 11

Caring for the Woman Experiencing Complications During Pregnancy 291

Early Pregnancy Complications	292
Perinatal Loss	292
Ectopic Pregnancy	293
Gestational Trophoblastic Disease	294
Spontaneous Abortion	295
Incompetent Cervix	296
Hyperemesis Gravidarum	297
Hemorrhagic Disorders	297
Obstetric Causes of Vaginal Bleeding	298
Placenta Previa	298
Placental Abruption	299
Preterm Labor	300
Incidence	300
Etiology and Risk Factors	300
Morbidity and Mortality	301
Diagnosis	301
Biochemical Markers	301
Management	301
Premature Rupture of the Membranes	303
Pathophysiology	303
Diagnosis	303
Management	303
Hypertensive Disorders of Pregnancy	304
Classifications and Definitions	304
Preeclampsia	305
Pathophysiology	305
Risk Factors for Preeclampsia/Eclampsia	306
Maternal and Fetal Morbidity and Mortality	306

Management of Preeclampsia/Eclampsia	307
Nursing Assessments	309
Identifying Hypertension	310
Significance of Proteinuria	310
Assessing Edema	310
Central Nervous System Alterations	310
Eclampsia	311
HELLP Syndrome	312
Disseminated Intravascular Coagulopathy	313
Nursing Care	313
Multiple Gestation	313
Incidence	313
Associated Complications	313
Maternal and Fetal Morbidity and Mortality	314
Diagnosis	314
Management	314
Nursing Implications	314
Infections	315
Urinary Tract Infection	315
TORCH Infections	316
Sexually Transmitted Infections	316
Tuberculosis	323
Inflammatory Disease and Pregnancy	323
Systemic Lupus Erythematosus	323
Hemoglobinopathies of Pregnancy	324
Sickle Cell Disease	325
Thalassemia	325
RH ₀ (D) Isoimmunization	326
Pathophysiology	326
Management	328
Summarizing Care for the Sensitized RhD-Negative Patient	328
ABO	328
Respiratory Complications	328
Pneumonia	328
Asthma	329
Cystic Fibrosis	329
Cardiovascular Disease	330
Management	331
Nursing Implications for the Pregnant Cardiac Patient	332
Mitral Valve Prolapse	332
Peripartum Cardiomyopathy	332
Diabetes in Pregnancy	333
Definition and Classification of Diabetes Mellitus	333
Risk Factors for Gestational Diabetes	333
Pathophysiology	333
Maternal and Perinatal Morbidity and Mortality	334
Screening and Diagnosis	335
Management	335
The Thyroid Gland and Pregnancy	335
Hyperthyroidism	335
Hypothyroidism	337
Venous Thrombosis and Pulmonary Embolism	337
Pathophysiology	338
Incidence and Risk Factors	338
Psychiatric Complications During Pregnancy	338
Consulting with the Pregnant Psychiatric Patient	338
Depression	339
Management	339
Substance Abuse in Pregnancy	339
Substance Addiction	339
Antepartum Fetal Assessment	340
Chorionic Villus Sampling	340
Percutaneous Umbilical Blood Sampling	340
Amniocentesis	340
Additional Invasive Tests	341
Ultrasonography	341
Kick Counts	341
Doppler Ultrasound Blood Flow Studies (Umbilical Velocimetry)	341
Fetal Biophysical Profile	342
Nonstress Test	342
Acoustic Stimulation/Vibroacoustic Stimulation	342
Contraction Stress Test	342
Electronic Fetal Heart Rate Monitoring	343
Special Conditions and Circumstances that May Complicate Pregnancy	343
The Pregnant Woman Who Requires Antenatal Bed Rest	343
Adolescent Pregnant Patient	344
Advanced Age Pregnant Patient	344
The Pregnant Patient Who Has Suffered Trauma	344
Surgery During Pregnancy	345
Cancer During Pregnancy	345
Obesity	345
The Patient with a Disability	346
Intimate Partner Violence During Pregnancy	346

unit four

The Birth Experience

353

chapter 12

The Process of Labor and Birth 355

Theories Concerning Labor Onset	356
The Process of Labor and Birth	356
Powers	357
Passageway	359
Passenger	359
Passageway + Passenger	364
Psychosocial Influences	366
Signs and Symptoms of Impending Labor	366
Lightening	366
Braxton-Hicks Contractions	366
Cervical Changes	367
Bloody Show	367
Rupture of the Membranes	367
Energy Spurt	367
Weight Loss	367
Gastrointestinal Disturbances	367

Distinguishing True Labor from False Labor	367
Childbirth Settings and Labor Support	369
Routine Hospital and Birth Center Admission Procedures	369
Establishing a Positive Relationship	370
Collecting Admission Data	370
Initial Admission Assessments	370
The Focused Assessment	370
The Psychosocial Assessment	371
The Cultural Assessment	371
Laboratory Tests	371
Documentation of Admission	371
First Stage of Labor	372
Latent Phase	372
Active Phase	372
Transition Phase	372
Nursing Care During the First Stage of Labor	372
Labor Support	374
Presence	374
Promotion of Comfort	374
Anticipatory Guidance	376
Caring for the Birth Partner	376
Ensuring Culture-Centered Care	376
Assessment of the Fetus During Labor and Birth	377
Fetal Position	377
Assessment of the Fetal Heart Rate	378
Variability	381
Accelerations	382
Decelerations	382
Interpretation of FHR Tracings	384
Nursing Interventions and Diagnoses	384
Second Stage of Labor	385
Promoting Effective Pushing	385
Achieving a Position of Comfort	386
Preparation for the Birth	386
Episiotomy	386
Birth	387
The Cardinal Movements	387
Clamping the Umbilical Cord	388
Possible Nursing Diagnoses for the Intrapartal Patient	389
Third and Fourth Stages of Labor	389
Third Stage of Labor	389
Nursing Care of the Mother During the Third Stage of Labor	391
Immediate Nursing Care of the Newborn	392
The Apgar Scoring System	392
Identification of the Newborn	393
Fourth Stage of Labor	393
Nursing Care During the Fourth Stage of Labor	393

chapter 13

Promoting Patient Comfort During Labor and Birth 399

The Physiology of Pain During Labor and Birth	400
Defining Pain	400
Physical Causes of Pain Related to Labor and Birth	401

Pain Perception and Expression	401
Factors that Affect Maternal Pain Response	402
The Effects of Prepared Childbirth on Pain Pathways	403
Benefits of Comfort and Support on Pain Perception	404
Providing Comfort and Pain Relief	404
Nonpharmacological Pain Relief Measures	405
Pharmacological Pain Relief Measures	410
Sedatives and Antiemetics	411
Differentiating Analgesia from Anesthesia	412
Systemic Analgesia	413
Nerve Block Analgesia and Anesthesia	415
General Anesthesia	421
Nursing Care for the Patient Receiving Interventions to Promote Comfort During Labor and Birth	422
Nursing Assessment and Diagnoses	422

chapter 14

Caring for the Woman Experiencing Complications During Labor and Birth 427

Dystocia	429
Dysfunctional Labor Patterns	429
Hypertonic Labor	429
Hypotonic Labor	430
Precipitate Labor and Birth	431
Pelvic Structure Alterations	432
Trial of Labor	432
Obstetric Interventions	432
Amnioinfusion	432
Amniotomy	432
Pharmacological Induction of Labor	433
Indications for Induction	433
Nursing Considerations	436
Instrumentation Assistance of Birth	437
Maternal Conditions that Complicate Childbirth	439
Hypertensive Disorders	439
Diabetes	440
Preterm Labor and Birth	441
Complications of Labor and Birth Associated with the Fetus	442
Fetal Malpresentation	442
Version	443
Shoulder Dystocia	444
Cephalopelvic Disproportion	445
Multiple Gestation	445
Non-reassuring FHR Patterns	446
Amniotic Fluid Complications	448
Oligohydramnios	448
Hydramnios	448
Meconium	448
Nuchal Cord	448
Complications Associated with the Placenta	448
Placenta Previa	448
Placental Abruption	450
Disseminated Intravascular Coagulation	451
Rupture of the Uterus	451
Uterine Inversion	453

Umbilical Cord Prolapse	453
Variations Related to Umbilical Cord Insertion and the Placenta	455
Amniotic Fluid Embolism	456
Collaboration in Perinatal Emergencies	456
Perinatal Fetal Loss	457
Cultural Aspects of Loss	458
Cesarean Birth	458
Definition and Incidence	458
Indications	458
Ethical Considerations of Elective Cesarean Birth	458
Surgical Procedures	459
Nursing Care	459
Surgical Care	460
Postoperative Care	460
Vaginal Birth After Cesarean	460
Nursing Implications	460
Research Findings and Implications	461
Postterm Pregnancy/Prolonged Pregnancy	461
Medical Management	462
Nursing Implications	462

unit five

Care of the New Family

467

chapter 15

Caring for the Postpartal Woman and Her Family 469

Ensuring Safety for the Mother and Infant	470
Early Maternal Assessment	471
Vital Signs	471
Fundus, Lochia, Perineum	472
Hemorrhoids	473
A Concise Postpartum Assessment Guide to Facilitate Nursing Care	473
The BUBBLE-HE Mnemonic	473
Maternal Physiological Adaptations and Continued Assessment of the Patient	481
Hematological and Metabolic Systems	481
Neurological System	483
Renal System, Fluid, and Electrolytes	483
Respiratory System	483
Integumentary System	483
Cardiovascular System	483
Immune System	484
Reproductive System	484
Gastrointestinal System	484
Musculoskeletal System	485
Care for the Multicultural Family	485
Enhancing Cultural Sensitivity	485
Cultural Influences on the Puerperium	485
Clinical Implications of Culturally Appropriate Care	486

Promoting Recovery and Self-care in the Puerperium	486
Activity and Rest	486
Nourishment	486
Elimination	486
Perineal Care	487
Discomfort Related to Afterpains	487
Special Considerations for Women with HIV/AIDS	487
Care of the Postpartal Surgical Patient	488
Permanent Sterilization (Tubal Ligation)	488
Care of the Patient After a Cesarean Birth	488
Care of the Incisional Wound	488
Recovery from Anesthesia	488
Facilitating Infant Nourishment: Educating Parents to Make Informed Choices	489
Enhancing Understanding of the Process of Lactation	490
Assisting the Mother who Chooses to Breastfeed: Strategies for Breastfeeding Success	491
Evaluation of Nourishment: Infant Weight Gain	494
Positions for Breastfeeding	494
Problems that Result in Ineffective Breastfeeding	495
Collecting and Storing Breast Milk	496
Infant Weaning	497
Assisting the Mother Who Chooses to Formula-Feed Her Infant	497
Promoting Family and Infant Bonding	498
Facilitating the Transition to Parenthood	498
Assuming the Mothering Role	498
Bonding and Attachment	499
Maternal	499
Paternal	500
Factors that May Interrupt the Bonding Process	500
Adjustment of Siblings to the Newborn	501
Adjustment of Grandparents to the Newborn	501
Emotional and Physiological Adjustments During the Puerperium	502
Emotional Events	502
Physiological Responses to Emotional Events	502
Postpartal Discharge Planning and Teaching	503
Promoting Maternal Self Care	503
Components of Maternal Self-assessment	503
Planning for the Follow-up Examination	506
Patients with Special Needs During the Puerperium	506
Care of the Adolescent	506
The Woman Who is Placing Her Infant for Adoption	507
The Older Woman	507
Community Resources for the New Family	507
Support Groups	507
Home Visits	507
Telephone Follow-up	507
Outpatient Clinics	507

chapter 16

Caring for the Woman Experiencing Complications During the Postpartal Period 511

Postpartum Hemorrhage	512
Incidence and Definition	512
Early versus Late Hemorrhage	513

Uterine Atony	513
Trauma	513
Tissue	514
Thrombin	514
Late Postpartum Hemorrhage	514
Hypovolemic Shock	514
Collaborative Management of PPH	515
Hematomas	518
Definition, Incidence, and Risk Factors	518
Signs and Symptoms	518
Collaborative Management	518
Puerperal (Postpartum) Infections	520
Definition and Incidence	520
Types of Puerperal Infections	520
Nursing Assessment	520
Collaborative Management	520
Thrombophlebitis and Thrombosis	527
Definition, Incidence, and Risk Factors	527
Pathophysiology	527
Signs and Symptoms	527
Diagnostic Tests	528
Collaborative Management	528
Pulmonary Embolus	530
Postpartum Psychosocial Complications	530
Postpartum Blues	530
Postpartum Depression	530
Postpartum Psychosis	532
Summarizing Postpartum Psychosocial Nursing Care	534
Postpartum Nursing for Vulnerable Populations	534
Victims of Abuse	535
Undocumented Immigrants and Minority Health Care	536
Homelessness and Limited Access to Care	537
Postpartum Care of Vulnerable Populations	537

chapter 17

Physiological Transition of the Newborn 541

Adaptations of the Respiratory System	542
Intrapulmonary Fluid, Fetal Breathing Movements, and Surfactant	542
The First Breath	543
Factors that May Interfere with Initiation and Maintenance of Respirations	544
Cardiopulmonary Transitions	545
Cardiovascular Adaptation	546
Changes After Placental Expulsion	546
Assessing the Cardiovascular Transition	547
Thermogenic Adaptation	547
The Neutral Thermal Environment	547
Factors Related to Cold Stress	548
Physiological Adaptations for Heat Production	548
Mechanisms for Neonatal Heat Loss	548
Preventing Hyperthermia	549
Hematopoietic Adaptation	550
Blood Volume	550
Blood Components	550

Hepatic Adaptation	551
Glycogen and Blood Glucose Maintenance	551
Iron Storage	552
Conjugation of Bilirubin	552
Coagulation of Blood	555
Gastrointestinal Adaptation	555
Stomach and Digestive Enzymes	555
Intestinal Peristalsis	555
Genitourinary Adaptation	555
Kidney Function	555
Immunological Adaptation	557
Psychosocial Adaptation	557
Early Stages of Activity	557
Newborn Behavioral States	558
Sleep States	558
Alert States	558

chapter 18

Caring for the Normal Newborn 563

The Immediate Neonatal Assessment	564
Identification	566
Infection and Injury Prevention	567
The Later Neonatal Assessment	569
Body Positioning	569
Skin Color	570
Body Size	571
Level of Reactivity	571
Obtaining Measurements and Determining the Gestational Age	571
Conducting and Documenting the Neonatal Physical Assessment	574
Assessment of the Neonate: A Systems Approach	574
Enhancing the Neonate's Transition to Extrauterine Life	593
Temperature Assessment	593
Bathing the Newborn	593
Nail Care and Umbilical Cord Care	594
Clothing	594
Diapering	594
Fostering Attachment	595
Circumcision	596
Ensuring Optimal Nutrition	597
Discharge Planning for the Infant and Family	598
Child Care	598
Newborn Metabolic Screening Tests	599

chapter 19

Caring for the Newborn at Risk 603

The High-Risk Newborn	605
Classification of the High-Risk Newborn	605
Small-for-Gestational-Age Infants	606
Conditions Affecting the SGA Newborn	607
Large for Gestational Age Infants	610
Conditions Affecting the LGA Newborn	611

The Premature Newborn	614
Physical Assessment of the Premature Newborn	614
Conditions Affecting the Premature Newborn	614
The Postterm Newborn	621
Conditions Affecting the Postterm Newborn	621
Additional Conditions Affecting the High-Risk Newborn	622
Metabolic Conditions	622
Neurological Conditions	624
Gastrointestinal Conditions	625
Abdominal Wall Defects	626
Infections in the Newborn	627
Developmental Delay	628
Care of the High-Risk Newborn	629
Blood Pressure	629
Nutritional Care	629
Developmental Care	631
The Neonatal Intensive Care Unit	632
Classification of the Neonatal Intensive Care Unit	633
Transporting the Preterm Newborn	633
Discharge Planning	634

Psychosocial Development	656
Moral Development	656
Discipline	656
Temper Tantrums	656
Early Childhood (Preschooler) (3 to 6 years)	657
Physical Development	657
Cognitive Development	657
Language	657
Psychosocial Development	658
Moral Development	658
Discipline	658
School-Age Child (6 to 12 years)	658
Physical Development	658
Cognitive Development	659
Language Development	659
Psychosocial Development	659
Moral Development	659
Discipline	660
Adolescence (12 to 19 years)	660
Physical Development	660
Cognitive Development	660
Language	660
Psychosocial Development	660
Moral Development	660
Discipline	660

unit six

Caring for the Child and Family 639

chapter 20

Caring for the Developing Child 641

Influences on Growth and Development	642
Principles of Childhood Growth and Development	642
Growth and Development Theories	643
Psychosocial Development Theories	643
Attachment Theories	645
Learning Theories	645
Cognitive Theories	646
Intelligence Theories	647
Moral Development Theories	647
Spiritual Development Theories	650
Family Development Theories	651
Temperament	651
Newborn and Infant	652
Reflexes and Neurological Development	652
Sensory Development	652
Physical Development	653
Cognitive Development	653
Language	654
Psychosocial Development	654
Discipline	655
Toddler (1 to 3 years)	655
Physical Development	655
Cognitive Development	655
Language Development	656

chapter 21

Caring for the Child in the Hospital and in the Community 664

Gathering the Child's Health History	665
Establishing a Relationship with the Patient and the Family	665
Asking Questions	666
Comprehensive Health History	666
Health Assessment	672
Anthropometric Measurements	672
Vital Signs	673
Physical Assessment	673
Routine Health Screening	681
General Care Measures for the Child in the Hospital or Clinic Setting	682
Bathing	682
Feeding	683
Rest	683
Safety Measures	683
Infection Control Measures	684
Fever-Reducing Measures	684
Emotional and Spiritual Support	685
Common Procedures for the Child in the Hospital or Clinic Setting	685
Explaining Procedures	685
Informed Consent	687
Intravenous Lines	687
Measuring Intake and Output	688
X-Ray Exams	688

Specimen Collection	688
Restraining the Child	691
The Child in Pain	692
Pain Assessment and Management	692
The Child with Disabilities	694
Emotional Concerns	694
Developmental Concerns	696
Physical Concerns	696
Caregiver Fatigue	696
Resiliency	696

chapter 22

Caring for the Family Across Care Settings 701

Across Care Settings	702
Primary Health Care Provider or Clinic Setting	703
The Hospitalized Child	704
Twenty-Four-Hour Observation Unit	709
Ambulatory Surgery Center	709
Critical Care Unit	709
Emergency Department	710
Community Settings	710
Clinics	711
Specialty Camps	711
Churches, Synagogues, Mosques	711
Care in School Settings	712

unit seven

Ongoing Care of the Child in the Hospital and in the Community 715

chapter 23

Caring for the Child with a Psychosocial or Cognitive Condition 717

Developmental Psychopathology	718
Vulnerability and Resilience	719
Culture, Diversity, and Health Disparities	719
Barriers to Child and Adolescent Mental Health	720
Psychopathology in Children	720
Anxiety	720
Posttraumatic Stress Disorder	722
Mood Disorders	722
Depression	723
Bipolar Disorder	723
Suicide	725
Schizophrenia	726
Autism Spectrum Disorders	728
Psychosocial and Cognitive Disorders	729
Reactive Attachment Disorder	729
Failure to Thrive	730

Attention Deficit Hyperactivity Disorder	731
Oppositional Defiant Disorder and Conduct Disorder	732
Tic Disorders	734
Tourette's Syndrome	734
Maltreatment of Children	735
Substance Use and Abuse	736
Eating Disorders	737
Obesity	738
Sleep Disorders	739
Developmental Conditions	740
Developmental Disabilities	740
Down Syndrome	742
Fetal Alcohol Spectrum Disorder	742
Learning Disorders and Cognitive Impairment	743
Elimination Disorders	743
Enuresis	743
Encopresis	744

chapter 24

Caring for the Child with a Respiratory Condition 750

The Child's Respiratory System	751
Congenital Respiratory Conditions and Structural Anomalies	752
Choanal Atresia	752
Esophageal Atresia and Tracheoesophageal Fistula	753
Congenital Diaphragmatic Hernia	754
Respiratory Distress Syndrome	756
Bronchopulmonary Dysplasia	757
Cystic Fibrosis	758
Upper Airway Disorders	761
Sinusitis	761
Nasopharyngitis	762
Pharyngitis	763
Tonsillitis	764
Croup or Laryngotracheobronchitis	765
Otitis Media/Externa	766
Otitis Media	767
Lower Airway Disorders	768
Bronchitis	768
Respiratory Syncytial Virus	768
Pneumonia	769
Severe Acute Respiratory Distress Syndrome	771
Infectious Conditions	771
Pertussis	771
Tuberculosis	772
Influenza	774
Pulmonary Noninfectious Irritation	774
Foreign Body Aspiration	774
Smoke Inhalation	776
Passive Smoking	777
Respiratory Conditions Related to Allergens	778
Allergic Rhinitis	778
Asthma	778

chapter 25***Caring for the Child with a Gastrointestinal Condition 785***

- Developmental Aspects of the Gastrointestinal System 786
- Structural Gastrointestinal Disorders 787
 - Inguinal Hernia 787
 - Umbilical Hernia 788
 - Anorectal Malformations 788
- Obstructive Gastrointestinal Disorders 789
 - Hypertrophic Pyloric Stenosis 789
 - Intussusception 790
 - Malrotation and Volvulus 791
- Inflammatory Disorders 792
 - Irritable Bowel Syndrome 792
 - Inflammatory Bowel Disease 793
 - Appendicitis 795
 - Omphalitis 797
 - Meckel Diverticulum 797
- Functional Gastrointestinal Conditions 797
 - Infantile Colic 797
 - Acute Diarrhea 798
 - Chronic Diarrhea 800
 - Vomiting 800
 - Cyclic Vomiting Syndrome 802
 - Constipation 803
 - Encopresis 805
 - Gastroesophageal Reflux and Gastroesophageal Reflux Disease 806
 - Hirschsprung Disease 807
- Malabsorption Disorders 808
 - Lactose Intolerance 808
 - Celiac Disease 809
 - Short Bowel Syndrome 810
- Hepatic Disorders 811
 - Biliary Atresia 811
 - Cirrhosis 812
 - Hepatitis 813
- Abdominal Trauma: Injuries 814

chapter 26***Caring for the Child with an Immunological or Infectious Condition 819***

- The Immune System 820
- The Body's Defense 821
- Congenital Immunodeficiency Disorders 821
 - B-Cell Disorders 822
 - T-Cell Disorders 822
 - B-lymphocyte Disorders 822
 - Combined Immunodeficiency Disorders 822
- Immunodeficiency Disorders 822
 - Human Immunodeficiency Virus 822
- Transplantation 827
 - Nursing Care 827

- Autoimmune Disorders 827
 - Systemic Lupus Erythematosus 827
 - Juvenile Rheumatoid Arthritis 829
- Allergic Reaction 830
 - Anaphylaxis 830
- Infectious Diseases of Childhood 831
 - Infection 831
- Common Viral Infections 841
 - Cytomegalovirus Infections 841
 - Herpes Zoster 842
 - Smallpox 842
 - Infectious Mononucleosis 842
- Common Fungal Infections 843
 - Candida Albicans* (Oral Thrush) 843
- Immunizations 844
 - Nursing Care 846
- Animal-Borne Infectious Diseases 847
 - Rabies 847
 - West Nile Virus 847
 - Avian Influenza 848
- An Emerging Issue in Infectious Disease: Resistant Organisms 849
 - Antibiotic Alternatives 849

chapter 27***Caring for the Child with a Cardiovascular Condition 853***

- Congenital Heart Disease 857
 - Cyanotic Versus Acyanotic Congenital Heart Defects 857
- Segmental Classification of Congenital Heart Defects 857
 - Defects in the Septum 857
 - Defects of the Vessels and Valves 860
 - Conal-truncal Defects 864
 - Combination Defects 865
- Cardiac Diseases 866
 - Subacute Bacterial Endocarditis 866
 - Kawasaki Disease 866
 - Cardiomyopathy 867
- Additional Cardiac Conditions 868
 - Cardiac Trauma 868
 - Hypertension 869
 - Idiopathic Pulmonary Arterial Hypertension 869
 - Neurally Mediated Syncope 870
 - Long Q-T Syndrome 870
- Rhythm Disturbances 871
- Invasive Tests 871
 - Cardiac Catheterization 871
 - Angiography 873
 - Biopsy 874
 - Closure Devices 874
 - Opening Devices 874
 - Nursing Care 874
- Surgical Interventions 875
 - Pacemakers 875
 - Cardiac Transplantation 875

- Nursing Care for the Child with a Cardiac Condition 879
 - Caring for the Child in the Pediatric Intensive Care Unit 879
 - Transferring the Stable Child to a Surgical or Medical Unit 880
 - Caring for Children with Cardiac Conditions Across Care Settings 881

chapter 28

Caring for the Child with an Endocrinological or Metabolic Condition 885

- Pathophysiological Conditions of the Endocrine System 887
 - Conditions of the Anterior Pituitary 887
 - Conditions of the Posterior Pituitary 892
 - Conditions of the Thyroid 895
 - Conditions of the Parathyroid 897
 - Conditions of the Adrenals 899
- Metabolic Conditions 906
 - Diabetes Mellitus Type 1 906
 - Diabetes Mellitus Type 2 912
 - Diabetic Ketoacidosis 914

chapter 29

Caring for the Child with a Neurological or Sensory Condition 921

- Altered States of Consciousness 922
 - The Unconscious Child 923
 - Persistent Vegetative State 925
 - Increased Intracranial Pressure 926
 - Seizure Disorders 929
- Inflammatory Neurological Conditions 933
 - Meningitis 933
 - Encephalitis 934
 - Brain Abscess 936
 - Reye Syndrome 936
 - Guillain-Barré Syndrome 938
- Developmental Neurological Conditions 939
 - Spina Bifida 939
 - Hydrocephalus 941
 - Cerebral Palsy 944
- Neurological Injuries 945
 - Near Drowning 945
 - Head Injury 946
 - Shaken Baby Syndrome 947
 - Spinal Cord Injury 947
- Nontraumatic Neurological Conditions 949
 - Headaches 949
- Sensory Conditions 950
 - Eye Disorders 950
 - Eye Injuries 954
 - Hearing Loss 955
- Language Disorders 957

chapter 30

Caring for the Child with a Musculoskeletal Condition 962

- Immobilizing Devices 965
 - Casts 965
- Principles of Traction 968
 - Skin Traction 968
 - Skeletal Traction 969
- Common Musculoskeletal Conditions found in Children 972
 - Clubfoot 972
 - Legg-Calve-Perthes Disease 973
 - Slipped Femoral Capital Epiphysis 974
 - Fractures 975
 - Soft Tissue Injuries 977
- Sports Injuries 978
 - Osgood-Schlatter Disease 979
- Osteomyelitis 979
 - Juvenile Arthritis 980
 - Muscular Dystrophies 982
 - Scoliosis 983
 - Kyphosis 986
 - Lordosis 986
 - Spinal Fusion 987
- Tetanus 987
 - Osteogenesis Imperfecta 989
- Osteoporosis 991

chapter 31

Caring for the Child with an Integumentary Condition 995

- Skin Lesions 997
- Wounds and Wound Healing 998
- Skin Infections 998
 - Bacterial Infections 1002
 - Viral Infections 1007
 - Fungal Infections 1009
- Dermatitis 1011
 - Contact Dermatitis 1011
 - Atopic Dermatitis 1011
 - Seborrheic Dermatitis 1012
 - Cutaneous Skin Reactions 1012
- Infestations 1013
 - Lice 1013
 - Mite Infestation 1013
- Bites and Stings 1014
 - Insects 1014
 - Animal Bites 1015
 - Human Bites 1017
- Diseases from Bites 1017
 - Lyme Disease 1017
 - Rocky Mountain Spotted Fever 1018
 - Cat Scratch Disease 1018

Burns	1019
Thermal Burns	1019
Chemical Burns	1020
Electrical	1020
Radiation	1020
Classification of Burns	1021
Nursing Care	1022
Hypothermia	1025
Frostbite	1027
Pressure Ulcers	1027

chapter 32

Caring for the Child with a Renal, Urinary Tract, or Reproductive Condition 1033

Fluid and Electrolyte Balance	1035
Disorders of the Renal and Urinary Systems	1038
Urinary Tract Infections	1038
Vesicoureteral Reflux	1039
Unexplained Proteinuria	1042
Hematuria	1043
Glomerular Disease	1044
Hemolytic Uremic Syndrome	1046
Henoch-Schönlein Purpura	1047
Chronic Glomerulonephritis	1047
Structural Defects of the Urinary System	1048
Renal Trauma	1048
Acute Renal Failure	1049
Chronic Renal Failure	1053
Dialysis in Pediatric Nursing	1055
Peritoneal Dialysis	1055
Hemodialysis	1056
Renal Transplantation	1057
Functional Disorders of the Urinary Tract	1058
Dysfunctional Elimination Syndrome/Voiding Dysfunction	1058
Enuresis	1059
Exstrophy of the Bladder	1061
Reproductive Disorders Affecting Girls	1061
Vulvovaginitis	1061
Labial Adhesions	1062
Amenorrhea	1062
Reproductive Disorders Affecting Boys	1063
Varicocele	1063
Cryptorchidism	1064
Hypospadias and Epispadias	1064
Testicular Torsion	1065
Reproductive Disorders Affecting Both Girls and Boys	1066
Ambiguous Genitalia	1066

chapter 33

Caring for the Child with a Hematological Condition 1071

Common Hematological Conditions	1073
Anemia	1073

Iron-Deficiency Anemia	1075
Epistaxis	1076
Sickle Cell Disease	1077
Thalassemia	1081
Hereditary Spherocytosis	1082
Hemophilia	1082
Von Willebrand's Disease	1084
Idiopathic Thrombocytopenia Purpura	1085
Disseminated Intravascular Coagulation	1086
Aplastic Anemia	1087
Neutropenia	1090
Blood Transfusion Therapy	1092
Blood Product Administration	1092
Sensitivity to Cultural and Religious Beliefs	1096
Transfusion Reactions	1096
Febrile Reaction	1096
Allergic Reaction	1096
Bacterial Contamination	1097
Circulatory Overload	1097
Acute Hemolytic Transfusion Reaction	1097
Bone Marrow Transplantation	1098
Apheresis	1098
Thrombosis	1100

chapter 34

Caring for the Child with Cancer 1104

Differences Between Childhood and Adult Cancers	1105
Common Childhood Cancers	1106
Leukemia	1106
Solid Tumors	1110
Bone Tumors	1114
Lymphomas	1116
Other Cancers	1117
Nursing Care of the Child with Cancer	1118
Nutrition	1118
Infection	1118
Chemotherapy	1118
Radiation	1119
Surgery	1122
Pain Control	1123
Psychosocial Support	1123
Negative Effects of Chemotherapy	1123
Nausea and Vomiting	1124
Alopecia	1124
Extravasation	1125
Mucositis	1125
Diarrhea and Constipation	1125
Anemia	1125
Thrombocytopenia	1126
Neutropenia	1126
Long-term Effects of Cancer Treatments	1126
Medical Emergencies	1126
Hemorrhagic Cystitis	1126
Tumor Lysis Syndrome	1127
Septic Shock	1128
The Psychological Impact of Pediatric Cancer	1128

chapter 35***Caring for the Child with a Chronic Condition or the Dying Child 1133***

A Chronic Condition and Its Relationship to Technology	1135
Impact of a Chronic Condition	1135
Impact of a Chronic Condition on the Infant	1136
Impact of a Chronic Condition on the Toddler	1136
Impact of a Chronic Condition on the Preschooler	1137
Impact of a Chronic Condition on the School-age Child	1137
Impact of a Chronic Condition on the Adolescent	1138
Impact of a Chronic Condition on the Sibling	1138
The Child Living with a Chronic Condition	1139
Emotional Responses to a Chronic Condition	1140
Important Aspects When Caring for a Child with a Chronic Condition	1140
Establishing a Therapeutic Relationship	1140
Growth and Development	1141
Education	1141
Cultural Issues	1141
The Dying Child	1142
Perceptions of Death	1142
Before the Child Dies	1143

Palliative Care, Hospice Care and End-of-Life Care	1144
After the Child Dies	1146
Grieving	1147
Grief Theories	1147
Saying Good-bye	1151
The Sibling Says Good-bye	1151
Remembrance Packet	1152
Organ Tissue Donation	1152
Funerals	1152
Caring for the Professional Caregiver	1152

Appendix A: Centigrade to Fahrenheit Temperature Conversions 1157***Appendix B: Expected Temperatures in Children 1158******Photo and Illustration Credits 1159******Index 1165***

Special Features

Across Care Settings

A Team Approach 890, 911
American Heart Association 867
Bladder Exstrophy 1061
Burn Prevention 1019
Car Seat Safety 598
Care Collaboration to Prevent Postpartum Infection After Discharge 527
Care of the Dying Child 1143
Caring for the Child with an Infectious Disease 840
Caring for the Child with Cystic Fibrosis at Home 760
Childbirth Options in the Local Community 405
Children Who Receive Renal Transplants 1058
Clinics 711
Community Education about DEET (N, N-diethyl-*m*-toluamide) 936
Complications from Encephalitis 935
Decreasing Exposure to Lead 682
Education 778
Education about Sickle Cell Disease 1080
Empowering Through Education 177
Enhancing Contraceptive Decision Making 142
Ensuring Cultural Sensitivity and Reliable Information 11
Facilitating Newborn Transition in a Birth Center 547
Family Care in Inpatient, Outpatient, and Hospice Settings 66
Family-Centered Care 7
Health Protection for Families 6
Infant Temperament 652
Insurance for Children 694
National Cancer Institute 1146
Optimizing Senior Health 103
Planning the Multiple Gestation Birth 446
Practice Possibilities for Advanced Practice Nursing 19
Prevention 1013
Prevention of Childhood Obesity in Schools 739
Promoting Bed Rest at Home 307
Promoting Growth 794
Promoting Respiratory Function 759
Providing Parenting Information 598
Respite Care 1139
Reye Syndrome 938
Schools, Day Care, and Community 800
Serving the Community through Parish Nursing 38

Successful Maternal Transition into the Letting-go Phase 499
Supporting the Child during Treatment 1009
Teaching Simple Strategies for Stress Relief 6
Tetanus Prophylaxis 988
The Clinic 881
The Health Care Safety Net 220
The Linus Project 608
The Transplantation Team 878
Variations in Practice Environments for Perinatal Nurses 378
Visiting Nurse 974
What to do in Cases of an Acute Asthma Attack 781
Women Infants and Children (WIC) Program 1075

Assessment Tools

Body Mass Index (BMI) 672
Classic Symptomatic Triad for Intussusception 791
Classification by Type of Break 975
Classification of Fractures by Location 975
Gower Maneuver 982
Head Circumference Measurement 942
Hemolytic Uremic Syndrome (HUS) 1047
Hirschberg Asymmetrical Corneal Light Reflex Test 952
Irritable Bowel Syndrome 793
Kernig's or Brudzinski Sign 933
Key Components of Physical Assessment for the Child with an Infectious Disease 840
Lyme Disease Presents in Three Stages 1017
Orlowski Scale 946
Pain Assessment 1080
Pediatric Respiratory Emergencies 775
Recognition of Physical Signs of Impending Death 1143
Signs and Symptoms of Diabetes Insipidus 892
Slipped Capital Femoral Epiphysis 974
Sprains are Classified According to Severity 977
Strabismus 952
Valsalva Maneuver 1064
Visual Acuity 675

Be Sure To

Administer and Document RhoGAM When Clinically Indicated 328
Administer Medication Properly 879

Advocate for Newborns at Risk 247

Allow the Pregnant Adolescent to Make Health Care Decisions 248

Assess and Reassess During the Intrapartal Period 412

Assume Nursing Responsibilities Associated with a Vacuum-Assisted Birth 438

Be Aware of Legal Considerations in Immunization Education 845

Check Identification Bracelets 471

Document After a Patient Seizure 312

Document Appropriate Birth Information 569

Document Family Education 529

Ensure the Patient is Informed About Available Pharmacological Methods of Pain Relief 410

Explain HIPAA 633

Follow Rules Set Forth in the Individuals with Disability Education Act of 2004 957

Include the Adolescent in the Informed Consent Process 660

Inquire About Latex Allergy 145

Investigate Legal Concerns 1047

Isotretinoin (Accutane) 1003

Legal and Ethical Responsibility Related to Shaken Baby Syndrome 947

Monitor and Document FHR during AROM 433

Observe Federal Laws Providing Educational Services for Children 1141

Obtain Consent for Genetic Testing 810

Obtain Transfusion Consent 1092

Obtain Written Consent Before a Procedure 687

Perform a Daily Cardiovascular Assessment on Patients with Preeclampsia 310

Protect the Infant from Abduction 471

Provide Patients with Accurate Information on Menopausal Hormone Therapy 100

Recognize the Adolescent Father's Lack of Legal Rights 249

Record Accurate Weight Measurement 1053

Report Cases of Child Abuse 736

Take Care with Documentation 345

Teach About Toxic Shock Syndrome 147

Teach the Patient Taking Oral Contraceptives to Report ACHES 148

Transfusion Reaction Procedure and Documentation 1097

Understand Federal Regulations that Relate to Obstetric Care 369

Understand Institutional Guidelines Related to Intravenous Immune Gamma Globulin (IVIG) 1086

Understand the Type of Technological Equipment Required 1135

Use Appropriate Terminology during Documentation of FHR Auscultation 384

Use Ethical Considerations when Conducting Research Involving Children 761

Use of Restraints 692

Voice Concerns about Difficulties with FHR Monitoring 346

Case Studies

A Pregnant Adolescent in the Emergency Department 450

A 3-Year-Old Child with Type 1 Diabetes Who is Vomiting 917

Adolescent Primipara with a Possible Bonding Difficulty 501

An Infant with a Chronic Condition 1136

Baby Boy Goldman 581

Baby Girl Emily 545

Early Childhood Development 658

Elder Abuse in the Family 64

Enuresis 1060

Excessive Weight Gain during Pregnancy 269

Family Dilemma 1129

Gastroesophageal Reflux 806

Hypothermia 1026

Idiopathic (Immune) Thrombocytopenia Purpura 1086

Infant Amy Moore 945

Infant with a Heart Murmur 866

Infant with Pertussis 844

Iron-Deficiency Anemia 1076

Kimberly Stallings 312

Patient Experiencing a Vulvar Hematoma 519

Poststreptococcal Glomerulonephritis 1046

Premature Newborn 614

Respiratory Distress Syndrome 757

Scoliosis 986

Sickle Cell Disease 1080

Sleeping Issues 740

The Birth Experience of a Multigravida 394

The Child with a Fracture who has Complications 977

The Family Members of an Alcoholic 64

The Family of a Diabetic Teen 65

The Family of a Young Adult with Schizophrenia 63

The Family with Same-Sex Partners 50

The Frequently Hospitalized Child and His Family 1139

Wilms' Tumor 1113

Young Adult with Cervical Dysplasia 95

Young Woman Who Believes She is Infertile 149

Clinical Alerts

A Severe Reaction to a Bite 1015

Abdominal Pain 804

Abdominal Pain in Children 787

- Accidental Overdose of Magnesium Sulfate Administration Can Pose a Significant Risk to Both Mother and Newborn 309
- Accumulation of Iron (Hemosiderosis) 1081
- Administration of Steroids 827
- Adverse Effects of Immunizations 846
- An Overweight Child Diagnosed with Iron-Deficiency Anemia 1076
- Anaphylactic Reaction in Children who Receive Antithymocyte Globulin (ATG) 1089
- Anorexia Nervosa 738
- Appendicitis 796
- Aspiration 630
- Aspirin (Salicylates) 684
- Assisted Mechanical Ventilation 757
- Autonomic Dysreflexia 948
- Avoiding Extremity Massage When DVT is Suspected 528
- Avoiding the Knee-Chest Position 503
- Blood Loss and Vital Signs 514
- Blood Pressure Postinterventional Catheterization 875
- Blood Transfusion Safety Measure 1092
- Bowel Sounds in the Scrotum 585
- Calculating Standard Newborn Formulas 631
- Calculation of Daily Maintenance Fluid Requirements 1035
- Checking the Mother's Obstetric History 753
- Chronic Osteomyelitis 980
- Clusters of Human H5N1 Cases 848
- Common Problems of Critical Illness 709
- Complication of the Child with a Fracture 976
- Complications of a Central Venous Line 811
- Complications of Cardiac Transplantation 878
- Contraindications to the Use of Oxytocin to Stimulate Labor 436
- Cortisone Insufficiency 902
- Cricoid Pressure 946
- Critical Thinking Question 893
- Dangerous "Attachment Therapies" 730
- Dehydration 892
- Diabetic Ketoacidosis 916
- Discarding Chemotherapy Drugs 1117
- E. coli* 0147.H7 1046
- Early Identification of Maternal Hemorrhage 298
- Epi-glottitis 689
- Exogenous Hormones 890
- Flumazenil to Reverse the Effects of Benzodiazepine Sedatives 412
- Fractured Clavicles 614
- Gastrostomy Tubes 691
- Group A Streptococcus 1007
- Hand washing 684
- Hematoma After an Episiotomy 478
- Hematuria 1048
- Hyponatremia 895
- Important Respiratory Signals 678
- Increased Risk for Infection 821
- Intracranial Bleeding 1086
- Irritable Bowel Syndrome 793
- Kawasaki Disease 866
- Keeping Children Safe in the Home or Hospital 683
- Material Safety Data Sheets 1020
- Maternal Diabetes and Preterm Labor 334
- Microcephaly 625
- Monitor Closely the Intravenous (IV) Site 1125
- Monroe-Kellie Hypothesis 926
- Naloxone (Narcan) 693
- Off-label Use of Misoprostol for Postpartum Hemorrhage 515
- Osteomyelitis 979
- Other Emergencies 1128
- Other Etiologies of Hypothermia 1026
- Pathophysiology of Dehydration 1036
- Patient Safety 928
- Postcatheterization 873
- Postexposure Treatment for Rabies 847
- Postoperative Hemorrhage 859
- Postoperative Vital Signs 879
- Postpartal Blood Loss 514
- Preoperative and Postoperative Suctioning 755
- Preventing CMV Infection in Immunocompromised Children 841
- Principles of Pain Medication Administration 1146
- Privacy 659
- Probiotics 809
- Proper Technique for Uterine Palpation 475
- Protecting the Infant from the Sun 594
- Radiation Side Effects 1122
- Reflexes 652
- Renal Failure 859
- Retractions 751
- Reye Syndrome Risk with Use of Aspirin 840
- Risk of Infection 688
- Rupture of the Tympanic Membrane 768
- Screening Guidelines 1073
- Seizure Precautions 928
- Septic Shock 1128
- Shock 791
- Signs of Bleeding after Tonsillectomy 765
- Signs of Kidney Transplant Rejection 1058
- Signs of Perforation and Peritonitis 791
- Signs of Short-Term Complications After Clinical Termination of Pregnancy 154
- Stevens Johnson Syndrome (Erythema Multiforme) 1013
- Suicidal Behavior related to Antidepressant Therapy 726

Surgical Resection 1111
 Survival 863
 Symptoms of an Addisonian Crisis 901
 Systemic Lupus Erythematosus 829
 Tetralogy of Fallot 865
 The Administration of Intravenous Anti-D Antibody 1085
 The Administration Process for Blood Products 1095
 Thrombus Formation 867
 Thyroid Storm 897
 Transfusion-related Acute Lung Injury 1097
 Types of Dehydration 1035
 Vomiting 790
 Wet Clothing 1026
 When a Child is Asplenic 1079
 When Using Aromatherapy 409

Collaboration in Caring

A Child with Muscular Dystrophy 983
 A Father's Story 1146
 A Severe Allergic Reaction 1011
 A Team Approach 889, 1025
 Acupressure and Acupuncture as Modalities for Labor Pain Relief 410
 Caring for a Child with a Fracture 977
 Caring for Children in the Community: Where They Live, Play, and Go to School 710
 Child Care for New Families 599
 Child Life Specialist 1138
 Clubfoot 973
 Collaboration between the Family and Others 826
 Collaboration with Parents 894
 Culturally Sensitive Community Approaches to Enhanced Health Care for Older Citizens 106
 Dealing with a Molar Pregnancy 295
 Education about Food-Drug Interactions 529
 Encopresis 805
 Enhancing Family and Patient Coping 15
 Five Functions of the Family 49
 Helping Impoverished Families 18
 Impaired Fecundity 171
 Increasing Public Awareness of the Problems of Prematurity 300
 Nurses Caring for Children with Heart Arrhythmias 871
 Partnering with an IBCLC and Other Community Resources 491
 Peanut Allergies in School 830
 Preparing the Family for Community-Based Care 9
 Promoting Optimal Care for the Family 21

Providing a Nursing Perspective for Resolving Ethical Dilemmas 39
 Radiology 615
 Raising Public Awareness 742
 Resources for the Postpartal Patient 530
 Spinal Cord Injury 949
 Spiritual Care 685
 Supporting the Family That Uses CAM 12
 Teaching Tips for Families 704
 The Child with Addison's Disease 902
 The Health Care Team 651
 The Heimlich Maneuver 776
 The Nurse's Role in Health Screening and Surveillance 711
 The Role of a Nutritionist 1118
 Types of Hospitals 704

Complementary Care

Anxiety and Depression 93
 Ayurveda to Enhance the Preconception Period 259
 Behavioral Management and Biofeedback 1059
 Blogging as Therapy 38
 Cabbage Leaves to Diminish Breast Swelling 495
 Chiropractic Care and Chronic Sinusitis 762
 Commonly Used Herbal Preparations 667
 Complementary and Alternative Medicine 1144
 Diarrhea 799
 Distraction 1023
 Enuresis 1060
 Exercise and Bracing 985
 Guided Imagery 707
 Herbal Supplements and Infertility 159
 Managing the Symptoms of Menopause 100
 Measures for Induction of Labor 436
 Methods to Decrease Perineal Trauma 387
 Mindful Breathing 721
 Muscular Dystrophy 983
 Nausea and Vomiting of Pregnancy 297
 Nonpharmacological Adjuncts to Pain Management 826
 Nonpharmacological Pain Interventions 1079
 Premie Massage 632
 Promoting Stress Management during Pregnancy 264
 Red Raspberry and Blue Cohosh 222
 Tea Tree Oil to Facilitate Episiotomy Healing 479
 The Benefits of Massage 925
 Therapeutic Touch 889
 Therapeutic Touch Enhances Comfort 597
 Therapies for Postpartum Depression 532

Topical Agents 1008
 Understanding Spirituality 651
 Vaginal Candidiasis 1061
 Visualization and Distraction 1107
 Yoga to Reduce Discomfort during Labor 409

Critical Nursing Action

Accurate Administration of Intravenous Calcium 898
 Accurately Determining Blood Loss 513
 Adventitious Lung Sounds 678
 After Prolapse of the Umbilical Cord 454
 Anaphylaxis 830
 Anticipatory Guidance 655
 Arteriovenous Fistulas (AV) 1057
 Assessing for a Systemic Allergic Response 1012
 Assessing for Hypothermia 928
 Assessing for Maternal-Infant Attachment 499
 Assessing Respiratory Status 757
 Assessing the Cardiac Patient During Labor and Birth 332
 Assisting with a Precipitous Birth 431
 Assisting with Intrauterine Resuscitation 447
 Basal Skull Fracture 947
 Before, During, and After a Procedure 686
 Care of the Child in Restraints 692
 Care of the Jaundice Infant 619
 Care of the Pregnant Patient Post-seizure 311
 Caring for a Child with a Fracture in a Cast 976
 Caring for the Child at Home After Minor Surgery 709
 Cast Syndrome 966
 Chemical Burns 955
 Cleansing the Adolescent's Face 1003
 Controlling Epistaxis (Nosebleeds) 1077
 Criteria for Transfer to a Burn Center 1022
 Daily Weights to Ensure Accurate Medication Doses 888
 Determining and Documenting Fetal Position 365
 Do Not Obtain a Rectal Temperature 940
 Do Not Resuscitate 1142
 Education about Oral Iron 1076
 Establishing Trust with the Family 1140
 Extracorporeal Membrane Oxygenation 622
 Facilitating Effective CPR for the Pregnant Patient 307
 Fourth-Stage Risk Signs 394
 Hemoglobin and Hematocrit Levels 609
 Holistic Care for the Dying Child 1145
 Hypoglycemia in the Newborn 609
 Identifying Contraindications to Immunizations 846
 Immediate Intervention for Uterine Atony 515
 Interpreting Fetal Monitor Tracings 384
 Intravenous Therapy 943
 Intraventricular and Periventricular Hemorrhage 625
 Key Actions in Caring for the Child Confined to Bed 683
 Lactose Intolerance 809
 Liver Biopsy 937
 Logrolling 985
 Managing Minor Burns 1022
 Necrotizing Enterocolitis (NEC) 626
 Nursing Assessment 754
 Nursing Care for Septic Shock 1128
 Nursing Care for the Child Having a Seizure 931
 Outcomes of a Medical Home and Coordinated Care 703
 Palpitation of the Abdomen in a Child with Wilms' Tumor 1113
 Pheochromocytoma 906
 Pneumococcal and *Haemophilus influenzae* Type B (Hib) Vaccine 1082
 Postoperative Management 859
 Preparing a Preschooler for a Procedure 685
 Preparing a School-Age Child for a Procedure 686
 Preparing a Toddler for a Procedure 685
 Preparing an Adolescent for a Procedure 686
 Preparing an Infant for a Procedure 685
 Prevent Supine Hypotension 378
 Preventing Atopic Dermatitis Secondary Infection 1012
 Preventing Injury of the Sac 940
 Prevention of Hepatitis A and Hepatitis B 814
 Prevention of Respiratory Illnesses in Patients with BPD 758
 Proper Growth Assessment 888
 Recognizing Acute Abdomen in the Neonate 584
 Recognizing an Ophthalmic Emergency in the Infant 579
 Recognizing and Responding to Problems During Labor Induction With Oxytocin 436
 Recognizing Contraindications to Oral Contraceptive Use 148
 Recognizing Hypoglycemia in the Neonate 552
 Recognizing Immediate Neonatal Respiratory Distress 566
 Recognizing Negative Effects of Chemotherapy 1124
 Recognizing Normal Newborn Vital Signs 571
 Recognizing the Infant with Imperforate Anus 586
 Recognizing Thromboembolism 338
 Retinopathy of Prematurity 620
 Safe Positions to Prevent SIDS 569
 Seeking Immediate Help 841
 Severe Maternal Hypotension and Decreased Placental Perfusion 418
 Skin Care and Nutritional Support 839
 Steroid Administration 900

Supportive Care 1089
 Teach “PAINS” Warning Signs to IUD Users 152
 Testicular Torsion 1065
 The Administration of Blood 1096
 The Hospice Approach 1145
 The Neonatal Intensive Care Unit 633
 The Neutropenic Child 1091
 The Nurse Role Models for the Child 707
 The Sibling 1152
 Transient Tachypnea of the Newborn 611
 Understanding Autism Spectrum Disorder 729
 Weaning the Newborn from the Incubator 608
 When Amniotic Fluid Embolism Develops 456
 When Attending a Forceps-Assisted Birth 437
 When Caring for a Patient Undergoing Amnioinfusion 432
 When Combining Butorphanol with Other CNS
 Depressants 415

Diagnostic Tools

Audiologic Testing 956
 Body Mass Index (BMI) 672
 Calculating the Absolute Neutrophil Count (ANC) 1126
 Cardiac Catheterization 871
 Chest Radiograph 770
 Determining Increased Intracranial Pressure (ICP) 927
 Determining Problems with the Urinary Tract 1039
 Determining Reason for Amenorrhea 1063
 Diagnosis of Diabetes Insipidus 893
 Further Testing for Infants Suspected of having Sickle
 Cell Disease 1078
 Hydrocephalus 941
 Hysterosalpingography (HSG) 156
 Identification of an Infectious Disease 839
 Intussusception 791
 Lumbar Puncture 1107
 Newborn Metabolic Screening 600
 Orthopedic Imaging Tests 964
 Serum Levels 894
 Testicular Torsion 1066
 Tilt Test 870
 Tourette’s Syndrome 734
 Ultrasound 790
 Voiding Cystourethrograms (VCUG) 1041
 X-Ray Films 621

Ethnocultural Considerations

Accepting Customs and Traditions 596
 Anemia during Pregnancy 267
 Antibiotic Use Around the World 849

Asthma 778
 Attachment 645
 Avoiding Stereotyping 666
 Bacille Calmette-Guérin Vaccine 773
 Boundaries and Receptivity to Information 51
 Breast Cancer Screening 96
 Caring for a Hispanic Child 991
 Caring for a Hispanic Child with Cancer 1123
 Communication Difficulties during Labor 430
 Consuming Non-nutritive Substances 270
 Converting Weights 606
 Cultural Differences in Communication 376
 Cultural Influences and Interventions for Breastfeeding
 Discomfort 496
 Cultural Practices 1146
 Cultural Prescriptions and Proscriptions for Women and
 Children 11
 Diapering Practices 595
 Disparities in Childhood Obesity 739
 Empacho 796
 Enuresis 1059
 Ethnicity and Factor V Leiden Mutation 527
 Exploring Differences in Ethnicity and Race in
 Adolescent Violence 87
 Gestational Diabetes 333
 Head Circumference and Infants of Asian Heritage 942
 Hypertension 869
 Hypertension and Pregnancy 234
 Infant Feeding 75
 Israel 798
 Jehovah Witness 1096
 Kidney Failure 1053
 Lead Exposure in Folk Medicines 682
 Maintaining and Communicating a Caring and Accepting
 Attitude 183
 Minority Women and Level of Care Received 442
 Myths, Taboos, and “Old Wives’ Tales” 211
 Neonatal Jaundice and RBC Enzyme Defects 554
 Obtaining a Sexual History for Infertility Care 155
 Occurrence of Celiac Disease 809
 Occurrence of Hypertrophic Pyloric Stenosis 789
 Occurrence of Lactose Intolerance 808
 Patterning Effective Communication Styles 16
 Patterns of Family Structure 48
 People from Some Ethnic Backgrounds are More Prone
 to Type 2 Diabetes 912
 Perception of Intelligence 647
 Perceptions of Desired Health and Health Outcomes 5
 Pregnancy-Related Skin Changes in the
 Puerperium 483
 Pressure Ulcers 1027

Preterm Labor and Birth 441
 Promoting Understanding of Culture in Diverse Families 719
 Puberty 659
 Racial Disparities 614
 Realities of the Cultural Model 402
 Shock in Dark-Complexioned Children 900
 Sickle Cell Disease 1077
 Skin Assessment 674
 Tetanus 988
 The Hispanic Culture and Grief 1150
 The Royal Disease 1082
 Use of Imagery, Chanting, and After-Life Encounters 6
 Vitamin D Deficiency 266
 Vulnerable Populations 1019
 When Assessing Families 56
 Women and Battering 535

Family Teaching Guidelines

Breast Self-Examination 97
 Caring for the Child with a Cardiac Condition 882
 Caring for the Child with a Disability 696
 Cellulitis 1006
 Common Herbs to Avoid During Preconception and Pregnancy 275
 Dealing with a Hypoglycemic Crisis 911
 Dealing with Food Jags with Young Children 804
 “DEEPER CARE” for Promoting Family Health during Pregnancy 221
 Esophageal Atresia with or without Tracheoesophageal Fistula 754
 Fostering Relationships During Evaluation and Treatment for Infertility 159
 Helping Older Siblings Adjust to the New Baby 501
 Herpes Simplex Virus (HSV-1) 1009
 Home Discharge Instructions Following a Tonsillectomy 764
 Home Management of the Pregnant Patient with a Hypertensive Disorder 307
 How to Avoid Sinusitis 762
 How to Recognize Breathing Difficulties 582
 Hypercholesterolemia-hyperlipidemia 869
 Immunizations 846
 Introducing Solid Foods to Infants 76, 654
 Language Disorder 958
 Lice (Pediculosis) 1014
 Parent Teaching for Hydrocortisone (A-Hydrocort) Administration 904
 Performing Vulvar Self-Examination 89
 Preparing for an Influenza Pandemic 849

Preventing Plagiocephaly 78
 Preventing Prematurity 302
 Preventing Sudden Infant Death Syndrome 621
 Prevention of Infection 522
 Promoting Family Attachment 595
 Signs and Symptoms of Infection 1119
 Sleep Hygiene 740
 Teaching Tips for Families 704
 Testicular Self-Examination 93
 The Child with Clubfoot Who is Wearing a Cast 972
 The Child with Hemophilia 1084
 The Sibling Needs to Say Good-Bye 1152
 Vulvovaginitis 1062

Labs

Analysis of Cerebrospinal Fluid 689
 Basic Infertility Evaluation and Workup 155
 Blood and Body Fluid Analysis for the Child with Alterations in Musculoskeletal Conditions 965
 Blood Culture 825
 Blood Values According to Age 1073
 Brain Abscess 936
 Complete Blood Count, Reticulocyte, and Peripheral Smear Lab Values for Children 1073
 Differential White Blood Cell Count 628
 Epistaxis Diagnostic Workup 1077
 Findings with DIC 517
 Hemoglobin Electrophoresis 1081
 HIV Testing 824
 Hyperaldosteronism 905
 Laboratory Findings for Ulcerative Colitis 795
 Laboratory Values 880
 Liver Enzymes 1003
 Neonatal Blood Glucose Assessment 552
 Potassium Depletion 900
 Results and Rocky Mountain Spotted Fever (RMSF) 1018
 Sputum Culture and Sensitivity 770
 Tests for Amenorrhea 1063
 Tuberculin Skin Test 773

Medications

Accurate Administration of Hormone Tablets 896
 Accurate Administration of Intranasal Medication Doses 893
 Amphotericin B (Amphocin) 844
 AquaMEPHYTON 568
 Benzathine Penicillin G (Bicillin L-A) 1007
 Beractant (Survanta) 615

- Betamethasone, Dexamethasone 544
 Butorphanol 415
 Carvedilol 868
 Chloral Hydrate (Aquachloral)—Points to Remember 692
 Common Antiemetics 1124
 Diphenhydramine (Benadryl) 831
 Dosage Recommendations for Acetaminophen (Children's Tylenol) 684
 Epinephrine (Adrenaline) 830
 Erythromycin 568, 762
 Fentanyl 414
 Ganciclovir (Cytovene) 842
 Hematopoietic Growth Factors 1089
 Herbal Medication: Echinacea Purpurea 522
 Imipramine 1060
 Insulin Dosage and Frequency 907
 Magnesium Sulfate 309
 Mannitol (Osmitrol) 929
 Medications for Candida Vulvovaginalis 1062
 Medications Used for Vomiting 803
 Methylergonovine 478
 Methylprednisolone (A-Methapred) 828
 Morphine Sulfate (Astramorph) 693
 Oseltamivir (Tamiflu) 775
 Oxytocin 391
 Pharmaceuticals Used for Tetanus 989
 Rh_o(D) Immune Globulin 327
 Somatic Therapies for Depression 723
 Steroid Side Effects 794
 Toradol (Ketorolac) 1079
 Treatments for Juvenile Arthritis 982
 Trimethoprim-sulfamethoxazole (TMP-SMZ; Bactrim or Septra) 825
 Valproate (Depakote) 725
 Warfarin 529

Moving Toward Evidence-Based Practice

- Childhood Depression and Alcohol Use 717
 Choice of Elective Cesarean Birth 355
 Compliance with Care for Urinary Tract Infection 1033
 Concept Maps and Learning Style Preference 3
 Connection between Epilepsy and Migraine Headache 921
 Decline in Adolescent Pregnancy 215
 Dental Care 701
 Development Risks in Participants with Hypoplastic Left Heart Syndrome and Transposition of the Great Arteries 853
- Eating and Activity Habits of Adolescents 71
 End-of-Life Care for the Neonate 603
 Glycemic Control of Children with Diabetes 885
 Grandparents 641
 Informing Parents about Newborn Screening 563
 Maintaining Peripheral Intravenous Locks 819
 Maternal Engagement 541
 Maternal Placental Syndrome as it Relates to Cardiovascular Health 427
 Menstrual Cycle Variability 113
 Nonchemical Head Lice Treatment 995
 Parent Satisfaction with Care of Developmentally Disabled Children 664
 Parental Efficacy 193
 Parenting Concepts among Culturally Diverse Cultures 46
 Postpartum Depression 511
 Probiotic Use in Antibiotic-Associated Diarrhea Prevention 785
 Quality of Life in Children with Cancer 1104
 Quality of Life in Chronically Ill Children 1133
 Reducing Health Disparity 26
 Risk of Adverse Pregnancy Outcomes Related to Weight Changes 291
 Sickle Cell Patients with Acute Chest Syndrome and the Incidence of Asthma 1072
 The Influence of Norms on Breastfeeding Decisions 469
 Therapy for Unexplained Infertility 137
 Use of a Doula to Support Women in Labor 399
 Use of Antibiotics for Acute Otitis Media 750
 Use of Calcium in Children with Juvenile Rheumatoid Arthritis 962
 Vitamin D Status during Pregnancy 257
 Vitamin E and Fetal Growth 164

Now Can You

- Apply family nursing diagnoses to a family? 62
 Apply theories to nursing practice? 651
 Apply tools and concepts to assess a family? 61
 Assess FHR by auscultation? 379
 Assess FHR patterns detected by EFM? 385
 Care for postpartal patients with special needs and identify community resources for the postpartal family? 507
 Care for the patient experiencing preterm labor? 302
 Compare and contrast the caring base of nursing as described by Nightingale, Watson, and Leininger? 14
 Complete a neonatal musculoskeletal assessment? 589
 Complete a neonatal neurological assessment? 593
 Correctly calculate the EDB? 227
 Define pica and describe the benefits of exercise during pregnancy? 272

- Define the essential characteristics of caring? 15
- Describe changes in the eyes, nose, and throat and respiratory, gastrointestinal, and urinary systems? 203
- Describe conditions of the anterior and posterior pituitary? 895
- Describe congenital respiratory conditions and structural anomalies? 761
- Describe early postpartal physiological adaptations in the metabolic, neurologic and renal systems? 483
- Describe major changes that occur in the reproductive system during pregnancy? 196
- Describe nursing actions that can serve to improve the current status of children's health in the United States? 32
- Describe postpartal physiological adaptations in the respiratory, cardiovascular, and reproductive systems? 485
- Describe structural defects of the urinary system? 1058
- Describe the assessment related to the infant's head? 581
- Describe the effects of hospitalization on a child? 705
- Describe the role of the nurse as a teacher, collaborator, and provider? 13
- Describe the role of the nurse in antibiotic-resistant organisms? 849
- Describe why critical thinking is key to the successful clinical practice of nursing? 16
- Differentiate between depression and bipolar disorder? 725
- Discharge the new family? 600
- Discuss a pain control theory, pain perception, and considerations for the childbirth setting? 405
- Discuss abuse during pregnancy? 347
- Discuss anatomy of the female breast? 124
- Discuss aspects of an ethical framework for nursing practice? 41
- Discuss aspects of care for the pregnant woman older than age 35? 251
- Discuss aspects of circumcision? 597
- Discuss aspects of cultural practices for healing and comfort, transpersonal care, and components of the family unit? 7

Foundations in Maternal, Family, and Child Care

Traditional and Community Nursing Care for Women, Families, and Children

As a Family-Centered Nurse

Learn of the essence of family-centered nursing,
while you walk with a worried family
until you wear side-by-side paths in the carpet;
Suffer the emotions of a troubled family
When they soar in their hope for healing and recovery;
Stay through the darkest hour of a mother, father, sister or brother,
as they silently cry for a member's pain;
Experience the failure, disappointment and challenges
presented with each health care encounter;
Never cease to be amazed at the resilience
of a family's strength, spirit and protective value.

—S. Caves

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Explore the impacts of ethnocentrism, ethnopluralism, paternalism, the medical model, and consumerism on nursing.
- ◆ Compare the roles of nurses, families, and patients in various health care settings.
- ◆ Discuss theories of caring and holism as they apply to the nursing care of women, families, and children.
- ◆ Clarify nursing responsibilities using NANDA, NIC, and NOC taxonomy related to diagnosis, management, and outcome evaluation of family-centered medical and nursing problems.
- ◆ Summarize the importance of cultural competency in fulfilling the role of nurse teacher.
- ◆ Evaluate the nurse's role in promoting self-healing.
- ◆ Discuss how responsibility and professional accountability are enhanced by evidence-based knowledge.
- ◆ Contrast the focus of the advanced practice nurse with that of the professional registered nurse.

moving toward evidence-based practice Concept Maps and Learning Style Preference

Kostovich, C.T., Poradzisz, M., Wood, K., & O'Brien, K.L. (2007). Learning style preference and student aptitude for concept maps. *Journal of Nursing Education, 46*(5), 225–231.

The purpose of this study was to describe the relationship between nursing students' learning style preference and aptitude for concept mapping. A correlational, descriptive study conducted at a private Midwestern university included 120 students enrolled in an adult medical–nursing course taken in the

junior year. The students completed the Kolb's Learning Style Survey (LSS) and a Concept Map Survey, instruments developed by the researchers. The LSS consists of several phases and is designed to determine preference for learning experiences, i.e., concrete, active experimentation, abstract conceptualization,

continued

moving toward evidence based practice (continued)

and reflective observation. The Concept Map Survey consisted of nine open-ended questions related to preference for creating concept maps.

The students were also given a concept map assignment, which included both written and verbal instructions since the majority of the students had not created a concept map before this class. Concept maps were graded using a rubric. As the course was co-taught, each faculty member corrected one half of the concept maps using the same criteria. The interrater reliability was reported as moderately low. Final course grades and concept map grades correlated weakly ($R = 0.37, p < 0.01$). A one-way analysis of variance (ANOVA) was performed to assess the influence of learning preference on concept map grades. The researchers reported that although “students in the abstract conceptualization group had higher mean concept map grades than did students with other learning preferences, the difference was not significantly higher.” Students were also

asked whether they preferred concept maps or case studies as a learning tool. The researchers reported that nearly twice as many students in the abstract learning preference group preferred the use of concept maps. The researchers concluded that learning style preference does not impact students’ abilities to use concept maps as a learning tool, and hence they can be used for all learning style categories.

1. Based on the information provided in the synopsis of this study, do you believe that sufficient evidence exists to require students to use strategies that are not consistent with their learning style preference in order to develop a range of problem-solving skills?

2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

Most nurses and students have personal understandings of what it means to be a nurse caring for women, families, and children—the field of family and child nursing. They may have even developed a broad range of strategies, knowledge, values, and competencies to use when caring for women, families, and children. Nurses conversely may approach family and child nursing no differently than they would if providing care for any other patient. Realizing how the nurse, the patient, other health care providers, and outside forces of influence have framed family and child nursing through the last century provides the nurse with insights into the level and outcome of care historically and currently received and given to families and children.

There is a fairly consistent view of how family and child patients are defined, from one of three family and children perspectives: as an individual affected by some health event; the family unit involved in that event; and the whole of supporting mind-body-spirit, culture, and community affected by the experience (Harmon Hanson, Gedaly-Duff, & Kaakinen, 2005). Nurses as well as families are being challenged by ever-increasing numbers of health care and societal changes to adapt and expand these perspectives on family and child health.

The traditional hospital that served as the center of care for families and children has been replaced by a myriad of community-based settings. With this change in setting, often the thrust of power has shifted from the traditional nursing and medical models to one of family-centered decision making.

Becoming a part of this care experience, engaging in the patient’s lived experience throughout its entirety instead of functioning as a part of the process by doing “for” the patient, is one of the emerging roles for the family and child nurse. Using this engaging transpersonal approach to understanding the experience of the patient’s entire mind-body-and-soul during times of health threats

may offer one of the most fulfilling roles for the nurse, and one of the first experiences of empowered caring for the patient. This return to the development of a therapeutic nurse–patient relationship through communication and the artistry of nursing provides the nurse the opportunity to experience the ultimate caring component of nursing for which the profession is known.

This chapter begins with an historical overview of nursing, family and child health care, and the influences that have shaped and driven some of the changes toward a more contemporary approach to family and child nursing. It discusses the many professional roles of the family and child nurse, how they have changed over time, and where the future will take them, irrespective of the type of care setting. The focus of the chapter is on the art of caring and its centrality to the family and child nurse experience.

Traditional Nursing Care

Taking a look at the traditional role of nursing in the care of families and children helps identify the significance of both positive and unfavorable changes that have occurred during the past century and framed current standards of care.

HISTORICAL PERSPECTIVE

Physicians, the general public, and the nursing profession historically viewed health as the absence of disease and the presence of optimal functioning. Illness was seen as pathological and something of which the health care provider worked to rid, heal, or cure the patient. This curative approach commonly was referred to as the **medical model**. It often entailed a paternalistic, one-way channel of communication between the powerfully dominant and more knowledgeable health care provider and the submissive and uneducated patient or family. The power base for all decisions rested with the medical or, infrequently, the

nurse provider who together often took an objective, detached biomedical approach (Gordon & Nelson, 2005).

Over the previous quarter century, a number of influences have affected how family and child health and nursing care are now defined in the 21st century (Fig. 1-1). The infusion of multiple cultures and beliefs about health care systems, along with exponential growth in scientific and technological capabilities, have been major forces in shaping the structure and delivery of nursing care. In addition, increased consumer access to health-related information via the Internet, mass media, and other sources that may or may not be accurate, the unprecedented rise in health care costs, and increasing imposition of cumbersome regulations have also contributed to change.

Now Can You— Discuss elements of contemporary nursing and health care for families and children?

1. Identify a major force that accounts for the present-day shift toward family-centered decision making in health matters?
2. Describe a nursing approach that fosters empowered caring for the patient?
3. Name four factors that have shaped contemporary family and child health and nursing care?

The growth of **ethnopluralism** (diverse cultures) daily impacts health care systems and providers. Often each culture comes with its own beliefs, values, and practices about health and illness. The United States Department of Commerce, Bureau of the Census, projects that within the next 10 to 12 years, only one-half of the U.S. population will be of Euro-Caucasian descent, although the medical model formed and that continues to be supported is based on this group (U.S. Census Bureau, 2008). The population of other ethnicities and cultures will double and triple in that time, rapidly making up the other half of the U.S. population and bringing to the forefront their beliefs, values, and health practices.

During the past century the values, beliefs, and practices of the predominantly Euro-Caucasian male health care provider system drove health care decisions, interactions, and treatments based on the belief that these were unquestioningly in everyone's best interest and by far superior to all others: a belief referred to as **ethnocentrism** (Leininger & McFarland, 2002).

In a culture changing as rapidly as is that of the United States today, ethnocentrism can critically compromise effective health care. One of the predominant problems with a health care system founded on ethnocentrism, paternalism, and the medical model is the system's closed-mindedness and prejudice toward other solutions and viewpoints of health. It is this viewpoint that often alienates people in need of health care and deters them from seeking or accepting help.

HEALTH–WELLNESS CONTINUUM

For decades, the goal of nursing has been to move the patient toward well-being and away from disease and pathology. The aim of the nurse–patient relationship was to facilitate the attainment of that goal. The relationship process had a beginning (illness), middle (treatment), and end (wellness). This prominent emphasis on treating illness defined the scope of the nurse's practice, or the **nursing process**: assess for signs of illness, diagnose alterations in health, determine interventions to restore health, conceptualize a targeted health outcome moving away from illness, and evaluate the treatment plan for nurse-determined modifications (Fig. 1-2).

In nursing there has recently been a shift in this health–wellness continuum and process. The emphasis is changing from a linear beginning-to-end, illness-to-wellness process. No longer is the predominant nursing perspective to return the patient from illness (beginning) to a prior disease-free state (end) but toward a shared experience of transcending or controlling the health threat and changing it into one of purposeful meaning (LeVasseur, 2002). The nurse–patient relationship now is a circular or spiral process formed to motivate the patient or family toward promotion, maintenance, and restoration of health; health potential; prevention of illness; and self-care (Fig. 1-3).

Ethnocultural Considerations— Perceptions of desired health and health outcomes

Based on personal beliefs, values, and practices, an ever-increasing culturally diverse population has many differing definitions of health and the outcomes desired during health-seeking encounters.

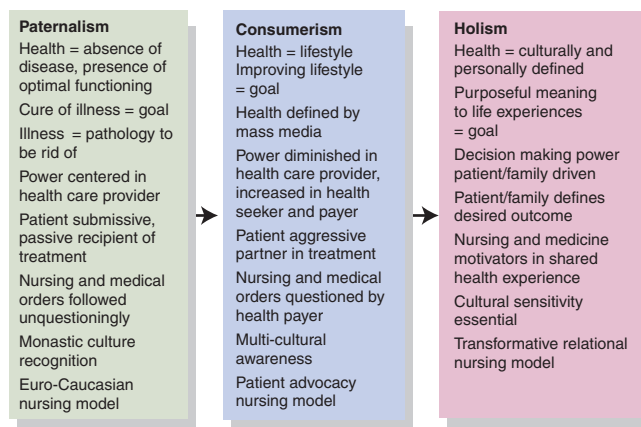

Figure 1-1 Evolution of family and child health nursing model.

Figure 1-2 Traditional nursing process.

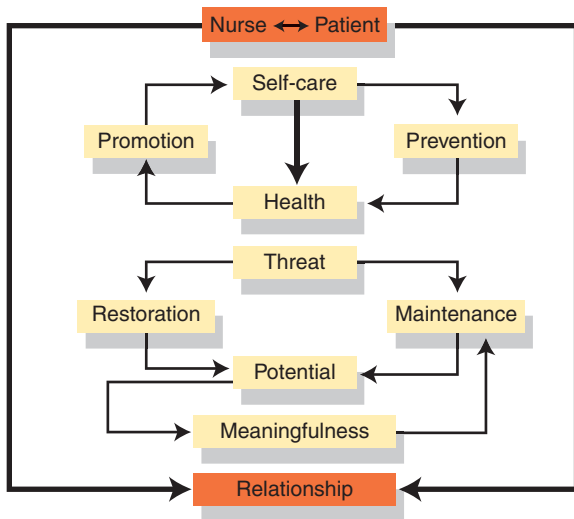

Figure 1-3 Health promotion nursing process.

Through health promotion, the nurse helps the woman, child, or family understand health risk factors and adopt lifestyle changes that foster health maintenance, prevent health threats through early detection and recognition, and explore options for health restoration.

Across Care Settings: Health protection for families

With increasing international travel comes also the transport of illness vectors previously unknown in certain locales. Providing information about ways to protect children and families from these new sources of illness and injury through the use of individual instruction, educational videos, and use of the mass media can help the family maintain confidence in their ability to protect themselves from new threats.

This form of nursing entails a shared connectedness between patient and nurse. The goal is to experience the illness or health threat in the same way the patient perceives it. The nurse moves with the patient beyond the illness through the patient's own inner healing process to a patient-defined state of coping, harmony, wholeness (**holism**), and unity with the illness and healing outcome; and hope, purpose, meaning (**spirituality**), and health potential beyond the illness toward healing. The power base for this healing and future health decisions rests within the patient and his belief in his health potential.

The approach of the nurse provider is to form a caring relationship through listening, understanding, experiencing, presencing, facilitating, valuing, and using nursing aesthetics. **Nursing aesthetics**, or the art of nursing, is the low-tech, high-touch artistry of caring that strengthens the patient's confidence in her or his ability to manage the healing process, make change, or master the threatening health event (Stichler & Weiss, 2001). It is the way the nurse and patient help each other find meaning in the experience. It is a transformative, spiral process with a beginning (a threat), middle (relational building of trust and connection), and future (experiencing new possibilities for health change and outcomes) (Rhea, 2000).

Now Can You— Discuss aspects of health promotion and nursing aesthetics?

1. Describe present-day trends in nursing focus related to the health–wellness continuum?
2. Identify the elements of a health promotion nursing process?
3. Define “nursing aesthetics” and the role it plays in realizing health potential?

Some nursing interventions that fall under this art of aesthetics include imagery, music therapy, and touch (Ward, 2002). Guiding the family or child's imagination (**guided imagery**) to visualize repeatedly a positive outcome has been demonstrated to enhance healthy outcomes. Music therapy helps bond the mind–body–spirit components of health and is especially successful with children. Touch and speech patterns of the nurse have descriptively been shown to soothe, calm, and encourage patients toward the health outcome of their choosing. One only needs to watch a caregiver stroke, rock, and sing to a sick child to know that this form of the nursing art works.

Across Care Settings: Teaching simple strategies for stress relief

Most have heard of the beneficial effects of slow, deep, deliberate abdominal breathing patterns on the stress, anxiety, and pain associated with labor and birth. Nurses can teach these simple techniques to patients who anticipate stress, anxiety, or pain in any care setting.

Ethnocultural Considerations— Use of imagery, chanting, and after-life encounters

One often thinks of imagery as a collection of nurse-initiated instructions given to the patient. To the woman undergoing treatment for cancer, the nurse may suggest: “Imagine all of the cancer cells flowing up through your body, gathering all of the bad cells with them, and finally bursting into an explosion of color and sparkles like an explosion of fireworks from your body. Out into the atmosphere they go, floating higher and higher as they disintegrate into outer space.” But, have nurses considered the healing power connected with objects used by some non-European Caucasian cultures? For example, the healing feather used by Native Americans, or the “seeing” of spirits practiced in Asian cultures, the casting of spells performed in the Caribbean Island culture, and the prayer beads used in Middle Eastern cultures. The healing effects of music and speech patterns have been well documented. But do health professionals consider of equal value the healing value of chanting by the Native American, or the wails of sorrow of the Central and Eastern European culture? One's awareness of various cultural practices is important. Even more important to their healing powers is the nurse's sensitivity and incorporation of them into a shared perspective of healing with the patient and family.

While the family or child relates stories of a lived experience, maintaining en-face eye contact, symbolically enfolding them through proximity, and staying focused solely on them acknowledges their worthiness. Imagina-

tively being in the patient's experience, reflectively sharing that experience through the use of body language, and avoiding demonstrations of disappointment and frustration gives the nurse a shared point of reference from which to help the family and child create meaning out of a threatening health experience (Fig. 1-4).

CHANGING DEMANDS AND DEMOGRAPHICS

This nursing approach of **engaging transpersonal care** has evolved from the simple nursing basics of providing treatment-driven, high-technology-centered care. It is an opportunity for the family-child nurse to utilize the nursing process in a new way. The nurse assesses the patient and family's confidence to address and manage the health threat, diagnoses the health alteration from the patient's viewpoint, conceptualizes the outcome as the patient and family envision it, and supports the patient in his or her chosen changes directed at restoring health or transcending the threat. Finally, the nurse evaluates the ongoing maintenance of health as it is lived by the patient and family.

Over the last half century, public trust in health care providers has continually declined. Some surveys have noted that the public trusts health care providers only slightly more than they do the Internal Revenue Service and the tobacco industry (Ford & Fottler, 2000). According to data from the National Coalition on Health Care (2006), much of this is likely due to health care providers' minimal awareness of consumer preferences and desire for personal control. Starting in the 1960s, health care seekers became increasingly critical of health care providers.

Family-child nursing responded to this call for consumer advocacy (consumerism) by supporting the consumer demand for a shift in the thrust of decision-making power. Other strategies included advocating for the provision of health care in facilities outside of the standard hospital setting (accessibility) and by providing family-centered approaches to care that emphasized health promotion and education. During the next half-century, other societal changes occurred that continued to alter health care delivery.

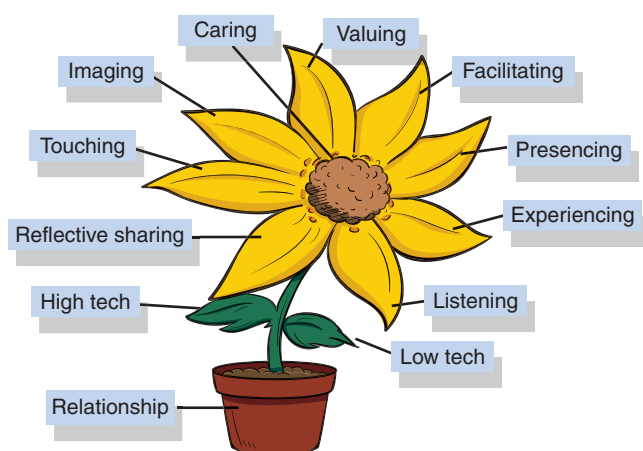

Figure 1-4 Nursing aesthetics that strengthen confidence in mastering a health threat.

Across Care Settings: Family-centered care

The need for family members to feel significant and competent to care for their loved ones is universal, and should not be affected by the setting in which care is provided. Being friendly, encouraging family participation, and modeling of care are techniques that accomplish this goal in any setting.

Family structures (who the members are), functions (the roles members play), and definition of the family (a group of people sharing interpersonal bonds, tasks, and activities) have changed during the last half-century. Dyad families can comprise two cohabitating companions or spouses; traditional nuclear families of husband, wife, and children; extended multigenerational families; communal families of shared religious or social beliefs and values; blended families from separate prior marriages; families of same-sex unions; foster families; and adoptive families (see Chapter 3).

Social and technological advances of the past half-century have changed family structure, function, and definition. With the increasing acceptance and technologically available birth control options made available to families since the 1970s, family size has also changed. The sexual revolution of the 1960s resulted in an increase in the number of single-parent families. The feminist movement of the 1970s sent ever-growing numbers of mothers outside the home into a second work environment. As the workforce increased, industries flourished, cities grew, and families became more mobile in search of better lives for themselves, often leaving behind the extended multigenerational family they had learned to depend upon.

In the family's search for a better life, family health consciousness increased, as did usage of health care services and costs. The changes had implications for the way nursing delivered care and families sought it. Smaller families, single-parent families, families dispersed in search of better lives, and dual-income families meant fewer support persons present during family illnesses and crises. As a result, the role of the nurse inevitably changed from a focus on carrying out medical orders to a fuller scope of providing family support services.

Now Can You— Discuss aspects of cultural practices for healing and comfort, transpersonal care, and components of the family unit?

1. Explain why nurses should develop awareness and understanding of cultural practices intended to foster comfort and promote healing?
2. Discuss a nursing approach that incorporates engaging transpersonal care?
3. Differentiate among family, family structures, and family functions?

PROFESSIONAL NURSING ROLES

Since the time of Florence Nightingale, nurses have played a role that involved clinical interventions, patient and family education, empathetic support, development of therapeutic relationships, and unique opportunities to make a difference in the lives of families during illness.

Nursing's domain in the earlier times consisted of being a provider of care and a teacher. As a provider of care, the nurse would change elements of the patient's environment through hygienic measures, nourishment, and comfort to enable the best opportunity for recovery. As a teacher, the nurse would prepare the patient for procedures, surgery, and the uncertainties of hospitalization.

Even in the 1860s, nurses saw their patient responsibilities not only for the individual for whom they ministered but also for the living conditions of the individual's family. The most frequent cause of illness and death during these years was infectious diseases. The nursing emphasis on sanitation, nutrition, and family education played a key role in the decline in deaths well into the 1950s when antibiotic drugs and scientific treatments became widely available.

Until the late 20th century, nurses continued to be seen as passive, deferential, and compliant advocates to paternalistic physicians. Nurses still practiced from the male dominated, ethnocentric, patriarchal medical model of the professional nurse. In 1963, the nursing process began to change that.

The **nursing process** was developed as a framework of systematic problem solving and actions to be used by nurses in identifying, preventing, or treating the individual health needs of patients. The nursing process was problem oriented, goal directed, and involved critical thinking and decision making. Clear differentiations were made between nursing and medical diagnoses, interventions, and outcomes. Ten years later, the North American Nursing Diagnosis Association (NANDA) developed a list of standardized nursing diagnoses used by the nurse through individualized patient care plans to express to other caregivers the findings of the nurse's assessment, diagnosis, and plans of action (Johnson et al., 2006). An example of the use of the NANDA-I Diagnosis to formulate a nursing care plan for a child with culturally different verbal communication is presented in Box 1-1.

Now Can You— Follow the evolution of today's nursing professional roles?

1. Explain the central focus of the nurse as a provider of care and teacher before the 1950s?
2. Describe how the introduction of the nursing process as a systematic framework changed the nurse's professional role?

Contemporary Nursing Care

As families became more prosperous in the late 20th century, they also became more conscious of health promotion and advanced health technology. They demanded more knowledge about how to stay healthy, prevent common illnesses, and use technology to detect and treat early signs of health alterations. With this increased demand on the health care system came increasing costs. In response to increased health care costs, health care systems and third-party payers focused on monitoring, controlling, and curtailing expenditures. As the costs for health care rose, the resultant changes impacted family and child health, and nursing's professional role.

Hospitals and third-party payers responded to increasing costs in a number of ways that included managed care systems and the development of alternative settings for health care delivery. In addition, greater emphasis was placed on patient and family accountability and responsibility for their own health promotion and disease prevention. This approach shifted the thrust of decision making power to the consumer. Other measures included a redefining of nursing functions, work loads, and methods for care delivery.

CURRENT HEALTH CARE SETTINGS

Cost containment, tightened reimbursement for services, and advanced technology have become important determinants of the current settings in which health care is received. Patients are being discharged earlier from acute care hospitals. Care is being provided in the home by family members using highly technical equipment. Many conditions that previously required acute care hospital stays are now being treated in ambulatory settings and the community-based health care service sector is almost limitless. Hospitals, homes, and community service centers have become interdependent providers in the ever-expanding health care arena.

Regional and specialized acute care hospitals for women, families, and children have undergone a multitude of changes since their inception in the late 1950s. Liberalized family, sibling, and children visiting; 24-hour family partnering with caregivers; policies, and procedures based on theories of child and family growth and development; and a heightened level of acuity in these acute care settings have had both beneficial and challenging effects on nurses, families, and children. A strong knowledge base in the care of families and children, highly developed critical thinking skills, expertise with advanced technology, and dedication to evidence-based practice are stringent requirements for nurses caring for families and children in all settings.

When referred to these modern, highly technologically advanced facilities, family members are often separated by great distances from children and other support persons. Emotions of separation, anxiety, abandonment, fear, and guilt compound already tenuous physical conditions. The accessibility to follow-up care in these comprehensive settings is frequently made difficult by time, distance, and coordination of return visits to multiple providers of segmented and specialized care.

Even with the heightened acuity of patients in acute and tertiary care hospitals, the length of stay in the settings continues to decrease. With these decreasing hospital stays, alternative settings were created for what once was considered "inpatient care."

At the other end of the health provider environment, from the specialized tertiary and acute care hospitals, are the acute care 24-hour observation unit, freestanding short stay, and urgent care centers. The facilities are less costly than acute care settings, in part because they minimize the high cost of advanced technology in specialized hospitals. These settings present their own challenges for the nurse, family, and patient. Assessment, risk identification, counseling, and teaching must all be accomplished

Box 1-1 Use of NANDA-I Diagnosis to Formulate a Nursing Care Plan

Care Plan for the Patient with Culturally Different Verbal Communication

Patient and Family Data: Extended three-generational family comes to the health care provider with a complaint of weakness and loss of appetite in a 3-year-old family member. The family has arrived from a Middle Eastern country within the previous 2 weeks; they do not speak English and converse among themselves loudly and with much gesturing.

NANDA Nursing Diagnosis: Impaired Verbal Communication related to patient-care provider cultural and language difference

Measurable Short-term Goal: The family will have an opportunity through appropriate interpretation resources to share and interpret information regarding the well-being of the child.

Measurable Long-term Goal: The family will express concerns, needs, wants, ideas, questions and understanding about immediate and long-term home care of the child.

NOC Outcome:

Communication (0902): Reception, interpretation, and expression of spoken, written, and nonverbal messages

NIC Interventions:

Active Listening (4920)
Culture Brokerage (7330)

Nursing Interventions:

1. Assess contributing cultural and language factors that may impede simple communication.

RATIONALE: A shared understanding of culture and language is necessary for communication to take place.

2. Evaluate extent and level of impairment.

RATIONALE: Misunderstandings of intent and content are heightened with increased levels of communication disparity.

3. Establish a therapeutic relationship by listening carefully.

RATIONALE: Communication is enhanced when intent of trust and understanding is established.

4. Assist the family and patient to establish means of communication via an interpreter.

RATIONALE: Law mandates that interpretation services be made available for accurate and precise basic understanding of medical terminology and care provided.

5. Validate the meaning of nonverbal and verbal communication.

RATIONALE: Words and gestures can easily be misinterpreted, and affect the delivery and reception of important concepts.

Documentation Focus:

1. Assessment of pertinent patient physical, psychological, and cultural concerns
2. Description and meaning of nonverbal cues as related by interpreter
3. Type of interpreter services utilized
4. Teaching and explanations communicated
5. Level of outcome (NOC) completion/accomplishment
6. Discharge needs, referrals and stated family/patient understanding

NIC = Nursing Interventions Classification; NOC = Nursing Outcomes Classification.

Adapted from Doenges, M.E., Moorhouse, M.F., Murr, A.C., & Murr, A.G. (2006). *Nursing care plans: Guidelines for individualizing client care across the life span*. Philadelphia: F.A. Davis.

in a crucially compressed time. The nurse in these settings may be responsible for direction of unlicensed assistive personnel who may not have the highly developed expertise needed to recognize subtle physiological changes in a patient's condition before discharge. Follow-up procedures that once were performed and monitored by nurses in the acute care setting now must be taught to the patient and family as they prepare for a rapid return to their home.

Collaboration in Caring—Preparing the family for community-based care

The nurse can prepare the patient and family for care outside of the acute setting by:

- Discussing the feasibility of using specialized equipment in the home
- Encouraging the patient and family to investigate health insurance coverage for home care

- Suggesting the parents of a young patient contact school officials before a child returns after an illness
- Evaluating the family's transportation needs for follow-up care
- Discerning when an interaction in the acute care setting is conducive to teaching and learning

Since the early 1990s, there has been a dramatic increase in home- and community-based nursing care. Home- and community-based nursing care is provided in settings such as adult and child day care centers; public and private schools; churches and religious body parishes; penal systems; health and disease related camps; foster homes and homeless shelters; physicians' offices, public health clinics, and nurse managed care centers (Fig. 1-5). Nurses in these settings often experience different degrees of professional independence and accountability, yet still need to possess expert skills as providers of clinical interventions, health history interviewers, culturally competent teachers, coordinators of extended care services, managers of allied health colleagues, supporters of family functionality, and advocates for family-centered care.

Now Can You— Recognize the changes created by family-centered care for professional nursing in acute care settings?

1. List at least four characteristics of acute care hospitalization that have changed since the introduction of family-centered care?
2. Identify at least five community-based care settings in which the nurse may practice family-centered care?
3. Compare and contrast the role of the professional nurse in acute and specialized care hospitals and alternative care settings?

FAMILY-CENTERED CARE

Acute care providers have made strides toward keeping family members informed of hospital procedures and processes affecting their loved ones, and the patient outcomes expected. Acute care settings still, however, are major sources of family disruption during times of stress and illness. Placing family relationships, their coping mechanisms, values,

Figure 1-5 The nurse is instrumental in providing family-centered care in the community setting.

priorities, and perceptions at the center of a patient's health care needs is the essence of **family-centered care (FCC)**.

Family-centered care requires sensitivity to the beliefs, values, and customs of each family member and those of their supporting culture or community. The role of the family-centered nurse is to facilitate and assist the family in making informed choices toward the outcome the patient and family desire. Family-centered care necessitates that the nurse relinquish an authoritarian role that tells the family what is best for them while the nurse does things to and for them. The nurse becomes a human just like all other members of the family, each with their special abilities to support the patient. The center of power shifts from the one with the most clinical knowledge to the whole of the group's knowledge.

This is a large shift for the nurse educated under traditional Euro-Caucasian theories of nursing care. The global nature of health care as a multiethnic (ethnopluralistic), multicultural composite of health-seeking people requires an ever-growing sensitivity on the part of the nurse. Consideration of the family's cultural influences allows the nurse to take a more in-depth approach to health assessment and outcome-directed interventions. For example, the proximity and quality of the family's support systems; religious and spiritual beliefs; customs and traditions, especially as they relate to health, illness, and healing; micro-living environment of the home; and macro-living environment of the neighborhood all must be incorporated into the plan of care. Other elements to be considered include financial resources, including willingness to ask for and accept additional resources; significant historical events, especially crises, losses, and new beginnings; and the members' communication patterns and verbal abilities, coping strategies, and problem-solving techniques.

One format used for assessing the health of a family is the community health map (Falk-Rafael, 2004). With this tool, the nurse assesses the family structure, function, and support networks. The map provides a diagram of significant data and helps the nurse focus on the family as it interacts with the social systems within and around them (Fig. 1-6). Actively including the family members in the development of the community health map provides the nurse insights into the family's health experience and fosters the nurse-family alliance. The nurse should remember that the focus is on family health, past successes, and current strengths, not on family problems.

Learning, recognizing, and comprehending that these cultural factors are what shape a family's perception of their health and health-related events is known in nursing as **cultural sensitivity**. The nurse does not need to seek congruency between these factors, values, traditions, and beliefs and his or her own. The nurse does, however, need to recognize that how the patient and family comprehend and respond to a particular health event is shaped by these factors, values, and beliefs.

In order to use **cultural competence** as a nursing assessment tool, the nurse must be open and receptive to gaining awareness and respect of these cultural influences. Nursing interventions that are based on a solid knowledge of these values and practices have been demonstrated to achieve much higher levels of successful outcomes for families and patients (Locsin, 2002). Listening to the cultural voices and experiences of family and patients

Structural Family Assessment

- Number males/females
- Marriage status
- Number/order children
- Family members loss/death
- Significant contacts and strength of relationship (work, church, medical, school, friends, extended family, clubs/organizational participation)
- Ethnicity
- Religion
- Socio-economic status/environment
- Culture
- Health problems
- Living difficulties

Developmental Family Assessment

- Parent's family of origin
- Emotional reactions to changes
- Spiritual beliefs
- Recent life changes
- Degree of family stability
- Recent or expected shifts in family structure/relationships
- Affectional bonds
- Feelings about family roles
- Childcare-work-relaxation balance
- Alone time balance
- Hopes for future
- View of extended family
- Previous health crises
- Method of coping with crises

Functional Family Assessment

- Socio-economic systems in place
- Physical problems and strengths of patient
- Family strengths and weaknesses in shared caregiving
- Who identifies and problem solves what issues
- Parental discipline habits
- Perceptions of health, control over health, strengths and weaknesses
- Health priorities (individual and shared)
- Health values (individual and shared)
- Cultural values (individual and shared)
- Spiritual values (individual and shared)
- Goals for a fulfilling life
- Permeability of family boundaries — who is allowed into inner circle and for what function
- Willingness to accept help
- Communication styles, patterns
- Use of power, by whom, when
- Emotional closeness

Figure 1-6 Community health map.

affirms their value and is critically important to unifying the nurse–patient relationship as it motivates the patient toward positive health-promoting activities.

Across Care Settings: Ensuring cultural sensitivity and reliable information

In all care settings, nurses should use the services of professionals who can interpret word meanings correctly. Relying on family members often results in literal translation of words and omission of information—problems that create confusion and misunderstanding. In settings where professional interpreters are not available, the use of services like AT&T, Roget's International Thesaurus, or handheld personal information devices can be useful alternatives.

Delivering nursing care that is sensitive to and understands cultural differences, whether in knowledge, values, beliefs, or role expectations, should help the nurse evolve into a culturally competent professional who makes assessments and plans interventions from a holistic framework. Framing one's nursing assessment, intervention, outcome expectation, and evaluation with a holistic perspective gives the nurse a better assurance that no significant physiological, psychological, cultural, spiritual, or social component is excluded.

Ethnocultural Considerations— Cultural prescriptions and proscriptions for women and children

Cultural prescriptions are folk beliefs, practices, and values of a group that tell women and children what they should do—what their respective roles should be.

Cultural proscriptions are folk beliefs, practices, and values of a group that tell women and children what they should not do—what is “not” incorporated in their respective roles. When assessing cultural prescriptions and proscriptions, it is

helpful to consider elements such as clothing, exercise, sexual participation, disciplinary efforts, dietary habits, family roles and relationships, verbal and nonverbal communication, cleanliness, illness remedies, and displays of emotion.

In some cultures, women and children do not have the permission, the decision-making power, or the means to access the American health care system. Legal barriers, language differences that restrict access to medical care and lack of diversity in the health care workforce are some of the obstacles that may prevent immigrant minorities from accessing care. In addition to the barrier(s) that culture may place on accessibility of modern health care for women and children, in many situations, health care providers are not available in the areas where culturally bound groups reside. The real or perceived lack of accessibility, affordability, and availability of health care services to growing numbers of individuals leaves the provision of health care delivery to the family, especially in multicultural societies. In these situations, nurses must help family members identify needs, strengths, resources, coping mechanisms, and desired outcomes. The functions of the nurse and family are intertwined and require collaborative planning, delegation, coordination, and provision of care (Goldberg, Hayes, & Huntley, 2004).

COMBINING MODERN TECHNOLOGY WITH THE CARING TOUCH

In settings where modern health care may not be accessible, affordable, and available or is culturally restricted, **complementary and alternative health care/medicine (CAM)** methods often are used. The focus of these low tech-high-touch noninvasive, nonintrusive, nontraditional interventions is the support of the family and child's whole mind, body, energy, environment, and spiritual healing. The nurse approaches this healing methodology from a holistic philosophy of caring, aimed toward a goal of patient-centered autonomy and a patient-defined sense of well-being.

In 1998 an Advanced Practice Nurse (APN) established a “Nurses’ Tool Box” of CAM nursing interventions found to be effective in establishing patient and family autonomy; relieving various illness symptoms, controlling pain, improving immune function, decreasing anxiety and depression, improving circulation, excreting toxins, and enhancing healing (Ward, 2002). CAM interventions range from guided imagery, aromatherapy, imagining, creating art and writing; prayer, chanting, meditation, and channeling; therapeutic touch, stroking, and cuddling; acupressure, tai chi, magnetic forces and massage; music, singing, tonal vibrations, and various water therapies; to storytelling, joking and humor (Helms, 2006) (Fig. 1-7).

It is estimated that Americans spent more than 27 billion dollars on CAM in 2005. This statistic reflects the level of consumer interest and demand for low-tech medical and nursing interventions, and self-directed healing (Lucey, 2006). The nurse must be aware that not all CAM interventions are noninvasive, nonintrusive, or free from side effects and negative consequences. CAM also involves the use of nutritional and herbal supplements, diet adjustments and fasting, chiropractic and body manipulation, and the use of drugs that have not been fully tested for safety and efficacy. Today, much confusion about CAM remains in both the consumer and health provider sectors (Box 1-2).

Collaboration in Caring— Supporting the family that uses CAM

The nurse can provide support to the patient or family that uses CAM by:

- Investigating what they think caused a health event and how they have been able to avoid it in the past
- Encouraging them to seek all approaches of healing that are evidence-based, including both traditional and alternative medicine
- Respecting the participation of a family-chosen folk healer
- Acknowledging the patient’s/family’s religious and spiritual beliefs
- Reflecting on and understanding personal beliefs and recognizing when they may be in conflict with those of the patient
- Avoiding judgment

Figure 1-7 Storytelling, joking, and humor are therapeutic complementary and alternative medicine interventions.

The family-centered nurse has a responsibility to advocate for the patient and family who choose to use CAM; to assess for and educate about the implications, contraindications, and benefits of CAM to the family and patient; and to promote health practices that have been proven safe and effective in restoring well-being, whether via conventional treatments or CAM. The nurse must recognize that health can be achieved through various means, both high-tech and high-touch, and that individual well-being is most optimally accomplished when care is directed by concerns expressed, interventions chosen, and outcomes defined by the patient. It is easy to understand why the nurse–patient relationship and a focus on the patient as a whole being (mind, body, energy, environment, and spirit) are key to the success of CAM healing.

Also key to a healthy outcome when using CAM therapy, as with all nursing interventions, is the responsibility to encourage evidence-based decision making. This method of **evidence-based practice** is built on the premise that interventions need to be questioned, examined, and confirmed or refuted in their ability to support healthy outcomes. The nurse using evidence-based practice searches computer databases and current literature for reports that evaluate the safety, quality, and credibility of particular interventions. These searches produce reports from rigorous research studies, textbook and journal readings, stated expert opinions, and best practices resulting from quality improvement activities. It is the nurse’s responsibility to use the best evidence available and make decisions accordingly, especially when working with practices such as CAM that are viewed by many as mythical, magical, and nontraditional.

Another source of evidence-based guidelines available to the nurse is the standards of care/practice developed by nursing professional organizations such as the American Nurses Association (ANA); Society of Pediatric Nurses (SPN); National Association of Neonatal Nurses (NANN); National Association of Pediatric Nurse Associates and Practitioners (NAPNAP) and Association of Women’s Health, Obstetric, and Neonatal Nurses (AWHONN) (ANA, 2008; AWHONN, 2008). These published guidelines promote consistency and quality in nursing care and outcomes. Because of the time it takes to search and retrieve evidence-based knowledge, these guidelines provide the nurse a reliable source of high-quality interventions on which to base practice.

Box 1-2 Confusion about CAM Through the Ages

A HISTORY OF MEDICINE

(Author unknown)

- 2000 B.C. “Here, eat this root.”
- 1000 A.D. “That root is heathen. Say this prayer.”
- 1850 A.D. “That prayer is superstitious. Drink this potion.”
- 1940 A.D. “That potion is snake oil. Swallow this pill.”
- 1985 A.D. “That pill is ineffective. Take this antibiotic.”
- 2000 A.D. “That antibiotic doesn’t work anymore. Here, eat this root.”

 **Now Can You—** Discuss the community health map, aspects of complementary and alternative health healing, and evidence-based practice?

1. Discuss the value of a community health map as a nursing assessment tool?
2. Identify at least five ways that nurses can offer support for the patient/family who uses CAM?
3. Explain what is meant by evidence-based practice?

 **Now Can You—** Describe the role of the nurse as a teacher, collaborator, and provider?

1. Explain how the nurse functions in the role of patient/family teacher?
2. Discuss aspects of therapeutic nurse–patient collaboration?
3. Describe the need for accountability on the part of the nurse as a provider of care?

PROFESSIONAL NURSING ROLES

Ever since Florence Nightingale's time, helping patients and families gain understanding into their health practices has been integral to the profession of nursing (Nightingale, 1859). The role of the nurse as patient and family teacher has been sustained over the years as a foundation of the profession and continues to be reinforced through professional standards of care/practice. The professional nurse teaches the patient and family by helping them gain knowledge and skills about the health risk affecting them, and of behaviors that can assist in accomplishing the health outcome they desire. There is a sharing of knowledge, and through that knowledge a gathering of strength that can be directed toward the health condition.

The nurse, patient, and family combine their strengths, through collaboration, to describe what the health issue is and means in their lives, and what interventions and decisions are possible and preferable. This collaboration results from, and becomes an act of, mutual respect for each other's values, abilities, expectations, and experiences with the health event and life (Rhea, 2000). Collaboration with the patient and family about health education needs pulls the nurse away from the traditional "banking" concept of patient teaching and learning in which facts, skills, and knowledge are offered by the nurse and deposited for storage in the patient's vault (Freire as cited in Sanford, 2000, p. 6).

Collaboration requires two-way dialogue and sharing between the patient and nurse of both personal and health-related problems and solutions. Each participant is an equal possessor of knowledge and shares the power of determining what is to be learned. Each has a desire to learn more from and about the other. Participants become personally engaged and share a deeper level of understanding of each other, the health risk as each perceives it, and the available and chosen interventions to explore in collaboration.

The nurse still holds responsibility as the provider of care to implement the chosen interventions, or to accept accountability for their delivery. Even though family-centered care encourages patient and family involvement in therapy delivery, it is still expected that the nurse will be actively involved and skilled in the provision of health assessment, treatment, care, and follow-up evaluation. The nurse plays a vital role in collaborative care across a range of settings, especially in the follow-up evaluation and ongoing treatment. It is the nurse's task to collaborate with the discharge planner, child's teacher, physician, physical or speech therapist, dietitian, and community services worker to develop with the family the best plan of care for the desired long-range health outcome.

The nursing process is the foundation for the professional role as collaborator and provider of care and guides the nurse in helping the patient and family choose appropriate interventions, and in quantifying and evaluating the chosen outcome goal. By using the NANDA International **Nursing Outcomes Classification (NOC)** and **Nursing Interventions Classification (NIC)**, the nurse is able to evaluate more clearly associations between interventions and outcomes (Johnson et al., 2006). Using these standards also helps nursing students and novice professionals develop the intellectually and technically complex competencies required to link assessment cues accurately with outcomes and interventions (Lunney, 2006).

Nursing interventions are more than the actions nurses take to help patients and families toward their desired outcome. One NIC may entail up to 30 actions or activities the nurse and family selectively choose from in order to individualize the intervention to the specific health condition as it is perceived at that moment (Johnson et al., 2006). The NIC also involves the evidence-based practices and critical thinking processes the nurse undertakes when judging for appropriateness and feasibility of activities chosen to reach resolution of the health problem and achieve desired outcomes.

Nursing interventions must be appropriate for both the selected nursing outcomes and diagnoses. They require comprehensive, preliminary assessment of patient and family strengths and health concerns; acceptability to the patient and family of the chosen interventions; and the nurse's and family's capabilities to fulfill or coordinate with other health care providers, both professional and familial, the chosen health outcomes.

Before nursing interventions are selected, appropriate, feasible, and family-agreed-upon outcomes must be clearly identified. The chosen NOCs help the nurse identify, prioritize, and differentiate the critical from the sometimes exhaustive list of other relevant interventions and actions. Just as nursing interventions are more than the sum of outcome-directed actions, outcomes are more than the ultimate, end goal of the health state. Outcomes are dynamic and demand frequent measurement of the responsiveness of the chosen interventions. Outcomes should be evaluated for continuing meaningfulness, both physiologically and personally; for direction and purpose, whether health restoration, maintenance, promotion or threat prevention; and for consistency with the culturally lived experience of the patient and family.

The Caring Art and Science of Nursing

Just as a family's culture is their centering foundation in times of health and illness, caring is the centering foundation of nursing. "Caring transcends language, customs,

and cultural differences... it is universal” (Watson as cited in Rexroth & Davidhizar, 2003, p. 298). It “defines the characteristics and parameters of practice” (Falk-Rafael, 2005, p. 38). The National League for Nursing Accrediting Commission (NLNAC) supports caring as a vital core value of nursing (NLNAC, 2005). Caring often leads to new outcomes, ways of being, and experiencing life for a patient and family (Watson, 2002).

“Many circumstances in contemporary society have made caring more difficult now than in the past” (Rosalynn Carter as cited in Cluff & Binstock, 2001, p. 15). Advanced technology, the rapid pace of health care, and a focus on the legal ramifications of one’s professional actions have placed great demands on the time and support a nurse can offer a patient and family. Understanding the many dimensions of caring one brings to, and gets from, the patient encounter is essential to the nurse’s ability to recognize the pain, suffering, and vulnerability that patients experience.

THEORIES THAT FRAME CARING AS THE CORE OF NURSING

Florence Nightingale’s model of nursing encouraged a focus on the spiritual, physical/environmental, emotional, mental, and social needs of the patient and is known as a holistic view of the patient (Nightingale, 1859). She described the base of nursing activities as observation, experience, knowledge of sanitation, nutrition, caring, and compassion; and the focus of nursing as the patient rather than the illness (Nightingale, 1859). Nightingale viewed all people as equal in their abilities to attain health. In addition to her emphasis on improving the patient’s environment, she encouraged the use of imagination and retelling of pleasant life events as appropriate healing interventions to help restore the patient to the best possible condition so that natural healing could occur (Nightingale, 1859).

Watson and Leininger are two modern-day theorists known for their inclusion of caring as a core of nursing. The commonalities between these two theorists are especially important in understanding how to incorporate caring as a recognized nursing intervention with a measurable outcome.

In her Theory of Human Caring, **Jean Watson** contends that caring as a nurse demands that attention be given not only to the body but also to the soul and spiritual dimension of the patient and family (Watson, 2005). She defines the soul as the ideal self of an individual, and notes that the individual is constantly striving to achieve that ideal self by creating harmony among the body, mind, and spirit; between the ideal self (referred to as ‘I’) and the current self as living the experience (referred to as “me”) (Watson, 2005). The state of health is related to the congruence between I and me, and the effect that the differences in I and me is having on the body, mind, and spirit (Watson, 2005).

By participating in transpersonal therapeutic relational nurse–patient communication in which each participant gives and gains equally and learns to identify with the other, the nurse and patient demonstrate mutual caring, recognize the other as more than an object, and move the patient toward a desired state (Watson, 2005). This caring by the nurse begins with the feelings elicited and responses demonstrated toward the patient’s condition, allowing or

encouraging the patient to also release feelings and thoughts about the condition and self (Watson, 2005). The focus of the encounters, referred to by Watson as caring occasions, is on “caring, healing and wholeness, rather than on disease, illness and pathology” (Watson, 2005).

The goals of the nurse–patient transpersonal therapeutic relational communication are to find meaning and develop a wholeness in the body–mind–spirit; assist the patient in transcending beyond the current health state toward his or her ideal; give meaning to the patient’s being; and “release some of the disharmony, the blocked energy that interferes with the natural healing processes; thus the nurse helps another through this process to access the healer within, in the fullest sense Nightingale’s view of nursing” (Watson, 2005, p. 89).

Madeleine Leininger also believes that caring is the core value of nursing. “Caring is essential for curing, but curing is not essential for caring” (Leininger as cited in Jeffreys, 2006, p. 37). Her Theory of Transcultural Care Diversity and Universality sees caring and culture as embedded with each other. You cannot have one without the other.

Caring necessitates understanding of the patient’s cultural beliefs, values, methods of providing or showing caring, causes of illness and how it is viewed, and how wellness is achieved. This level of understanding only comes through a trusting relationship. Developing that trusting relationship is an ongoing process. When the nurse takes the time to clarify the patient’s health beliefs and practices, reflect on one’s own health values and actions, and validate through an unprejudiced and unbiased eye (avoiding judgment of what seems logical, sensible, or reasonable), the strengths and weaknesses of each, a caring relationship is established.

Now Can You— Compare and contrast the caring base of nursing as described by Nightingale, Watson, and Leininger?

1. Describe Nightingale’s focus of nursing?
2. List three of Watson’s goals for a caring, therapeutic nurse–patient relational communication?
3. Discuss Leininger’s advice for a nurse who wishes to develop a caring nurse–patient relationship?

ESSENTIAL CHARACTERISTICS OF CARING

Trust, built through an interactional relationship in which the nurse is cognizant of both personal and the patient’s feelings and meaning of the health experience, is an essential characteristic of caring. It can involve such concrete actions as listening and observing for cues as to what the health event means to the patient, and what the patient views as her needs, how they should be met, and what the desired outcome should be. It is the aesthetic engagement, or art of nursing, that is defined as caring (see Fig. 1-4).

Caring provides a sense of empowerment (some believe caring is the opposite of power), capability, inner peace, and self-determination. It requires an understanding of one’s own beliefs, prejudices, and values so that those of the patient can be addressed with respect and dignity (Davis, 2005).

A study of patients in an intensive care unit (Rosenthal as cited in Rexroth & Davidhizar, 2003, p. 301) helped divide caring characteristics into instrumental behaviors of caring and expressive behaviors of caring, or technical and non-technical components. It is important to know that nursing behavior that is considered caring first depends on clinical competence and technical expertise. “Without knowledge, caring is just a matter of good intentions” (Mayeroff as cited in Falk-Rafael, 1998, p. 41). It was found that where the patient perceived himself to be on the health-wellness continuum, or how critically ill, played a big role in the value he placed on the instrumental versus expressive caring behavior of the nurse (Meyeroff as cited in Falk-Rafael, 1998, p. 41) (Fig. 1-8).

Collaboration in Caring— Enhancing family and patient coping

The nurse caring for a patient in an intensive care unit can facilitate coping by:

- Encouraging family presence, interaction, and touching
- Encouraging the family to adhere to home/daily routines as much as possible
- Including the family in the plan of care; offering choices when possible
- Encouraging discussion of family fears and anxieties
- Offering to contact a spiritual leader or healer
- Encouraging the family to place familiar and comforting articles nearby

In a 2005 study on the components of caring as described by patients, expressive behaviors such as smiling, gentleness in touch, praising the patient for her efforts, and making the patient feel important were consistently classified as elements of caring (Davis, 2005). Communication was identified as another essential element. Communication with the patient and family that they mattered to the nurse personally; about the patient’s hopefulness for the future and awareness of a higher source of healing; and with the physician that things were going well or not going well as defined mutually by the patient and caregiver were all recognized as supportive, caring ways of conveying concern, interest and compassion (Cluff & Binstock, 2001).

In addition to instrumental and expressive characteristics of caring, a spiritual component was reported by patients. Spiritual caring, however, did not necessarily equate with attention to one’s religion, rituals, or beliefs. Rather, **spirituality** addressed the meaning of life, including the present as being experienced, the past, and the future. It entailed learning about a patient’s and one’s own perceived weaknesses, vulnerabilities, and mortality, and where the power lies to transcend or accept them (Kelly, 2004). Again, many of the same expressive characteristics were found when describing nurses who addressed spiritual caring (touching, listening, respecting, trusting, and humor). It is important to note that more than 80% of the patients questioned about caring stated they did not expect the nurse to address their spiritual needs, although they would have liked it (Davis, 2005).

Tolstoy said that “the essence of caring is the need to have one’s position grasped.” (Cluff & Binstock, 2001, p. 47) Caring’s “unifying essence, however, is concern for and responsiveness to the needs and worth of the person receiving it...How often do I turn my focus from my performance to the needs of the patient?” (Cluff & Binstock, 2001, p. 1).

Now Can You— Define the essential characteristics of caring?

1. List three nursing actions designed to build trust?
2. Discuss the importance of instrumental, expressive, and spiritual behaviors of caring?
3. Identify three ways that communication is translated into caring behavior?

PROFESSIONAL NURSING ROLES

Provider of Care

As a provider of care, the nurse expertly includes caring behaviors that address all the physical, psychosocial, and spiritual needs of the patient and family. Through careful assessment of all three categories of needs, diagnosis of the patient’s response to the health event, planning of interventions that promote the patient’s strengths and follow-up, and evaluation of the patient’s transition and potential for a new health state, the nurse can accomplish the most effective, efficient, and desirable outcome.

Figure 1-8 Health–illness continuum and the patient’s need for caring behaviors.

One of the major responsibilities of the nurse as a provider of care is to stay current and competent in the operation of technical procedures and monitoring equipment. This professional responsibility requires knowledge of not only how to perform the procedures and operate the equipment, but also an understanding of why the procedure and equipment are necessary.

It means the nurse is not only responsible for safely executing the procedure, but also accountable for recognizing and interpreting the data gathered during the procedure and from the equipment read-outs. This level of responsibility and accountability evolves from an ongoing development of critical, analytical thinking on the part of the nurse.

Critical Thinker

Critical thinking is the “precise, disciplined thinking that promotes accuracy and depth of data collection and seeks to clearly identify the problems, issues, and risks at hand” (Alfaro-LeFevre, 2004, p. 61). Much of what it entails comes from experience, knowledge seeking, practiced hands-on work, and contextual discernment. Much of critical thinking is also built on inner personal skills, including: ability and willingness to self-reflect on values and beliefs, open-mindedness to diverse and unique perspectives, persistence in seeking the most reasonable answer, comfort and confidence with calculated risk-taking, and devotion to listening with a passion for true comprehension and understanding (Alfaro-LaFevre, 2004). The overriding purpose of critical thinking always is to make the best clinical judgment possible.

Now Can You— Describe why critical thinking is key to the successful clinical practice of nursing?

1. Define critical thinking?
2. Name four avenues for developing successful analytical critical thinking?
3. Discuss the personal skills that help build critical thinking analysis?

Effective Communicator

Good listening and communication skills are essential to the nurse, especially when providing care for children and families. Often the nurse receives key information through subtle tones of voice and snippets of dialogue with a child or parent. Listening carefully allows the nurse to evaluate the level of language development of a child and to effectively use words that can be understood. It also offers the nurse an opportunity to view how the family communicates with each member, often delineating the family roles and structure. Listening to communication patterns can clue the nurse to components of the patient’s value system and cultural approaches. For example, some cultures consider it rude to offer an immediate response when asked a question. Silence signifies that the receiver values the question and the person, and is giving it serious consideration. Some cultures communicate through storytelling; “Remember when Aunt Margie was in the hospital and...” The nurse can use this insight to help tailor much of the interactions that will take place during the

health event encounter. Listening to the family communicate can provide insight into the most favorable method of interacting.

The nurse often has the potential to role model for the child, and even the parent, effective ways of verbally expressing ideas, thoughts, and feelings. One way of role modeling appropriate expressive language is by the use of reflective listening and rephrasing. A parent who tells a 3-year-old, “Now be a good boy and stop crying. Big boys don’t cry,” might benefit from the nurse rephrasing the statement for her by saying, “Mommy knows your head hurts, and it’s all right to cry. You did such a good job helping the nurse see how warm your body was.”

Tone and quality of voice sometimes communicate more than the actual words themselves. This is especially true with infants and toddlers. All audible sounds convey meaning, even when the tone is incongruent with the word. Caution should be taken when using a stern tone to express endearments like, “Get over here so I can put some love on you.” The young child is more likely to hear the stern tone of the voice than he or she is to hear the loving words. Touch, eye contact, and body language are also key components of communication the nurse must recognize as having the potential for enhancing or impeding a healthy outcome.

Ethnocultural Considerations— Patterning effective communication styles

Most of us have seen the way an infant responds to the pace of our speech. Talk slowly, and the infant’s body movements become slower to match the pace of the spoken words. Talk very quickly, and the infant becomes very active with her movements. To communicate effectively with various cultures, nurses need to become aware of the pacing of their speech. The pacing of the spoken word for people from the southern United States is often slow and drawn out, commonly called a “Southern drawl,” while the spoken word of the person from New York City is often rapid and clipped, commonly called “rapid-fire chatter.” Responding to a Southerner with rapid-fire answers, or to a New Yorker with slow, drawn out responses, may be perceived as rude. Listening to the speech pattern of the patient can allow the nurse to match that pattern when communicating with her.

Listening, touching, establishing eye contact, patterning, and paying attention to body language are all essential components of effective communication. The vital distinguishing factors of therapeutic communication, however, are that it is purposeful, goal driven, and focused on the outcome. Therapeutic communication should most often start with an introduction of the nurse, by name and role. This helps differentiate the purpose of therapeutic communication from that of social interaction. Maintaining focus of the communication on the outcome desired (i.e., meeting the patient’s needs) helps not only in the nurse’s time management but also in identifying data that is important from that which may be interesting but not necessary for a healthy outcome.

Teacher

The nurse's professional role as a teacher relies heavily on effective therapeutic communication. In order to meet the patient's desired health outcome, in addition to caring and competent nursing care, the patient needs information and education. Teaching what to expect regarding a procedure, surgery, or hospitalization; how to prevent complications, injuries, or illnesses; preparation toward discharge, continuing and self-care efforts; guidance in nutrition, safety and general wellness behaviors; and identification and avoidance of high-risk behaviors are all professional obligations of the nurse (DHHS, 2000). With patient encounters sometimes controlled by the clock, opportunities for effective teaching must be expertly recognized, planned, and executed.

Using multiple communication approaches can facilitate the nurse's health education encounter with the patient and family. Because children are introduced to television, animated computer games, and interactive learning early in their development, simple talking to them may not achieve the effect the nurse desires. Just as health assessment is a key role for the nurse when providing care, so is learning assessment. Finding out the desired educational outcome of the patient, her preferred learning style, and the most effective methods of delivery are fundamental to the nurse's role as a health teacher.

It is especially important to allow additional time for questions and answers. Most have experienced a precocious 3-year-old child's persistent and repeated use of the word "Why?" and the adolescent's ongoing "Yeah, but what if?" The nurse must feel comfortable in permitting the child all the time necessary to have these questions, no matter how seemingly insignificant, answered. Not only does it provide an avenue for teaching and learning, but it also demonstrates to the child and parent that the child is important to the nurse. Taking the time to exhaust all the questions helps establish and enhance therapeutic nurse-patient communication. Keep answers and explanations simple until asked for more elaboration.

Optimizing Outcomes— Identifying patient expected learning outcomes

Best Outcome: The nurse establishes the targeted learning outcome by talking and negotiating with the patient and family about what is most important. For example, an eight-year-old child learning how to control his asthma may be more interested in the mechanics of the use of the inhaler, while a 13-year-old might want to know how long he or she can wait to use his inhaler when he first experiences difficulty breathing (wanting to avoid at all costs the appearance of being different from the other children). Finding out what the child or adult wants to learn increases the success of changed behavior through new knowledge—always the underlying goal of teaching.

Mutually establishing the patient desired learning outcome is important to the success of the teaching encounter. Discussion of outcomes is futile if the patient is not ready to learn. Assessing readiness to learn is critical to the outcome of teaching. If there are basic needs yet unmet, such

as physical hunger, safety or pain; psychological anxiety, fear, or guilt; and spiritual rituals, fears, and traditions, then learning is likely to be less effective. After ensuring that basic needs are met, the nurse can then assess for the patient's readiness to learn while taking into consideration the language development; current level of knowledge and experience with the topic; growth and development stage of life and capabilities; psychomotor, cognitive, and emotional skills; cultural rituals, beliefs, and values; and the learning environment.

In addition to setting mutually understood learning outcomes and assessing the readiness of the learner, there are some other key principles the nurse needs to be cognizant of when performing health teaching. Praise and positive feedback foster feelings of competence and motivation to learn more. The nurse is the ultimate role model for health teaching. Actions are remembered and patterned much more easily and create a more lasting effect than words. It is important to remember that along with the topic that the child, his family and the nurse have chosen, growth and development learning tasks are also underway, so the teaching should be planned as not to overwhelm the child. Topics should be taught in a manner that moves from the simple to the complex, with the recognition that follow-up teaching may need to be delivered in another setting at a later date.

Collaborator

The nurse plays a key role as a collaborator and coordinator of health teaching, especially when it must occur and be reinforced across multiple care settings and with multiple caregivers. Continuity of care involves not only addressing the continuing physical, emotional, and spiritual needs of the patient, but also the learning needs. Planning, implementing, and evaluating a teaching plan should involve members of multiple health disciplines: dietitians, community health nurses, social workers, home health aides, discharge planners, respiratory therapists, criminal justice workers, school teachers, pharmacists, physical therapists, ministers, respite providers, physicians, clinical nurse specialists, nurse practitioners, and family supporters.

In today's managed care health environment where patients are being pushed farther and farther away from the acute care setting, it is unreasonable to expect the patient's learning needs to be assessed, met, and adequately evaluated all during the brief initial nurse-patient encounter. Coordinating and collaborating about the learning needs of the patient with health care providers present during the provision of continuing care beyond the initial encounter are critical to a successful outcome.

Now Can You— Discuss three professional nursing roles that rely heavily on therapeutic communication?

1. Explain why listening skills are important to the nurse's role as provider of care?
2. Discuss five areas of readiness to learn that the nurse must assess before teaching begins?
3. Clarify the professional nursing role of collaborator as it relates to patient teaching and learning?

Advocate

When coordinating care for the patient who is receiving services from multiple providers, the nurse may be called upon to speak on the patient's behalf. As the number of providers increases, the potential for patient confusion and disillusionment also increases. Making certain that the patient's wishes, needs, plans, decisions, resources, and expected outcomes are recognized and guiding the provision of care is a vital role for the nurse. In this role as advocate, the nurse can promote patient- and family-centered care, all the while ensuring that the patient's and family's vision of health and healing remain the ultimate goal.

As an advocate for the patient and family, however, the nurse must take caution to avoid influencing the care from a personal values perspective rather than from that of the patient and family. Self-reflection of one's own values, beliefs, perceptions, and moral standards can help the nurse minimize the imposition of health-related decisions driven by personal values rather than the values of the patient and family. Advocacy should always provide the patient more control, power, and self-determination of the outcome of the health experience (Falk-Rafael, 2005). There should be clear agreement concerning when the patient wants, or needs, the nurse to speak for him or her. A well-established transpersonal relationship can foster this level of understanding and agreement.

Advocating for patients through group organizations (political, social and professional; local, state-wide, national and international) can also have an important impact on health care. Finding solutions to broad-based health problems and disparities among groups of people, such as children, women, and the poor, can be accomplished through nurses' political and social advocacy on their behalf.

The percentage of children living in poverty has remained between 17% and 20% for the past two decades (Forum on Child and Family Statistics [FCFS], 2005). Economic security has been identified as a key indicator of well-being and health (FCFS, 2005). Poverty affects the child and family's ability to access health care, educational opportunities, housing, transportation, health prevention measures, adequate nutrition, and continuity of care (FCFS, 2005).

Impoverished children are at higher risk for a number of health threats including obesity, violence, asthma, lead poisoning, teen pregnancy, and mental disorders (Velsor-Friedrich, 2000). Nurses have the ability, opportunity, and ethical responsibility to advocate for this group of vulnerable individuals. Nurses can use their image, knowledge, and numbers to advocate for change in these and other health disparities that exist between the economically secure and the impoverished.

Collaboration in Caring— Helping impoverished families

The nurse can be instrumental in helping impoverished families by:

- Providing the telephone number/contact information for federal food stamps; reduced-fee community health clinics, dental and mental health programs; Women, Infants and Children Special Supplemental Food

Programs (WIC); State Children's Health Insurance Program (SCHIP); State Medicaid: HeadStart; Lion's Eyeglass Services

- Helping the patient investigate reduced-fee pharmaceutical options
- Connecting the family with Big Brother and Sister programs for family respite

EVIDENCE-BASED PRACTICE

The link between poverty as a risk factor and the health outcomes of obesity, violence, asthma, lead poisoning, teen pregnancy, and mental disorders has been demonstrated through epidemiologic, controlled quantitative, and qualitative studies and nursing research (FCFS, 2005). Nurses and others interested in improving the health of these vulnerable groups have taken research findings and developed **evidence-based practices (EBPs)** that promote, prevent, and protect health behaviors in vulnerable populations.

This scientific literature helps nurses not only stay current in their technical clinical abilities, but also in their choice of the most effective interventions. Professional organizations such as AWHONN, SPN, ANA, NAPNAP, and NANN have developed evidence-based clinical practice guidelines (CPGs) for the safest, most consistent, and effective provision of family-centered nursing care. Not only are these evidence-based practice guidelines beneficial to the individual nurse's practice, but they can also be used by the nurse to advocate for change in the ritualistic, unverified, rules-oriented, and opinion laced traditions (i.e., accustomed practice) of institutional nursing. With an ever-increasing level of patient knowledge and health-seeking sophistication, the demand for higher level nursing knowledge quickly becomes evident (Catalano, 2006).

Evidence-based guidelines are available for a number of interventions including newborn bathing, use of adhesives on premature newborns, positioning and snuggling of premature newborns, childhood asthma management, HIV/AIDS treatment, childhood cancer treatments, hypertension management, pregnancy weight gain, play therapy, and family-centered care (National Guideline Clearinghouse, 2006). The nurse must be diligent in seeking out these evidence-based guidelines so that excellence in practice can always be achieved, measured, and held up for scrutiny. However, as one nurse researcher (Schultz, 2005) cautions, nurses must be careful to remember that evidence-based practice is not "best practice" until it combines the investigational guidelines and scientifically sound interventions with clinical expertise and the patient's values and preferences.

Accessing a wide variety of evidence-based information is important when evaluating the quality of data to be used in one's nursing practice (Box 1-3). Examples of three sources of peer-reviewed, critically evaluated research summaries and reports available to the nurse for use in assessing research studies are The Cochrane Database of Systematic Reviews Library, the Agency for Healthcare Research and Quality (AHRQ), and MEDLINE.

Questioning nursing practice, collecting relevant evidence to support or change practice, and evaluating the best data for the desired patient outcome help provide the best care. As more responsibility and accountability for practice and patient outcome are shifted to the

Box 1-3 Evaluating Evidence-Based Data

- Ensure data have been reviewed by at least two or three experts in an area when using information from a journal or Web site.
- Check the author's and publisher's credentials.
- Evaluate for prejudice, bias, or vested interest of author.
- Check timeliness of data.
- Check for balance between explanatory graphs and text.
- Ensure consistency across populations, settings, and time.

Source: Catalano, J.T. (2006). *Nursing now: Today's issues, tomorrow's trends* (4th ed., pp 547-550). Philadelphia: F.A. Davis.

individual nurse, the role of the nurse will continue to change. Advancing nurses' accountability for the quality of care provided also advances autonomy of practice.

The advanced practice nurse (APN) enjoys the highest level of autonomy because of additional education, occasionally through certification but most often through a master's level of post-secondary education. There are various advanced practice nursing roles, including certified nurse midwife (CNM), family nurse practitioner (FNP), clinical nurse specialist (CNS), pediatric nurse practitioner (PNP), and certified nurse anesthetist (CRNA).

Across Care Settings: Practice possibilities for advanced practice nursing

The Advanced Practice Nurse can practice in all types of health care settings: nurse-owned and -run clinics, nursing homes, rehabilitation centers, hospitals, physician offices, sports health centers, surgical centers, student health centers, birthing centers, private outpatient practice, community health centers, primary and secondary schools, research centers, private consultation, academia, military fields, and state and federal legislature.

APNs make independent clinical judgments and provide primary care to individuals and groups of patients. Of the 2,909,467 licensed registered nurses living and working in 2004 in the United States, 4.8% were prepared to practice as nurse practitioners (NPs), 2.5% as clinical nurse specialists, 1.1% as nurse anesthetists, 0.5% as nurse midwives, and fewer than 0.5% as neonatal nurse practitioners (NNPs) (Health Resources and Services Administration, 2004).

The University of Pennsylvania conducted a 1-year study (Kennedy, 2004) to evaluate the effect of APN versus traditional hospital-based care on death, re-hospitalization, complications, and cost for elderly patients with congestive heart failure health problems. There was a 13.7% lower death and re-hospitalization rate, an average of 110 days longer period of time without complications, and a savings of \$4,845.00 for patients cared for by APNs. Although not statistically linked, it was hypothesized that the difference resulted from the holistic mind-body-soul perspective taken by the APNs in their approach to patient care; the more patient-friendly atmosphere of a primary, non-acute care setting; and a focus on health prevention, promotion, and protection.

Now Can You—Discuss evidence-based practice and contrast the focus of the advanced practice nurse with that of the professional registered nurse?

1. Describe the difference(s) between "best practice" and "evidence-based practice"?
2. Explain six key elements to look for when evaluating the quality of evidence-based data found in journals or on Web sites?
3. Compare and contrast the licensed Registered Nurse and the Advanced Practice Nurse's role and preparation?

THE NURSING PROCESS

Evidence-based practice constantly questions the status quo and focuses on the outcome rather than the process of treatment. It helps to take the nursing process to the next level, from treating illness to predicting and preventing health problems, complications, and risks (Alfaro-LeFevre, 2004). A nurse using the traditional nursing process of assess, diagnose, plan, implement, and evaluate most likely uses some form of a body systems approach to data collection, focused primarily on medical systems health problems. A nurse practicing from an evidence-based focus assesses for health risk factors; patient and family strengths and self-worth; learning needs; family role and relationship patterns; values, cultural beliefs and spiritual health; and patient perception of or response to the risk or problem, in addition to the medical body systems assessment (Alfaro-LaFevre, 2004).

The evidence-based nurse diagnoses not only health problems but is also able to predict potential problems based on knowledge of prior research. That evidence-based knowledge includes awareness of signs, symptoms, and related health factors of potential problems as well as a grounded understanding of their etiology. The use of a concept map, clinical pathway, or care map can aid the nurse in this awareness of relationships. The maps also help in prioritizing diagnoses.

The concept map is a five-step process, just as the traditional nursing process is. It is built on the nursing process and is especially helpful in the analysis of relationships of data to the health problem and the development of critical thinking.

Although there are different ways to create a concept map, a format that is often used parallels the steps in the traditional nursing process. First, assessment data is gathered. In Step 2 of the map, the nurse analyses the data to determine the patient's key medical and nursing problems. The medical diagnosis occupies the center of the map. The nursing diagnoses are those problems or responses the medical diagnosis has caused for the patient.

When creating a concept map, one begins by drawing a skeleton diagram with the medical diagnosis placed in the center and the nursing diagnoses, patient responses, or general impressions of health threats surrounding the medical diagnosis (Fig. 1-9). At this point in the map development, potential problems are yet to be addressed. The initial focus is on problems that are currently major issues in maintaining wellness.

Figure 1-9 Concept map construction begins with gathering and analyzing assessment data.

After the initial diagram is constructed, depicting what is believed to be the key problems, it is then time to investigate the medical diagnosis and gain knowledge of the treatment options. A review of assessment and evidence-based information on the following patient areas guide the nurse in the next step of the map:

- Growth and development tasks
- Past medical history
- Current laboratory values
- Medication taken and likely to be ordered
- Allergies
- Pain rating
- Diet and fluid intake, needs, and preferences
- Recent elimination patterns
- Usual activity rituals and current limitations

Step 2 in developing the concept map is to categorize the assessment data gathered under one or more of the identified patient problem areas (Fig. 1-10). Then the nurse describes the essential ongoing assessment data that

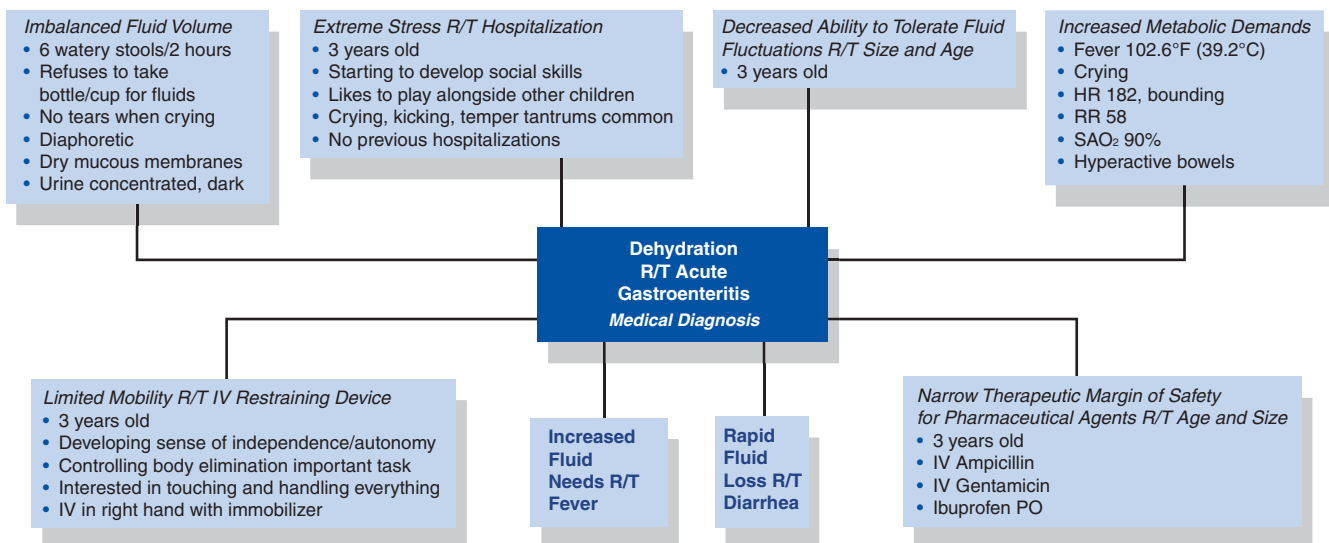

Figure 1-10 Categorizing the assessment data.

signifies improvement or deterioration in the health status of the primary medical diagnosis (Fig. 1-11). Step 3 of the map involves analyzing the relationships among, and prioritizing the patient responses that led to the nursing diagnoses. The problem or diagnosis with the most supporting data is usually the most important (Fig. 1-12).

Step 4 of the concept map requires the nurse, along with the patient and family, to develop the beneficial goals and outcomes they hope to attain. This step corresponds to the planning phase of the nursing process. The outcomes are what drive the selection of interventions to be initiated by the nurse, patient, and family and other caregivers. They should describe the assessment data that determines if there has been successful progress toward achieving them. The outcomes should address clinical health (the medical diagnosis, signs and symptoms), functional health (mind–spirit–emotions), quality of life (as defined by the patient), health risk reduction, health protection, health promotion, therapeutic relationships and personal satisfaction (Alfaro-LeFevre, 2004). “Simply put, determining expected outcomes requires you to reverse the problem (state what happens when the person doesn’t have the problem)” (Alfaro-LeFevre, 2004, p. 173).

Whether the nurse uses Maslow’s hierarchy of needs or a professional theorist to determine the priority status of outcomes and interventions, it is important to recognize that the context or circumstances in which the health problem is occurring plays a key role in the prioritization and implementation. When the above mentioned steps are completed, it becomes much easier to choose interventions that are achievable within the time and environmental constraints of the health event; build upon the strengths of the patient and family; and increase the likelihood that they will be carried out by all those providing care.

Step 5 of the map is the evaluation of the patient’s response to the health event, interventions, and progress toward the outcome goals. Evaluation is not a one-time nursing responsibility, but an ongoing process. The nurse is looking for a pattern of patient responses to the health event that should guide ongoing reassessment, planning,

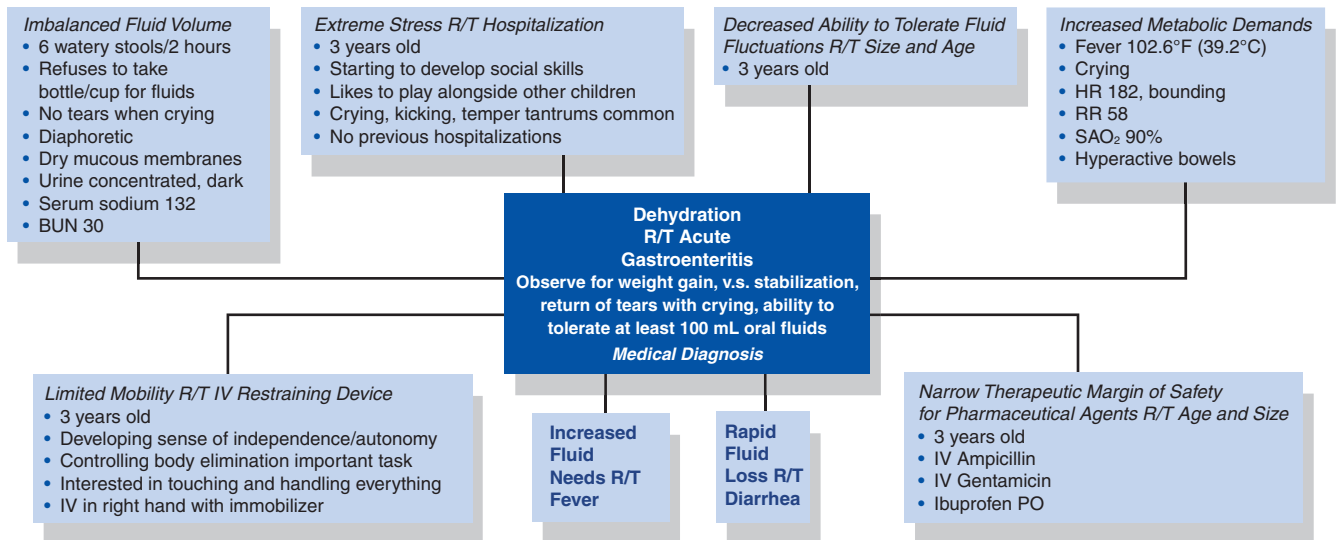

Figure 1-11 Identifying essential assessment data to evaluate the health status.

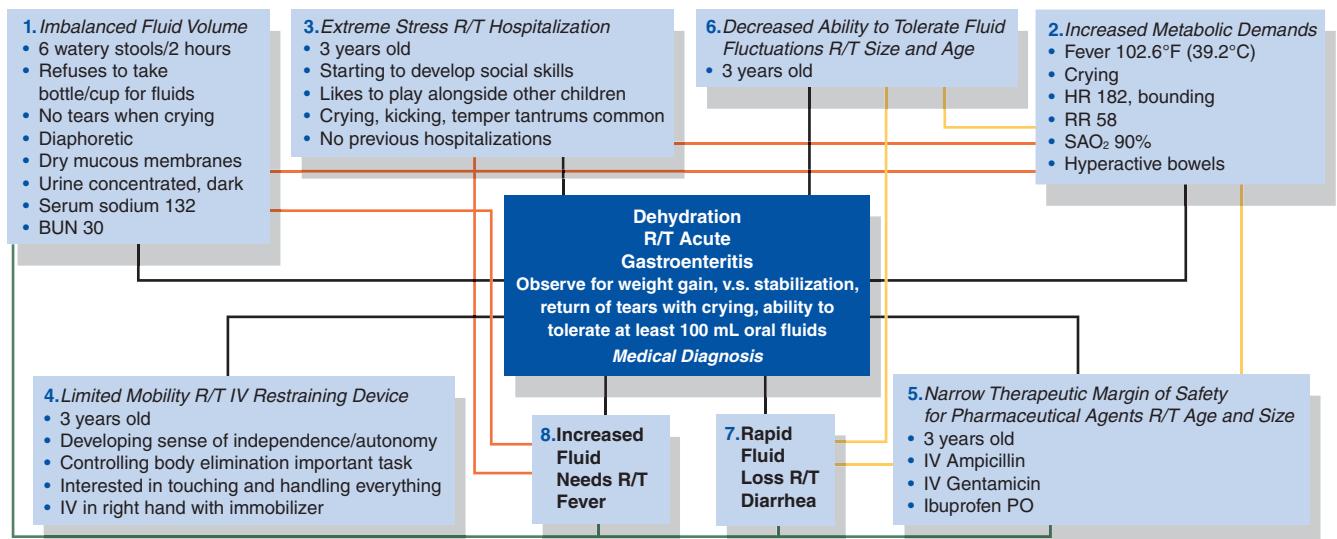

Figure 1-12 Analyzing relationships and prioritizing patient responses.

and provision of safe and effective care. Concept mapping helps the nurse develop disciplined, critical thinking that promotes accuracy, depth of data collection, early identification of risks, realistic goals, and a broader understanding of patient health problems (Alfaro-LeFevre, 2004).

- Consulting with the case manager when evaluating the concept map outcomes
- Investigating evidence-based practice from all health care disciplines (i.e., medicine, nursing, pharmacology, respiratory therapy, primary school education, criminal justice, and social sciences)

Collaboration in Caring— Promoting optimal care for the family

- The nurse can manage the care of the family best by:
- Establishing therapeutic communication with the patient and family
 - Developing relationship-centered, patient-focused encounters
 - Discussing the concept map with other caregivers
 - Designating discharge planning needs and personnel in the concept map

summary points

- ◆ Contemporary family and child health care nursing has shifted to a framework that emphasizes health promotion, protection, prevention, maintenance, and caring.
- ◆ Modern family-centered nursing applies a circular or spiral process that builds a nurse–patient–family connectedness by mutually identifying health threats, potentials, and meaningfulness for the family.

- ◆ Nursing aesthetics is the low-tech, high-touch component of providing health care, and the centering, caring foundation of nursing.
- ◆ The use of a community health map can help the nurse assess the family's support systems, strengths, and coping mechanisms.
- ◆ Today, health care may be provided in the acute care hospital, tertiary research center, free standing short stay unit, community health center, school, nurse-managed center, and private home. Different settings require increased independence, accountability, and expertise from the nurse.
- ◆ The essence of family-centered care is the placement of family relationships, coping mechanisms, values, priorities, and perceptions at the center of the health event.
- ◆ A holistic view of the patient and family includes the spiritual, physical, emotional, mental, social, and cultural indicators of patient health.
- ◆ Concept mapping helps the nurse develop critical thinking that promotes accuracy, depth of data collection, early identification of risks, realistic patient centered goals, and a broader understanding of patient health problems.
- ◆ When coordinating care for the patient and family who are receiving services from multiple providers, the nurse must advocate for the patient's wishes, needs, plans, decisions, resources and expected outcomes, and ensure that they are recognized and are the guiding force in the provision of care.

review questions

Multiple Choice

1. The new nurse explains to the clinic nurse that the nursing process currently being taught has an emphasis on:
 - A. Health promotion
 - B. Disease and illness
 - C. Linear progression of the illness
 - D. Assessment for signs and symptoms of disease
2. As a vital part of family-centered care, the clinic nurse works with the patient and family to discover what the health issue is and what interventions are preferable in a process of:
 - A. Collaboration
 - B. Assessment
 - C. Development
 - D. Knowledge

Fill-in-the-Blank

3. The clinic nurse collaborates with other multidisciplinary members to provide care to a 60-year-old woman with uterine cancer who is anticipating a hysterectomy. The patient's care includes _____ and _____ needs as well as _____ needs.
4. The clinic nurse knows that the patient's _____ and preferences as well as the nurse's clinical expertise combined with the use of national guidelines is described as _____ practice.

5. The clinic nurse demonstrates for the new nurse strategies that are helpful to children in a crisis. The nurse maintains _____ eye contact, stays _____ on the children and _____ shares their experiences.
6. The clinic nurse understands that increased _____ has led to many patients and families having an increased focus on health _____ and _____.
7. The clinic nurse demonstrates elements of spiritual caring by learning about a patient's _____ or _____.

True or False

8. The nurse who is able to share the patient's perception of a health threat, and support the patient's changes in order to cope and understand their outcomes is part of a process of engaging transpersonal care.
9. The nurse collaborates with a family on outcomes that are realistic and culturally appropriate prior to the development of any interventions.
10. The clinic nurse defines critical thinking as promotion of an accurate and strong data collection that clearly identifies problems, issues and risks for a patient.

CONCEPT MAP

- Now Can You:**
- Identify a major force that accounts for the present-day shift toward family-centered decision making in health matters
 - Define present-day trends in nursing focus related to the health-wellness continuum
 - Discuss a nursing approach that incorporates engaging transpersonal care
 - Explain what is meant by evidence-based practice
 - Identify how the nursing process has changed the professional role of the nurse
 - Identify the essential characteristics of caring

Contemporary Issues in Women's, Families', and Children's Health Care

In these days of investigation and statistics, where results are described with microscopic exactness and tabulated with mathematical accuracy, we seem to think figures will do instead of facts, and calculation instead of action. We remember the policeman who watched his burglar enter the house, and waited to make quite sure whether he was going to commit robbery with violence or without, before interfering with his operations. So as we read such an account as this we seem to be watching, not robbery, but murder going on, and to be waiting for the rates of mortality to go up before we interfere; we wait to see how many of the children playing round the houses shall be stricken down. We wait to see whether the filth will really trickle into the well, and whether the foul water really will poison the family, and how many will die of it. And then, when enough have died, we think it time to spend some money and some trouble to stop the murders going further, and we enter the results of our "masterly inactivity" neatly in tables; but we do not analyse and tabulate the saddened lives of those who remain, and the desolate homes in our "sanitary districts."

—Florence Nightingale, writing on rural hygiene

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Describe a multilevel approach for prevention and intervention in addressing contemporary health care issues.
- ◆ Discuss the major purpose and goals of *Healthy People 2010* and their relevance to nurses.
- ◆ Explain social, political, economic, and cultural trends that affect the health status of women, children, and families.
- ◆ Compare morbidity and mortality statistics between different populations and age groups of women, children, and families.
- ◆ Evaluate current gaps in health care delivery systems that impact women's, children's, and families' health.
- ◆ Discuss examples of major barriers to accessing health care in the United States.
- ◆ Apply four bioethics principles to analyze ethical issues in maternal–child and family health.
- ◆ Describe trends in integrative health care as it is used with women, children, and families.
- ◆ Identify examples of public policies and programs that have benefited childbearing families.
- ◆ Describe vulnerable populations in the United States and the nurse's role in advocating for neglected and stigmatized persons.
- ◆ Discuss some potential concerns that a nurse of the future might face and what skills will be needed.

moving toward evidence-based practice Reducing Health Disparity

Shoultz, J., Fongwa, M., Tanner, B., Noone, J., & Phillion, N. (2005). Reducing health disparities by improving quality of care: Lessons learned from culturally diverse women. *Journal of Nursing Care Quality, 21*(1), 86–92.

The purpose of this study was to view culturally diverse women's perspectives on health care services as a framework for improving the quality of health care using Fongwa's Quality of Care Model. The study design was based on an analysis of existing data from 15 focus groups that consisted of participants from 5 different cultural subgroups. Findings from three previous studies completed by the researchers were applied to Fongwa's Model. The model was selected for its usefulness in identifying ways to improve the health care system and enhance quality of care from the perspective of diverse cultures. The original studies were conducted to gain women's perspectives on alcohol and drug use, smoking cessation, and domestic violence. Themes that emerged from these studies were reflective of the women's perceptions of the care they received. The findings led the researchers to reframe their focus for the improvement of health care by exploring three common aspects: patient/client/consumer, provider, and setting.

From the patient/client/consumer perspective, women identified that they wanted to include their partners in health promotion activities. They also requested that education on domestic violence be integrated into a variety of community activities. The participants believed that this approach would allow them to access the information without fear that the perpetrator of violence would be suspicious of their activities. The women further stated that they preferred a female provider of their own ethnicity or one who understood their values and

beliefs. They felt it would be easier to discuss difficult topics with such a provider.

The study participants reported that their providers frequently appeared rushed and overly busy, which was perceived as a barrier to receiving quality care. They believed that in order to develop a trusting professional relationship, it was important for the provider to take time and listen, remain nonjudgmental, and ensure confidentiality. They felt that any care given should be modified to fit the specific needs of the individual.

The women preferred that the clinical environment include brochures and flyers written in appropriate languages. In their view, these actions would help to create an environment responsive to the participants' needs, and supportive of their making changes to improve health.

The researchers concluded that encouraging women's input, listening to their needs and modifying the system based on their suggestions would encourage the women to recognize their power in improving their own health and the health care system in general.

1. Based on the study do you believe that sufficient evidence exists to generalize these findings to all culturally diverse populations?

2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

This chapter examines contemporary trends in women's, children's, and families' health care from a holistic, action-oriented perspective. Emphasis is on the professional nurse's role as change agent using the intervention wheel model and *Healthy People 2010* as guides for improvement. Biostatistical data are used to assess the current status of women, children, and family health, highlighting health inequities, vulnerable populations, and gaps in health care access and delivery. Societal trends and issues are examined from political, social, economic, and cultural perspectives, illustrating how these important dimensions become determinants of health. An overview of legal, ethical, and social justice is presented, with the nurse as a key player in transforming and maintaining a more effective health care system in the future.

Framework: The Public Health Intervention Model

Nurses have always been tenacious in their responsiveness to the rapidly changing health and societal landscape, and are well situated to address contemporary family

health issues. This is an era of unprecedented change in health care. Some of these fast-paced trends include rapid technological advances, escalating health care costs, managed care, demands for increased accountability for public agencies, and terrorism threats. Modern nurses maintain a readiness to address new and resurfacing health-related issues, illnesses, or disaster management responsibilities. Nurses frequently serve as catalysts to help coordinate societal, community, and individual efforts to help achieve health and wellness goals.

It is useful to have a framework when thinking critically about the complex topics encountered in family health. The Intervention Wheel, formerly known as Minnesota's "public health intervention model," is particularly well suited for examining health issues with an action-oriented, holistic lens. The lens used to view the intervention model is population-based, meaning that epidemiology of the population's health status as a whole is assessed (Keller, Strohschein, Schaffer, & Lia-Hoagberg, 2004b) (Fig. 2-1).

The model is an inclusive framework and was developed, refined, and extensively critiqued by more than 200 nurses throughout the country (Keller et al., 2004a). It encompasses three levels at which interventions can be initiated, from the micro-level of the individual to the

Figure 2-1 The Public Health Intervention Model.

macro-level environment. Interventions are targeted toward individuals/families, communities, and larger institutional and societal systems. Thus, broad determinants of health such as environment, employment, insurance, class, race, social support, access to health services, genetic endowment, and personal histories can be integrated, making health care interventions more comprehensive and effective.

In short, the public health intervention model is population-based, defines levels of practice, and has a comprehensive prevention focus. There are 17 categories of intervention tactics outlined in the model: social marketing, advocacy, policy development, surveillance, disease investigation, outreach, screening, case finding, referral, case management, delegated functions, health teaching, counseling, consultation, collaboration, coalition building, and community organizing (Keller et al., 2004b).

HOW THE INTERVENTION WHEEL WORKS

The issue of childhood obesity provides a good example for demonstrating how the Minnesota public health intervention model can be used to confront a contemporary health problem. Approaches that are currently being used to address the problem of childhood obesity range from those at the micro-level to the macro-level spheres of practice.

Childhood obesity has traditionally been framed as an issue of personal or parental responsibility. Viewing childhood obesity as merely a personal responsibility excuses society's responsibility and limits shared solutions. Nurses need to broaden their scope to examine health processes more globally. For example, nurses need to ensure that social, political, and structural conditions are addressed so that it is possible for people to achieve health.

There are many interesting and promising strategies for addressing childhood obesity. Some urban areas are proactively collaborating to redesign their communities. One

intervention is to build community sidewalks, establishing a more inviting environment for children to bicycle or walk to school. Communities have formed coalitions that advocate for neighborhood safety, so that walking, biking, and running can be safe. Some have looked at the strategic geographical proximity of fast food restaurants to schools, and have brought those observations to public consciousness. Fast food restaurants are clustered three to four times more often within walking distances of schools (Austin et al., 2005). This deliberate geographical placement exposes America's children to poor quality food that is frequently inadequate for health promotion.

Other strategies are targeted at schools, such as altering choices in school vending machines and cafeterias to include healthy alternatives to junk food. Some schools have already done so on their own. Others are advocating interventions at the state and federal levels, such as bringing back physical education courses in schools where they have been eliminated.

Currently, only 8% of U.S. public schools require daily physical education. Some schools collaborate with community health programs and screen for body mass index (BMI) and refer overweight children for early intervention and follow-up. Several schools have implemented the *Planet Health* program, developed by The Harvard School of Public Health. The *Planet Health* curriculum is intertwined with existing lessons already being taught in middle schools, such as science, math, and English. Students who participated in the pilot *Planet Health* interdisciplinary studies increased their fruit and vegetable intake, decreased their television viewing time, and lowered their BMI (Gortmaker et al., 1999).

Television presents another avenue for targeting obesity in children. Television is used more as an electronic babysitter than ever before. According to a 2006 Kaiser Foundation study, children younger than 6 years of age average 2 hours of media viewing per day (Kunkel et al., 2004). It is "used by parents to help manage busy schedules, keep the peace, and facilitate family routines such as eating, relaxing, and falling asleep" (Rideout & Hamel, 2006). Television viewing contributes to childhood obesity because it fosters physical inactivity as well as exposes children to a bombardment of junk food advertising (Fig. 2-2).

The American Psychological Association has a task force that researches television advertising that is specifically aimed at children. The task force has learned that children younger than the age of 8 do not yet have the experience and knowledge to critically evaluate advertising messages, and they tend to accept advertising as factual. American children view an average of 40,000 television ads per year (Kunkel, 2001). Many messages are aimed at marketing unhealthy foods to children, and are aired strategically at times when children are most likely to watch. One study demonstrated an average of 11 food commercials per hour during children's Saturday morning cartoons (Kunkel, 2001). Therefore, an average child is exposed to approximately one food commercial every five minutes. Advertising strategies for snacks, sugared cereals, soft drinks, and fast food contribute to the epidemic of childhood obesity, and the task force is urging policymakers to better protect young children from this exposure (Kunkel et al., 2004).

Figure 2-2 Typical American child fixed on the television set while snacking on popcorn.

There are initiatives at the federal level to address the childhood obesity problem as well. For example, the U.S. Food and Drug Administration (FDA) recommends strengthening food labeling in grocery stores as well as in restaurants. In some cases, consultation with restaurants is resulting in healthier portion sizes and the offering of lower fat options. The Centers for Disease Control (CDC) is using a multicultural social marketing technique to spread the word nationally about exercise benefits to children.

The public health intervention model gives an integrated view because it includes both the local and the more global system realms. The use of this model guides health professionals toward enhancing the capacity of all segments of society to move toward health and wellness. For nurses, it is becoming increasingly clear that the traditional approach to “caring” must be broadened beyond the individual patient, and instead become oriented toward the public’s health in order to effect real change in health outcomes. Intervention programs must be multitiered and oriented toward the broader social context because this is where most patients are located.

Now Can You— Discuss the public health intervention model?

1. Describe the three levels of intervention in the public health intervention model?
2. Apply the intervention model to the health problem of childhood obesity?
3. Discuss why the public health intervention model provides an integrated view of health and wellness?

Healthy People 2010: A Blueprint for Action

Healthy People 2010 is the guide that defines health priorities for the United States. It is the nation’s compass that points to specific focus areas that will guide progress toward the ultimate goal of optimal health for all Americans. The *Healthy People 2010* blueprint for action is coordinated by the Office of Disease Prevention and Health Promotion in the U.S. Department of Health and

Human Services. Prominent health scientists, both inside and outside of government, use population-based studies to create this blueprint for national health goals which are renegotiated every decade. *Healthy People 2010* can be accessed at www.healthypeople.gov.

Healthy People 2010 includes two overarching health outcome goals that overlie all others:

- To increase the quality and years of healthy life
- To eliminate health disparities within America’s population

The *Healthy People 2010* document contains a comprehensive set of 467 measurable disease prevention and health promotion objectives for the nation to achieve over the first decade of this century. There are 28 focus areas. Leading health indicators include several prevention factors such as physical activity, control of overweight and obesity, abstention from tobacco use and substance abuse, and responsible sexual behavior. Other leading indicators include mental health, prevention of injury and violence, environmental quality, immunization, and access to health care.

Ideally, the best method to address health priorities is through the early prevention of health problems. There are three levels of prevention. The most desirable level is **primary prevention**, which encompasses health promotion as well as activities specifically meant to prevent disease from occurring. **Secondary prevention** refers to early identification and prompt treatment of a health problem before it has an opportunity to spread or become more serious. Finally, **tertiary prevention** is intended to restore health to the highest functioning state possible. These three levels of prevention may be applied to a child’s day care setting. Primary prevention would involve teaching children and workers proper hand hygiene to prevent illness. Secondary prevention would encompass screening and isolating children who develop signs and symptoms of infection to prevent its spread. Tertiary prevention would involve strategies such as keeping the child at home, administering fluids, encouraging rest, and administering antibiotics if indicated, until the child is once again restored to health. This focus on prevention has the potential to make an enormous difference in family health status.

Current health indicators demonstrate that Americans today are healthier than they have ever been, with a steady upward trend to an average life expectancy of 77.3 years. Dreaded diseases that struck terror in families 100 years ago such as plague, polio, tetanus, and whooping cough (pertussis) are under control even though new health problems continually threaten to surface. Although heart disease remains the leading cause of death in the United States, rates have plummeted in recent years, most likely due to the present emphasis on healthy lifestyles and the availability of cholesterol-lowering medications.

However, there is no room for complacency regarding the present state of the nation’s health. Despite some positive trends, the United States lags behind other industrialized countries. The World Health Organization ranks the United States as 37th in health system status, even though health spending per capita in the United States exceeds that of all other countries. Remarkably, health spending consumes one-seventh of the United States’ gross national budget.

Despite large health care expenditures, health care and other resources are unevenly distributed in the United States. Persistent health disparities remain disturbing. An African American baby, for example, is more than twice as likely to be low birth weight and two and one-half times more likely to die during the first year of life than a European American baby. Sudden infant death syndrome (SIDS) is more than three times higher in American Indian and Alaska native babies than in European American babies. Additional information about health disparities can be accessed at the Centers for Disease Control's Web site, <http://www.cdc.gov/>.

 **Now Can You—** Relate the value of having national *Healthy People 2010* goals to align health care improvement efforts?

1. Discuss the two overarching goals of *Healthy People 2010*?
2. Define the three levels of prevention and give an example of each?
3. Describe prevention measures that have made a difference in reducing heart disease, the leading cause of death in the United States?

Overview of Selected Societal Trends

What is meant by the term “health”? Is health merely the absence of illness? If nurses are to effect improvements in national health status, a more comprehensive definition of health is needed. A holistic definition would include more than the physical body and instead extend into the interconnected mental, social, and spiritual realms. Health would encompass energy levels, balance, and resiliency. The World Health Organization defines health as a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity. Purnell and Paulanka (2003) expand this definition by describing health as a state of wellness that includes physical, mental, and spiritual states and is defined by individuals within their ethnocultural group.

Health as a concept may be self-defined, but to examine a population's health, one is limited to using health status indicators that can be directly measured. The health of a nation is measured by collecting statistical data and making inferences. **Epidemiology** is the statistical analysis of the distribution and determinants of disease in populations over time. **Mortality** (death) and **morbidity** (illness) rates are examined for trends. For example, epidemiological studies of heart disease reveal how many people develop heart disease, what type of heart disease they have, and what factors are associated with heart disease, such as smoking, obesity, diet, hyperlipidemia, working hazards, family dynamics, and other environmental factors. Mortality rates provide information about where nursing efforts should be focused. Morbidity rates identify populations where the illness occurs most frequently.

There have been many achievements that translate to measurable improvements in health status indicators. Yet the nation still has a long way to go. According to the United Nations 2006 Human Development Index, the United States ranks 38th in the world in life expectancy,

lagging behind countries with half the national income per capita and with a fraction of the expenditure on medical care. Certain national health problems, including acquired human immunodeficiency virus (AIDS), drug abuse, family violence, and homelessness continue to signal special cause for concern. More than 3 million people will experience homelessness in a given year and families with children comprise 33% of the homeless population. In addition, more than 38 million individuals living in the United States have experienced what has been termed “food insecurity” (Los Angeles Homeless Services Coalition [LAHSC], 2007).

To understand better the myriad of issues that impact the nation's health, it is helpful to consider some of the major trends that exert an influence on health status. These include the aging population, ethnic diversity, health care disparities, childbirth trends, and patterns of physical fitness.

 **Now Can You—** Discuss why analysis of statistical health data in the United States is useful?

1. Define the term epidemiology and describe how analysis of epidemiological data may guide public health interventions?
2. Discuss why mortality/morbidity biostatistics about disease and illness are useful?
3. Describe three health problems in the United States today that are of particular concern?

AGING POPULATION WITH MORE CHRONIC ILLNESSES

The population of persons ages 65 and older (one in eight in the United States) is growing steadily. This trend is attributed to the present increase in life expectancy and is expected to continue as the baby boom generation ages. It is predicted that by 2030, one in five persons will be elderly (U.S. Census Bureau, 2006). With the increased length of life comes more chronic illnesses, such as strokes, diabetes, arthritis, and Alzheimer's disease. Management of chronic illnesses presents a major challenge to health care systems that is expected to continue well into the years ahead.

INCREASED RACIAL AND ETHNIC DIVERSITY

The composition of the U.S. population is rapidly changing, and racial and ethnic diversity (difference) is greater than ever before. The historically designated U.S. minority populations can be classified as Hispanic, Black/African American, Asian, and Native American. The percentage of minority populations increased from 16% in 1970, to 27% in 2006, and it is projected to rise to 50% of the population by 2050, if current trends continue. As the population becomes more diverse, delivering culturally competent care becomes crucial for nurses. The delivery of health care within a culturally appropriate framework will help patients to feel better satisfied with their care and empower nurses to contribute more actively to the healing process.

Everyone, regardless of his or her professional status, is interested in the concept of racial and ethnic diversity. However, a most important point to remember is that

racial and ethnic categories (Hispanic, Black/African American, Asian, European American, and Native American) are constructed by social systems (i.e., people) and their differences are based on visible physical characteristics. In scientific terms, these differences are phenotypic genetic expressions. There is no known biological basis for what society calls “race.” Scientists have noted that there is more diversity within each of these artificial categories than there is between them. Migration, intermarriage, and genetic modifications have served to form one race, the human race. Despite the fact that “race” cannot be supported by scientists as a biological concept, as a social concept (i.e., how persons see one other and label one other) it is still very real.

DISPARITIES IN HEALTH CARE

Health disparities can be viewed as the extra burden carried by certain racial, ethnic, gender, and age groups for different health problems. Statistics indicate that the risk of death for women of color, for example, is nearly four times higher than it is for white women. More than half of 45- to 64-year-old African American women have hypertension, an incidence that is twice the rate for European Americans. Although Hispanic and African American women have a lower incidence of breast cancer than European Americans, they experience greater mortality from this disease. For reasons that include gender bias and difficulty establishing a correct diagnosis, a woman who presents to the hospital with symptoms of a heart problem is less likely than a man to receive a heart catheterization or to be given certain heart medications. The same scenario applies to Hispanics and African Americans of both genders.

Access to health care is disproportionate among different population groups. The status of one’s health insurance remains the greatest factor that determines access. Insurance status is also the largest predictor of the quality of the health care that one receives. Yet insurance status alone cannot explain racial and ethnic disparities. Disparities exist even when clinical factors, such as comorbidities, age, stage of disease presentation, and severity of disease, are taken into account (Issacs & Schroeder, 2004).

Many other factors, such as the role of discrimination and stereotyping in health care settings, must also be considered when health disparities are analyzed. Nurses have long considered themselves to be “caring professionals.” However, nurses are not immune from societal beliefs and values that result in discrimination and stereotyping of different populations. Nurses must continually remain vigilant for signs of these attitudes in themselves, and in turn, develop an awareness of how they influence their nursing practice. To heighten awareness of these issues, the Institute of Medicine published *Unequal Treatment: Confronting Racial and Ethnic Disparities in Health Care* in 2002. This compilation of studies clearly demonstrated that racism does indeed exist in medicine—and nursing is no exception.

Racism can be defined as the assumption that one’s “race” is superior to others’, resulting in unfair and harmful treatment. Racism can include attitudes and behaviors, it can be overt or covert, and it can exist at the individual and the institutional levels. Porter and Barbee (2004)

reviewed nursing research from the 1970s to the present. One study examined by these authors was an investigation by McDonald in 1994, which retrospectively explored pain medication administration after uncomplicated appendectomies. Record reviews revealed that “there were large and unexplainable differences in total doses that were received by Asian, Black and Hispanic Americans compared to White patients” (Porter & Barbee, 2004, p. 21). These findings provided a clear example of how nurses’ beliefs and values influenced their clinical practice.

Now Can You— Discuss health inequities and limited access to health care?

1. Identify both the age and racial/ethnic diversity trend of the U.S. population and discuss what that means in terms of nursing and health care provision?
2. Describe the greatest factor that limits access to health care?
3. Explain the roles that discrimination, stereotypes, and racism play in perpetuating health inequities?

CHILDBIRTH TRENDS

Today, many women are choosing to delay childbirth, and this trend is believed to be due to the desire to complete education and to securely establish careers, relationships, and finances. In 1970, the average age for a woman to have her first baby was 23.4 years; in 2001, the average age had risen to 27.6 years. In 1970, 9% of first-time mothers were older than age 30; by 2001 that proportion had risen to 34%. Because fertility decreases with age, some couples may miss the opportunity to have children altogether. Other related trends in society include children leaving home later and forming unions such as marriage at an older age.

In addition, more women are electing to give birth by Cesarean section even when there is no medical reason for doing so. Patient-choice Cesarean births in 2001 accounted for 1.87% of births. However, by 2003, this figure had risen to 2.55%, representing an increase of 36.6% in only 2 years (Wax, Cartin, Pinette, & Blackstone, 2004). Much controversy continues to surround this trend, since a Cesarean birth is major abdominal surgery with all of the accompanying risks.

PATTERNS OF PHYSICAL FITNESS

Physical inactivity and its consequences are becoming a significant health problem for families in the United States. According to the Centers for Disease Control and Prevention ([CDC], 2005), only 13% of American women “engage in the recommended physical activity sufficient to reduce the risk of cardiovascular disease and other chronic debilitating diseases” (Peterson, Yates, Atwood, & Hertzog, 2005, p. 94). Research by the American Heart Association has shown that physically active women have a 60% to 75% lower risk of cardiovascular disease than inactive women (Peterson et al., 2005).

Obesity has made a steady climb upward. More than half of all Americans are overweight or obese (Ogden et al., 2006). It makes sense that increasing physical activity and reducing obesity are underscored in *Healthy People*

2010 as a primary means for reaching the nation's major health outcome goal: increasing the quality and years of healthy life.

THE INTERSECTION OF RACE, CLASS, AND HEALTH

While great strides have been made in family health, the progress achieved is not universal. The gap is widening between persons in lower and upper socioeconomic classes. "Upper class" in this context refers to those who live in contented neighborhoods, have a quality education, and bring home adequate wages. Persons from the lower classes, many of whom are African American, Hispanic, or Native American, live shorter and less healthy lives. Eighteen percent of all children in the United States currently live in poverty (U.S. Census Bureau, 2006).

It is important for nurses to work toward eliminating discrimination and racism, but if they are to make a difference in rates of illness and premature death, it is also important to work toward improving socioeconomic opportunities for all Americans (Isaacs & Schroeder, 2004). All too often, life and health choices are limited by socioeconomic status. The vision of the "American dream" and the ideology of "personal choice" obscure the fact that there are enormous constraints and limited choices that accompany poverty. A hungry and desperate person loses the capacity to choose.

Now Can You— Identify certain population trends that relate to health?

1. Discuss U.S. fertility trends and trends toward surgical birth and what it means for women's health?
2. Discuss the trend toward inactivity in the United States and describe what consequences might be seen in the future health care status of Americans as a result?
3. Describe the role poverty plays in increasing health care disparities?

The Current Health Status of the Nation

INFANTS AND YOUNG CHILDREN

The plummeting rates of infant mortality in the past century allowed health care professionals to move forward beyond infant survival and focus on prevention and early intervention with children's health. Ideally, health prevention strategies targeting children's health would begin as early as preconception. It has been learned, for example, that folic acid supplementation helps to prevent certain birth defects. A fetus' exposure to harm could potentially be prevented if a woman were counseled *before* pregnancy about the harmful effects of alcohol, tobacco, toxoplasma, and other **teratogens** (substances that adversely affect normal cellular development in the embryo/fetus). The fetal neurological system, especially the brain, is extremely vulnerable to even small amounts of potentially toxic substances.

Early intervention is especially important when it comes to growth and developmental delays. There is a well established link between developmental delays and learning difficulties (Shonkoff & Phillips, 2000). Once

children reach school age, interventions are less likely to be effective if they have already begun to fail academically or socially. Today, a number of infant and child development screening tools have been developed and refined. Unfortunately, however, close to one-third of developmental or behavioral disorders are not detected until children begin to attend school (Glascoe, 2000; Tebruegge, Nandini, & Ritchie, 2004).

The leading causes of death by age groups are revealing and offer clues about how to prioritize nursing interventions. SIDS is the leading cause of death among infants between the ages of 1 and 12 months. Accidents, or unintentional injuries, constitute the leading cause of death in children older than 1 year of age, which suggests that more community education and effort are needed to address child safety hazards. Although the incidence varies by age group, congenital malformations and malignant neoplasms shift between the second and fourth place for the leading cause of death in children.

Violence also takes a harsh toll on America's children. Homicidal assaults are the third leading cause of death of children in the 1- to 4-year-old age group, and also in the 15- to 19-year-old age group. Suicide is the third leading cause of death in teenagers and young adults, ages 15 to 24; it is the sixth leading cause of death among children ages 5 to 14. Family violence, child maltreatment, and violence in schools such as bullying are also issues of great concern.

Anthropologists such as Sanday (1994) note that in American culture, "inter-personal violence has become a national pastime" (p. 2). The most watched television shows of 2005, *Law and Order* and *CSI*, were routinely based on violent acts. It is estimated that the average child will witness 9000 media murders by the time he or she finishes elementary school (Kunkel, 2001).

Violent video games are a more recent trend and research is still sparse regarding their effects on children. A study by Anderson and Dill (2000) suggests that they may be even more harmful because they are interactive and the aggressor is the one glorified and with whom the player identifies.

There are other potentially preventable children's health issues. Lead exposure provides another example where early intervention and teaching can have a positive impact on children's health. Exposure to lead can occur from contact with lead-based paint in older homes; contaminated soil; a parent's occupation; certain vinyl mini-blinds; various folk remedies; living close to major highways; and from contact with imported pottery, jewelry or cosmetics. The American Academy of Pediatrics (AAP) recommends that all children between the ages of 1 and 2 years receive testing for lead exposure, since 25% of homes presently occupied by children younger than the age of 6 have known lead contamination. Lead exposure has been linked to a number of medical and developmental problems, including anemia, seizures, and mental retardation.

A trend not well understood is the alarming increase in childhood asthma, a condition that constitutes the most common cause of time missed from school. Asthma and allergies account for the loss of an estimated 2 million school days per year. In fact, the number one reason for pediatric emergency room visits due to chronic illness is for asthma-related problems.

Other trends in children's health status include a significant rise in the diagnoses of attention-deficit/hyperactivity disorder (ADHD) and developmental delays due to autism. Children with ADHD are typically fidgety, act without thinking, and have difficulty focusing. ADHD now affects 4% to 8% of all school-age children (Glascoe, 2000). Autism is the third most common type of developmental delay in the United States. An autistic child presents as a solitary child and notably lacks social responsiveness to others. Autism affects language, which is absent, abnormal, or delayed. Autistic children may demonstrate a strong resistance to change and show an abnormal attachment to objects. The prevalence of this disorder is difficult to gauge, since autism is not an easily accepted diagnosis, but it is estimated that it affects approximately 6 out of every 1000 children (Charles, 2006).

One way to visualize children's health is to view it as an obstacle course. The fortunate child is one who was desired and planned for before conception and who has parents with a good genetic profile, adequate resources, and who harbor no chronic illnesses. The fortunate child's mother would have healthy eating habits; maintain her ideal body weight; access early and regular prenatal care; and abstain from the use of alcohol, tobacco, and other harmful substances. The child who does well through fetal life must then encounter birth and avoid major complications such as prematurity or aspiration pneumonia.

Following birth, the child must encounter the hurdles of the first year of life to avoid becoming an infant mortality statistic. She has to dodge SIDS and shaken baby syndrome, and needs to be taken to health care providers for the hectic schedule of immunizations needed to prevent major childhood diseases. She must be fed and stimulated enough to grow physically, psychologically, socially, and emotionally. The child whose mother breastfeeds her gains an added bonus of immunities.

As the child matures, there are more obstacles to confront. The child who attends day care faces a significantly higher risk of infections. The tendency toward obesity and all the tempting fast food commercials on television offer additional stumbling blocks. She has to dodge all kinds of accidents that cause unintentional injury, tackle each developmental milestone, and land solidly in the "normal" grid of childhood growth charts. Ideally, she will not develop asthma, autism, or ADHD. She will hope to avoid the stumbling blocks of sexual abuse, or coping with poverty, and poor housing in unsafe neighborhoods. While parents work, the child's day care environment may be laden with communicable childhood illnesses to be avoided. School-age children need to dodge being one of the 16% who are bullied (Volk, Craig, Boyce, & King, 2006). The obstacle course continues to pose challenges throughout childhood, and when adolescence arrives, the child again faces new foothills and crags.

Adolescents

Adolescents represent a population group with a set of issues uniquely their own. With regard to health care, adolescents are most often at risk for falling through the cracks. The adolescent must confront issues of self-esteem

along with demands to meet a cultural ideal, while at the same time deal with pressure to conform to gain peer acceptance. The adolescent may have to cope with changes in appearance such as acne and awkwardness. Reproductive issues also arise. Girls must bridge the experience of menses, while boys encounter embarrassing erections and emissions. Issues such as sexuality, teen pregnancy, and sexually transmitted infections may pose further stumbling blocks. Alcohol, tobacco, and drug use as well as bullies, gangs, and school violence may force more hurdles in the envisioned obstacle course for the child to seek a full and healthy life.

One way nurses can make a difference is by learning and teaching others how to listen to children respectfully and value their experiences. Nursing can be called a "narrative profession" since patients present first and foremost with their narratives of symptoms and illness. Children do so as well but it takes patience to really listen.

Nursing Insight— Listening to our youngest patients

Children tell us that we do not respect their expertise. The child who lives with an illness day by day holds the greatest insight into what it is to experience that illness. They come to know what the illness feels like, what treatments are necessary, what works, and what doesn't. They often develop quite sophisticated knowledge about their medications and treatment. The difficulty is that we do not give this knowledge and experience the same value as that held by the adults around them. Children also tell us that we do not give them uninterrupted time to tell their story their way. Children, with their varying cognitive and communication abilities, need time to explain their illness experience and time to respond to our questioning. Sometimes, through adult eyes, their way of telling us seems long and convoluted, and we therefore cannot resist the temptation of jumping in or interpreting what we think they are trying to say. Long story-telling does not fit well in the busy world of practice (Dickinson, 2006).

Two of the priority goals for children in *Healthy People 2010* address childhood vaccinations. One goal is to achieve and maintain effective vaccination coverage levels for universally recommended vaccines to 90% of children from 19 to 35 months of age and increase routine vaccination coverage for adolescents. The second goal is to reduce vaccine preventable diseases as follows: (1) measles, mumps, and rubella to zero cases and (2) pertussis in children younger than 7 years to no more than 2000 cases per year (CDC, 2005).

Now Can You— Describe nursing actions that can serve to improve the current status of children's health in the United States?

1. Describe two benefits of preconceptual health guidance and early intervention?
2. Discuss major causes of child mortality and describe nursing interventions that can make a difference?
3. Compare and contrast communication strategies for children with those of adults?

FAMILIES

Today's world is full of complex, overlapping conditions and trends that influence the health of American families. Families are often the core unit where health habits are first formed. One of nursing's most important roles is to foster the health capacity of families, whether those families are blood-related or are families of choice.

Families do not exist in a vacuum, but are situated within communities and regions that often have unique social and physical characteristics. Surrounding environmental hazards affect family health. Natural disasters such as earthquakes, hurricanes, tornadoes, floods, and fires have favorite regional targets. Such disasters cause more damage when they strike high-population areas. Communities with high poverty rates are more likely to have older, run-down homes with more asthma-producing sources, such as mold, lead, and pests. Poorer neighborhoods are more likely to be closer to highways and regional waste sites.

Access to health insurance is an enormous factor that affects the health status of families in what is considered the richest country in the world. There is an ever increasing number of uninsured and underinsured citizens in the United States. More than 45 million Americans were uninsured at last count in 2004 (U.S. Department of Health and Human Services [DHHS], 2005b). One concerning trend is the erosion of employer-provided insurance. Today's employees are no longer guaranteed health insurance coverage through their jobs. According to the National Coalition on Health Care (2007), employer-sponsored health insurance fell 5 percentage points between 2000 and 2004, from 66% to 61%.

A recent study conducted by investigators at Harvard University found that illness and medical bills constitute the leading cause of personal bankruptcy and affect approximately 2 million Americans each year (Warren, 2005). Those with health insurance coverage frequently have gaps in coverage that can lead to missed appointments or the inability to fill a needed prescription. Health care problems among children extend beyond the millions who are uninsured, because for each of those children is another who misses a doctor's appointment or filled prescription due to coverage gaps in their parents' plans. Researchers suggest there are many more children in the nation receiving inadequate health care than are reflected in the uninsured figures. Persons without health insurance have limited access to health care and are left vulnerable to the effects of illness, both physical and financial. One of the more ambitious goals of *Healthy People 2010* is to increase to 100% the proportion of persons with health insurance.

WOMEN

The leading cause of death for women in the United States in 2005 was heart disease, which accounted for 28.6% of all female deaths. Cancer represented the second leading cause at 21.6%, followed by cerebral vascular disease (stroke) as third, which accounted for 8.0%.

There is plenty of room for improvement in health behaviors that are precursors to heart disease. According to the 2002 CDC's Behavior Risk Factor Surveillance System

(BRFSS), two-thirds of women in the 25- to 65-year-old age group do not get the recommended 30 minutes of daily physical activity. One in five adult women smoke tobacco. With regard to nutrition, 72% of women do not get the recommended five or more servings of vegetables and fruits per day. There are also deficiencies in calcium and folic acid intake, nutrients important to women's health. Folic acid is a B vitamin that is linked to prevention of certain birth defects. Calcium is important to bone health. Lack of calcium contributes to osteoporosis, which makes a person susceptible to fractures, which can lead to disability and death (U.S. DHHS, 2005a).

Perinatal Health

In the area of perinatal health, national statistics reveal that over the past 20 years, there has been no decline in the number of pregnancy-associated deaths. According to the CDC (2005), two to three women in the United States die from pregnancy complications each day. Studies show that at least one-half of pregnancy-related deaths could be prevented. One reason for the recent escalation in high-risk pregnancies is related to pregnancies that occur in women with preexisting chronic conditions. Complications before childbirth account for more than 2 million hospital days of care and more than \$1 billion spent each year in this country. In actuality, this number would be even higher if it also included complications that occur during and after childbirth.

Several years ago, health care professionals in Florida developed a program to address these issues at the state-wide level. Florida's Pregnancy Associated Mortality Reviews (PAMR) is a best practices example of how nurses initiated a plan to mobilize an entire state to work on improving pregnancy outcomes and reducing maternal mortality. PAMR started in 1996 in response to a cluster of maternal deaths noted in one particular county. Nurses organized an interdisciplinary team with wide representation, consisting of nurses, nurse-midwives, obstetricians, fetal-medicine specialists, family physicians, emergency medical services personnel, medical examiners, pediatricians, social workers, researchers from colleges of public health, and insurance payers. Using all available sources of data (i.e., physician office and hospital records, EMS records, autopsy reports), a nurse abstractor compiles the cases and sends them to each team member for review. The interdisciplinary team then meets, reviews each case, and collectively develops solutions for the identified problems. Confidentiality is key to the entire process. No providers' names are ever used and if team members recognize case details, they do not reveal that information. Contracts of confidentiality are signed at each quarterly session. To date, several important gaps in care have been discovered and recommendations and changes were made based on team findings. In addition, trends in pregnancy-associated deaths have been identified, leading to enhanced services and innovative approaches in caring for pregnant women.

Four million women give birth each year in the United States. Interestingly, in this day where there are more contraceptive methods than ever before, at least one-half of all pregnancies are unintended or mistimed. Another *Healthy People 2010* goal is to reduce unintended pregnancies to 30% or lower by 2010. Currently, there are some positive

trends in perinatal health. For example, women are starting their prenatal care earlier. In the latest CDC Behavioral Risk data (2004), 83.9% of women initiated prenatal care during the first trimester. Smoking during pregnancy decreased from 20% in 1989 to less than 11% in 2003. Also, today, there is more published information about proper nutrition, folic acid, and healthy lifestyles than ever before.

There is evidence that contemporary health care systems are more cognizant of women's needs. Children maneuvering giant balloons as they eagerly bounce down the postpartum hall en route to visit their mothers and newborn siblings is a welcome and familiar sight. There is more understanding in research circles about the differences in the health care needs of women and men. Women are being empowered more in health care settings, enabling them, in turn, to make better health care decisions for their families.

Now Can You— Discuss elements of the current health status of American families and women?

1. Discuss how recent national trends have affected families' access to health insurance?
2. Identify the three leading causes of death in women in the United States?
3. Describe a state-wide model developed by nurses to improve pregnancy outcomes and reduce maternal mortality?

Politics, Socioeconomics, and Culture: Contemporary Influences and Trends

To facilitate understanding of present-day health care issues, it is helpful to consider political, socioeconomic, and cultural influences and trends. Family health issues are shaped, in part, by other elements as well. These elements include historical factors, family features, and biological and ecological influences. All of these factors intermingle and intersect with personal life experiences to comprise a health issue.

POLITICAL INFLUENCES AND TRENDS

Health policy decisions always involve choices, and whenever there are choices to be made, values and the potential for values conflicts are involved. One of the most polarizing political debates in modern times concerns the issue of abortion. Throughout the years since the passage of *Roe vs. Wade*, "abortion has kept its grip on the American imagination...dividing the body politic on issues of control of women's bodies, rights to privacy, fetal viability, and broader concerns over the moral shape of our country..." (Ginsburg, 1998, p. ix).

How and where a nation spends money has a major influence on the overall health of the population. National economic policies often dictate who has access to health care and who will be able to obtain medications. Policies related to social income programs such as Social Security and welfare assistance significantly affect the health of populations. Transportation issues and housing policies are critical as well. Education policies, such as the removal of physical education requirements from schools, have far-reaching and long-lasting effects on the health of children.

Health Care Delivery

Changes in health care delivery are omnipresent. The current health care delivery system is less of a system than it is a collection of entities. Health care today is corporate, and thus is more market driven than based on the common good or the actual needs of populations. Care is increasingly centralized into major medical centers. Small hospitals are closing due to an inability to remain solvent. Managed care is the rule rather than the exception, and is expanding as more and more health care providers and institutions are pressured into joining networks for health care delivery. Many of the provider networks operate on capitation, where they negotiate and are paid a set amount in order to provide complete health care for a certain number of clients.

Quality of health care and consumer satisfaction are the drivers of health care, just as in the retail industries. National databases regarding quality of care and specific conditions are only now beginning to be organized. Although a dearth of information is available on the quality of health care in the United States, this is changing as the focus on accountability in government and institutions moves to the forefront. The trend toward increased media attention concerning health care errors represents a vivid example of a growing demand for accountability. Workplace satisfaction and nursing shortages are issues that need to be addressed as well.

Public Policies and Programs

There are several public policies and programs that make a difference in women's, children's, and families' health. One highly influential program is the Women, Infants, and Children (WIC) program. WIC targets pregnant women, infants, and children, age 5 or younger, who are nutritionally at risk and provides supplemental nutritious foods and nutrition counseling and education. WIC serves low-income families as well as any pregnant woman who has particular nutrition challenges such as diabetes or anemia. Forty-five percent of infants born in the United States participate in the WIC program. Another nutrition program, The National School Lunch/Breakfast program, provides free or reduced-price meals to children from low-income families.

Medicaid, legislated through Title XIX of the Social Security Act, is a major publicly funded program that helps to boost the health status of women, children, and families. Funding for Medicaid is shared between federal and state governing bodies. Medicaid offers medical assistance after specific sets of complex eligibility criteria have been met. The Medicaid program is the largest safety net source of funding for health care services for the poorest populations in the United States.

The Newborn and Mothers Health Protection Act was passed in 1996. This legislation ensures that mothers and their newborn infants can remain in the hospital for at least 48 hours after a vaginal birth, or 96 hours following a cesarean birth. Another influential source of legislation for families is the Family and Medical Leave Act (FMLA) of 1993. This law permits American workers to take up to 12 weeks of unpaid leave per year from their jobs for recovery from serious illness or to provide care for a sick family member.

SOCIOECONOMIC INFLUENCES AND TRENDS

The most egregious effects of inequality in the United States are seen on the streets of the inner cities among persons with little hope for the future. The more subtle but far-reaching effects are seen in workers with insecure jobs. These are persons who rightly fear that major illness would result in personal catastrophe. Many single mothers report that they are merely one sick child away from losing their jobs and entire paychecks (Edin & Lein, 1997; Redfern-Vance, 2000).

In addition, there are the elderly who must expend nearly all of their resources before they can accept public funding for needed long-term care. For the elderly, the cost of medications can add up at the same rapid rate as do the chronic health conditions associated with the aging process. There are also those who may be classified in a low- or a high-income group, may be young or may be elderly, may be living in a busy metropolis, in suburbia, or in a lonesome rural area, and yet maintaining lives that offer little opportunity for control or meaningful social participation. Certainly these inequalities are, in part, inequalities in income. However, more than an inequality of income is at issue. In a fundamental sense, these inequalities are reflective of a society that works well for those at the top, and far less well for everyone else.

The Increasing Rate of Poverty

Most persons consider items like adequate food, housing, clothing, heat, electricity, telephone service, and essential health care as necessities rather than luxuries. This is not true for everyone. Overall, 12.7% of Americans were living in poverty in the United States in 2004. The number has risen each year since 2000 (U.S. Census Bureau, 2006). Economic changes, racial inequality, suburban movement, manmade and natural disasters, and industrialization all contribute to poverty circumstances.

The Feminization of Poverty

Women are the most impoverished demographic group in American society (Edin & Lean, 1997). In 2005, 56% of persons older than age 18 living in poverty were women. Single mothers with their children constitute 82% of the poverty population. More than 60% of U.S. women with children younger than the age of 2 now work outside the home (U.S. Census Bureau, 2000).

In 2000, one-fifth of all U.S. children were living in poverty. Between 2000 and 2003, the number and percentage of single mothers living in poverty increased while the percentage of single mothers with jobs fell. At the same time, poverty among children rose, and the number of children living below half of the poverty line (about \$620 a month in 2003 for a single mother with two children) increased by nearly 1 million. These structural features of U.S. society have contributed to what has been coined as the "feminization of poverty."

Single mothers face oppressive barriers to achieve the "economic self-sufficiency," now legislatively prescribed for them, commonly referred to as "welfare to work." The essence of the new legislation, entitled Temporary Assistance for Needy Families (TANF), is that work now becomes compulsory and lifetime limits are imposed.

TANF replaces the former public assistance program that was known as Aid to Families with Dependent Children (AFDC). There is a maximum period that a person is allowed to receive public assistance at one time, and a lifetime limit. The mandates apply to pregnant women as well as those with infants older than the age of 3 months.

The Wage Gap

Gender inequity persists and the ratio of full-time working women's weekly earnings to those of men was 77 cents to the men's dollar in 2004. Proportionately, more families are being supported by women today than ever before. Three out of five U.S. families were headed by women and 22% of all children in the United States lived in mother-only families in 1990, an increase of 11% since 1970 (U.S. Census Bureau, 2006).

Now Can You— Discuss aspects of political and socioeconomic influences that impact the nation's health?

1. Identify and discuss three socioeconomic trends that have a negative impact on the health of persons living in the United States?
2. Describe two public programs intended to improve the health of American women, children, and families?
3. Describe what is meant by the phrase "the feminization of poverty"?

Communications and the Digital Divide

One of the factors promoting patient empowerment is the ready access to health care information over the Internet. Fox (2006), reporting on the Internet and health, found that "looking specifically at online discussion groups devoted to health and well-being, the audience is also stable – about half of internet users helped someone else through an illness in the past two years; one in five internet users dealt with their own illness during that time" (p. 5).

In modern society, however, there exists what has been termed the "digital divide" (Wagner, Bundorf, Singer, & Baker, 2005). Families with discretionary income and with some formal education are more likely to access health information and educational resources from the World Wide Web. Those with less income, in particular those from racial and ethnic minority backgrounds, are less likely to have access to electronic materials. In addition, there is what is called the "gray gap," referring to seniors who do not use Internet technology. Approximately 68% of Americans reported ready access to the Internet in 2005. In families with incomes of \$75,000, 95% of children have a computer at home. One out of five Americans claims they have never used the Internet or e-mail. Again, the "digital divide" separates and discriminates against the poor or elderly who do not have access to computers or who have not learned computer skills (U.S. Census Bureau, 2007).

Vulnerable Populations

Bellah, Madsen, Sullivan, Swiler, and Tipton (1991), who conducted a landmark study of mainstream American culture, articulated a problem described as "excessive

individualism.” The cultural norm of individualism focuses attention away from critical societal issues such as the ever-increasing gap between the “haves” and the “have-nots,” as evidenced by the alarming rise in homelessness, hunger, and violence. The dark side of individualistic thinking advocates a policy of “choosing and creating your own reality” which then leads to “blaming the victim” and ignoring the social context, where “choices” are not, and have never, been equal. As a society, it behooves Americans to focus on a shared vision and goals, such as those afforded to us by the *Healthy People 2010* initiative. To do so, it is important to consider the vulnerable populations in the United States. As Aday (2001) notes, “as members of human families and communities, we are all potentially vulnerable” (p. 53). Vulnerability encompasses threats to physical and psychological health, as well as vulnerable social circumstances and stages within the life course.

HOMELESSNESS. Homelessness is rising among all populations, but most noticeably for families. There is an increase in families at the extreme poverty level (about \$17,000 for a family of three in 2007). Income levels such as this are woefully inadequate to maintain a household. The increase in homelessness has resulted in more and more entire families who regularly visit homeless shelters and soup kitchens across the country. In New York City, 73% of the shelter population comprises children and their parents. The random collection of community shelters and free food kitchens that have proliferated throughout the United States during the past several years have had a difficult time keeping up with the needs. It has not helped that recent policy changes have resulted in the elimination of several programs that previously served as safety nets for health care and housing subsidies. Persons displaced as a result of wars and disasters have also added to the number of those desperately seeking assistance.

For homeless persons and families, health is a momentous challenge. The poverty, stigma, poor nutrition, and increased susceptibility to violence and mental illness all take their toll. Access to health care is a problem due to lack of transportation and finances, so that hospital emergency rooms are often the only option for medical attention. It is difficult to obtain accurate numbers on the homeless population but the Partnership for the Homeless estimates that currently there are about 2 million homeless persons in the United States, with 8105 homeless families in New York City alone.

Nursing Insight— Putting Homelessness into Proper Perspective

To enhance understanding of the magnitude of the problem of homelessness in the United States, it is useful to consider the following statistics. These figures relate to families who were sleeping in Department of Homeless Services (DHS) city shelters in New York City during 1 month in 2005:

- 8105 families
- 13,062 children
- 11,854 adults
- Average family size: 3.18
- Average length of stay: 361 days
- 32.3% remain in shelters more than 1 year

Source: <http://www.partnershipforthehomeless.org/>

UNDOCUMENTED IMMIGRANTS AND REFUGEES. Undocumented persons who enter the United States illegally in order to work constitute another highly vulnerable population. Many persons are from Mexico or Central America and are drawn to the United States for economic reasons or to escape political conflicts. Undocumented persons are willing to work in what are considered the lowest paid and least desirable occupations in the United States. They generally have no job security, health care access, or decent housing. Most face language barriers as well. Without financial resources, hospital and health clinic doors are generally closed to them. In addition, this population is experiencing mounting resentment from a public that is leaning more and more toward isolationism since the World Trade Center attack (Goldman, Smith, & Sood, 2006).

PERSONS RESIDING IN RURAL AREAS. Persons living in rural neighborhoods are less likely to have access to quality health care. Primary care providers are increasingly reluctant to locate in rural areas. Many small, rural hospitals have been forced to close because of centralization of intensive care services.

ABUSED AND NEGLECTED CHILDREN. The National Child Abuse and Neglect Data System (NCANDS) is the federal reporting system that analyzes data on child abuse that are collected on an annual basis. In 2006, NCANDS reported that the information obtained in the 2004 count included 3 million cases of reported child abuse. Child abuse can take many forms. The most common is child neglect, which can mean withholding food, clothing, shelter, love, supervision, or medical attention. Physical and child sexual abuse are other types and it is not uncommon for all three forms of abuse and neglect to overlap. According to the American Academy of Pediatrics, study estimates predict that one out of four girls and one out of eight boys will be inappropriately touched sexually by the time they turn 18 (Kellogg and the Committee on Child Abuse and Neglect, 2005).

NCANDS reports that three children die of child abuse in the home each day (U.S. DHHS, 2007). Fewer than 1% of children are abused by strangers. Children are most commonly abused by someone they know. In 79% of cases, the perpetrator is a parent. Child abuse can set up a perpetuating cycle of suffering and more violence later in life, potentially reaching into future generations.

Nurses have a legal obligation to report any observed known or suspected child abuse to child protective services. Thus, it is critical for nurses to learn to assess the signs and symptoms of child abuse (see Chapter 23).

VICTIMS OF SEXUAL VIOLENCE. Historical beliefs and attitudes toward women continue to influence women’s lives and health. In the past, women were viewed as physically and psychologically inferior to men. They were denied rights and privileges routinely granted to men, such as owning property and voting.

Sexual violence haunts the lives of all women, both with its frequency and its impact. In a U.S. Department of Justice, Office of Justice Programs, National Violence Against Women Survey (NVAWS), nearly one out of five to six women report having been raped (Tjaden & Thoennes, 2000). Some have called the United States a “rape-prone” society (Buchwald, Fletcher, & Roth, 1995).

Sexual violence is linked with deleterious long-term psychological, social, and physical effects such as substance abuse, major depression, gynecological disorders, and others (Koss & Harvey, 1991; Wolfe, 1996). Unwanted sexual attention also devalues women and takes a toll on their health. Lewd sexual comments, cat calls, whistling, and intrusive looks are demeaning actions that negatively affect women's health (Esacove, 1998).

VICTIMS OF INTIMATE PARTNER VIOLENCE. It is difficult to obtain accurate numbers about intimate partner violence (IPV) because of varying definitions and widespread underreporting. The National Violence Against Women Survey (National Institute of Justice and the Centers for Disease Control and Prevention) revealed that nearly 5.3 million incidents of IPV occur each year among U.S. women ages 18 and older, and 3.2 million IPV incidents occur among men. The majority of reported assaults did not result in serious injury and consisted of pushing, grabbing, shoving, slapping, and hitting (Tjaden & Thoennes, 2000a).

Research suggests that nurses in clinical settings are still reluctant to question patients about intimate partner violence. Nurses need to routinely ask the violence screening questions and offer to help abused patients develop a safety plan. It is important for nurses to know that the most dangerous times for abused women are during pregnancy and when a woman tries to leave her partner.

GAY/LESBIAN/TRANSGENDERED INDIVIDUALS. Studies repeatedly demonstrate that access to sensitive health care for gay, lesbian, and gender transitioning patients is extremely limited. Stigma and prejudice continue to prevail in attitudes toward those living an "other than heterosexual" lifestyle (see Chapter 6 for further discussion about specific health issues among this population).

INCARCERATED WOMEN. An invisible population of marginalized women exists within the hidden pockets of the richest country in the world. One hears very little about incarcerated women, yet they currently inhabit U.S. jails and prisons in ever increasing numbers, with a sixfold increase during the past 20 years (Braithwaite, Arriola, & Newkirk, 2006). The growth rate of women prisoners has now bypassed the growth rate of male prisoners, and at present, women constitute 10% of the total inmate population (Hufft, 2004). In this country, which has the highest incarceration rate in the world, there are approximately 1 million women behind bars.

As a population, incarcerated women are not healthy. They tend to have a myriad of health problems, particularly illnesses that stem from the stresses of poverty, physical and sexual abuse, addiction, and motherhood. Imprisoned women frequently do not have access to the benefits of health education. Mental health issues abound in this vulnerable population as well.

More than 70% of incarcerated women are mothers. This is an issue that greatly impacts the health of families. Approximately 1.3 million minor children have no mother to care for them on a daily basis. Inevitably, children are affected by the abrupt changes commonly associated with incarceration of a parent. They may experience a sudden change in caretaking arrangements, social stigma, the potential for abandonment, and the loss of family support and financial resources.

The Girl Scouts of America organization has developed a unique program for girls who are separated from their mothers because of incarceration (Hufft, 2004). Called "Girl Scouts Behind Bars," this program is similar to regular scouting programs and has the same goals of self-esteem building and incremental accomplishments. It includes prison visitation between mothers and daughters, and especially targets social risks for which these young women are more vulnerable. The program also attempts to help incarcerated women hone their parenting skills. Forensic psychiatric nurses play an important consulting role in this national program, now operational in 13 states.

A nurse who is able to deliver culturally competent care to incarcerated populations quickly becomes cognizant of the challenges as well as the importance of raising standards and improving the present system. Work performed with this vulnerable population is significant far beyond the prison walls. Nearly 95% of prisoners will eventually be released into communities where they will likely face poverty, stigma, unemployment, and deficiencies in health care.

PERSONS WHO ARE SUBSTANCE ABUSERS. Substance abuse is a major health issue for families. Unfortunately, children are often the ones who suffer the most. Children in families with substance use problems are likely to be abused and neglected. These same children are also more likely to become substance users themselves. See Chapters 11 and 23 for further information.

 **Now Can You—** Identify vulnerable populations of women, children, and families that exist in the United States today?

1. Identify and describe four vulnerable populations in the U.S.?
 2. Describe the population group at present experiencing the largest rise in homelessness?
 3. Explain why undocumented immigrants are considered a vulnerable population?
-

PERSONAL AND CULTURAL INFLUENCES AND TRENDS

The world of today has dramatically changed from the era when telephones, televisions, and airplanes were giant novelties. Now nursing students "text message" friends on their cell phones in real time. The population relies on mass media for news and entertainment and the electronic gaming industry is thriving. Even dating relationships have changed. According to the U.S. Census Bureau, of the 44% of American adults who are single, 40% have tried online dating (Madden & Lenhart, 2006). The global education businesses that use e-learning are estimated to climb to a worth of \$212 billion by the year 2010.

Other cultural changes include an increase in language barriers and cultural differences within the U.S. population. There is also a cultural component to many health issues. For example, the dramatic rise in eating disorders demonstrates how present-day popular culture can strongly influence health. Media images of so-called "perfection" flood the media, yet these images rarely represent healthy role models.

Self-Care and Patient Involvement

Autonomy and social participation have important influences on health status. Trends that present themselves in the health care arena include a focus on more consumer involvement and self-care tactics. Today there is an abundance of self-help groups, many of which are modeled along the lines of Alcoholics Anonymous, with varying purposes. For example, there are groups for tobacco dependency, “co-dependency” (CODA), drug addictions (Narcotics Anonymous), eating disorders (Overeater’s Anonymous), and for families of addicts (Al-Anon and Alateen). In addition, there are self-help groups for nearly every medical ailment or illness imaginable. Some communities offer peer visitation programs whereby a person with the same illness or condition shares personal experiences with the newly diagnosed patient to help him or her understand what to expect in the days ahead.

In many situations, increased patient autonomy has resulted in more of a partnership model for the nurse. The nurse’s role becomes increasingly one of facilitator and “cultural broker” to help the patient negotiate mutually acceptable plans of care. In obstetrics, it has meant that traditional childbirth practices of the past are increasingly challenged to become more personalized and family-centered. In pediatrics, it has meant that parents are encouraged to remain in their everyday roles as the primary support persons for their children.

The trend toward early discharge from hospitals has resulted in sicker patients in hospitals. Early discharge trends have also led to the blossoming of home health organizations. It is estimated that within the next few years, 70% of nursing care will be administered in the home setting. Literature has indicated that community-based care will be essential to nursing in the 21st century.

Complementary and Alternative Therapies

There is a growing trend toward the use of complementary and alternative medicine (CAM) therapies. The majority of persons in the United States now use some sort of CAM therapy, but many are reluctant to disclose that information to traditional medical personnel. There is sometimes the perception that nurses and physicians, since most are trained using the biomedical model, may not approve of the use of CAM. It is important for health care providers to have a working knowledge of CAM and try to integrate the two types of medicine. In this way, the patient obtains the benefit of each. Integrating CAM with conventional health care is called “integrative health care.” Ideally, the nurse can thread integrative health care with the practice of conventional maternal child nursing for the maximum benefit of the patient.

One common lay perspective that is difficult to counter is the belief that because something is marketed as “natural,” it means that it is harmless or without side effects. There have been publicized incidences of children being given unsafe treatments that resulted in harm or death. Mantle (2005) notes that the Children’s Act of 1989 states: the “interests of the child are paramount. This includes the child’s physical welfare and anything relevant to this, including nutrition and access to appropriate medical care” (p. 24).

Complementary Care: Blogging as Therapy

Some health programs recommend “blogging” to facilitate healing when faced with serious diseases. Patients write daily about their experiences in diary format on the Internet. Blogs are a recording of personal experience, a participatory form of self-expression. Blogs help the creativity of individuals to surface and can be comforting during health crises. Blogs bypass editors and publishers and can be produced at the person’s own pace. A strong sense of community can grow from blogging for health, and it is free of charge for those with computers and Internet access.

Now Can You—Discuss personal and cultural trends that may impact an individual’s health status?

1. Discuss some of the effects of self-care and autonomy on a person’s health status?
2. Explain what is meant by the term “integrative health care”?
3. Discuss why blogging may be viewed as a complementary care method?

Health Care for the Nation

Recent years have brought an exponential growth of information and knowledge in all areas, especially in the field of health care. It is estimated that the total amount of information doubles every 6 years. Knowledge becomes obsolete at a rapid pace. Learning how to access current and accurate knowledge is critical for all health care providers. The implementation of community-based programs that are responsive to population needs for health promotion, education, and screening is an important nursing strategy to help meet many of the national goals of the *Healthy People 2010* initiative.

Across Care Settings: Serving the community through parish nursing

Parish nursing, also known as faith community nursing, congregational nursing, or church nursing, is a phenomenon born from the marriage of nursing to the healing ministry of churches and religion. A **parish nurse** is a registered nurse who ministers to a church community, and honors the connection between faith, health, and well-being. The parish nurse has a holistic approach that recognizes the spiritual domain as an essential component of health. The parish nurse usually focuses on health promotion, health education, and prevention of illness. To achieve this goal, the parish nurse might conduct regular health seminars, perform health screening assessments, organize health support groups, or serve as a link from the parishioner to health resources in the community. Smaller congregations sometimes share a parish nurse with other congregations, while large congregations may hire a full-time nurse to serve their church community.

There is also a growing trend toward the use of “high-tech” medical care. Remarkable advances in technology have fostered the development of new strategies for

delivering health services across care settings. The United States leads the world in its investment in biomedical technology, and owns 85% of the intellectual property associated with biotechnology. Telemedicine/home telecare provides one example of an innovative approach that has become increasingly available during the past decade.

DELIVERY SYSTEMS

Telemedicine

Telemedicine, whereby specialists can be remotely based and still assess and counsel patients, is another growing trend in health care delivery systems. Digital photos can be sent by the Internet from the patient's location to the specialist, at substantial cost savings. For example, in sexual assault crisis centers, a nurse practitioner can capture a colposcopy image and have ready access to a consultant through telecommunications technology. Wireless technology has progressed to the point where remote telemetry is possible. Wireless sensors are capable of detecting changes in blood pressure, or respiratory rate and sending alerts. It is possible to monitor medication adherence, and when a pill is missed an alert can be sent to the patient's pharmacist or provider. Webcams can be used to assess patients who have disabilities or live in remote areas. As the aging population increasingly grows, so do chronic health disabilities. Because the majority of health care providers remain concentrated in metropolitan areas, this type of technology may help bridge the gap, especially for those in remote or rural locations.

Telemedicine technology can be used for access to medical interpreters, desperately needed in many areas with multiethnic populations. It can also be used for home surveillance of elderly persons. Eighty percent of elderly persons who need help with their activities of daily living are cared for by family members, most of whom work. It is now possible to turn on a webcam at work to "look in" on a grandparent who is at home alone. In some areas, pediatric remote home monitoring services are offered to reach underserved children who have asthma.

CHALLENGES FOR NURSES IN CONTEMPORARY SOCIETY

An Ethical Framework for Professional Practice

Nurses are intimately drawn into daily encounters with other humans, and as a result often face difficult legal and ethical concerns. The Patient's Bill of Rights, informed consent, confidentiality, pain relief, and end of life care are examples of ethical concerns.

There are four basic principles that are commonly used to help solve ethical dilemmas. Those principles are beneficence, nonmaleficence, respect for autonomy, and justice or fairness. **Beneficence** means acting for the patient's benefit. **Nonmaleficence** is known best by the saying that is credited to Hippocrates, "First, do no harm" or "*Primum non nocere*" in Latin. **Respect for autonomy** means that patients have a right to make decisions about themselves as well as the right to have the information that is needed to make certain decisions. **Justice** or **fairness**

means that all patients should be treated equally. Discrimination should not occur based on social or economic status or type of illness.

The problem is that it is not unusual for those principles to be in conflict. Consider, for example, the Jehovah's Witness mother who refuses to accept blood, even if it means the death of herself or her child. Beneficence and respect for autonomy are clearly in conflict. Jonson, Siegler, and Winslade (2002) suggest that beyond the four principles, ethics must consider contextual data to be more useful in the complex medical world that nurses work in today. These authors developed a clinical pocket guide to help clinicians analyze case circumstances in context (Table 2-1).

Collaboration in Caring— Providing a nursing perspective for resolving ethical dilemmas

Many health care settings have bioethics committees who confront the more difficult ethical problems. Nurses are often asked to sit on these types of interdisciplinary committees that usually include clergy, attorneys, social workers, physicians, and ethics consultants.

IMPLICATIONS OF THE HEALTH INSURANCE PORTABILITY AND ACCOUNTABILITY ACT (HIPAA)

The Health Insurance Portability and Accountability Act (HIPAA) is a law that was passed in 1996. It has several components, including procedural mandates designed to protect the privacy of an individual's health information. The portability component ensures that a person moving from one health plan to another will be able to continue his or her insurance coverage. Expanded federal sanctions attached to health care fraud are also included in the HIPAA law.

HIPAA resulted in a flurry of health care system-wide modifications. Many office settings were required to reorganize their sign-in procedures. Others had to rebuild patient interviewing spaces, install expensive computer safeguarding mechanisms, supply units with paper shredders, and extend continuous training to employees. With this law, patients clearly have the right to protected health information (PHI). The consequences for breaking a HIPAA law can be both civil and criminal charges. Substantial fines and imprisonment can be imposed if a patient's health information is knowingly disclosed.

Since nurses frequently have ready access to confidential patient data, extreme vigilance is required. Addresses, telephone numbers, occupations, and e-mail addresses need to be protected, along with the patient's medical history, diagnosis, and condition. Nurses must be particularly cautious with conversations that take place in public places such as elevators and lunchrooms. Communication needs to be limited to only those who *need* to know the specific information in order to provide care for the patient.

THE HUMAN GENOME PROJECT. The Human Genome Project (HGP) was a 13-year project completed by the U.S. Department of Energy and the National Institutes of Health. In 2003, the project produced the first draft of a

Table 2-1 Ethics Guide for Clinical Practice

Medical Indications	Patient Preferences

map that identified the estimated 20,000 to 25,000 genes in human DNA. More than 3 billion sequences of human DNA base pairs were revealed. The base pairs are the chemical building blocks (A, T, C, and G) that are contained in the long, twisted chains that make up the DNA of the 24 different human chromosomes. It is the DNA that provides the gene with detailed instructions about how to manage all the processes within the human body. In May 2006, Human Genome Project (HGP) researchers filled in gaps from the first draft and completed the DNA sequence for the last of the 24 human chromosomes.

Knowledge gained from the Human Genome Project offers great potential in health care. It also brings to the surface some difficult ethical issues. For example, who will control genetic information? Commercialization has already begun in the areas of genetic testing and exploration of the promise of gene therapy, including more targeted medications. Yet social consequences have not been fully resolved. If sophisticated genetic testing is available, how will privacy be maintained? What will be the psychological impact of having genetic information, especially if

it is thought to be predictive of a genetically related illness or condition? Could the information potentially jeopardize insurance coverage for an entire family? Technologies developed for more sophisticated fetal testing will invariably lead to more controversy regarding reproductive rights. The ethical, legal, and social issues associated with the Human Genome Project were built in as part of the scientific study, and many have called the project the "world's largest bioethics program."

The American Nurses Association (ANA) proactively produced a thoughtful position statement on cloning in preparation for future ethics challenges. In their statement, the ANA emphasizes that nurses "...must be able to participate actively in the public debate about the possibility of cloning human beings by means of blastomere splitting or somatic cell nuclear transplantation. It is likely that there will be attempts to clone human beings in the near future and nurses must be able to speak to the ethical implications of such developments and point out possible advantages and disadvantages for the human species" (ANA, June 2000, p. 1, see Chapter 7).

Nursing Insight— Professional responsibilities and genetics research

The possibility of using cloning techniques to create human embryos and possibly human beings raises profound ethical, social, and health concerns. It is crucial that nurses understand the science of cloning techniques and appreciate the implications of related developments in germ line gene therapy and stem cell research.

Now Can You— Discuss aspects of an ethical framework for nursing practice?

1. Describe the four basic principles involved in resolving ethical dilemmas?
2. Define HIPPA and give two examples of a breach of this legislation?
3. Discuss implications of the Human Genome Project for professional nursing practice?

Current Trends in Clinical Practice

Innovative approaches in health care delivery systems coupled with technological advances in patient management have prompted the emergence of new trends in nursing. Increased complexities in modern-day patient care are evident. Programmable electronic pumps that deliver specific rates of fluid and medications have replaced tedious bedside calculations of intravenous drips. “Paperless” (computerized) charting is quickly becoming the norm, replacing the alternating black and red inked pens that separated night shift from the day. Also gone are the large vats of medications that once lined the shelves of medicine rooms. Today, medications are dispensed in individually dosed packages stored in locked robotic machines that require computerized entry.

The aging of the population has created a shift in focus from acute to chronic care. Nurses in every specialty area are challenged to manage a rapidly expanding evidence base to guide their clinical practice. The global community, evident in patient populations, has underscored the need for collaboration and the use of “interdisciplinary” models to manage care.

Nurses are involved in cutting-edge approaches to health care delivery to patients in a variety of settings. Nursing resources and expertise have helped to develop cost-effective, innovative programs. For example, children with asthma can now be monitored in their own homes for blood pressure, pulse rate, temperature, blood oxygenation, and breathing rate. The results, quickly relayed by conventional phone lines to a secure server, are sent to health centers where nurses can assess and manage the patient who remains comfortable in the home environment.

In the area of maternal health care, a perinatal nursing service may be prescribed for women at risk for preterm labor. The service provides daily contact with a perinatal nurse and the use of an electronic device for conducting home monitoring to detect uterine contractions. Telecare is also used to monitor wound healing in medical-surgical patients. An inexpensive digital camera attached to a computer allows specialists to view the various stages of

wound healing, make clinical assessments, and provide patient consultation.

The use of telemedicine has great potential for reducing the need for hospital admissions and frequent office visits. Some nurses resist home telecare, fearful that “high-touch” care is being replaced by “high-tech” care. However, home telecare, when creatively and appropriately used, can serve to administer personalized patient care and communication, result in better outcomes, and increase patient satisfaction. The increased application of technology ensures that nurses’ caring presence in the virtual world will continue to expand. Despite the movement into “high technology,” nurses must remain cognizant of the need to provide “human-centered,” holistic care. Holism is a philosophy of care that is built upon a framework that values the human relationship and focuses on meeting the physical, emotional, spiritual, and social needs of the person.

To practice holistic nursing is to blend technology with healing while providing care that encompasses the interrelated relationships between the patient, the patient’s family and other support persons, the provider(s), and the community.

Nursing Insight— A holistic approach to care

The practice of holistic nursing encompasses approaches and interventions that address the needs of the whole person: mind, body, and spirit. Florence Nightingale recognized the value of caring for the whole person and encouraged the use of touch, light, aromatics, empathetic listening, music, quiet reflection, and other methods to empower the individual’s ability to draw upon inner strengths to promote healing (American Holistic Nurses’ Association, 2005).

NANDA-I Nursing Diagnoses for Holistic Nursing

NANDA-I Classification of Nursing Diagnoses, Nursing Interventions Classification (NIC) and Nursing Outcomes Classification (NOC) were described in Chapter 1 as classifications systems used to name nursing interventions. Examples of how holistic nursing and complementary therapies fit nicely into nursing taxonomies for documenting care are presented in Table 2-2.

Now Can You— Discuss current trends in clinical nursing practice?

1. Provide two examples of ways that home telecare can improve patient outcomes?
2. Explain how nurses can provide sensitive, personalized care that enhances the “high-tech” methods used?
3. Describe what is meant by holistic care?

CONTEMPORARY ISSUES AND NURSING ROLES

The scope and complexity of current health problems continue to present formidable challenges for nurses. There is no room for complacency in nursing’s future. Nurses will inevitably need to struggle to keep up with the exponential growth of information, evidence-based

Table 2-2 Selected Nursing Diagnoses and Nursing Interventions: Possible Pairings of Nursing Concerns and Complementary/Alternative Interventions

Impaired Comfort	Acupressure, therapeutic touch	To decrease perceived pain
Disturbed Sleep Pattern	Massage	To promote relaxation, rest
Social Isolation	Pet therapy	To provide affection
Impaired Coping	Humor	To facilitate appreciation of that which is funny, to relieve tensions
Hopelessness	Hope instillation	To promote a positive sense of the future
Spiritual Distress	Spiritual support	To facilitate a sense of inner peace
Spiritual Well-Being	Spiritual growth facilitation	To support growth/reflection/reexamination of values
Anxiety or Fear	Guided imagery, relaxation therapy, biofeedback, calming techniques	To reduce sense of anxiety
Impaired Communication	Art therapy	To facilitate expression

Source: Frisch, N. (May 31, 2001). Nursing as a context for alternative/complementary modalities. *Online Journal of Issues in Nursing*, 6(2), Manuscript 2. Available online: http://www.nursingworld.org/ojin/topic15/tpc15_2.htm

knowledge, and technological advances. Nurses are likely to deal with ethics questions that have never been faced before. The growth and diversity of the population will require more cultural sensitivity than ever before. The continual threat of chronic diseases demands creative, holistic approaches. Infectious disease threats will continue to challenge health care resources at the national and international levels. Terrible natural and manmade disasters will tax the nation's systems to their fullest extent. All citizens will feel the effects of HIV-AIDS as the disease trends toward women and children.

Nurses must extend their caring work beyond individual patients and families to communities, sociopolitical systems, and national and global health arenas if they are to have a significant impact on health promotion. Major disparities in health outcomes between families and children from racial and ethnic backgrounds and those of European American backgrounds must be confronted. Nurses have serious work to do to empower the many Americans who are without adequate health care coverage and access to services.

Broad-based efforts are needed to work through societal, economic, and cultural issues. Nursing's passion for evidence-based solutions must continue and remain focused on conditions that determine the health of individuals and populations. The *Healthy People 2010* national initiative is a step in the right direction. States, communities, and national organizations have rallied behind the priorities, goals, and objectives set in *Healthy People 2010* and have used it to guide their own health planning efforts.

A caring, holistic nurse is one who endeavors to develop and apply critical thinking skills to bring about changes, not only to bedside nursing of the individual, but to social justice issues that are determinants of health. Nurses have continually been ranked as the top professionals in the public trust in Gallup's annual Honesty and Ethics Poll since they were added to the list in 1999. The only exception occurred in the year after the World Trade Center attacks, when firefighters were ranked number one. As a profession, nursing's challenge is to step up and claim that popular power with the public and use it to be a dynamic force in transforming family and community health systems.

summary points

- ◆ There is much work to be done and health care challenges can best be faced by using multitiered, holistic approaches such as those articulated in the Intervention Wheel model.
- ◆ *Healthy People 2010's* visionary blueprint prioritizes national goals for health so that health promotion efforts can be focused and aligned.
- ◆ A priority goal of *Healthy People 2010* centers on resolving health inequities in the United States.
- ◆ An overview of societal trends reveals where present and future health problems are arising and where efforts should be concentrated.
- ◆ Technological trends such as the Internet, telemedicine, and genetics research highly influence health issues.
- ◆ Cultural trends must be used to guide the designing of effective, culturally acceptable health interventions and programs.
- ◆ Nurses need to be vigilant and confront the negative effects of racism and prejudice in all health care settings.
- ◆ Nurses need to be familiar with health policy and programs of assistance so that patients can be referred to needed resources whenever possible.
- ◆ There are numerous vulnerable populations in the United States and the "common good" ethic needs to be rediscovered.
- ◆ The nurse of the future will face unprecedented ethical challenges that can be analyzed using a systematic framework like the one described by Jonson and colleagues.

review questions

Multiple Choice

1. The clinic nurse is providing information to Tracy and her 5-year-old child who has just been diagnosed with rubella. The nurse encourages rest, acetaminophen (Children's Tylenol), and increased fluids. This intervention is an example of:
 - A. Primary health prevention
 - B. Secondary health prevention
 - C. Tertiary health prevention
 - D. Mandatory health care

2. The clinic nurse is aware that a specific health concern for Black women in the population between 45 and 64 years of age is:
 - A. Stroke
 - B. Breast cancer
 - C. Hypertension
 - D. Motor vehicle collisions
3. The clinic nurse understands that nonmaleficence is a concept used in ethical decision making. It means:
 - A. First do no harm
 - B. Acting on the patient's behalf
 - C. Patients have a right to information
 - D. Patients should be treated equally

True or False

4. The perinatal nurse is aware of the Intervention Wheel and its potential for nurses working with community leaders to examine health issues more holistically.
5. Nurses who are taking a more proactive approach to childhood obesity would support the Food and Drug Administration (FDA) program to increase food labeling and decrease portion sizes in restaurants.
6. The clinic nurse is aware that with telemedicine, photos may be sent to the clinic doctors from remote sites and diabetics may send their "logs" for review before their appointments.

Fill-in-the-Blank

7. The clinic nurse is aware of the *Healthy People 2010* report and its identification of health _____ for the nation.
8. The public health nurse understands that when studying effects of diseases, it is the _____ rate that should be the focus of attention.
9. The pediatric nurse is aware that "race" as a concept is best defined as how persons _____ one another and _____ one another.
10. The clinic nurse is aware of the effects of poverty on the families seen in the clinic as the poverty rate has _____ yearly since the year 2000. At present, the most impoverished group is _____.

See Answers to End of Chapter Review Questions on the Electronic Study Guide or DavisPlus.

chapter 3

The Evolving Family

Question of Family

What is a family but a collection of beings dwelling together?

But it is more than that

One person might see a refuge from the storms of society...

Another, a prison to prevent help from the outside world.

It can be both and more.

We draw our first breath in the presence of our family and hopefully

... we are held in family's arms when we sigh our last.

We learn all that is good in its caring boundaries or keep secrets of terror locked in its heart.

The difference between knowing love and trust and learning never to love or trust is in what passes between members of the family and what is passed on through members to their families.

What have you learned from your family?

What will you pass to your family?

— Brian Fennesbeck, 2006

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Identify different structures of the modern American family.
- ◆ Describe theoretical concepts that apply to the family.
- ◆ Assess the family using selected family assessment tools during an interview.
- ◆ Apply specific family nursing diagnoses and interventions to the family.
- ◆ Discuss special family problems that often require nursing intervention.
- ◆ Compare various family cultural characteristics that may impact nursing care.
- ◆ Expand patient care to include and involve the family in every nursing setting.

moving toward evidence-based practice: Parenting Concepts Among Culturally Diverse Cultures

McEvoy, M., Lee, C., O'Neill, A., Groisman, A., Roberts-Butelman, K., Dinghra, K., & Porder, K. (2005). Are there universal parenting concepts among culturally diverse families in an inner-city pediatric clinic? *Journal of Pediatric Nursing*, 19(3), 142–150.

The purpose of this study was to examine universal concepts in parenting philosophies and practices, which are in common across multiple cultures. The researchers used a grounded theory approach with ethnographic interviews of 46 English-speaking families representing 27 countries. All participants were from families of well children in an inner city hospital clinic in the Bronx, New York. The children's ages ranged from 7 days to 15 years of age. The researchers stated that New York City has

long established immigrant neighborhoods, tolerance, and plentiful jobs, factors that have been instrumental in attracting diverse cultures during the past century.

Interviews were completed using a question guide composed of open-ended questions, which were developed by the research team. The purpose of the questions was to elicit stories or examples from parents regarding the everyday care of their children. From transcribed interviews, 22 thematic categories

(continued)

moving toward evidence based practice (continued)

were identified, which were condensed into 11 common themes. The themes were subdivided into three broad headings: parenting philosophies; influence of American culture and perceived opportunities for children; and parenting practices. Similarities were identified among families in all categories.

Findings from the study indicated that a sense of community, family, and spirituality or religion was strong among all cultures, as was the importance of teaching values, respect, and the need for strict discipline. Television was considered to be an educational influence and parents believed that opportunities existed for jobs and higher education for their children. Parents expressed concern for child safety when playing alone outside

and mistrusted nonfamily babysitters. Parents also indicated a preference for medical treatment rather than home remedies during episodes of acute illness. They expressed concern regarding the desire for preserving individual cultural heritage versus becoming assimilated into American society.

1. Based on this research, do you believe that sufficient evidence exists to generalize the study findings to all culturally diverse populations?
2. How useful is this information to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

This chapter addresses the assessment of families and highlights interventions for families encountered in a variety of nursing settings. Viewed through the lens of the media, actual and perceived changes that have taken place in the American family since the 1940s are explored. Modern-day family structures and challenges are described and various theories from psychology, sociology, and nursing are presented to provide a reference point for family assessments and interventions. A nursing diagnosis is presented and described in detail to illustrate the possible goals, interventions, and evaluation criteria that could be used with a family that is experiencing problems with daily functioning.

Concepts such as developmental and group stages of the family, communication, roles and relationships, and special need families are presented to assist with the planning and implementation of family centered care. Cultural characteristics and comparisons of American family orientation with families from various ethnic backgrounds provide the nurse with a starting point for the delivery of culturally sensitive care for American and international families.

The Evolving Family

VIEWING THE FAMILY IN A NURSING CONTEXT

A nurse hears in report, "...that family is starting to get to me. They have a million questions and want to be involved in any decisions that are made related to the patient." Another nurse asks, "Why is this patient still a full-code status? Someone needs to clue the family in on what the actual prognosis is. They are grasping at straws!" Another's comments: "I had to ask the boyfriend to leave again...the family does not want him around their daughter any more."

The preceding statements reflect an often-prevailing narrow point of view related to families and their involvement in nursing care. The literature describes the ideal nursing approach as one that views the entire family as the recipient of care, rather than only the individual patient (Harmon Hanson, Gedaly-Duff, & Rowe, 2005). In most practice settings, under the best circumstances, the family is seen as contextual background for the patient, and,

under the worst, the family represents a pesky interference or additional stressor in the patient's hospitalization and treatment. Nurses should lead the team of health professionals who welcome and embrace the involvement of families in every care setting. In most situations, the family represents a rich source of information and support for the patient. An important role for nursing involves tailoring each plan of care to include the family in interventions that will assist the patient's reintegration back into the family unit following discharge.

THE HEALTHY PEOPLE 2010 NATIONAL INITIATIVE

The family is the starting point for societal changes needed to ensure the health of families in the future. The national initiative *Healthy People 2010* outlines objectives and indicators that provide the basis for interventions, education, and policy on improving health in this decade. All of the indicators encompassed in this important national health initiative have an impact on the family, such as physical activity, overweight and obesity, tobacco use, substance abuse, responsible sexual behavior, mental health, injury and violence, environmental quality, immunization, and access to health care (USDHHS, 2000). Target areas concerning social policy and access to health care for families are underscored in the charge to "...reduce the proportion of families that experience difficulties or delays in obtaining health care or do not receive needed care for one or more family members" (Hitchcock, Schubert, & Thomas, 2003, p. 435).

Families Today

The family is widely defined by many different sources reflective of the social, biological, and legal domains (Friedman, Bowden, & Jones, 2003; Harmon Hanson et al., 2005). Various definitions describe members who comprise the family, their inter dependence, and methods of interaction. A **family** consists of two or more members who self-identify as a "family" and interact and depend on one another socially, emotionally, and financially (Harmon Hanson, 2005). Most often, family structure involves either the **family of origin** (the family that reared the individual)

or the **family of choice** (the family adopted through marriage or cohabitation). A single person belongs to a family of origin, but may choose not to become a member of a family of choice. A single individual cannot constitute a family. Instead, most definitions of family include a prerequisite of at least one other person who is self-defined as being a part of the family (Harmon Hanson et al., 2005; Friedman et al., 2003; Wright & Leahey, 2005).

Nursing Insight— Differentiating among various family configurations

In contemporary society, the traditional **nuclear family**, which consists of a male partner, female partner and their children, actually represents only a small number of families. Other family members, termed **extended family**, may also live in the same household. According to the Urban Institute, there are five categories of families (Wherry & Finegold, 2004):

1. The **married-parent family** includes biological or adoptive parents. This family structure accounts for approximately 64% of American families. It describes 69% of Caucasian, 55% of Hispanic, and 26.6% of African American families (Wherry & Finegold, 2004).
2. The **single-parent family** consists of an unmarried biological or adoptive parent who may or may not be living with other adults (Wherry & Finegold, 2004). The **homosexual family** (lesbian and gay) consists of same-sex partners who live together with or without children. This family structure may also consist of single gay or lesbian parents or multiple parenting figures (Friedman et al., 2003).
3. The **married-blended family**, formed as a result of death or divorce, consists of unrelated family members who join together to form a new household.
4. The **cohabiting-parent family** describes one in which children live with two unmarried biological parents or two adoptive parents.
5. The **no-parent family** is one in which children live independently in foster or kinship care, such as living with a grandparent or aunt.

Ethnocultural Considerations— Patterns of family structure

Patterns of family structure tend to be culturally influenced. For example, Hispanic children are more than twice as likely as African American children to live in cohabiting-parent families and they are approximately four times as likely as Caucasian children to live in this type of family configuration (Wherry & Finegold, 2004).

THE CHANGING FAMILY AS REFLECTED IN THE MEDIA

Family changes and adaptations from the Cro-Magnon era to the present day have been well researched and documented, but it is useful to examine the more recent changes that have taken place over the past 20 to 40 years. During this time, family structure and roles have changed rapidly and at present seem to be in a state of flux. As American families transition and evolve, television and theater often provide useful insights into the predominant family themes of the time.

For example, in the 1950s and 1960s, a nuclear family was presented with little emphasis on the extended family. Programs such as *Ozzie and Harriet*, *Leave It to Beaver*, *The Dick Van Dyke Show*, and *Father Knows Best* portrayed the typical family as one that included the mother and father along with one to three children. Family roles typically portrayed a father-dominated household and a homemaker mother who would occasionally flex her decision-making authority when the father's advice did not work. Issues were generally simple and resolvable with an occasional foray into societal issues such as racism or mental health. When problems such as alcoholism were presented, they tended to be in the context of an outsider who temporarily touched the family and then left. Rarely was there depiction of a serious internal family mental health problem. Instead, scenarios involved events such as girlfriend-boyfriend situational crises or friend-related peer pressure. Occasional variations in family structure were offered in weekly programs such as *Bonanza*, *Family Affair*, and *My Three Sons* that portrayed households run by males who received assistance from a housekeeper or relative.

Programming during the 1960s and early 1970s reflected a growing trend toward themes that included blended families with shows such as *The Brady Bunch*. These weekly programs tended to present upper income families with housekeepers and stay-at-home mothers who deferred major decisions to the father. Widowhood, as opposed to divorce, usually constituted the reason for remarrying, and this situation neatly sidestepped the unpleasantness of a broken home resulting from divorce.

Family issues continued to relate primarily to difficulties associated with school and dating. Major breakthroughs were achieved with *All in the Family*, *The Jeffersons*, *What's Happening*, and other sit-coms in the 1970s that dealt with the turbulent issues of civil rights and sex equality and changing views on race and gender.

During this time, there were also shows that began to present selected variations of family. For example, *The Mary Tyler Moore Show* centered on a career woman whose close work relationships served as a central component of family. *Gilligan's Island* presented family-like associations that dealt with work or survival issues as a team and shared support and platonic love and loyalty that would have normally been received from a family. The 1990s to 2000s version of this theme was expanded in *Friends* and *Seinfeld*, programs that introduced the idea that people could remain single longer without the expectation that a family was defined by marriage and procreation. This trend is again reflected in more recent programs such as *Grey's Anatomy*, where unrelated individuals form a family with "ties" that sometimes are actually stronger than those with their biological relatives who may not always "be there" for them.

Television programs during the 1980s and 1990s also began to address variations in social class and politics with shows such as *Family Ties*, which explored social issues such as premarital sex, dealing with the death of friends, and Alzheimer's disease. Interestingly, the episodes did not always present a clean resolution of an issue but instead focused on the importance of family closeness and support in dealing with the problem within the context of battling political views. *The Cosby Show* depicted a black upper middle-class family in which both parents were white-collar professionals.

The 1990s brought increased awareness of the challenges facing families dealing with poverty, alcoholism, and abuse within their own ranks rather than as a problem that occurred only outside of the family. *Grace Under Fire* presented a single head of household who was a recovering alcoholic. *Roseanne* revolved around a matriarchal family structure in a lower economic setting where both parents had to work to make ends meet. One particular episode in this series dealt with how to write a check in a way that delayed cashing (and subsequently, “bouncing”) it, to allow extra time for sufficient funds to be deposited into the account.

Television sitcoms in the new millennium continue to reflect trends consistent with societal changes. Family structures such as the binuclear arrangement (two intact nuclear families sharing a home), and the divorced family living with a brother and sharing responsibility for rearing a son (*Two and a Half Men*) are examples of alternate family themes that have emerged in recent times. Programs such as these may be preparing the way for shows that depict same-sex unions with or without children.

Also reflective of contemporary society is the trend of sitcoms that feature extended family members such as the live-in father in *King of Queens* and the very intrusive parents in *Everybody Loves Raymond*. The success of the movie *My Big Fat Greek Wedding* opened the door for depicting ethnic families that were keeping their own values and beliefs separate from those of the prevailing culture. Hispanic, Jewish, Asian, and other ethnic groups have revealed their differences in humorous but culturally sensitive ways. The media, however, generally provides only a superficial representation of the varied and complex challenges faced by the modern-day family.

Collaboration in Caring— Five functions of the family

1. Physical Needs: Meets the primary basic needs such as food, water, clothing, and shelter.
2. Economic Needs: Access to enough financial resources to adequately meet the family's needs and wishes.
3. Reproductive Needs: Ways that add new life to the family unit and maintain a healthy sexual relationship between parents.
4. Affective and Coping Needs: Strategies to deal with everyday stresses of life and encourage a nurturing environment.
5. Socialization Needs: Processes whereby families acquire the skills, knowledge, attitudes, and values necessary for performing their social roles.

STRESSORS ON FAMILIES TODAY

Health Care

Today's families face varied and complex challenges. Baby boomers are aging and entering retirement. This shift in the contemporary workforce leaves openings and shortages in critical areas such as education and health care and at the same time adds increased demands on a health care system already burdened with an aging population. For many, insurance coverage changes and often becomes more expensive as retirees transition from employment insurance to retirement insurance options

such as Medicare and Social Security. In many instances, families have no options for insurance because of part-time work or unemployment.

At present, more than 45 million families in the United States are uninsured (U.S. Department of Health and Human Services [DHHS], 2005b) and as many as 13.5 million individuals have been homeless at some point during their lifetime (Harmon Hanson et al., 2005). All too frequently, families are counted among these staggering statistics. Health issues among homeless families and individuals are numerous and usually result from a lack of preventive care and a lack of resources in general. For example, in addition to the problems associated with extreme poverty, homeless women are at an increased risk for illness and injury and many have been victims of rape, assault, and domestic abuse (American College of Obstetricians and Gynecologists [ACOG], 2005).

The rural homeless are more likely to be families who are living with other families or migrant workers who live in vehicles and follow crop harvesting. Access to health care and discrimination in health care practices are major problems for this population. At present, there are approximately 3 million migrant and seasonal farm workers in the United States, and of these, 21% are women. Although the workers represent a number of ethnic and cultural groups, 75% were born in Mexico, 81% speak Spanish, their average age is 33, and the majority have not been educated beyond the seventh grade (U.S. Department of Labor National Agricultural Workers Survey, 2005). As the nation becomes more culturally diverse, there is a growing imperative to eliminate racial and ethnic health care disparities by providing ready access to quality care for diverse populations (Weissman et al., 2005).

Nursing Insight— Health care resources for women without U.S. citizenship

Approximately 26% of women who do not have U.S. citizenship lack a regular health care provider and 45.5% have no health insurance coverage. Their access to health care is further compromised by policies that restrict Medicaid eligibility for this population (Kaiser Commission, 2003a). In a study that compared the health care costs of immigrants to those of U.S. citizens, it was found that total health care expenditures for immigrant adults and children were significantly lower than those of U.S.-born citizens (Mohanty et al., 2005).

Mental Illness

Other problems that arise from both internal and external causes also impact families. In any given year, an estimated 57 million individuals and their families deal with mental illness (U.S. Census Bureau, 2005). Affected families not only face dealing with a potentially chronic illness that continues to be stigmatized by society, but they also must grapple with paying for treatment of a diagnosis that is largely exempt from insurance coverage. Challenges that come from external forces outside of the family system include environmental assaults such as catastrophic weather, forest fires, and earthquakes. An entire region of families continues to be affected by problems that follow in the aftermath of hurricanes, fires, and floods.

Nursing Insight— *Recognizing the relationship between family stressors and poor health outcomes*

Families may have multiple stressors that increase their vulnerability to poor health outcomes. Problems such as substance abuse, mental illness, domestic violence, and limited access to medical care due to unemployment, loss of medical insurance, or inadequate insurance coverage can affect families across all strata of society.

Societal Pressures

The family also faces societal pressures. The incidence of violent crimes has decreased in major urban areas, but suicide among children and adolescents continues to represent an important societal issue. The number of families currently affected by AIDS is increasing at a startling rate. Women and children, a vulnerable population due to barriers associated with access to health care, constitute the fastest growing segment of the population to contract HIV. Public education is in a state of crisis as demands increase on teachers who are confronted with diminishing resources.

These and many other issues continue to challenge families. Meanwhile, family structure and roles are undergoing changes that frequently increase the potential for further family problems. Present trends show a diminishing number of nuclear family households. The traditional family structure is being replaced by one that includes a single head of household, most frequently a divorced or abandoned mother. The number of unmarried mothers continues to increase. Statistics reflect the current trend: the percentage of children living with two married parents decreased from 85% in 1970 to 68% in 2004. A divorced or single woman is usually the head of household in those families, although recently there has been an increase in single male head of household families from 1% to 5% (Child Trends Data Bank, 2006). In other situations, the head of household is homosexual or sharing a home with a same-sex partner.

These trends reflect increasing opportunities for alternative forms of parenthood within contemporary American society. The nontraditional parenting arrangements result from more liberal social mores as well as the technological and medical advances that now offer the possibility of parenthood to single men and women (Greenfield, 2005). Homosexuality and same-sex partnerships/marriages and their effects on the family raise political, social, and religious issues that have increasingly found their way into present-day discussions. Although the far-reaching impact of same-sex relationships on family structure and function has not been adequately studied, areas that frequently must be addressed concern child custody, legal consent, power of attorney, and confidentiality. The following case study provides an example of some of the issues and questions that may need to be addressed by the family and the patient's care providers.

“What to say” — *Effective tools for families*

Covey (2006) discusses effective tools that may enhance family performance. The nurse can communicate these principles to families that may promote healthy family functioning.

- Be proactive: Become an agent of change in the family.
- Begin with the end in mind: Develop a family mission statement.
- Put first things first: Make the family a priority in a turbulent world.
- Think “win–win”: Move from me to we.
- Seek first to understand then be understood: Solve family problems through empathetic communication.
- Synergize: Build family unity through celebrating differences
- Sharpen the saw: Renew family spirit through traditions

case study The Family with Same-Sex Partners

Julia, a 37-year old comatose woman, is dying of ovarian cancer. She is on life support in the hospital. The family, which includes ex-husband, Dan, and two children—John, age 12 and Tami, age 14—has gathered in the visitors' lounge. Cindy, Julia's life partner, is also present in the lounge. The family is discussing whether to extend Julia's present level of care or to begin to wean her from life support. Although Julia has a living will, there is concern and conflict among the family members and Cindy regarding how and when the will should be honored. Dan questions the appropriateness of Cindy's being in attendance for the discussion.

1. What would the nurse need to know to help the family problem-solve in this situation?
2. What resources are available to the family and the nursing staff to help clarify these issues?

◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

The **skip generation**, an arrangement in which the grandparents rear grandchildren with or without the parents' help, describes another present-day variation in family structure. In 1994, 16% of preschool children of working parents were cared for by a grandparent. Today, 2.4 million grandparents assume primary responsibility for more than 6 million children and many of these households do not have the children's parents living in the home with them (AARP, 2006).

Now Can You— *Discuss contemporary family changes and stressors?*

1. Define family and identify five family categories?
2. Identify three changes in family structure that have been highlighted in the media?
3. Identify five stressors faced by the American family today?

Family Theories and Models

Development of a specialized body of knowledge provides the foundation for a profession. While nursing theories and models are essential in defining nursing and nursing practice, theories from other disciplines are important in providing insights into other dimensions of health and human behavior. For example, family theory, which draws

from a number of related disciplines (Harmon Hanson et al., 2005), helps to guide assessment and intervention within a holistic framework that views the entire family as client. The following discussion presents several theoretical models representing a cross section of useful concepts to assist in the nursing assessment and to facilitate a creative application to various family interactions.

FAMILY SYSTEMS THEORY

A systems approach to understanding the family centers on the recognition that changes that occur in one member affect the entire family. The family systems theory, which views persons as “open systems,” has at its central theme: “The sum of the parts is greater than the whole” (Harmon Hanson et al., 2005). According to this theory, the family shares a unique identity that is far more complex than that of its collective members. The family is dynamic, constantly adjusting to information that filters in from the surrounding environment and from within the family.

Nursing Insight— Clinical application of the family systems theory

When working with families, the nurse uses the family systems theory to “view the family as a unit and focus on observing the interaction among family members rather than studying family members individually” (Wright & Leahey, 2005).

The following situation helps to illustrate application of the family systems theory: An addicted member receives help for the addiction and then returns to the family system. The changes in the recovering family member have a significant impact on how the entire family acts and reacts. A new system of communication is established. In the new system, the family members communicate assertively and supportively with each other and no longer adhere to the former framework of denial that a problem exists and secret keeping. The nurse working with the family recognizes that teaching and referrals to appropriate community resources are most likely be needed to facilitate the family’s healthy adjustment to the changes.

Boundaries

Another concept inherent in family systems theory concerns boundaries. Each system contains a boundary that affects how the outside world is allowed to interact with the family members. Stated another way, boundaries identify the family’s control of how the family system interacts with the outside world. A family whose children obtain food and shelter by begging from the neighbors demonstrates a problem with boundaries that are too permeable. Permeability refers to the degree that information and interchange are allowed to flow between systems. An ideal system is one that is semipermeable. In a semipermeable system, the boundaries are secure enough to keep the family intact, but still allow for free interchange with the outside world. In this situation, the family system readily interacts with outside systems. A healthy family has a semipermeable boundary that allows and encourages interaction with outside agencies such as work, school, church, and family, and friends.

A closed boundary serves to keep family secrets inside and therapeutic interventions outside. Closed boundaries often occur in families with issues of addiction or abuse.

Families of alcoholics soon learn not to disclose information about their problems to outsiders. Conversely, a family that is so lacking in structure that it allows an uninterrupted free flow of information/intervention to and from outsiders can be said to have an open boundary or no boundary at all. For example, an open boundary exists with a family whose children are so neglected that they rely on friends or neighbors to feed them.

Nursing Insight— Recognizing the childbearing family’s boundary permeability

The extent to which the **suprasystem** (the broad system that surrounds the family unit, such as the cultural community) influences the childbearing family’s participation in activities such as childbirth education, prenatal care, and infant care is dependent upon the family’s boundary permeability.

Subsystems

Family systems are further divided into subsystems. A family of four may constitute the “main” system. The mother and father represent a subsystem that has a permanent or temporary relationship that is a part of, yet separate from, the main family system. Children often form alliances with other siblings or with one parent. A subsystem can develop when a sibling marries or cohabits with another individual who is temporarily or permanently accepted into the family. Subsystems are necessary parts of family functioning, especially in health crisis situations when families must make decisions for sick or disabled members, or when new dependent members join the family. For example, the birth of a baby introduces a new member who becomes part of the family system, but is also a subsystem with the mother or father or other family caregiver(s).

Ethnocultural Considerations— Boundaries and receptivity to information

Families that have recently immigrated to this country may be receptive to health information only from extended family members or from persons within their cultural community.

Balance and Homeostasis

The family system continually strives to return to balance or achieve homeostasis after a crisis. When a family member is sick or injured, or when an emergency arises that requires a reorganization of the family (i.e., an evacuation during a storm), the family quickly attempts to return to former routines and rules as a way of reestablishing homeostasis. At certain times the family is unable to return to former normalcy and instead must adjust or form adaptive behaviors. For example, the family may learn to work with a wheelchair and other adaptive devices when a member suffers a stroke or spinal cord injury. Over time, adaptations become the norm for the family.

Maladaptive behaviors are an alternate adaptation that involves the use of unhealthy or abnormal behaviors to adapt to a family crisis. Enabling and codependency are common maladaptive behaviors that are often adopted by an addictive family (Townsend, 2005). Enabling involves making excuses or obtaining substances for the addictive

family member. Codependency is a maladaptive behavior in which the nonaddicted family member joins the addicted member in the use of alcohol or other substances as a way of interacting or communicating.

FAMILY DEVELOPMENTAL STAGES AND THEORY

Developmental theory (Friedman et al., 2003; Harmon Hanson et al., 2005) has at its core the idea that every life moves through developmental stages with tasks that need to be accomplished before moving on to the next stage. Duvall identifies eight family stages: beginning, childbearing, preschool children, school-age, teenagers, launching, middle-aged, and retirement (Friedman et al., 2003). Each stage is accompanied by specific tasks that are performed to assist with the physical and emotional development of the family members in that particular stage.

When working with families, the nurse should identify what stage(s) the family is in and assess how well the needs for that particular stage are being met. Learning, attachment, and grieving represent specific tasks that are affected by the developmental stage. Teaching needs and nursing interventions are structured and implemented according to the developmental stages of the family and its members. Although the stages follow one another in a linear progression, some families may simultaneously be in more than one stage or they may revert to previous stages (Wilkinson & Van Leuven, 2007).

Beginning Families

Beginning families are those that have just been formed through marriage or that self-identify as family, as in the case of common-law unions. The beginning family identifies shared goals that may include career paths, homebuilding, and planning for children. Creating shared time together in order to build the relationship constitutes a central developmental task for all families and this special together time traditionally is initiated during the honeymoon period. Combined households and property are common features of all families. One of the limitations of Duvall's theory concerns its application with the childless family. If the family has no children, many of the developmental stages are not applicable until the couple reaches middle age and beyond. If the family does have a child, the family developmental stage parallels the age of the child. When more than one child is present, the family is usually in more than one developmental stage.

Childbearing Stage

The childbearing developmental stage begins with conception. Early tasks during this stage include seeking prenatal care and planning for space for the child. If there are other children already in the home, the family begins to prepare and socialize the other children into a sibling role. Ideally, the family involves the children in decision making related to preparation for the expected baby. For example, siblings can help to choose paint colors for the baby's room or offer advice regarding toys or clothes to select for the baby. When the baby is born, the family must adapt its routines to include the various tasks associated with feeding and caring for the baby. Family teaching needs may include dealing with sleep

pattern disturbances related to feeding and changing diapers through the night. Along with strategies for successfully coping with these adjustments, the nurse can offer support and reassurance. The nurse assesses the family's readiness and openness to learn and receive help (an open boundary) and, according to specific needs, may provide additional information concerning nutrition, the importance of well-baby visits, car seats, immunization schedules and infant crib monitors.

Optimizing Outcomes—Applying developmental theory when caring for the childbearing family

An understanding of the normal phases of the life cycle helps the nurse to provide anticipatory guidance for the childbearing family. Strategies to bolster the young child's sense of security when a newborn is brought home may divert a potential family crisis.

Preschool Stage

The preschool developmental stage includes toddlerhood and attending kindergarten. During this stage, the child has learned to walk and actively explore her world, which encompasses siblings and other family members and friends. At this time, families need information about the prevention of injuries and interventions for accidents that usually result from the child's increased motor abilities coupled with less-developed judgment and coordination. The nurse should be alert for signs of abuse or neglect during this stage. Points of contact that allow the nurse to assess developmental progress occur during well-child checks, immunization appointments and office or hospital visits for the child or other family members.

School-Age and Adolescent/Teenage Stages

The school-age and adolescent/teenage developmental stages provide the optimal opportunity for teaching about drugs, sex, and health promotion. Personal values are shaped and clarified and ethical development occurs during this time. Surveys have shown that nurses are included among the top ten trusted people sought by school-aged children to discuss issues important to them.

Launching, Middle Age, and Retirement Stages

The launching, middle-age, and retirement developmental stages bring the family full-circle back to the early issues of self and couple-building with less emphasis on children (if successfully launched) and more involvement in community and hobby-related interests. The young adult who is not successfully launched from the childhood home presents a complication of incomplete launching. This situation may represent a temporary arrangement necessary for continuing education or it may provide a convenient and economical "non-action" by the son or daughter until ties with others have been established. The nurse's role in this situation is to assess whether the living arrangement creates a problem (e.g., anger, frustration, and delay in meeting goals) for either the parents or the child. Interventions may include strategies to improve communication between the parents and the child and/or community referrals for assistance with goal setting and vocational training.

STRUCTURAL–FUNCTIONAL THEORY

Structural–functional theory focuses on the functioning of the family and the roles assumed by each family member to promote family function. Necessary roles include provider, housekeeper, child caregiver, socializer, sexual partner, therapist, recreational organizer, and kinship member. Although a family member often assumes more than one role, some roles may be exclusive to only one identified member. This arrangement takes on added significance concerning the family's ability to move forward when a member is unable to fulfill his or her exclusive role (Friedman et al., 2003; Harmon Hanson et al., 2005; Wright & Leahey, 2005). According to structural–functional theory, if any of the roles are not managed by one or more members of the family, problems such as disorganization, deficits in hygiene, isolation, and other negative situations will emerge that may require a nurse's intervention to help the family return to balance (Harmon Hanson et al., 2005).

Provider Role

The provider role is the money-earner or the resource gatherer. One or more family members pay the bills and distribute resources to other family members for clothing, food, and recreation. If the provider is sick or hospitalized, the family identifies an alternate provider to temporarily meet that need or identify other resources such as savings, insurance, or public assistance in order to pay bills.

Housekeeper

During recent years, the housekeeper role has evolved from the traditional stay-at-home mother as increasing numbers of women are engaged in full-time employment outside of the home. Housekeeping involves not only the physical cleaning and maintenance of the family environment but also the organization of family duties to maintain a stable, healthy living situation for the family.

Child-Caregiver

The child-caregiver role is assumed by the person (usually the mother) who is designated as the primary care provider for the children. This role is performed by a designated member such as the mother, father, grandmother or uncle, depending on the family structure. Someone (i.e., childcare facility, babysitter) is responsible to ensure that the children are supervised and cared for even when the primary child-caregiver is away from home.

Socializer and Recreational Organizer

The socializer and recreational organizer roles may not be as consciously directed as the previous roles, but they encompass how the family interacts with others. Initially, the parents or guardians may arrange interactions for the children through family and friend gatherings, trips, and activities. Eventually, most members begin to organize their own social events through personal friendship choices and preferred activities outside the home. Socialization is taught by the family and may be a role that is shared equally among family members unless a problem occurs. Family trips, holidays, and birthdays are important events that teach family patterns that children will later use to help them develop their own family's social and recreational roles.

Sexual Partner

The sexual partner role should exist between the parental units. Variations exist in different family structures. In every structure, children should have education and role modeling on how to interact in socially and sexually appropriate ways. Healthy family interactions constitute the first defense against abuse and violence.

Therapist

The therapist role is assumed when one family member expresses concern for another's health or emotional well-being. For example, concern about the husband's blood pressure prompts the wife to make a doctor's appointment for him. The therapist role can also involve active listening and other expressions of caring as family members help one other through a loss or a crisis.

Kinship

The family member who organizes family reunions, corresponds with friends, sends birthday and holiday greetings, and reminds children to write thank you notes assumes the kinship role. The wife most often assumes this role and is charged with the responsibility of remembering important dates for her spouse's family as well as for her own.

Optimizing Outcomes— Applying the structural functional theory

Structural–functional theories view the family as a social system and focus on outcomes, not process. Nurses can use structural functional theory to assess how well the family functions internally among family members and externally with outside systems.

COMMUNICATION THEORY

Communication theory asserts that emotional problems result from the way people interact with each other in the context of the family (Harmon Hanson et al., 2005). Healthy families have clear rules such as “we don't interrupt each other when speaking” or “we don't yell at each other.” Communication is clear and congruent and nonverbal cues match what is being said. Unhealthy families give mixed or double-binding messages, which are statements accompanied by nonverbal expressions that are inconsistent and incongruent with the verbal message. Healthy families communicate love and support clearly and often. Verbal communication is matched by nonverbal communication (such as hugs, voice tone, and eye-contact) that supports the intended message. Families check with each other to make sure the intended meaning is understood. For example, a parent explains; “I am setting a curfew because I care about you and want you to be safe. Does that make sense to you?” The parent then encourages discussion to ensure clarity and understanding of the purpose of curfew.

Nursing Insight— Family communication patterns

Patterns of family communication reveal much about family functioning. In addition to providing information about “who is saying what and to whom,” they also convey information about the structure and functions of family relationships in

relation to the power base, decision making processes, affection, trust, and coalitions. Dysfunctional communication inhibits healthy nurturing and diminishes personal feelings of self-esteem and self-worth.

The nurse or family therapist assesses a repeating negative pattern such as excessive drinking to determine if it has been replaced instead by an assertive yet supportive and positive communication. For example, a wife complains to the nurse that her husband drinks more whenever they have an argument about their children. The husband notes that his wife complains to him about the children whenever he tries to relax by drinking. The nurse educates the family that interventions regarding either the arguing or the drinking could help to break the pattern of negative communication and refers them to a support group or a counselor to learn new patterns.

GROUP THEORY

Group theory can be applied to the family as a group. Norms (rules of conduct), roles, goals, and power structure are inherent family concepts along with the division of household chores, expectations of completed homework, and curfew enforcement. According to group theory, stages of groups (forming, storming, norming, performing, and adjourning/terminating) explain expected behaviors that occur in any given stage (Clark, 2003; Johnson & Johnson, 2003).

Forming describes the beginning phase of the group. In families, the forming stage usually occurs through marriage or cohabitation. Storming, the next stage, is the disordered time of confusion or chaos when two or more distinct personalities discover their differences. Norming describes how groups (or families) adjust to individual members by applying rules and procedures that the members agree to obey. Performing is the ideal stage in which the group (i.e., the family) accomplishes their goals and produces results. In the family, desirable results would include good citizenship, education and health of its members, and active contribution to society. Adjourning/terminating represents the final stage in a group when it has accomplished its goals and disbands to possibly form a different group. Families experience this stage when members die, divorce, or leave the family to begin their own families.

Since families represent long-term relationships anchored in the performing stage of meeting goals and taking care of one another, the stages tend to be more stable than with groups. Forming occurs when a child is brought into the family by birth or by adoption. Storming describes the emotional clashes that occur during times of transition (i.e., an adolescent testing the rules) or crisis (i.e., adjusting to a move or job change). Norming generally occurs when parental rules are imposed. For example, family norming may involve teaching the children to talk more softly inside the house than when playing in the yard. Performing occurs as each family member performs specific duties to accomplish the daily tasks of life. Adjourning or termination may follow a death in the family, or it can also follow the launching of a high school graduate into college. The healthy family adjusts for the loss and resets roles and norms to fit the new family structure.

BOWEN'S FAMILY SYSTEMS THEORY

Family systems theory, based on Bowen's concepts, is useful when identifying family problems or challenges that are rooted in family processes such as communication, connecting between members, and teaching values (Harmon Hanson et al., 2005). The nuclear family emotional system describes the pattern of adaptive/maladaptive emotional expression that exists as a theme in the family. According to this theory, one family could be characterized as stoic or cold in their interactions with others, while another is described as emotional and highly reactive to situations and circumstances.

According to family systems theory, differentiation of self is demonstrated when a family member breaks away from the learned emotional system and instead expresses emotions that differ from the learned family pattern. For example, a father whose family of origin is nondemonstrative of love and caring may openly hug and kiss his spouse and children and verbally express his love for them. In an emotional cut-off, a family member has separated from the original family pattern in a dramatic and sometimes permanent way. This may occur when a family member who was reared in a dysfunctional family chooses not to perpetuate the learned pattern of alcoholism or abuse.

Family systems theory also views birth order as a predictor of certain patterns of behavior that may be desirable or conflicting, depending on the birth order of the chosen mate. A firstborn child with behaviors related to high responsibility and control may clash with a spouse who is also a firstborn. The "baby of the family" (youngest sibling) may seek out a spouse who was a firstborn to serve as a caretaker.

With the family systems approach, most interactions take place in the form of a duo or dyad. Triangulation occurs when the dyad diverts attention away from its own conflict by focusing on a third person such as the child, teacher of the problem child, or police officer who comes into a domestic disturbance. Police, nurses, and counselors have often taken the displaced anger of a couple they are trying to help and have instead unwittingly become the third part of a triangle.

The multigenerational transmission process describes how one learns or transmits family emotional systems across generations. Watching grandparents express affection teaches patterns to grandchildren who will model similar behaviors to their children (unless self-differentiation or an emotional cut-off changes the pattern). Family projection process is how and what children are taught. Societal regression describes patterns of the family projection process that exist in cultures as part of a dominant theme. For example, in the United States, independence and individuality are recognized as desirable qualities and thus are replicated throughout family culture. This is in contrast with some Asian cultures that value interdependence and the importance of being a part of a group.

NURSING THEORIES

Nursing theories define the family–nurse relationship in various ways. Nightingale viewed family as a support system for the primary patient. King described interactions that result in a shared or mutual transaction (similar to the nursing care plan). Roy placed family in the context of

the adaptive system of the client. Neuman viewed families as systems and subsystems. According to this framework, the family can become the self-care agent of a patient who is unable to meet her own needs. Rogers described the family as an open system that interacts through the exchange of matter and energy (George, 2002).

Many nursing theorists and practitioners blend theories, which then become “integrated” nursing theories. Friedman et al. (2003) merged concepts from general systems theory and structural functional theory to form an assessment model. Harmon Hansen and colleagues (2005) used the family assessment intervention model with the Family Systems Stressor-Strength inventory to apply Neuman’s theory in a quantitative measurement tool for assessing families. The Calgary Family Assessment Model (Wright & Leahey, 2005) draws on postmodernism, systems theory, cybernetics, communication theory, change theory, and biology of cognition to form a multidimensional assessment model for family nursing care.

The theories described in this chapter have been selected for their clarity and applicability to a variety of family structures and situations. Many theories from nursing and related disciplines have utility in a range of family settings and can be successfully applied to guide and direct nursing care. Familiarization with a variety of theories allows for selection of the theory or theories that best fits the family nursing assessment and interventions. Nursing is both an art and a science. The science component involves the research of concepts and development of theories to describe phenomena. The art of nursing is the application of theory or theories to a specific family interaction.

Now Can You— Discuss family theory for nursing practice?

1. Identify at least four types of theories used in family nursing?
2. Name three components of Bowen’s Family Systems Theory?
3. Discuss a theory that describes stages experienced by the family during the life span of the children?

FAMILY ASSESSMENT

Theories are useful for helping to explain and categorize behaviors of individuals and families. The next logical step, applying theory to the assessment of families, provides information from which to base interventions to either improve or correct the family’s health. The nurse is sensitive to family needs and is in a unique position to interact with the family during the assessment process.

THE NURSING ROLE IN FAMILY ASSESSMENT

It is difficult to fit modern American families into any particular mold. Variations in size and structure and parenting style, along with religious, cultural, and socioeconomic orientation all affect how the family deals with economic, educational, social, and health care issues. To guide the delivery of appropriate care to the family unit, it is helpful to examine the nurse’s role in assessment and intervention and explore some of the major factors that influence family structure. During the assessment interview, the nurse addresses important concepts including family size and structure; parenting style; and religious, cultural, and socioeconomic orientation.

Family Size and Structure

Family size has generally decreased since the founding of the country when large families ensured more workers for the family business. As recently as one generation ago, families consisting of more than six members were more reflective of the norm than today’s families that average two and a half children. Birth rates have declined in Caucasian families while remaining the same in some ethnic cultures. It has been predicted that by the year 2020, the “minority” family will represent 51% of the total American population.

Family structure is becoming increasingly different from the traditional two-parent, two-child nuclear family portrayed during the 1950s. Single-parent (mother or father head of household), binuclear (two families living together), skip-generation (grandparents rearing grandchildren), and extended family (grandparents or other relatives living with the nuclear family) are all represented in the American family of today.

Parenting Style

Parenting style is the manner in which knowledge and values first observed and ingrained during one’s own upbringing and other observed experiences are then used in rearing one’s own children. Parenting style includes discipline, communication, and distribution of power. Blue collar or working class families tend to view corporal punishment (usually in the form of spanking) as the normal approach to discipline. Conversely, white-collar (professional class) families favor disciplinary measures that include times-out, positive reinforcement, and other non-physical methods. Three distinct styles of parenting have been identified:

- **Authoritarian or dictatorial:** Enforces absolute rule; parents enforce rules and strict expectations of each family member; children have little say in decision-making and punishment follows any deviation from the established rules; punishment is not necessarily corporal but often includes withdrawal of approval; children from this style of parenting tend to be shy, sensitive, conforming, submissive, loyal, and honest.
- **Laissez-faire or permissive:** Allows the children control over their environment and subsequent behavior with less input from the parents; few rules to follow; children are able to make their own decisions; punishment is inconsistent when used; children from this family tend to be disrespectful, aggressive, and disobedient, possibly growing up to be irresponsible members of the community.
- **Authoritative or democratic:** Parents have a combination of characteristics from both the authoritarian and laissez-faire parenting styles; parents find a common ground between enforcing rules and allowing some freedom for their children to participate in decisions; parents are firm, set realistic standards and punishment centers on assisting the child develop an inner consciousness about behavior; produces children who are assertive, self-reliant, and highly interactive with high self-esteem (Wilson, Hockenberry-Eaton, Winkelstein, & Schwartz, 2001). Although each type of parenting style has benefits and drawbacks, authoritative parenting tends to meet the child’s needs better than the other styles.

The nurse recognizes that disciplining children is an important concept for parents to understand. Discipline is training the child to meet a pattern of behavior with the intention of instilling good moral judgment, achieving competence and maintaining self-control, promoting self-direction, and learning to respect others. Consistency with rule setting is a key concept that parents must understand. A reliable and steady discipline approach by parents reinforces to the child that their misbehavior will be corrected. Often, redirecting the child away from the behavior to alternative activity can be an effective way to discipline. With older children, reasoning or explaining to the child why the behavior is unacceptable may also be useful. The nurse can help parents understand that positive and effective child-rearing practices can be straightforward and firm without being negative or abusive.

During the family parenting style assessment, the nurse observes for indicators of neglect or physical abuse, but otherwise supports consistent and predictable consequences and rewards appropriate to the age of the child. Parents should be given information about disciplining consistently and without anger. When indicated, parents can be referred to parenting courses or support groups.

Religious, Cultural, and Socioeconomic Orientation

Religious orientation has varying effects on families. The majority of Americans claim some affiliation with a church or spiritual group, but fewer than 30% actually attend a spiritual institution on a regular basis (McIntosh, 2004). Values that tend to be rooted in religious beliefs include practices concerning the observation of holidays and beliefs toward abortion, birth control, marriage, and advance directives (legal documentation that directs that “no heroic” measures be taken to extend life).

Religion also influences attitudes toward alternate lifestyle choices such as homosexuality and sexual abstinence and other moral choices such as euthanasia or suicide. Religious beliefs can provide comfort and a sense of peace to believers in times of sickness or grieving. Religion-based movements such as the “Promise-Keepers” and the “Million Man March” were created, in part, as a positive force to encourage men to become more responsible fathers and husbands.

The nurse assesses the family’s religious or spiritual affiliation and, when indicated, assists in contacting the appropriate spiritual advisor or clergy member. Hospitals provide clergy and chaplain services for a variety of needs and occasions. The nurse avoids imposing personal beliefs and values on the family, but instead helps them obtain the resources necessary to help them to regain balance in crisis situations.

Cultural orientation includes family communication styles, structure of family, health beliefs, and power distribution. The nurse assesses family cultural affiliation and avoids generalities or stereotypes by validating all cultural information with the family.

Ethnocultural Considerations— When assessing families

It is important for the nurse to be aware of ethnocultural variations that may exist in family structure and communication styles. Many cultures emphasize the extended family to a much greater extent than the American nuclear family. Often, grandparents as well as aunts, uncles, and cousins may be

considered a part of the primary family. In some Native American tribes, a sister or aunt or grandparent may be the primary caretaker of the family and this individual needs to be included in health planning and teaching. Certain cultures give preference to the matriarch while others are more male-dominated. In some Hispanic cultures, the adult son makes health care decisions for the family. Nonverbal forms of communication can vary widely across cultures. There may be differences in eye contact, the practice of formal and informal touch, the level and tone of voice, and how respect is shown. A nod by individuals in some Pacific Rim countries may be an indicator of respect but does not necessarily convey an understanding of the nursing instructions given. Although a family member translator may be comforting to the family, this situation is not reflective of best practice methods, especially for informed consent purposes. Instead, a non-family professional translator should be used (Ehrlich, McCloskey, & Daly, 2004; Wilkinson & Van Leuven, 2007).

Socioeconomic status impacts the family’s ability to access and pay for health care and other services. The nurse assists with referrals to social workers or other community experts to secure resources appropriate to the family’s needs. Available resources include state and government supplemental programs, insurance sources, loans and grants, and church or community programs that aid families through catastrophic losses such as fire or health crises.

Historically recognized as important advocates for the family, nurses lead efforts to change or adjust laws and legislation to assist and empower families in areas such as child care, elder care, work leave for births or care of sick family members, tax breaks for dependents including elderly members, assistance with health care costs, and public service education for health care choices. Legislation concerning helmets, seat belts, and child safety seats illustrates several government interventions designed to foster and enhance the well-being of families and individuals. Policies concerning stem-cell research, same-sex marriage, property laws, pro-choice rights, and minimum wages are but a few examples of the government’s far-reaching impact on the family.

TOOLS TO FACILITATE THE FAMILY ASSESSMENT

Qualitative and Quantitative Surveys

For most hospital settings, assessment of the family is limited to gathering a history, usually during admission, related to the patient’s illness. However, in a family nursing approach that encompasses care of the entire family, more thorough formats for family assessment are used. Friedman et al. (2003), Harmon Hanson et al. (2005), Wright and Leahey (2005), and others have developed family nursing assessment forms to provide either a qualitative or a quantitative view of the family. A variety of assessment tools are available and those frequently used include surveys, genograms, ecomaps, and strengths and problems lists.

Qualitative tools assess the description and depth of family experiences. **Quantitative** tools measure the frequency with which behaviors or situations exist. Most survey tools emphasize either the qualitative or quantitative dimensions of family, but usually contain elements of both. Friedman et al. (2003) have developed both a long form and a short form to qualitatively assess the roles and structure of the family and its members. Harmon Hanson et al. (2005)

utilize the Family Systems Stressors-Strength Inventory, an instrument that elicits a numbered ranking of each family member's perception of the severity of stressors in selected categories. Wright and Leahey (2000) use the Calgary Family Assessment Model (CFAM) and combine this tool with the Calgary Family Intervention Model (CFIM) to provide a complete assessment and treatment map.

Before implementation of the selected assessment tool, agreements and sometimes written consents are obtained that relate to the confidentiality of the information sought, how it will be used, and what treatment options and referrals may be recommended. Before the assessment, it is important for the family to understand that the nurse is legally bound to mandatory reporting obligations in cases of abuse or violence, and also that member safety remains a priority above all other interventions. Following these disclosures, or "ground rules," the family may choose to end the therapeutic relationship with the nurse before any information is shared.

Genogram and Ecomap

Family assessment usually begins with a simple diagram (of the family history) in the form of a **genogram** (Fig. 3-1). A genogram is a set of symbols that is used to illustrate the present family structure and compare generations within the same family. The genogram may be used to highlight generational influences of behaviors, illnesses, vocational information, or any other pertinent information that provides a larger picture of patterns that exert influence on the family's current situation. Dates of births, divorces, deaths, stillbirths, and other pertinent elements of family information are represented. A key to guide interpretation of the various symbols is included on the form. Depending on the situation, the nurse either assists the family in drawing the genogram or instructs them in producing a genogram that will be reviewed during the next assessment visit. To make the information more meaningful to the assessor, the genogram should include at least three family generations.

The nurse also helps the family create an ecomap. An ecomap is a tool that displays the various outside systems used by the family. An ecomap illustrates the relationship between the family as a whole system and the various systems with which the family most often interacts, including school, job, church, and other institutions (Fig. 3-2).

To create a family ecomap, the nurse inquires about schools, health care agencies, employment, church, and other outside systems with which the family has routine interaction. Families may have closed boundaries with some systems and maintain open boundaries with others. For example, the parents may conduct home schooling yet contract with the public schools to provide their children with opportunities for extracurricular involvement. During the family assessment, the nurse looks for balance and self-regulation in the family system.

Strengths and Problems Lists

Early in the assessment process, the nurse asks the family to list their strengths (strengths list). The strengths list gives the family an opportunity to express the positive characteristics, or attributes, of their family as a whole and strengths that each member brings to the constellation. The family also creates a problems list, which identifies the difficult or negative characteristics. The family and the nurse collaboratively create both lists. The nurse can

provide input based on observations related to the family's strengths and weaknesses, but should not take over this process. In the therapeutic situation, the family must assume ownership of all identified strengths and problems so that they can participate fully during the assessment and treatment phases of the nursing intervention. The nurse helps the family focus on major issues or problems that will form the starting point of intervention.

Next, the family makes a commitment with the nurse and appropriate referral agencies to participate in the mutually agreed upon interventions. Depending on the situation, the family may be assisted in completion of the assessment tools or the tools may be given to each member to complete and return at a later date. Usually, more tools are completed when the family is assisted with this task in the nurse's presence.

The nurse compiles and summarizes the information provided and discusses the results with the family. The initial assessment, which utilizes the selected assessment

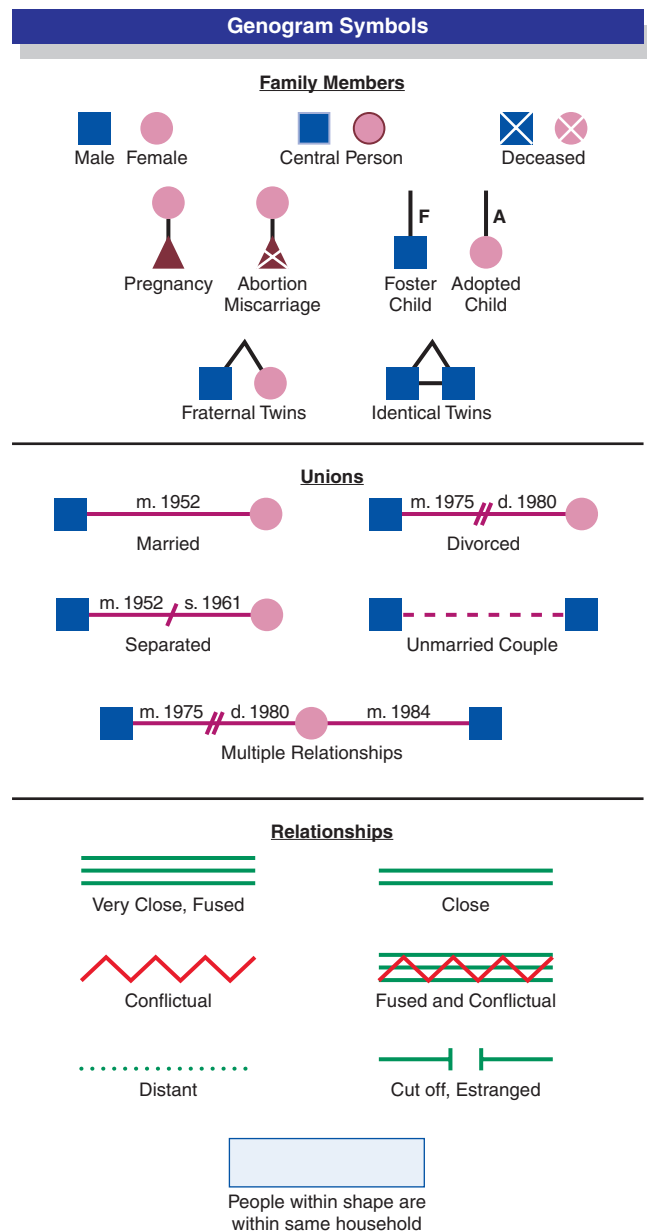

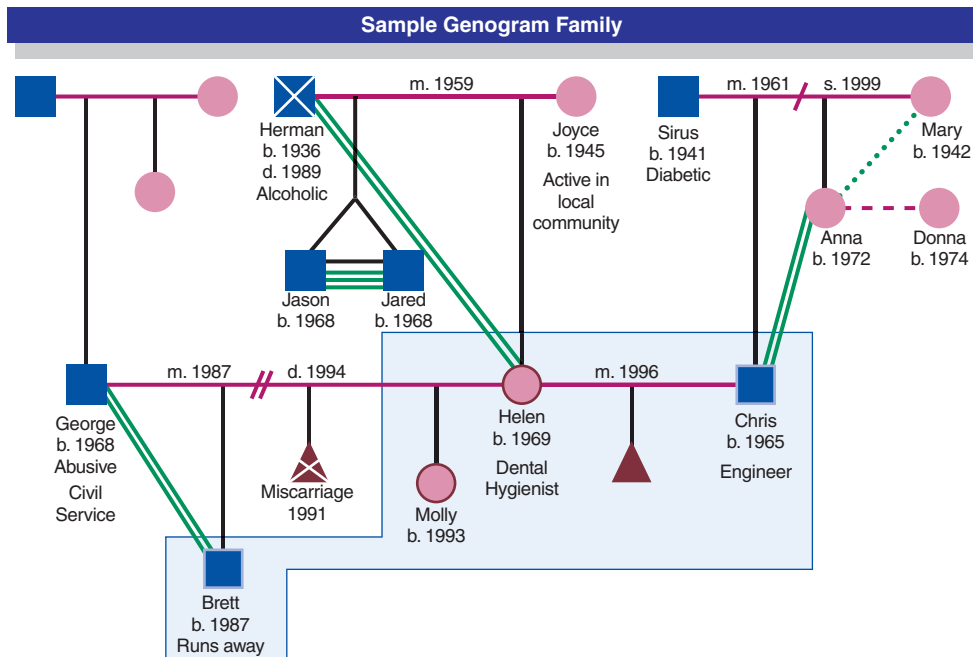

Figure 3-1 Example of a genogram template.

Our “Identified Family” consists of Helen, Chris, Molly and Brett.

They all live in the same household.

Helen married Brett and Molly’s father George in 1987.

George, a Civil Service worker, was abusive and the couple divorced in 1994.

Not much is known about George’s family and there is little contact with Helen.

George and Brett continue to be close and have weekly visits.

Brett was born in 1987 and is currently troubled, running away often to his father George’s house.

Helen had a miscarriage in 1991.

Molly was born in 1993.

Helen and Chris married in 1996 and are currently expecting their first child together.

Helen is a Dental Hygienist and Chris is an Engineer.

Helen’s Background:

Helen’s parents Herman and Joyce were married in 1959 until Herman’s death in 1989.

Herman was an alcoholic.

Helen was closer to her father than to her mother.

Joyce is very active in her local community.

Helen has brothers who are identical twins, Jason and Jared. They are very close.

Chris’ Background:

Chris’ parents Sirius and Mary were married in 1961, but have been separated since 1999.

Sirius has health difficulties due to diabetes and relies often on Chris to help him.

Chris’ sister Anna is in a relationship with Donna, which has distanced her from their mother Mary.

Chris is close to Anna.

Figure 3-1 cont’d Example of a genogram template.

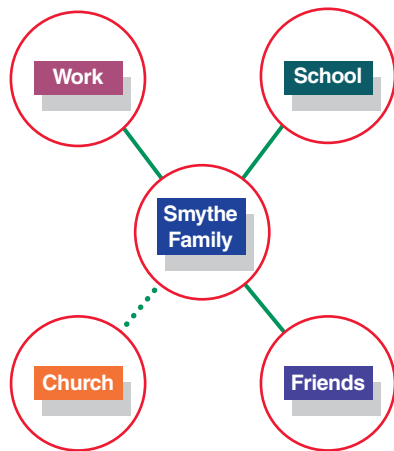

tools and surveys, is frequently completed within an hour and is then followed by daily or weekly conferences, depending on the setting and the time available. The follow-up conference provides an opportunity to review the assessment information and to identify progress made toward achieving the goals. During these conferences, the nurse and family agree upon priority issues and begin to formulate a treatment plan.

Many of the following components of the family assessment were introduced earlier in the discussion of theories. They are included in the discussion that follows to demonstrate types of information that can be obtained during assessments conducted via observation, direct questioning, or through the administration of various assessment tools and surveys. Components of family assessment include but are not limited to communication, roles and relationships, family developmental stages, rituals, family building activities, triangulation, and other concepts from selected theories.

COMPONENTS OF THE FAMILY ASSESSMENT

Assessment of Communication Patterns

Communication is how the family exchanges information, values, and emotional connection. The nurse assesses the type, frequency, and direction of communication among the family members. For example, the nurse seeks answers to questions such as: “What is the nature of the interpersonal messages—supportive or attacking?”; “What emotional content is expressed?”; “Who is sending and receiving the messages?”; and, “Are there any patterns of dominance or powerlessness?”. In some situations, one family member may dominate the responses to the assessment. The nurse assesses whether the entire family agrees with the information presented or if one member’s point of view is ignored or suppressed. A family with addiction issues may present information cautiously and censure members who give information that indicates a problem.

Key to Ecomap

Circles represent systems that interact with Smythe Family
Dotted line indicates strained relationship

Figure 3-2 Example of an ecomap.

The nurse looks for themes of emotional connectedness or isolation among the family members. There may also be clues that indicate the presence of family violence or neglect. In their interactions, the healthy family conveys a sense of connection and an appreciation of the family unit and of its individual members. The healthy family is open with problem identification and exploring coping patterns. There may also be clues that indicate the presence of family violence or neglect. Conversely, the unhealthy family tends to control or hide information or block access (of information) from other family members. The nurse should always conduct follow-up interviews with family members who were absent or not accessible during the initial interview.

Optimizing Outcomes— During assessment of family communication patterns

During the family interview, the nurse should be cautious not to rely solely on information provided by family members. Often, dysfunctional communication patterns are suppressed as members attempt to present themselves most favorably. It is important to observe verbal and non-verbal communication with and *among* family members.

ASSESSMENT OF ROLES AND RELATIONSHIPS

Roles and relationships are the job descriptions and connections of the individual family members. One or more family members assumes the responsibility of earning or obtaining money and resources, paying bills, providing meals, cleaning the living space, transporting family members, choosing entertainment and recreation activities, and promoting health and emotional security. The nurse assesses (through observation and/or application of assessment tools/surveys) for the delegation of tasks that meet the family needs on a daily basis. Certain roles clearly fall in the domain of specific family members, such as the parent who pays the bills.

Other roles may be more fluid, like the mother or older sister with a driver's license who takes turns transporting the younger child to soccer practice. Relationships are usually clearly delineated: father, mother, brother, and sister. Relationships may also be self-declared or assigned. Examples of these types of relationships include brothers or cousins who are best friends or an oldest sibling who becomes the “boss” of younger siblings while the parents are away. Some roles and relationships are blended together: the mother who is also the nurturer; the father who is also the enforcer of rules. Roles and relationships should have an observable outcome on the family home/household.

Nursing Insight— Family roles, cultural influences, and maternity care

When working with the childbearing family, nurses need to be aware that social class and cultural norms frequently affect the roles of various family members. The male's likelihood to participate in the childbearing experience, for example, is culturally influenced. Traditional Mexican and Arab families may view pregnancy and birth as events that are strictly “female affairs.”

The nurse assesses the effectiveness of family roles by observing the condition of the house and living conditions (by conducting a home visit, if possible, or by obtaining the information during the interview), the clothing and personal hygiene of the family members, and gathers other information to determine if family members are carrying out individual role assignments. There is much variation on how different family members meet their role requirements. For example, a single mother may need to seek public assistance in order to fulfill the provider role and obtain essential resources for her family. This process involves contacting various agencies, completing lengthy forms, waiting in lines, and engaging in other activities that can sometimes take as much time as working at a job to meet the family's needs. Fulfilling roles also encompasses the completion of tasks appropriate to each member's and the family's stage of development.

ASSESSMENT OF THE FAMILY DEVELOPMENTAL STAGE

The **Family Developmental Stage** (Friedman et al., 2003; Harmon Hanson et al., 2005; Wright & Leahey, 2005) is the time in the family's lifespan that is focused on a particular age of a child or a specific family situation. This stage is assessed by means of the interview, the application of tools and surveys, and during observation of the family. At any given time, most families exist in simultaneous stages. They may be launching a high school graduate off to work or college and still have an infant (their child or grandchild) in the home. The family must accomplish a specific set of tasks for each stage. An infant requires feeding and changing and napping and nurturing throughout the day. The high school graduate most likely needs assistance and support whether planning for college or making career choices. An extended living situation at home may be needed while a family member is in transition. The nurse assesses (by the observation of the presence or absence of resources and material goods such as clothing, food, and furniture appropriate to the family

stage) that the family is successfully meeting the tasks for each stage or that they are obtaining appropriate assistance from outside resources (e.g., a student loan) to help meet their needs.

ASSESSMENT OF FAMILY RITUALS

Family rituals consist of routines or activities that the family performs and teaches its members as a part of continuity and stability. Rituals encompass meal and bedtime routines, greeting and dismissing behaviors (a kiss goodbye or goodnight; a hello or a good-morning shout across the room), and observation of celebrations or terminations (birthdays or funerals). The nurse assesses (through observation and direct inquiry, or as guided by the assessment survey) for family member agreement on how important days are observed or if they are acknowledged at all. For example, birthday celebrations may be elaborate, informal, or summarily dismissed. Holiday presents may be opened before or during the holiday or not exchanged at all. Families may always or never share meals together.

Nursing Insight— Family building activities, rules, mottos, and beliefs

Family-building activities are an extension of rituals that center on recreation and leisure, such as family trips and vacations. Although a best friend may be invited to participate in some family events, a healthy family generally designates special “together time” that isn’t open to non-family members. Family rules, mottos, and beliefs are the ways the family views itself and describes itself to others. “We always finish what we start” or “We stick together through thick and thin” are oft-used sayings that a family may identify with, whether or not they are consistent in holding to those beliefs. As a component of the assessment, the nurse can ask for three or four sayings or beliefs that the family feels are important in maintaining their family system. The nurse then asks for examples of responses to situations that illustrate or confirm this belief.

ASSESSMENT FOR TRIANGULATION

Triangulation, assessed through family observation, occurs when two family members focus on or team up against a third family member to compensate for friction between the two members (Bowen, 1978; Harmon Hanson et al., 2005). Triangulation balances the family in a manner similar to how a furniture builder adds a third leg to balance a two-legged stool. The family reaches out or even attacks a third member or outside person as a way to decrease tension between two members and to obtain balance. For example, rather than blame one another for the child’s asthma symptoms, the parents instead focus on seeking outside medical help for the condition. This scenario illustrates a positive use of triangulation.

Conversely, tobacco-using parents who focus on their child’s asthma symptoms while ignoring their own tobacco addiction (and the unhealthy environment that accompanies it) illustrate a potentially negative triangulation. Two brothers who team up against the policeman called to break up their drunken dispute is an example of triangulating with an outside source. Family therapists are particularly vulnerable to triangulation when working with families, and they must learn to recognize when

triangulation is being negatively used and teach families other strategies for maintaining stability.

ASSESSMENT FOR THE PRESENCE OF DYADS AND OTHER SUBSYSTEMS

A dyad (Bowen, 1978; Harmon Hanson et al., 2005) is a structure in which two family members form a bond to become a subsystem of the greater family system. Within a family of four, existing dyads generally include the husband–wife dyad, father–son dyad, brother–sister dyad, or other combinations. The dyad may be a natural alliance for the purposes of intimacy or play or related activities. Dyads may form as siblings team up against a perceived unfair parental rule. The nurse observes for the presence of dyads, and notes whether or not they are self-identified, and whether a positive or negative impact on the family is known or acknowledged.

“What to say” — Specific questions to ask during the family assessment

To elicit family identifying data, the nurse may ask:

“Who in your family lives in your home?”

“What other family members live elsewhere?”

“What are the sources of income or other resources for your family?”

Questions to determine the family’s developmental stage can include:

“What are the ages of the children in family?”

“What jobs or tasks take up the most time in providing care for the children?” Environmental data includes information about the neighborhood of residence and local resources such as stores, schools, hospitals, and entertainment centers. Other questions are intended to elicit information concerning family structure (“Who makes decisions?”), function (“How is emotion and affection shown?”), and health care (“What health appointments are made and by whom?”) (Friedman et al., 2003).

Once all pertinent information has been obtained and documented, the nurse elicits the family’s assistance in prioritizing the most pressing and problematic issues. These issues are then addressed in the family treatment plan that forms the basis for all family-centered interventions. Depending on the specific situation, nursing interventions for families most often include referrals, education, and counseling.

Optimizing Outcomes— With nursing interventions for families

Referrals may be made to support groups (i.e., Alcoholics Anonymous, Al-Anon, Gamblers Anonymous), physicians, social services, and mental health agencies. Education may center on the use of prescribed medications and therapies, nutrition, and family health promotion. When indicated, licensed professional counselors, nurse practitioners, psychologists, and family therapists provide in-depth family counseling.

Now Can You— Apply tools and concepts to assess a family?

1. Describe two tools used to diagram family structure and function?
2. Discuss at least five concepts that can be assessed in the family?
3. Explain the nurse's role in the assessment of the family?

Family-Centered Care

After the assessment process has been completed, the nurse selects all applicable nursing diagnoses and formulates the family care plan. The family's assistance is elicited to ensure that they are in agreement with the identified diagnoses. The nurse guides the family in writing mutually agreed-upon goals that they will work on together. Diagnoses may be psychosocial, physiological, or both and they may be focused on the individual or on the family (Box 3-1).

In the following discussion the nursing diagnosis "Altered Family Processes" is presented and described in detail to illustrate the possible goals, interventions, and evaluation criteria that could be appropriate for families experiencing problems in their day to day functioning.

NURSING DIAGNOSIS: ALTERED FAMILY PROCESSES

This nursing diagnosis describes a family that experiences problems in their everyday functioning. Problems often center on communication issues or difficulties with member role fulfillment. In these situations, the family is in need of education and/or intervention to help them return to normal daily functioning. As an example, a family with an infant may not be communicating about sharing the

new roles brought about by the baby's arrival. The mother feels resentful that the father is not helping more; the father senses the resentment but doesn't recognize what is wrong. The nurse identifies clues to tension in the relationship during well-baby check-ups or perhaps even prior to discharge from the hospital.

GOAL: RETAIN/MAINTAIN OPEN LINES OF COMMUNICATION. The family will discuss feelings openly and nonjudgmentally with each other using "I feel" statements (Clark, 2003) and avoiding defensive communication techniques (Johnson & Johnson, 2003). All members will negotiate what it is they would want for the other member to understand about their feelings and needs.

GOAL: ADAPT TO CHANGES IN FAMILY PROCESS/SITUATION BY SHARING RESPONSIBILITIES. To meet this goal, various family roles need to be adjusted. For example, having an older sister help babysit the infant in order to give the mother more time for rest represents a family adaptation necessitated by a change in the home situation. After the birth of a baby, the father may need to take family leave so that he can share in child care. In another family, the mother-in-law may be asked to assume a more active role in assisting with newborn or child care.

GOAL: RESPECT THE INDIVIDUALITY OF EACH MEMBER'S ACTIONS. The family may need to allow a member to isolate from an event until he or she is able to handle the situation with the rest of the family. For example, it is developmentally appropriate for a teenager to want to continue with contact from friends while the family is experiencing a situational crisis.

GOAL: PARTICIPATE IN THE CARE OF INDIVIDUALS. The family needs to prioritize care for its sick or disabled members over lesser psychosocial needs such as having friends over for the school-aged children. All needs should be addressed eventually, but safety and physiological needs should be addressed first.

GOAL: SEEK/ACCEPT RESOURCES AS NEEDED. As a system, the family opens its boundaries to appropriate outside sources (i.e., the pediatrician, internist, and social worker or community health department) as needed to help provide appropriate health care for its members. Families with issues such as domestic violence often have difficulty trusting another system due to the fear of legal intervention. The family may have difficulty accepting help if they do not perceive or acknowledge the problem. The nurse may use a number of interventions to help the family obtain their goals under this nursing diagnosis.

The following are examples of applicable nursing interventions.

INTERVENTION: IDENTIFY FAMILY DYSFUNCTION AND THE FAMILY'S AWARENESS OF THE PROBLEM(S). As part of an ongoing collaborative process with the family, the nurse adds entries to the problem list as needed to keep the list current and applicable. The problem list is then reviewed during each nursing visit. For example, the nurse may recognize that the family does not use proper car safety seats for the younger children. Throughout the collaborative process, as problems are identified by a family member, the nurse assesses other members' understanding and willingness to participate in the proposed solutions.

Box 3-1 Examples of Family Nursing Diagnoses

Any NANDA diagnosis may be appropriate for describing an individual family member's health status. A family diagnosis is intended to describe the health status of the family as a whole. Examples of family diagnoses include the following:

- Caregiver Role Strain (actual and risk for)
- Dysfunctional Family Processes: Alcoholism
- Family Coping: Compromised
- Family Coping: Disabled
- Impaired Parenting (actual and risk for)
- Ineffective Family Therapeutic Regimen Management
- Readiness for Enhanced Family Coping
- Readiness for Enhanced Parenting
- Risk for Parent-Infant-Child Attachment
- Social Isolation
- Spiritual Distress

NOC outcomes specifically for families as units are included in the NOC domain "Family Health." This category includes the following classes: Family Caregiver Status, Family Member Health Status, Family Well-Being and Parenting. Outcomes from other domains may also apply. *NIC interventions* for families as units are included in the NIC domain "Family." This category includes the following classes: Childbearing Care, Childrearing Care and Life-Span Care.

Sources: Carpenito-Moyet (2006); Wilkinson & Van Leuven (2007).

INTERVENTION: GUIDE THE FAMILY THROUGH MEDICAL ADMISSIONS/INTERVENTIONS. The nurse acts as the liaison with family member hospitalizations and other referrals. In this role, the nurse provides information about medical procedures, coordinates care with various community resources and helps to clarify medical explanations to the family when one of the members receives medical assistance.

INTERVENTION: ASSESS THE IMPACT OF IDENTIFIED PROBLEMS ON THE STABILITY AND FUNCTIONING OF THE FAMILY. The nurse identifies roles or functions that are neglected by the family and helps the family adjust as they struggle to meet the health needs of members.

INTERVENTION: LISTEN ATTENTIVELY TO ALL MEMBERS. The nurse helps the family to identify the meaning of the dysfunction and assists the family in improving communication among its members.

INTERVENTION: SCHEDULE FAMILY CONFERENCES. Family conferences give all members an opportunity to express themselves and share in the family situation. This strategy is particularly important in an emergency hospitalization when the family members are not all initially involved in the decision making concerning treatments received. For example, a sister who arrives late from out of town may not initially understand the decision to withhold treatment in respect to advance directives.

INTERVENTION: IDENTIFY, REFER, AND INFORM THE FAMILY OF AVAILABLE RESOURCES. After hospitalization of a family member, the nurse may identify a social worker to assist with discharge plans and payment issues. In another situation, the nurse may serve as an advocate to help the family receive rehabilitative care for a member with a head injury.

INTERVENTION: DISCUSS ROLE CHANGES AND THEIR IMPACT ON FAMILY MEMBERS. A family situation may involve a sister caring for a parent with Alzheimer's disease who needs support and respite care to meet her own needs and those of her children. The nurse has the objectivity to identify the sister's needs and facilitate her communication of these needs to other family members.

Periodically, the nurse and family assess the extent to which the goals have been accomplished and the effectiveness of the nursing interventions. Adjustments in goals and interventions are made when necessary.

Evaluation

Expected outcomes may include the following:

- Effective communication takes place among family members in an assertive and nonthreatening manner that allows members' needs to be expressed and met.
- Family tasks and roles are appropriately distributed so that students attend school and employed members go to work, medical appointments are made and kept; and food and shelter is adequately provided.

Many other nursing diagnoses are applicable for the family experiencing health or social problems. For example, Family Coping: Potential for Growth is particularly useful for the family that is not experiencing health or social crisis, but can still benefit from nursing education for improvement in selected areas.

Now Can You—Apply family nursing diagnoses to a family?

1. Identify two family nursing diagnoses that may be applied to a variety of situations?
2. List three goals for each nursing diagnosis identified?
3. List three nursing interventions for each nursing diagnosis identified?

Families with Special Needs

Sometimes families are in special need of nursing intervention due to situational or developmental crises that go beyond the family's internal resources. Situational crises include environmental disasters such as floods, hurricanes, or fires. The loss of a home, job, family member, or close friend are all unexpected and unplanned for events that initially send the family into a state of chaos and often require outside help for the process of reorganization. Developmental crises occur as part of expected growth events that can take place during any developmental stage of the family or its individual members. Toddlerhood and adolescence are examples of two developmental stages that often disrupt family balance if no preparations were made in anticipation of the changing needs of the child and young teen.

Whether related to developmental stages or situational changes, certain events often require some level of intervention to help restore the family's balance and function, such as hospitalization, chronic mental illness (i.e., Alzheimer's disease, attention deficit disorder, autism, schizophrenia), substance abuse, sexual or physical abuse, posttraumatic stress disorder, chronic illness, and loss of a family member.

HOSPITALIZATION

The hospitalization of a family member often triggers a crisis that requires assistance and interventions from various outside sources. The scope of the family's needs is related to their resources, level of adaptability, and prior experience. In most situations, intervention includes treatment and education provided by the physician, care and additional education provided by the nurse, and discharge planning with community support arranged by designated hospital staff. Depending on the circumstance, the chaplain, social worker, community health nurse, and rehabilitation professional may all be members of the health care team that assists in the transition from the hospital to the home or community facility. At times, the nurse is responsible for identifying and coordinating these resources to facilitate the patient's and family's transition and may involve various other interventions.

CHRONIC MENTAL ILLNESS

A family with a member who has a chronic mental illness such as schizophrenia or bipolar disorder is a lifelong partner with the mental health system. This partnership can be therapeutic or antagonistic, depending on the resources available, the family's history in using these resources, and the amount of continuity that exists between the professionals and the families as they work

together. The nurse's role is that of mediator/facilitator between the family system and the mental health system.

Establishing a diagnosis serves as the beginning point in helping the family to proceed with care for their family member. This task can be accomplished with the assistance of outpatient experts such as psychiatrists, social workers, psychologists, and advanced practice nursing specialists. Diagnostic work-ups are usually conducted as a team approach and most often involve an initial hospitalization for patient stabilization and medication. The family should be educated about prescribed medications, their side effects and planned treatments, and provided with information about financial resources such as Medicaid, Social Security, vocational rehabilitation, and other resources. The family is also in need of information and guidance concerning voluntary and involuntary commitment, guardianship, and other legal issues that often emerge as the illness progresses.

In many cases, problems with treatment are related to noncompliance or taking medications improperly (i.e., skipping doses or combining them with other substances). Sometimes the family assumes responsibility for the administration of medications for the family member. Another issue that often arises concerns an inability to pay for the medication. The nurse assists the family and/or family member in securing financial resources.

An important problem that should be addressed with families that have a mentally disabled member concerns social isolation. Social isolation is a situation that occurs when the ill family member is afraid or does not have the energy to participate in activities without continued prompting and encouragement by the family. Another potential problem involves nutritional deficit due to paranoia about harmful substances in the food or changes in eating habits related to depression. Certain medications are associated with weight gain, a problem that can lead to other health issues. Mental illness can also affect sleeping and rest patterns, and this problem is often associated with bipolar disease.

Special attention must be paid to the patient's suicidal potential and risk for harm to others. The nurse teaches the family to be especially vigilant when the patient is recovering from an immobilizing depression, an especially vulnerable time associated with newfound energy to carry out a plan. The person suffering from depression, bipolar disorder, or schizophrenia is also at risk when the normal impulse control becomes affected by influences such as drug or alcohol abuse or the rapid cycling associated with bipolar disorder. An important nursing role involves teaching the family techniques to assess for deficits, strategies for intervention, and recognizing when to call for assistance. Extended family should be recruited to help prevent caregiver strain by being available to help with the family member or offer respite care. Caregiver strain occurs when the main caregiver becomes overwhelmed and feels "under helped" in regard to the tasks concerned with the care of the family member. In this situation, mounting bitterness and withdrawal from other family members may cause caregivers to push away any potential helpers. Respite care occurs when someone else assumes the care of the sick family member in order to give the caregiver time off to rest.

case study The Family of a Young Adult with Schizophrenia

Ricky, age 24, was diagnosed with schizophrenia at the age of 16. His symptoms include paranoia, auditory hallucinations (hearing voices), and social isolation. He has been hospitalized several times over the years but his symptoms are currently stable on a newer antipsychotic medication. The family is willing for him to be discharged from the state hospital where he had been receiving treatment and come back home to live with them.

1. What information would the family require to be able to properly care for Ricky at home?
2. What are some of the resources the nurse should provide to help Ricky and his family cope with his illness?

◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

SUBSTANCE ABUSE

Substance abuse negatively affects the family system. Family functions frequently become reorganized to sustain and cover up the addiction. If a parent is the substance abuser, parental roles are shifted to the other parent or to a child to provide meals, wash clothes, get the children to school, and call in sick for the affected parent. This process, termed enabling, is necessary in order for the addicted member to appear to be functioning normally. Sometimes another member of the family is so closely enmeshed with the affected member's addiction that he or she becomes codependent (Townsend, 2005). Although the codependent member may not be abusing substances with the addict, he or she is equally impaired through the continued cooperation in the addiction.

Often the remaining family members assume roles that help the addiction to continue. One child, usually the oldest, takes on the learned role of responsible child. This responsible child, who is either self-selected or is family assigned by default, takes over for the mother if she is drinking with the alcoholic partner or engaging in other enabling behaviors that make her unavailable to the family, and makes sure the younger children are being cared for. The responsible child makes lunches, gets the siblings off to school and extracurricular activities, and may even help with paying the bills. The hero is another role that may evolve in children of families with an impaired member. The child in a hero role serves as the family standard-bearer, ready to proclaim that the family cannot really be impaired if it produced such a star. The hero is academically successful and excels in sports and other extracurricular activities.

Two additional roles that may be found in the substance- or alcohol-impaired family are the scapegoat and the lost child. The scapegoat is the opposite of the hero. The scapegoat fails at school and social activities and may have run-ins with the law for vandalism or shoplifting or fighting at school. The family presents the scapegoat to the world with the message: "Look at what we have to endure! No wonder we have a difficult life!" The hero and the scapegoat are actually diversions for what is really happening to the family due to substance abuse. The lost child is a symptom of a family that is too chaotic to meet the needs of the child or notice the child at all. The lost child keeps a

low profile at home and school and does not usually fail but also does not particularly stand out in anything, either.

Along with the family roles are family rules that are implicitly followed by all members, such as: “Don’t talk and don’t feel.” Family members know not to discuss family problems with outsiders such as teachers, nurses, or even friends. Secrets are the hallmark of addictive families both for social and legal reasons. Family members also learn not to feel the disappointment or anger or sadness that the addiction causes them. Parents do not make it to the children’s games or teacher conferences, or even to major events such as graduation. The children deny that the parent’s lack of involvement impacts their feelings. If changes do not take place in these types of family systems, there is a great likelihood that the children will be socially and personally impaired and a high percentage turns to substance abuse themselves (Townsend, 2005).

The nurse and the family with substance abuse/alcohol abuse must assess the amount, type, and length of time the addiction has been a part of the family. If the main substance abuser is actively engaged in treatment, the family should be referred to therapy or support groups such as Al-Anon that can help them to identify and change their own behaviors, wants, and needs apart from those of the alcoholic. If treatment is not obtained for the affected member, the nurse should refer family members to organizations such as Alcoholics Anonymous or to legal agencies that can identify options for getting the member into treatment or strategies for keeping the family safe from the member.

case study The Family Members of an Alcoholic

A 9-year-old boy has been sent home from school several times for fighting. The father has a history of scrapes with the law related to public drunkenness and bar fights. The mother tells the school nurse that the father has been laid off at work and has a lot of issues on his mind to work through. She further states that the boy has been nothing but trouble and is an embarrassment to the family, unlike his sister, who is a junior high cheerleader and “straight A” student.

1. What roles are being played in this family?
2. What is the purpose of these roles?
3. What interventions would the nurse bring to this family?

◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

SEXUAL OR PHYSICAL ABUSE

Sexual or physical abuse in the family is similar to substance abuse in how it affects the family system. In general, this problem can exist only in a family system that keeps secrets and creates specific roles that allow its continuance. When an incestuous father/child sexual relationship occurs, the mother or marital partner has taken on the role of either ignoring or covering up the abuse. In some situations, the mother feels threatened and acts as a sexual competitor (against the daughter) for the husband’s affection. In many cases, one person is singled out for the physical or sexual abuse. Other family members have a relatively normal

relationship with the abuser and with one other. If the abused member is removed from the family, there may be a transfer of the behavior to another member.

In all situations, the nurse is legally obligated to report the abuse to the proper investigating agency. However, the nurse is not responsible for investigating or intervening with the family once the report has been made. When unsure, the nurse can verify suspicions of abuse with other treatment team members, but once the suspicions are confirmed, either the nurse, nursing supervisor, or treatment team leader is mandated to report the abuse. The nurse then makes a therapeutic alliance with the family unit (probably without the abuser) to help return them to normal roles and relationships. The nurse must remain vigilant for signs of continued abuse or violence with the remaining members or with the primary abuser if he (or she) is returned to the family.

case study Elder Abuse in the Family

The nurse is conducting a home visit with an 85-year-old mother who is being cared for by her adult daughter. The daughter exhibits an attitude of detachment toward her mother. A general assessment of the elderly patient is remarkable for strong body odor, stained clothes, and an overall disheveled appearance. The mother is alert but hesitant to talk with the nurse and evasive with her answers. The daughter appears to be impatient and explains that she needs to go shopping.

1. What other assessment information would be needed to verify whether or not the patient was being neglected?
2. What steps should be taken if abuse or neglect is suspected?

◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

POSTTRAUMATIC STRESS DISORDER

Posttraumatic stress disorder (PTSD) is a condition that results from experiencing a catastrophic event such as rape, battering, accident, mugging, or war. The survivor or survivors of the traumatic event may experience nightmares and flashbacks (vivid re-experiencing of events while awake) and frequently develop a detached view of life. Involved families “lose” an active participant in their lives while the family member with PTSD vacillates between apathy and extreme vigilance and overprotectiveness. The affected family member may also turn to substance abuse in an attempt to dull the memories associated with the event.

An entire family may experience PTSD after a shared event such as surviving a flood or tornado that destroyed everything and left them homeless. Often, symptoms do not appear for days or weeks following the event. The delay may result from the initial gestures of support provided by the family and the community. The nurse assesses for symptoms of PTSD during the interview, with questions focused on sleep disturbances or flashbacks of the traumatic event and the individual’s inability to participate fully in the family’s life. When identified, the family member(s) is referred for appropriate intervention. Alternately, the nurse may elicit the assistance of an expert trained in Critical Incident Stress Debriefing or who has experience with other proven techniques for

treating survivors. Support groups are usually therapeutic in helping both the victim and the family ease the affected member back into their world.

CHRONIC PHYSICAL ILLNESS

Asthma, diabetes, and Crohn’s disease are often viewed as medical conditions that are affected by psychological factors (Kneisl, Wilson, & Trigoboff, 2004) because of the strong emotionality involved. Although emotions do not cause these illnesses, they may exacerbate the symptoms by decreasing the family member’s compliance with the treatment or by increasing the anxiety related to the symptoms. Families need to be educated about various aspects of daily care for members who experience chronic illness. For example, the nurse may teach about monitoring the diabetic family member’s blood glucose analysis or self-administration of insulin or how to assist the asthmatic with inhalation therapy.

In some situations, a teenager may not fully accept his illness and choose not to take prescribed medications. This behavior often stems from a need to prove to self or others that he does not truly need the medications or treatment. An older adult living in the home may not fully understand the temporal demands associated with a medication schedule and may require additional teaching and close monitoring, especially if the medications have recently been changed. The nurse helps the family transition from dependence on the health care worker to family member independence, although, depending on the circumstances, some supervision by the family may always be necessary. The family benefits through an ongoing partnership with a provider or clinic that enables them to receive progress reports, treatment updates, and needed medications. The nurse facilitates family empowerment by helping

them to get the information necessary to provide continued support and treatment of their family member. To learn more about caring for the family with chronic physical illness, see Chapter 35.

case study The Family of a Diabetic Teen

Shelley is a 15-year-old with type 1 diabetes mellitus who presents periodically to the emergency department with a blood sugar level of greater than 300 mg/dL. The family states she has been snacking on foods not on her diet, is sporadic with her blood sugar testing, and inconsistent in the management of her sliding scale method of insulin administration. The nurse’s conversation with Shelley reveals that Shelley is resentful of her illness and angry that she has to do things that “the other girls do not have to do.”

1. In view of Shelley’s developmental stage, what information should the nurse give to Shelley and her family regarding diabetes?
2. How would the information be presented differently if Shelley were 6 years old?

◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

DEATH OF A FAMILY MEMBER

The nurse is often the first point-of-contact when a family member has died in the hospital or at home if home nursing was involved in the member’s care. The particular developmental stage affects the way in which each family member grieves. While the length of time that elapses between the stages of grief and the manifestations of grief vary, all family members grieve in some manner. Stages of grieving have been described by a number of theorists; several are presented in

Table 3-1 The Grieving Process as Described by Various Theorists

Kubler-Ross’ Stages of Grieving	Rodebaugh’s Stages of Grieving	Harvey’s Phases of Grieving	Epperson’s Phases of Grieving	Rando’s Reactions of Bereaved Parents
Denial (shock and disbelief)	Reeling (stunned disbelief)	Shock, Outcry, and Denial (external response to loss)	High Anxiety (physical response to emotional upheaval)	Avoidance (confusion and dazed state, avoidance of reality of loss)
Anger (toward God, relatives, the health care system)	Feelings (emotionally experiencing the loss)	Intrusion of thoughts, distractions, and obsessive reviewing of the loss (internal response, isolation)	Denial (protective psychological reaction)	Confrontation (intense emotions, anger, sadness, feeling the loss)
Bargaining (trying to attain more time, delaying acceptance of the loss)	Dealing (taking care of details, taking care of others)	Confiding in others to emote and cognitively restructure (integration of internal thoughts and external actions to move on)	Anger (directed inwardly, toward another family member, or toward others)	Reestablishment (intensity declines, and the parents resume their lives)
Acceptance (readiness to move forward with newfound meaning or purpose in one’s own life)	Healing (recovering and reentering life)		Remorse (feelings of guilt and sorrow)	
			Grief (overwhelming sadness)	
			Reconciliation (adaptation to existing circumstances)	

Table 3-1. The nurse provides time and space (family visiting room, chapel, or the patient's room) for the family to gather. The nurse also inquires about the family's preferences concerning participation in preparation activities before the arrival of the mortuary representatives. Some cultures and religions wish to ritually bathe and dress the body.

The family must also decide which members should be involved in the various tasks and this decision is affected by the age or developmental level of the child or adult. For example, a developmentally challenged adult may need the same approach as a younger child. In most situations, viewing the deceased (after equipment such as tubes and drainage bags have been removed) helps family members of all ages accept that death has occurred. They can then begin the grieving process.

The nurse participates in the accepting/searching for answers stage that often occurs early during grieving by providing answers regarding the illness or procedures or treatments that were involved. As appropriate, the nurse may seek assistance from the physician, other members of the health care team, or from other resources. The family's minister or hospital chaplain may be asked to offer spiritual support, provide counseling, and address concerns. The nurse may wish to participate in prayer led by the family's clergy or hospital chaplaincy. Providing a presence and remaining with the family as long as possible are often the best nursing approaches for the family that has experienced a loss. The nurse may also have an opportunity to advise family friends that a critical time for them to be available to the family is around the third or fourth week after the funeral, when the family is left to deal with the full impact of the loss (Wilkinson & Van Leuven, 2007).

Across Care Settings: Family care in inpatient, outpatient, and hospice settings

In hospital inpatient units, families should be oriented to visiting hours, waiting rooms, meals, and overnight accommodations. Nurses reinforce patient admission data such as advance directives and organ donation policies and encourage an open discussion between the patient and family to prevent confusion regarding who would act as the patient's agent to make decisions in the event of incapacity or death. Families often need assistance with medical information, billing information, and admission and discharge information. In pediatrics units, families should be alerted to policies concerning staying with their sick child and assistance should be offered in making arrangements for the care of other children. In long-term inpatient settings, families rely on visits, telephone calls, mail, and e-mail to stay in touch with members. In outpatient units, nurses can educate the family about strategies to enhance patient recovery, reinforce discharge instructions, and provide written information about follow-up visits.

In home health and hospice settings, the nurse assists the family in reaching a comfortable balance between direct involvement in the family member's care and respite time for family building activities with other members. Demystifying medical procedures such as medication administration, catheterization, and tube feeding empowers the family to decide what they can do and how and when to seek assistance from the nurse and other care staff.

Now Can You— Identify and plan care for special problems and issues faced by the American family?

1. List eight special problems that may be experienced by families?
2. Identify various nursing roles and interventions appropriate for these families?
3. Describe the nurse's role when abuse is suspected?

Family Cultural Characteristics

An understanding of the prevailing concepts of acculturation, assimilation identity, time, connectedness, communication, and social class facilitates the nursing assessment and guides the application of interventions within different cultural frameworks. To enhance understanding of the concepts, it is helpful to examine characteristics of the "typical" American family. General comparisons with selected cultural groups provide the nurse with a starting point for understanding and interacting with families in a culturally appropriate way.

ACCULTURATION AND ASSIMILATION

The American family exhibits many variations owing to its unique blending with other cultures. The rich cultural heritage that has evolved from the mixing of various ethnic groups that comprise the American family constitutes the hallmark of this relatively new culture. **Acculturation** describes the changes in one's cultural pattern to match those of the host society (Spector, 2004). The changes occur within one group or among several groups when individuals from different cultures come into contact with one another. Certain characteristics of the primary culture may be retained while other practices of the dominant cultural society are adopted. For example, culturally influenced customs and traditions such as food choice and preparation, language patterns, and health practices are usually retained for long periods of time. **Assimilation** is the process in which the family loses its unique cultural identity and identifies instead with the prevailing or dominant culture (Spector, 2004).

IDENTITY

The identity (how the family views itself) of the American family is related to whether or not the family aligns itself with a particular ethnic group (e.g., Italian American, Irish American) or instead only sees itself as "American." Identifying with a particular ethnic group usually involves adopting that group's world view or approach to life. Anglo-Americans, for example, view themselves as independent individuals often separate from families (Friedman, 2003). Other cultures (i.e., Hispanic, Asian, and Pacific Islander) consider individuals in the context of family members and place less of an emphasis on who they are as individuals (Wilkinson & Van Leuven, 2007).

The American family may influence a member's choice of occupation, but usually to a lesser degree than that found in some cultures. For example, in earlier times, the English names of "Butcher" and "Baker" reflected a family occupation and set of expectations. In general, an American child is free to choose a career based on

personal preferences and talents that have been developed in outside systems such as school, church, or extracurricular activities rather than one exclusively imposed by the family.

Time orientation is a concept that refers to whether or not the family views itself to be strongly connected to previous generations. The American family tends to be focused on the present and future much more so than many cultures. This current-future time orientation may be related to the relative newness of America as a country, as compared to an ancient civilization such as China. In the American family, the individual is expected to be punctual and conform to deadlines at school and work. Making future plans by saving money or pursuing higher education is also valued. Many industrialized countries share a present and future time orientation, while other countries value a slower pace with greater emphasis on the connection to the past in terms of ancestors and traditional beliefs (Friedman et al., 2003; Townsend, 2005).

CONNECTEDNESS

Connectedness is a concept that emphasizes who the family identifies with and relates to as family members. The generality that American families are often organized into smaller nuclear families that consist of one or two parents and children is being replaced by the fact that only 52% of American families presently fit that pattern (Friedman et al., 2003). Some American families and many other cultures highly value and place great importance on the inclusion of grandparents, aunts, uncles, and cousins in their family circle. That level of extended connectedness may also include the community, especially if other members of the same ethnic group live in the neighborhood. In some American families, members spend more time commuting to outside interests than engaging in neighborhood and home-based family activities.

COMMUNICATION PATTERNS

Patterns of communication vary according to ethnic group. Cultural customs often guide selection of the family member who will be designated as the primary historian in a health care interview. American families tend to be more fluid and open in designating which member speaks to outsiders, although legal contracts most often favor the parents. Other cultures (i.e., Hispanic families from Mexico) may be more patriarchal (male dominant) or matriarchal (female dominant) and the caregiver role may rely heavily on a grandparent or aunt rather than the parents. The designated caregiver is usually the communicator in the health care setting. When planning interventions, it is important to consider the cultural role of the family member who makes the primary decisions (Wilkinson & Van Leuven, 2007).

Nursing Insight— Culture, communication and emotional expression

Culture is the essence of what defines us as people. Gaining an understanding of culture gives insights into family patterns of human interaction as well as expressions of emotion (Munoz & Luckmann, 2005).

The American family member is more likely to speak on her own behalf in public situations such as in schools and health care settings and is encouraged (within legal limits) to do so. Language other than American English often contains built-in formal and informal variations of words intended to convey respect to parents and elders, who frequently serve as spokespersons in settings such as hospitals and physicians' offices.

SOCIOECONOMIC CLASS

Social class refers to occupation and economic status. In America, status is related to social and economic variables, and mobility between the different classes is more fluid than in some countries. Religious and political influences significantly influence how the family interacts and responds to outside systems such as schools and community health programs. For example, some religious groups advocate home, rather than public schooling; political and religious orientation often shapes family beliefs about abortion or birth control. Other values are influenced by the prevailing societal view. For example, the contemporary American family tends to value its members according to the individual's line of work and educational achievements rather than the family's identity (Harmon Hanson et al., 2005).

HOLISTIC NURSING ENCOMPASSES A CULTURALLY SENSITIVE FAMILY APPROACH

Family assessment is integral to the delivery of competent, appropriate, holistic care. For most nurses, developing a knowledge base that is sensitive to the cultural variations of structure and function in the American family presents a personal challenge. Awareness of personal perceptions and values that may negatively impact therapeutic interactions with families is a professional responsibility. Nurses at every level of preparation and throughout their professional careers must engage in an ongoing process of developing and refining attitudes and behaviors that will promote culturally competent care (Taylor, 2005). The professional nurse grows in cultural competence by seeking more knowledge through review of literature and evidence-based practice, attendance at cultural seminars, and exposure to other cultures in a variety of settings. The more we learn about other cultures, the more we learn about ourselves as nurses and as human beings.

Now Can You— Recognize cultural differences that may impact the nursing assessment and interventions with the family?

1. Identify "typical" characteristics of the American family related to time and goal orientation?
2. Explain how culture influences the family's degree of connectedness and patterns of communication in the health care setting?
3. Describe adjustments the nurse may make to heighten cultural awareness and enhance a culturally appropriate family assessment and intervention?

summary points

- ◆ The competent nurse views the family as a focus of care, not as an inconvenient intrusion into the nursing routine.

- ◆ While family structure has undergone dramatic changes over the past 60 years, the importance of family has not diminished.
- ◆ Family theories and models give the nurse a reference point from which to analyze the information obtained from a family assessment.
- ◆ The nursing process is applicable and appropriate to guide nursing interventions with the family.
- ◆ The family nurse possesses an understanding of the norms related to roles, relationships, developmental stages, and family functioning, and uses this information to guide the family assessment and plan appropriate interventions.
- ◆ The nurse recognizes special needs that affect family functioning and applies strategies to assist the family in the fulfillment of healthy roles and relationships.
- ◆ Culture is the context by which family behavior is understood.
- ◆ Working with families in the home and in community health care settings is a challenging and rewarding aspect of nursing.

review questions

Multiple Choice

1. The clinic nurse is taking a history from Karen and her common-law husband, Dave. The best description of this type of relationship is that of a:
 - A. Family
 - B. Family of origin
 - C. Family of choice
 - D. Extended family
2. The obstetrical nurse who understands the systems theory of family interaction is aware that an integral part of the nursing role is to facilitate the development of a bond between the:
 - A. New subsystem of mother/infant and the father
 - B. Subsystem of mother/father and new infant
 - C. Subsystem of mother/father/infant and extended family
 - D. New subsystem of mother/infant and significant others
3. The pediatric nurse who understands the developmental theory of families would provide information to families with preschool children on:
 - A. Injury prevention and immunization
 - B. Sibling rivalry
 - C. Sleep-wake patterns
 - D. Couple building and family adjustment
4. The clinic nurse is providing assistance to the Macy family who has just lost their son in a tragic motor vehicle collision. Future planning would include counseling the Macys that one of the most critical times in their grieving occurs when they will need to deal with the full impact of their loss. This usually takes place in the:
 - A. First two weeks
 - B. Third to fourth week
 - C. Fifth to sixth week
 - D. Eighth to tenth week

True or False

5. The clinic nurse is aware that in the 1990s, the media began to depict family challenges such as poverty and substance abuse.
6. The nurse who understands communication theory is aware that emotional problems surface with the interactions that occur within the family.

Fill-in-the-Blank

7. The pediatric nurse recognizes that the most ideal way to describe a patient/family's involvement in a patient's care provision is that the entire family is the _____ of care.
8. The perinatal nurse understands that the process of passing values and cultural heritage between generations is described as the _____ process.
9. The clinic nurse talks to a family who has come in to describe their situation after a fire in their home yesterday. This type of crisis would be described as a _____ crisis that would require the nurse's _____ to locate helpful community resources.
10. The clinic nurse understands that awareness of any form of _____ in a family involves a legal obligation to report it. However, the nurse is not required to _____ or _____ once the report has been made.

See Answers to End of Chapter Review Questions on the Electronic Study Guide or DavisPlus.

CONCEPT MAP

Caring for Women, Families, and Children in Contemporary Society

chapter 4

The secret of health for both mind and body is not to mourn for the past, not to worry about the future, or not to anticipate troubles, but to live the present moment wisely and earnestly.

—The Buddha

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Determine appropriate timing for health screening examinations based on national recommendations.
- ◆ Discuss health promotion and disease prevention strategies related to infants and children, including nutrition, dental care, safety, activity, immunizations, and sexuality.
- ◆ Discuss health promotion and disease prevention strategies related to adolescents, including nutrition, dental care, safety, health promotion screening, sexual behavior, and menstrual disorders.
- ◆ Discuss health promotion and disease prevention strategies related to young adults, including safety, health promotion screening, and gynecological disorders.
- ◆ Discuss health promotion and disease prevention strategies related to middle-aged adults, including health promotion screening, perimenopause, menopause, and gynecological disorders.
- ◆ Discuss health promotion and disease prevention strategies related to older adults, including health promotion screening, gynecological disorders, prostate cancer, and mental and emotional health.

moving toward evidence-based practice Eating and Activity Habits of Adolescents

Sweeney, N.M., Glaser, D., & Tedeschi, C. (2007). The eating and physical activity habits of inner-city adolescents. *Journal of Pediatric Health Care, 21*(1), 13–21.

The purpose of this study was to analyze the body mass index (BMI) percentile and eating and physical activity habits of adolescents in relation to gender, ethnicity, country of birth, and household type. An additional purpose was to evaluate diet and activity analysis software for use by practitioners and clients.

A convenience sample of 74 participants included 9th-grade students enrolled in physical education classes, Jr. ROTC, and cooking classes. The age range of the participants was from 14 to 18 years and 53% were females. Sixty percent were Hispanic; 22% were Asian, Pacific Islanders or Philippino; 16% were African American or African; and 3% were Caucasian. Sixty percent of the participants were U.S. born and 65% were from two-parent households. Twenty percent lived with a single mother, 11% lived with a single father, and 4% lived with other relatives.

For study purposes, a 24-hour recall form was developed to obtain information related to eating and physical activity habits. Questions focused on the number of hours of sleep and awake time, participation in sports or exercise, time spent doing homework and engaged in other school-related activities, and time spent watching TV and engaging in tobacco use (smoking). Private interviews were conducted to ensure accuracy of the information provided, and each participant's height and weight were recorded at this time.

Participants were assisted in developing a personal profile on the MyPyramidTracker program available online through the U.S. Department of Agriculture (2005). Each participant's age, gender, height and weight, and 24-hour recall data were entered into the program. Exercise and eating habits in relation

(continued)

moving toward evidence-based practice (continued)

to personal characteristics were analyzed and each participant received a report that included the percentage of each food group consumed, a comparison of the food consumed, and established dietary recommendations, the overall intake of calories and nutrients and the total number of calories expended during participation in physical activity.

Data from the MyPyramidTracker program were coded and imported into SPSS (Statistical Package for the Social Sciences). Parametric and nonparametric methods were used to test the associations and between group comparisons.

- Fifty-four percent of the participants were considered to be at a healthy weight; 22% were at risk for overweight or (already) overweight according to the MyPyramidTracker statistical analysis. Of the “at risk for” or “already” overweight group, 50% were Hispanic and 41% were African Americans.

The following findings were related to eating habits: 62% of the participants ate before coming to school, 35% ate between 7:30 A.M. and lunchtime, 77% ate at lunch time, and 97% ate during the time interval between returning home from school and bedtime.

- Boys tended to eat more often and before coming to school.
- Foreign-born students were less likely to eat during all four periods.
- African Americans were less likely than Hispanics and Asians to eat during the periods before lunchtime.

The participants’ total caloric and nutrient intake was also examined. Forty-five percent consumed more calories than the recommended daily allowance (RDA). In addition,

- 92% consumed more than the RDA for carbohydrates.
- 68% consumed more than the RDA for sodium.
- 23% consumed more than the RDA for cholesterol.
- 89% consumed less than the RDA for fiber.
- 69% consumed less than the RDA for calcium.
- 16% consumed less than the RDA for protein.

Girls consumed more calories and fiber; boys consumed more nutrients. Hispanic participants consumed more calories, calcium, and sodium. Asians and African American participants tended to include more protein, carbohydrates, and cholesterol in their diets although none of the differences among the ethnic groups were significant.

When addressing the purpose of the study, analyzing the BMI percentile and physical activity habits of adolescents, the results showed:

- The average BMI scores were higher in Hispanics and African American participants. Of the total group of participants, females, Hispanics, foreign-born, and those residing in a home with a single-parent mother had the highest mean BMI percentiles, consumed the least healthy diets and engaged in the least amount of physical activity.
- Seventy-three percent of the participants engaged in sports or exercise. Students born in the United States were more likely to engage in physical activity than were foreign-born students. African Americans were the ethnic group least likely to participate in sports or exercise although the differences were not significant. The difference was significant for the participation of boys over girls in sports.

When addressing the additional purpose of the study, evaluating diet and activity analysis software for use by practitioners and clients, the results showed:

- The MyPyramidTracker software was determined to be suitable for use by adolescents for tracking nutrition, diet, and activity habits.

1. What may be considered as limitations to this study?

2. How is this information useful to clinical nursing practice?

Introduction

This chapter focuses on health promotion and disease prevention across the lifespan. Health promotion refers to the advancement of health to the highest degree possible for an individual. Disease prevention focuses on the implementation of strategies to reduce the incidence of disease or the development of comorbid illnesses in individuals with existing diseases. Health promotion has become a focus of health care since the advent of managed care. *Healthy People 2000* identified areas of priority for people of all ages regarding health promotion, which have been updated in *Healthy People 2010*, and include physical activity, control of overweight and obesity, responsible sexual behavior, and immunization (U.S. Department of Health and Human Services [USDHHS], 2000).

Health assessment and health promotion screening are perhaps the most important aspects related to promotion of health and prevention of disease. For women, this includes breast cancer screening and pelvic examinations on a recommended basis. For men, it is important to encourage screening for testicular and prostate cancer. Colon and rectal cancer screening should be routinely performed on all adults.

Nurses are perfectly situated to provide anticipatory guidance in areas of health promotion, thereby making accurate information available to family members. With all of the health information currently available in popular magazines, television programming, advertisements, and the Internet, patients do not always have the backgrounds to separate accurate information and practices from propaganda. A solid foundation in anatomy, physiology,

sociology, and psychology, along with knowledge of current health promotion research, enables nurses to provide accurate patient information in the areas of nutrition, physical activity, stress management, and safer sexual practices.

Nurses assume many roles when caring for families. Theory-driven knowledge, experiential understanding, and evidence-based clinical practice are essential tools that enable nurses to teach patients at a variety of age and developmental levels. In the areas of infant and child health, major health promotion concerns include nutrition, safety, activity and play, and immunizations.

Adolescents can be considered to be relatively healthy individuals. As such, health promotion for this age group is often ignored. Because peer relationships constitute an important component of adolescent development, peer pressure can precipitate high-risk behaviors that may lead to health complications and the early initiation of chronic illnesses. Nurses play a vital role in the education of adolescents in health care settings and in the community. A holistic approach is tremendously beneficial with this patient population. Teaching healthy practices regarding nutrition, safety, health screening, and safe sexual practices and sexual health can provide avenues for improvement in health practices that can last a lifetime.

During young adulthood, there continue to be health concerns related to nutrition and safety. However, the primary focus of health promotion for this population shifts to reproductive concerns, as this is the time when many patients are engaging in more mature relationships, marriage, and childbearing. For women, gynecological disorders, including infertility, may be diagnosed, requiring additional education for maintaining health and preventing complications.

Health screening is essential for patients in middle adulthood. For this age group, health promotion screening includes mammography, colonoscopy, cholesterol and lipid screening, and osteoporosis screening. While gynecological disorders are still a major health concern for women, reproductive health begins to concentrate on the period preceding menopause, known as perimenopause, with interest targeted on the physiological and psychological changes that occur, the hormone replacement debate, and the use of alternative therapies for symptom relief.

Older adults experience physical and psychological changes due to the aging process. These changes shift health promotion concerns for older adults, including concerns related to sexual functioning, exercise and activity, and cognitive functioning. Gynecological topics that nurses should address for women include menopause, osteoporosis, cancer, and pelvic floor dysfunction.

Health Promotion Screening

Health screening is essential for all family members. Recommendations for examinations, laboratory, and diagnostic tests have been developed by diverse professional and community agencies. Guidelines for addressing high-priority services through preventive screening delivery (Institute for Clinical Systems Improvement, 2005) have been developed and are presented in Table 4-1.

HEALTH SCREENING SCHEDULE

The health maintenance examination (HME) (Michigan Quality Improvement Consortium, 2005a, 2005b) is one of the primary components of health promotion screening. Screening should begin in adolescence and should cover a diversity of health promotion topics (Box 4-1). According to these guidelines, adolescents and young adults 18 to 49 years of age should have one HME every 1 to 5 years according to their risk status. Adults 50 to 64 years of age should have one HME every 1 to 3 years based on their risk status, and older adults 65 years of age and older should have one HME at least every 2 years regardless of risk status.

Infant and Child Health

Health promotion and anticipatory guidance are particularly important in infant and child health. Parents need to have an understanding of nutritional needs, including selection of healthy snacks. Proper dental care is also important in maintaining a child's health. Since infants and children are developing cognitively and physically during this time, there are specific considerations that must be given to safety needs. Immunizations provide protection from and prevention of disease and selection of appropriate toys encourages developmental play that meets safety requirements and facilitates development of social roles. Sexual development and sexual education promote healthy sexual behavior in later years.

NUTRITIONAL GUIDANCE

Infant Feeding

The first decision that parents make regarding infant nutrition is the decision to breast feed or bottle feed their newborn. Although the composition of infant formula is similar to that of breast milk, and many babies thrive on proprietary formula, breast milk is still considered to be the best option for optimal health promotion and disease prevention in the newborn. One of the primary benefits of breastfeeding is the decreased incidence of bacterial and viral infections as a result of passive immunity, acquired via the transfer of maternal antibodies. According to the U.S. Department of Health and Human Services' Office on Women's Health (2005), breastfed infants are less likely to develop allergies, gastrointestinal tract diseases, respiratory tract diseases, ear infections, and childhood obesity. They also have fewer systemic bacterial infections, urinary tract infections, and bacterial and viral infections of the respiratory tract.

Since an infant's immune system does not become fully mature until 2 years of age, the maternal transfer of antibodies and immune factors enhances development of the immune system and facilitates the neonate's immune system response. The longer the time that an infant is breastfed, the stronger the protection against infection and the earlier the maturation of the infant's immune system. In addition, some studies have indicated that breastfed infants experience lower rates of diabetes, lymphoma, leukemia, Hodgkin's disease, and sudden infant death syndrome (SIDS) (American Academy of Pediatrics [AAP], 2005).

Table 4-1 Preventive Services Delivery Schedule: High-Priority Services

Service	19–39 Years	40–64 Years	65+ Years
Aspirin Prophylaxis	Discuss with women post-menopause, men over age 40, and younger individuals at increased risk for coronary heart disease		
Breast Cancer Screening		Annual mammogram for women with risk factors; every 1–2 years for women 50 to 64 years of age with no risk factors	Annual mammogram for women with risk factors; every 1–2 years for women 65 and older with no risk factors
Cervical Cancer Screening	First Pap smear at age 21 or 3 years after first sexual intercourse, whichever is earlier; every 3 years after 3 consecutive normal results	Every 3 years after 3 consecutive normal results	Pap smear with new sexual partner
Chlamydia and Gonorrhea Screening	All sexually active females, including asymptomatic women aged 25 years and younger		
Colon Cancer Screening	All persons 50–79 years of age		
Hypertension Screening	Blood pressure screening every 2 years if less than 120/80 mm Hg; annual blood pressure screening if 120–139/80–89 mm Hg		
Influenza Vaccine	Annually between October and March for individuals aged 50 and above, those with chronic illnesses, members of the health care team, and others at high risk		
Pneumococcal Vaccine	Immunize individuals at high risk once; re-immunize once after 5 years if at risk for losing immunity		Immunize at age 65 if not done previously; re-immunize once if first vaccination received greater than 5 years ago and before age 65
Problem Drinking Screening	Screen for problem drinking among all adults and provide brief counseling		
Tobacco Cessation Counseling	Assess all adults for tobacco use and provide ongoing cessation services for those who smoke or are at risk for smoking relapse		
Total Cholesterol and HDL Cholesterol Screening	Fasting fractionated lipid screening for men older than age 34 every 5 years	Fasting fractionated lipid screening for men older than age 34 and for women older than age 44 every 5 years	
Vision Screening	Asymptomatic elderly adults

Box 4-1 Components of Health Promotion Screening

Beginning in adolescence, screening should include:

- Height, weight, and body mass index (BMI)
- Risk evaluation and counseling: Nutrition, obesity, physical activity, dental health, tobacco use, immunizations, human immunodeficiency virus (HIV) prevention, sexually transmitted diseases prevention and sexual health, sexual abuse, preconception counseling for all women of childbearing age, medication use, and sun exposure
- Safety: Domestic violence, seat belt use, use of helmets, firearm safety, and use of smoke and carbon dioxide detectors in the home
- Behavior assessment: Depression, suicide threats, alcohol and drug use, anxiety, stress reduction, and coping skills

Data from Michigan Quality Improvement Consortium. (2005, July). *Adult preventive services (ages 18–49)*. Southfield, MI: Author.

Human breast milk contains more carbohydrates, less protein, and less casein than cow's milk or infant formulas. This difference in chemical composition facilitates digestion of breast milk and enables the infant to more readily utilize the nutrients provided. At 1 year of age, breastfed

infants are leaner than their formula-fed counterparts. In addition, breastfed infants tend to gain less weight during childhood, a factor that may lead to reduced overweight and obesity in later life.

While breastfeeding and breast milk are associated with many benefits, commercially prepared formula, based on cow's milk, also provides the essential nutrients for infant growth and development. Soy-based formulas are available for infants who have an intolerance to formulas based on cow's milk. Sucrose and corn syrup, the carbohydrates in soy formulas, tend to be more easily digested than lactose, the carbohydrate in cow's milk-based formula. However, cow's milk formulas provide a better source of protein than the soy formulas. Hydrolyzed-protein formulas are also available for infants with intolerance to cow's milk-based formula. Because the protein has already been broken down, the likelihood of an allergic response is diminished.

Whole milk should be introduced into the infant's diet at 1 year of age. By this time, the infant's digestive system has developed enough to provide the enzymes necessary for appropriate absorption and use. The use of whole milk is important in ensuring that the child receives enough fat and calories to meet nutritional and developmental needs (Table 4-2).

Table 4-2 Infant Feeding Patterns

Birth–1 month	Breast every 2–3 hours
	Bottle every 3–4 hours
	2–3 oz. per feeding
2–4 months	Breast or bottle every 3–4 hours
	3–4 oz. per feeding
4–6 months	Breast or bottle 4–6 times per day
	4–5 oz. per feeding
6–8 months	Iron-fortified rice cereal
	Breast or bottle 4 times per day
	6–8 oz. per feeding
8–10 months	Finger foods
	Chopped or mashed foods
	Sippy cup with formula, breast milk, juice or water
	Breast or bottle 4 times per day
10–12 months	6–8 oz. per feeding
	Self-feeds with fingers and spoon
	Most table foods are allowed
	Breast or bottle 4 times per day
	6–8 oz. per feeding

Ethnocultural Considerations— Infant feeding

Culture plays an important role in infant feeding. For many new immigrants and members of ethnic minorities, the traditions of their homeland, the consumption of traditional foods, and maintaining traditional food preparations provide comfort in an environment that is new and unknown, and is a way of sustaining cultural identity. Some cultural practices include breastfeeding on demand and early introduction of solid foods, where others feel that exposure of the breast is indecent—a view that decreases the mother's comfort with breastfeeding. It is imperative for nurses to recognize biases that the Western view of health and nutrition is the only appropriate method to feeding an infant. Nurses need to evaluate the effect of the cultural practices objectively and intervene only if the mother or baby is at risk for harm.

Introduction of Solid Foods

As a child moves from infancy to toddlerhood, parents should introduce solid foods into the diet, including finger foods. The foods that should be introduced are based on the developmental stage and nutritional need. Solid food should not be introduced until the infant is at least 4 months of age since the digestive tract is still developing until this point. In addition, solid food should not be put

in an infant's bottle. Instead, the child needs to learn that food is to be eaten and taken from a spoon.

Between 4 and 6 months of age, infants begin to exhibit signs of readiness for the introduction of solid foods. These signs include the ability to hold up the head, sit in a high chair, and move the tongue around the mouth without pushing food out of the mouth (as the extrusion reflex disappears). In addition, the infant should be teething, gaining weight (should be doubled from the birth weight), and remain hungry after 8 to 10 breast feedings or after consuming 40 ounces of formula per day. The first solid food offered to the infant should consist of an iron-fortified rice cereal prepared by mixing one teaspoon of cereal with 4 to 5 teaspoons of breast milk or formula. Over the following weeks, the cereal mixture consistency should be thickened, and the amount gradually increased to 1 tablespoon of cereal per day. New cereals, such as those containing oats and barley, may be added, but parents should wait at least 1 week before adding each new food in order to identify signs of potential allergy.

Between the ages of 6 and 8 months, the infant's cereal intake should increase to 3 to 9 tablespoons per serving, given two to three times per day. In addition, parents should introduce pureed or strained fruits, such as bananas, pears, apples, and peaches, into the diet, beginning with 1 teaspoon and increasing to one-fourth to one-half cup in two to three feedings. At 1-week intervals, pureed or strained vegetables such as carrots, squash, sweet potatoes, avocado, green beans, and peas should also be introduced in the same form as the fruit.

Finger foods can be introduced once the infant reaches 8 to 12 months of age. Signs of readiness for finger foods include the ability to pick up objects with the thumb and forefinger (known as development of the pincer grasp), the ability to transfer items from one hand to the other, and the tendency to put everything into the mouth. Examples of appropriate finger foods include small pieces of lightly toasted bagels, small pieces of ripe bananas, well-cooked spiral pasta, teething crackers, and low-sugar "O"-shaped cereal. During this age, mixed cereals may also be introduced, along with small amounts of yogurt and cottage cheese, small amounts of protein (e.g., egg yolk, pureed meats and poultry, mashed beans with soft skins), and apple and pear juice. Citrus juices should not be introduced, as the digestive system has not developed enough to utilize the nutrients.

From 1 year to 18 months of age, the toddler should begin to use a spoon and eat some of the same foods (mashed or chopped into bite-size pieces) as the older family members. Whole milk, eggs, full-fat yogurt, and cottage cheese, and citrus juices can be introduced at this time. New vegetables, such as broccoli and cauliflower can also be introduced.

New foods are then introduced over the next 18 months as the infant begins to feed himself more and make his own choices. Fruit, cut up into bite-size pieces, and diced vegetables may be added to the diet. As the toddler develops his own taste, combination foods such as macaroni and cheese and spaghetti may also be introduced.

Family Teaching Guidelines... Introducing Solid Foods to Infants

The baby is ready for the introduction of solid foods at approximately 6 months of age. To help determine if the baby is ready for solid foods, look for developmental cues such as the ability to sit well with support and the decrease or disappearance of the extrusion reflex. The baby may watch very intently as you eat, and may seem hungry between bottles or breastfeeding.

- ◆ Iron-fortified rice cereal is recommended as baby's first solid food for a couple of reasons. Rice is the least allergenic of the grains and the iron helps the baby replenish the iron needed for growth and development. When introducing the rice cereal to the baby, you can mix it with formula, breast milk, or boiled and cooled water until it is very soupy. As the baby becomes accustomed to solid foods, the consistency of the cereal can be gradually adjusted to create a less soupy texture.
- ◆ When the baby is eating about 4 tablespoons of cereal twice a day, introduce vegetables and fruits. It is recommended to start with vegetables and then expose the baby to the sweet taste of fruits, as babies are typically more accepting of the sweet tastes.
- ◆ Introduce one food at a time, waiting 3–5 days between new foods so you will be able to identify any reactions to particular foods.
- ◆ Introduce food before formula or breastfeeding when the infant is hungry, and follow each solid food meal with breast milk or formula.

Seeking Additional Help:

- ◆ If the infant is not growing or gaining weight, if he is unable to suck or swallow or shows any signs of an allergic reaction, it is important to promptly seek help from the primary health care provider, nearby clinic, or emergency room.

Essential Information:

- ◆ Keep salt, sugar, and additives to a minimum or avoid them altogether. If you make your baby's food, do not add salt or sugar.
- ◆ **Never** put food in bottles or mix food with formula because it can cause choking.
- ◆ Offer only small bites of food to prevent choking and pay close attention to your baby when feeding.

Data from American Academy of Pediatrics. (2005). Policy statement: Breastfeeding and the use of human milk. *Pediatrics*, 115(2), 496–506.

Now Can You— Discuss infant and child nutrition?

1. Discuss the benefits of breastfeeding when compared to bottle feeding?
2. Describe the recommended process for introducing solid foods into an infant's diet?
3. Identify at least four safe, nutritious finger foods for infants and toddlers?

Childhood Nutrition

Once the child reaches 3 years of age, parents should be introduced to the Food Pyramid for Kids (U.S. Department of Agriculture, 2005). As with the Food Pyramid developed for adults, the servings per day are calculated based on weight and activity. Specific suggestions are included, such as limiting the intake of juice, ensuring that all juices are 100% natural, and incorporating whole grains to comprise half of the daily grain intake (Fig. 4-1).

Snacks for children are often the most difficult aspect of planning meals. Parents need to be taught that snacks should be nutritious, and that any food item that is appropriate for a meal is appropriate for a snack. Children typically need to eat every 3 to 4 hours to maintain energy needs. Thus, parents must consider portion sizes when providing snacks for their children. Nutritious snacks include grain products, fruit and vegetable juices, fresh fruits and vegetables, dried fruit, nuts, and seeds (Box 4-2).

DENTAL CARE

Teething typically begins between 4 and 7 months of age. The first teeth to erupt are usually the bottom central incisors followed by the upper central and lateral incisors. The next to erupt are the bottom lateral incisors followed by the first molars. An infant may have any range from no teeth to eight or more teeth by her first birthday. Most children will have all 20 of their primary teeth by their third birthday.

Signs of teething include increased drooling, irritability, desire to chew on objects, crying episodes, disrupted sleeping, and eating patterns. Caregivers can be encouraged to give teething infants a cool wet washcloth, teething rings that have been cooled in the refrigerator, or a clean finger rubbed on the gums to help ease the discomfort.

The American Dental Association (ADA) recommends that a dentist examine a child within 6 months of the eruption of the first tooth and no later than the first birthday. Daily dental care can begin even before the first tooth emerges. Gums can be gently wiped with a damp washcloth or gauze, and when the first tooth emerges, a soft toothbrush and water can be used. Toothpaste cannot be used until age two.

SLEEP AND REST

Newborns sleep approximately 15 to 20 hours per day in 2- to 3-hour increments. By 3 months of age, infants sleep approximately 15 hours in a 24-hour period. At 6 months, the infant may have two naps of 2 hours each during the day and sleep 9 to 14 hours per night. From 9 months to 1 year, the length of naps may decrease slightly, with nighttime sleep remaining in the 9- to 14-hour range.

Infants are not born knowing how to put themselves to sleep. To help the infant learn to fall asleep on his own, caregivers can put the infant to bed drowsy but awake, rather than breastfeeding or rocking the infant to sleep. By training the infant to fall asleep independently, if he awakens in the night, he is more likely to self-soothe back to sleep.

Dr. T. Berry Brazelton describes six states of behavior in the newborn: quiet sleep, active sleep, drowsiness, quite alert, active awake, and crying. These states include body activity, eye movements, facial movements, breathing patterns, and response to external and internal stimuli. The nurse can provide anticipatory guidance by educating

Figure 4-1 MyPyramid for Kids.

Box 4-2 Snacks for Children

- Grain products
 - Bread products: Yeast breads and quick breads, made from whole wheat, rye, oatmeal, mixed grains, and bran; rye crisps; whole-grain crackers. Serve with crackers and cheese, peanut butter, or milk.
 - Cereals: Dry cereals with less than 5 grams of sugar. Serve with milk. Add dried fruits.
 - Popcorn: Top with grated cheese instead of butter and salt.
 - Cookies: Use whole-wheat flour for baking. Try oatmeal or peanut butter cookies. Serve with milk.
- Beverages: Fruit juices and vegetable juices. Serve milk with breads, cereals, and cookies. Blend fruit with milk in a blender.
- Vegetables: Cut up raw vegetables. Serve with peanut butter, cheese, or milk. Include broccoli, carrots, celery, green beans, zucchini, and others.
- Fresh fruit: Serve with peanut butter, yogurt, or milk. Include apples, bananas, grapes, melons, oranges, and peaches.
- Nuts and seeds: Include almonds, cashews, and peanuts

caregivers about how to recognize these states in the newborn. Often caregivers think the infant is waking, when the infant is actually in a period of active sleep and if left for a few minutes, he will settle back into a quiet sleep state.

In 1992, the American Academy of Pediatrics recommended that infants be placed on their backs to sleep to reduce the risk of sudden infant death syndrome (SIDS). According to the Centers for Disease Control and Prevention (CDC), SIDS rates have declined up to 50% in recent years. Premature infants and infants with certain illnesses may be required to sleep in a prone or side lying position.

Toddlers and preschoolers require the same amount of sleep per day as do infants. Toddlers and preschoolers sleep approximately 14 hours in a 24-hour period, 11 of those hours at night. One 1.5- to 3-hour afternoon nap provides the additional needed rest. Bedtime resistance is likely to appear in this developmental stage. The nurse can provide anticipatory guidance by recommending sleep strategies for caregivers to implement with toddlers.

School-age children require about 10 to 12 hours of sleep per night. Depending on activity level, some children may require a little more or a little less. The nurse can educate the caregiver to assess their child's mood, temperament, and energy levels throughout the day to determine if the amount of sleep they are getting is sufficient.

Family Teaching Guidelines... Preventing Plagiocephaly

- ◆ Infant skulls are soft and flexible during the first year of life as the skull enlarges to accommodate the growing brain. During this time, the infant skull can become misshapen or deformed by external pressure. This condition is rarely life threatening, but can cause permanent facial and skull deformities, or in severe cases, the child's vision can be affected.
- ◆ Constant pressure on one area of the infant's head can flatten or reshape it. The Back to Sleep campaign initiated by the American Academy of Pediatrics has had the unintended effect of increasing the incidence of plagiocephaly. Proper positioning during sleep and waking periods spent in car seats and baby chairs often require the infant to spend considerable time on his or her back.
- ◆ Place the baby on the stomach to play for several times each day. When the baby is very young, placing a rolled towel or blanket under his arms for support helps the infant to be more comfortable. This intervention removes pressure from the skull and facilitates the development of strong neck and arm muscles needed for sitting and crawling.
- ◆ Alternating the direction the baby faces in the bassinet or crib during sleep times is also helpful. If the baby's crib is positioned against a wall, alternating the end of the bed where the baby's head is placed allows her to look out toward the room rather than at the less stimulating wall.

SEEKING ADDITIONAL HELP

- ◆ If you notice a flattened area on the baby's skull that does not seem to be improving with positioning changes, you should talk with the physician. The baby may need to be fitted with a customized helmet that is worn for 23 hours a day. This helmet is designed to prevent the baby's head from assuming one position, and allows the skull to expand into the flattened area.

ESSENTIAL INFORMATION

- ◆ The baby may also be placed on his side while he is awake. The mother can lie on her side, face the baby, and both parties can entertain each other with toys and facial expressions. It is a wonderful way to bond with the baby. Newborn babies love to look at their parents' faces, so this is a very enjoyable activity for them.

Data from American Academy of Pediatrics (1992).

SAFETY

Infants and children are at particular risk for accidents and injuries as a result of their cognitive and physical development during these years. Parents need to be taught how to prevent injuries and accidents, as well as how to prepare for risk-taking behaviors that may arise in late childhood. These risk-taking behaviors may include experimenting with substance use and sexual activity.

Injury Prevention

One of the best methods for prevention of injury to infants and children is for parents to prepare and keep their homes safe. This process, ideally begun before the infant is brought home from the hospital, should be re-evaluated and modified as the child moves through each developmental stage. Smoke and carbon monoxide detectors should be installed throughout the home. Medications and chemicals should be moved to a high shelf, placed in a sealed area, or stored in a cupboard equipped with child safety locks. A fire extinguisher should be readily available on every floor in the home and an additional unit placed in the kitchen. A fire escape route should be planned.

An appropriate car seat should be obtained in anticipation of bringing the new infant home from the hospital. Proper use of a car seat, which has been shown to reduce the chance of injury by 70% and the chance of death by 90%, includes placing the unit in a backward-facing direction in the back seat.

When the infant is brought home from the hospital, new areas of concern must be considered. Crib safety is one of these. Parents should be cautioned about buying older (made prior to 1989) models of cribs, as they do not meet current safety standards. The distance between the slats of the crib railings should be less than 2 3/8 inches to prevent head entrapment and potential strangulation. There should be no sharp edges, and the crib mattress should fit snugly with the end panels extending below the mattress to prevent suffocation. Bumper pads should be used to pad the crib; these should be removed once the infant is able to stand. The furniture paint should be non-toxic and all furniture in the infant's nursery should be positioned to avoid windows, curtains, blinds, lamps, electrical cords, outlets, and appliances.

With regard to infant feeding and safety, teach parents to warm bottles slowly, never to use a microwave oven to heat breast milk or formula, and never prop a bottle in the infant's mouth, as this practice creates a choking hazard. Remind parents to keep all hot liquids and foods away from the baby and to place them well away from the edges of tables and counter tops. If a pacifier is used, one with shields large enough to prevent placement of the entire pacifier in the mouth should be selected, and the pacifier should be frequently inspected for breakage or cracks. Never place the pacifier on a cord around the infants' neck or attached to the infant's clothes with a clip or cord.

At 3 months of age, infants begin to roll over from stomach to back and to turn toward loud sounds. These activities can pose a safety hazard related to the changing tables used for changing diapers. Teach parents to keep one hand on the infant at all times and never to leave the infant alone on the table. Powders, oils, and lotions should be used cautiously to prevent poisoning or illness if swallowed. To prevent aspiration, powders should never be shaken close to the infant's face. Current recommendations for powder use include having the parents first place the powder in their hands and then rub it onto the infant.

Since serious falls and injuries can occur with the use of high chairs, playpens, strollers, and swings, these items should be used only under supervision of an adult. Playpens should not be used in place of cribs in order to prevent injury from suffocation that can occur while the infant is asleep. The use of walkers is not recommended, as

serious brain injury, fractures, and concussions have resulted from accidents that involve the walker tipping over or falling down a staircase. Also, the development of gross motor skills may be hindered with walker use, as babies who use them learn to walk on the tips of the toes.

Play time and bath time are associated with potential hazards as well. Risks of accidental choking and suffocation are significant for children younger than the age of 6 months who tend to place small objects in their mouths as their cognitive and fine motor skills are developing. Parents must ensure that crib gyms and mobiles are placed at an appropriate height, toys and stuffed animals have no removable parts or sharp edges, and pull toys do not have long cords. Bath safety includes ensuring that the water temperature is below 120°F. Teach parents to test the water temperature before placing the child in the bath and to use bath mats or towels to prevent slipping. During the bath, the parent should keep both hands positioned securely on the infant, while using one hand to constantly hold the infant and the other hand to wash the infant.

By 14 months of age, the child has developed the skills necessary for walking; the majority of children walk well by this time. Once the child begins to crawl, creep, and walk, additional environmental safety hazards are present. Kitchen and bathroom cabinets should be equipped with firm latches or locks to prevent injury from medications, poisonous chemicals, and sharp implements. Stove guards should be placed over knobs and burners to prevent accidental injury from burns. Remind parents to turn all pot handles away from the front of the stove and to install locks or latches on appliance doors to prevent entrapment and suffocation.

Stairs and windows present safety hazards related to falls. Safety gates at the tops and bottoms of staircases should be used at all times; accordion gates are not recommended. Railings on steps, decks, and balconies should be covered with netting to prevent children from getting trapped between the posts or falling. Safety guards can be placed on windows to prevent them from opening more than 4 inches; however, these should not be used on windows designated for fire escape. Furniture should not be placed near windows as children can climb on the furniture and fall through the windows. Poisoning accidents can occur through the ingestion of harmful plants or peeling paint chips, particularly in homes built before 1978 that contain lead-based paint.

Now Can You— Discuss strategies to ensure infant and toddler safety?

1. Describe methods for ensuring crib safety?
2. Identify ways to promote bath safety?
3. Discuss strategies for making stairways and window areas safe?

By 24 months of age, cognitive skills have developed that allow the toddler to begin logical reasoning. During this time, play activities pose the greatest risk of injury. While playing indoors, children should not be allowed to run or jump, and the kitchen and bathroom should be off limits. Refrigerators and freezers should be locked, and closets, attics, and basements should be sealed to prevent accidental injuries. Outside safety includes having a

fenced-in yard with a locked gate and ensuring that all playground equipment is installed securely. A soft surface should be placed under playground areas to provide cushioning for falls. All yard equipment should be safely stored away from children.

Water safety is also important. Swimming in pools, lakes, and rivers should take place only under adult supervision, and children should not be allowed to dive or jump into water less than 12 feet in depth. Chemicals used in pools and hot tubs are poisonous and should be kept out of the reach of children. If possible, a separate fence should be placed around the pool, equipped with a safety alarm system to alert parents when children are near the water.

Risk-taking Behaviors

Children engage in risk-taking behaviors as a normal progression through cognitive development. Risk-taking enables children to develop skills and self-confidence as well as to understand their strengths and limitations. Through risk-taking behavior, children learn boundaries and develop an awareness of the outside world.

TESTING LIMITS. Risk-taking actually begins in infancy, as infants explore their worlds, place objects in their mouths, and learn to identify parental facial expressions and gestures. Once the child begins to walk, limit-testing heightens through activities such as climbing, reaching, and balancing. Parents who allow the child's exploration send a message that when performed in appropriate situations, a certain degree of risk-taking is necessary for development. Conversely, parents who do not allow exploration convey the message that experimentation is undesirable and should not be done. Close to age 2, when the child enters the developmental stage of *autonomy versus shame and doubt*, risk-taking may present itself in the form of saying “no” to parents.

Preschoolers may engage in risk-taking behaviors as a result of their physical development. As gross motor skills develop, their physical abilities exceed their ability to logically reason the danger associated with their activities. Parents need to monitor their children's activities, while allowing them to maintain a sense of control. In so doing, the parent helps the child to develop the confidence needed to try something new or difficult in the future and facilitates the child's successful mastery of the developmental task associated with *initiative versus guilt*.

School-age children's risk-taking behavior, as opposed to the preschoolers' behavior, is more closely related to cognitive rather than physical development. At this time, the child has moved into the stage of *industry versus inferiority* and is developing a sense of self-esteem. Risk-taking allows the school-age child to experience heightened feelings of self-worth following success and to learn to evaluate mistakes and develop alternative strategies for the future when they meet with failure. See Chapter 20 for more information on developmental stages.

PLAY

Play enables children to explore their world, express their thoughts and feelings, and meet and solve problems. The foundation for play begins immediately after birth. The infant reflexively grasps objects or moves extremities and through this, discovers enjoyment of the sounds, tastes,

textures, and smells. These discoveries gradually lead the infant to perform such activities purposefully. Playing with an infant begins with engaging all of the senses. Infants enjoy looking at faces, black-and-white objects, hearing voices, and sucking on hands in the reflexive play stage. It is important for caregivers to play with their babies, as much of an infant's learning occurs through play. For the first few months, the caregiver must play with the baby during quiet alert periods. This is the best learning time for a young infant. As the baby grows and abilities and mobility increase, the infant plays for longer periods and becomes adept at expressing feelings. Signs of boredom or lack of interest become more obvious, at which point the caregiver can switch to a new game.

As physical coordination and sensory ability increase rapidly, the infant is able to examine objects more closely. By looking, touching, and placing objects in the mouth, the infant discovers different textures, tastes, and colors. As the infant develops, he learns cause and effect. For example, when an infant shakes the rattle, it makes a pleasant sound. This recognition of cause and effect encourages the infant to repeat activities to achieve the desired result.

As the infant approaches the 1-year mark, the play environment increases dramatically as the infant learns to crawl and walk. In addition, the ability to communicate increases steadily as the infant reaches 12 months. At this time, the infant can point to objects, voice frustrations at having toys taken away, and use body language and sounds in an attempt to express emotions. Play in childhood is based on cognitive as well as physical development. While there are five types of developmental play in which older children can participate, children must progress from the lower levels to the higher levels. In order to meet the developmental needs of each stage of play as the child grows and matures, specific activities, toys, and games should be introduced (Table 4-3).

- Solitary play (type 1): The child plays alone, without regard for those around him.
- Onlooker play (type 2): The child observes the other children around him as he plays alone; may alter own play activities based on what he sees the others doing or may be content to continue in his play while simply talking with the other children; play activities are different (e.g., one child may be bouncing a ball while another is playing with jacks).
- Parallel play (type 3): Children play with the same materials and items, but they do not yet play together.
- Associative play (type 4): The peer group is developed to the extent that children play together, but in a loosely organized manner.
- Cooperative play (type 5): Children assume designated roles in the games, have goals for the games, and rely on one another for the game to continue and progress.

Now Can You— Provide developmentally appropriate play activities for school-age children?

1. Identify the five types of play?
2. Describe the developmental tasks associated with each type of play?
3. Identify play activities that are appropriate for each type of play?

IMMUNIZATIONS

Immunizations are the child's first and best defense against several diseases that can be fatal or cause serious disability. Since the child's immune system is immature, the administration of vaccines enables the child to develop antibodies against specific potential organisms. The CDC (2006b) has developed a recommended schedule to enable health care practitioners and parents to ensure that early and appropriately timed immunization is in place (Fig. 4-2).

SEXUALITY

It is never too early to begin sexual education with children. Correct information enhances appropriate decision-making regarding sexual behavior in the later years. The infant is aware of the differences in touch in certain parts of the body and is capable of deriving comfort and pleasure from touch. Male babies have erections and female babies experience vaginal lubrication. Infants can experience orgasm as early as 4 or 5 months of age. Sexuality at these young ages is an expression of exploration and comfort.

As early as 18 months of age, toddlers begin to explore their bodies and express concerns and questions about their bodies. Parents should teach their children the proper names for sex organs and allow masturbation, in a private manner, as children begin normal body exploration. By age 4, children can be taught that males and females have different sexual organs. While sexual exploration with other children is normal developmentally, the parents should set limits and discourage it if seen. During the preschool years, the question of where babies come from usually arises. It is best if parents are direct and honest and provide a simple and straightforward answer that babies come from inside the mother. School-age children, who tend to associate and play more with children of their same gender, are still attempting to learn the difference between the sexes. At this time, parents must continue to provide truthful, direct information and encourage questions to prevent their children from receiving incorrect information from friends.

During the years between 8 and 11, children begin to focus on their own development and contrast it with that of their friends. Reassurance from parents decreases anxiety and helps children to realize that they are in the normal range of development. At this time, parents should begin to educate their children about the names and functions of the male and female sexual organs, puberty, the menstrual cycle, sexual intercourse, pregnancy, pregnancy prevention, same-sex relationships, masturbation, and the spread of sexually transmitted infections. They should also encourage dialogue about personal expectations and values regarding sexual activity.

ADOLESCENT HEALTH

Adolescents are in a vulnerable life stage as they are between the states of childhood and adulthood and are experiencing significant physical and emotional growth. A number of developmental tasks are associated with this period (Box 4-3). The most important changes that occur between the ages of 11 and 18 are sexual developmental changes. The influx of sexual hormones, combined with the growth of primary and secondary sexual characteristics

Table 4-3 Play Activities for Children

Developmental Age	Type of Play	Purpose of Play	Activities
Infant	Solitary	To stimulate sensorimotor development with simple imitative games	<ul style="list-style-type: none"> • Patty cake • Peek-a-boo • Itsy-bitsy spider • Finger painting • Ball rolling • Songs • High chair fishing
Toddler	Parallel	To help children make the transition from solitary play to associative play by stimulating sensorimotor and psychosocial development	<ul style="list-style-type: none"> • Matching games • Simple puzzles • Blowing bubbles • Bean bag toss • Catching fireflies • Ring around the Rosy • London Bridge • Duck-duck goose • Hide and seek • Coloring • Drawing
Preschooler	Associative	To help children learn how to share, play in small groups and to learn simple games with rules, concepts of language, and social rules	<ul style="list-style-type: none"> • Memory • Chutes and Ladders • Candyland • Hokey Pokey • Hot Letters • Alphabet games • Color games • Checkers
School-age	Cooperative	To teach children how to bargain, cooperate, and compromise in order to develop logical reasoning, which increases social skills	<ul style="list-style-type: none"> • Baseball • Soccer • Gymnastics • Swimming • Dodge ball • Board games • Simple card games • Computer games • Video games • Puzzles • Crosswords • Word search puzzles
Adolescent	Cooperative	To teach children how to bargain, cooperate, and compromise in order to develop logical reasoning, which increases social skills	<ul style="list-style-type: none"> • Video games • Computer games • Board games • Card games • Team sports • Spin the bottle • Charades

Box 4-3 Developmental Tasks of Adolescence

- **Formal Operational Thought:** Piaget's Theory of Cognitive Development indicates that adolescents' thought becomes more abstract. They develop the ability to logically reason, generating hypotheses and potential consequences of action.
- **Learning Identity:** Erikson's Theory of Psychosocial Development suggests that the adolescent experiments with different roles in an attempt to identify the role with which he or she is most comfortable. The adolescent, through achievement, becomes more confident in his abilities and gradually develops a set of ideals with which he can identify. As the adolescent experiments with different societal roles, peer influences play an increasingly important role in development.
- **Sexual Identity:** Freud's Theory of Psychosexual Development proposes that, as adolescents enter puberty, instinctual impulses create stress and uncertainty. As the adolescent develops a sense of sexuality, the stress is decreased, and balance is restored, allowing the adolescent to engage in healthy sexual relationships.

and the focus on peer relationships, place adolescents at increased risk of injury and disease. During this developmental period, special attention needs to be placed on nutrition, safety, sexual health promotion, and prevention of illness.

NUTRITION

Diet and nutrition are especially important for facilitating optimal growth and development during adolescence. Adequate nutritional intake is essential to accommodate the growth spurt that occurs during this time. Adolescents gain approximately 25% of their adult height and 50% of their adult weight throughout this time period. In addition to the nutritional needs to promote growth and

development, adolescents are tasked with developing a positive body image and a personal identity. When conflicts exist, adolescents are at increased risk for eating disorders, which can lead to overweight, underweight, hypertension, and diabetes mellitus.

Obesity in Adolescence

During adolescence, it is common for the appetite to increase. In addition, adipose cells develop rapidly, leading to an increased potential for adipose tissue development and overweight. This growth is dependent on both nutritional and environmental factors. It is essential to balance the energy intake and output in the adipose cells to prevent the growth of larger adipose cells, which can lead to obesity. Overweight and obesity result from a decreased ability to release fat during periods of energy expenditure.

The effects of heredity and environment should be considered as contributing factors in adolescent obesity. A child born to two obese parents has a 75% chance of being obese. A child born to parents where only one is obese has a 25% chance of being obese. However, the influence of heredity must be considered in the context of the adolescent's environment. Psychological, social, and health factors collectively shape the adolescent's environment and its impact on nutritional health.

PSYCHOLOGICAL FACTORS. Perhaps the factor that has the greatest psychological effect on body image and nutritional health is the media. Television and advertising both encourage and condone the eating of high-fat, high-carbohydrate foods, using thin, attractive people in the commercials. In addition, the mere fact that adolescents spend approximately 3 to 4 hours each day watching television adds to the problem of obesity, as television viewing is a sedentary activity.

The impact of the media on the developing adolescent's body image is crucial. Body image is affected by physical

characteristics, body-related experiences, social response to appearance, and social value placed on body characteristics. Each of these factors has an effect on personality development, and is influenced by individual responses. Many times, these factors combine to create a focus on excessive dieting and scale-weighting behaviors. In addition, there is a relationship between impaired body image in adolescents and depression.

SOCIAL FACTORS. Social factors such as the influence of family and peers interact with the psychological factors that impact adolescent obesity. In many families, eating and mealtime behaviors are instituted at an early age. Little time may be spent on meal preparation, and time spent with family members while eating may be nonexistent. As the dual-income family has become the norm in modern society, fast food and eating “on the go” has also become the norm. Eating patterns that lead to adolescent obesity may include the regular consumption of high-calorie, low-nutrient-dense foods, a lack of understanding about nutrition, a lack of structure and sociability in eating patterns, a tendency to eat late in the evening, binge eating when hungry or bored, and the habit of eating rapidly.

Adolescence is also a time when peer relationships become extremely important in the development of a personal identity. Adolescents frequently congregate and socialize in areas where food is consumed, such as fast food restaurants, pizza parlors, and at parties. For many, eating becomes a social event in and of itself. In these settings, peer pressure may influence the healthy eaters to consume high-fat, high-caloric food in order to fit in with the majority. Over time, many adolescents become conditioned to eat poorly and to elude structure in their eating behaviors.

One’s level of physical activity is associated with weight, and a sedentary lifestyle constitutes a significant factor in obesity. When adolescents are not with their peers, they are often engaging in sedentary activities, such as watching television, using the computer, talking on the telephone, and text messaging. Without energy expenditure, the excess in calorie consumption increases the number of adipose cells and leads to further weight gain.

MEDICAL FACTORS. The psychological and social factors may predispose to an increased risk for disease related to overeating and obesity. Depression is one of the most common disorders associated with adolescent obesity. While attempting to fit into the peer group by engaging in unhealthy eating behaviors, adolescents are meanwhile being bombarded with media images of thin, attractive individuals overeating and societal messages that obesity is unattractive and shameful. There is an unspoken viewpoint that obese individuals are overindulgent and lack self-control. These influences negatively impact the adolescent’s body image and self-esteem, and create a risk for depression, feelings of social isolation, rejection, failure, and thoughts of suicide.

Obesity in adolescence leads to medical problems, including cardiovascular disease, type 2 diabetes mellitus, kidney disease, gallbladder disease, liver disease, and orthopedic problems. Hypercholesterolemia and hyperlipidemia increase the workload on the heart, resulting in hypertension. These disorders, when combined with

hyperinsulinemia, result in insulin resistance syndrome. Insulin resistance is highly associated with the development of type 2 diabetes mellitus, long thought to be an adult disease. Over the past 10 years, however, there has been an increased incidence of type 2 diabetes mellitus developing in childhood and adolescence (Menon, Burgis, & Bacon, 2007).

For the adolescent female, insulin resistance and obesity may affect reproductive and gynecological health. Insulin resistance causes an increase in circulating insulin, and stimulates an increase in the production of androgens. Increased androgens, combined with the increased levels of circulating insulin, have been reported to trigger polycystic ovarian syndrome (PCOS) (Dunaif, 2006). PCOS is associated with anovulation, and is manifested by dysmenorrhea, hirsutism, and acne. Insufficient progesterone production results in infertility and an increased risk of endometrial cancer.

“What to say” — *When talking with an adolescent about losing weight*

Discussions about weight loss can be a sensitive issue for many overweight patients. During adolescence, body weight has a dramatic effect on the development of self-image and self-esteem and can be an even more sensitive issue for discussion. An important strategy in discussions about weight and weight loss with adolescents is to begin the conversation with expressions of respect that are sensitive to cultural differences related to food choices and eating patterns. Regardless of whether or not the patient is ready to begin a weight control program, she may still benefit from talking openly about healthy eating and exercise. To open the conversation, the nurse can begin with a simple question to determine if the patient is willing to talk about the issue:

“Cindy, can we talk about your weight? What are your thoughts about your weight right now?”

To determine the degree of readiness to engage in weight control, additional questions can be asked:

“What are your goals concerning your weight?”

“What kind of help would you like from me regarding your weight?”

Nurses should avoid the use of words that may make patients feel uncomfortable, such as “obese,” “obesity,” “fat,” and “excess fat.”

Eating Disorders

In addition to overweight and obesity associated with overeating, other eating disorders such as anorexia nervosa and bulimia nervosa may develop during adolescence. These two eating disorders adversely affect nutrition and the overall health status and impact growth and development. The underlying issue associated with eating disorders concerns the improper use of food: eating too little, eating too much, or eating too much and purging in an attempt to rid the body of excessive calories.

Eating disorders are rooted in issues related to body image development. The core of the problem involves a distortion in body image and a delay in achieving progress

toward a healthy, adult body image. In essence, adolescents with severe eating disorders are struggling with another developmental task, that of autonomy. They tend to have an unrealistic view of themselves, and depend on social opinions and judgments, as evidenced by their preoccupation with food, dieting, and exercise patterns.

ANOREXIA NERVOSA. *Anorexia nervosa* is a chronic eating disorder that stems from a distorted body image. This condition develops as a result of obesity or a perception of obesity that creates an obsession with weight loss and a denial of hunger. The fear of gaining weight, combined with a low self-esteem, creates a life-threatening disorder that can, if not properly treated, lead to serious medical complications and death. Individuals with anorexia nervosa undertake strict and severe diets and engage in rigorous excessive exercise in order to maintain an unrealistic body weight. Psychological traits associated with anorexia nervosa include perfectionism, obsessive–compulsive behavior, social isolation, a focus on high achievement without satisfaction, and depression (Menon et al., 2007).

Due to a pervasive malnutrition that affects all organ systems, symptoms include weakness, dizziness, excessive weight loss, intolerance to cold, bradycardia, hypotension, bone loss with consequent fractures, constipation from dehydration, and the development of lanugo. The continued restriction of calories suppresses the hypothalamic–pituitary–adrenal axis, and results in decreased production of cortisol and growth hormone. In females, luteinizing hormone and follicle-stimulating hormone are suppressed, resulting in a decreased production of estrogen. Decreased estrogen levels are associated with anovulation, amenorrhea, loss of secondary sex characteristics, and infertility. Over time, inadequate nutrition results in blood and electrolyte abnormalities, which may lead to death.

BULIMIA NERVOSA. *Bulimia nervosa* is a syndrome that consists of a cycle of binge eating and purging. Binge eating entails eating large amounts of food at least 2 days per week for at least 3 months. When this behavior is combined with extreme measures to rid the body of the excess food, a cycle ensues. Adolescents with bulimia may use laxatives, diuretics, or emetics to rid the body of excess calories (purging behavior), or they may engage in excessive exercise or fasting (nonpurging behavior). These behaviors are performed in an effort to alleviate the guilt associated with overeating; as the guilt feelings pass, the tension returns, and the bingeing behavior begins once again.

Adolescents with bulimia nervosa typically maintain a normal weight, although psychological factors associated with bulimia include poor impulse control, low self-esteem, depression, and anxiety disorder. In addition, comorbid behaviors such as alcohol and substance abuse, unprotected sexual activity, self-mutilation, and suicide attempts may be present. Similar to anorexia, bulimia is an eating disorder that is usually associated with some degree of depression.

Physically, the adolescent with bulimia nervosa may present with symptoms related to forced excessive vomiting: cracked and damaged lips, tooth damage, callused fingers and hands, and broken blood vessels in the face. Symptoms that may not be physically noticeable include

throat irritation, esophageal inflammation, and parotitis from vomiting, as well as rectal bleeding from overuse of laxatives. While life-threatening conditions are less common in adolescents with bulimia than in adolescents with anorexia, they may still be at risk for dehydration, electrolyte imbalances, ruptures in the gastrointestinal tract, kidney disease, and cardiac arrhythmias.

DENTAL CARE. For adolescents, twice yearly dental visits for check-ups and cleaning are required. It is common for adolescents to have dental work performed to correct tooth malformations. Obvious dental correction can create body image problems, particularly if wearing braces or a headgear is required. Education regarding the proper care of teeth with dental appliances must be received at the dentist's office and reinforced by caregivers at home.

SLEEP AND REST

Adolescents are commonly chronically sleep deprived as activities, schoolwork, and after-school jobs keep them up later at night. Often the adolescent sleeps extensively on weekends to make up for the deficiency during the week, but this is generally more detrimental as the body has difficulty adapting to irregular sleeping patterns. Sleep deprivation can impair memory and inhibit creativity, making it difficult for sleep-deprived adolescents to learn.

The nurse can encourage caregivers and adolescents to keep evening activities to a manageable level that allows for some quiet time before bed and an appropriate bedtime. Involving the adolescent in the decision-making process regarding which activities to reduce or eliminate will help the teen comply with the limits set. In addition, if the adolescent adheres to a similar bedtime and wake time on the weekends as during the week, excessive fatigue can be controlled.

SAFETY

Since adolescents are still developing formal thought operations, they may not have the cognitive abilities to make appropriate decisions regarding safety. Their decisions are likely to result in accidents and injuries and risk-taking behaviors for which adults may not be at risk. However, the accidents and injuries most common in adolescents differ from those in infancy and childhood. In addition, adolescents must be taught information related to safe sexual practices, substance use and abuse, violence, and suicide prevention.

Accidents and Injuries

The three leading causes of death in adolescents are motor vehicle accidents, homicide, and suicide, respectively. The risk for motor vehicle accidents is greater among adolescents than for any other age group, with more than 5000 adolescents between the ages of 16 and 19 dying from injuries related to crashes (Insurance Institute for Highway Safety, 2005). For male adolescents, the risk is two times higher than that of female adolescents. Risk factors for these statistics include the inability to assess hazardous situations while driving, speeding, driving under the influence of drugs or alcohol, and a low compliance with seat belt use.

In relation to homicides, approximately one-third of all homicides in the United States occur among adolescents. Individual factors related to this level of violence in adolescence include a history of abuse and the observation of violent acts at home. Certain familial characteristics have also been linked to adolescent homicide: distant, passive, or absent fathers; dominant, overprotective, and sexually inappropriate mothers; violence between family members; turmoil in the home setting; and feelings of distrust among the children in the home. Health care providers need to be aware of protective factors that have been identified in order to provide health care teaching to adolescents and empower them with strategies to reduce their risk. Education, spiritual support, improved economic conditions, conflict resolution skills, and reduced use of drugs and alcohol are areas of education focus and patient advocacy that can be addressed by health care providers. Finally, since access to guns impacts the adolescent homicide rate, implementation of gun safety classes is another appropriate area for intervention.

Suicide is the third leading cause of death in adolescents, and, as such, needs to be understood and addressed by health care providers. As a result of their developing personality and peer and family pressures, adolescents may become easily overwhelmed and anxious and look to suicide as an answer to their distress. Although female adolescents are more likely to engage in suicide attempts, males are more likely to complete them, and account for approximately 85% of all suicides, while females account for 15%. Adolescent Native Americans and Alaskan Natives have the highest rates of suicide; African Americans, Hispanics, and Asians have the lowest rates of suicide (Menon et al., 2007).

Common symptoms of suicidal ideation that can be addressed by health care providers include the following: reports of crying frequently, fatigue and insomnia; feelings of isolation; and changes in body weight. Adolescents may exhibit additional symptoms, such as behavior problems, violence, sexual promiscuity, a drop in academic performance, and school absence. Nurses who are aware of any of these symptoms should ask if the adolescent has plans to commit suicide, the means to commit suicide, and if there have been any previous attempts at suicide. Adolescents who are determined to be at low risk for suicide should be referred to a mental health professional; those determined to be at high risk for suicide should be immediately evaluated by a mental health professional.

Risk-taking Behaviors

As in childhood, it is normal for adolescents to engage in risk-taking behavior. Taking healthy risks provides an avenue for discovering and developing one's own identity. Parents need to be taught that they can facilitate healthy risk-taking through talking with their adolescent openly and honestly and helping their child to understand the consequences of healthy versus non-healthy risk-taking behaviors. Ongoing dialogue provides an opportunity to explore alternative actions and sharing a personal history of past risk-taking behaviors conveys the message that making mistakes is not a fatal act.

Health care providers and parents can assist adolescents in finding alternative behaviors to provide outlets for identity development through providing them with challenges that create risk while promoting healthy decision making (Box 4-4).

Injury Prevention

Unhealthy risk-taking often leads to injuries for adolescents, and the most common injuries are related to motor vehicles, bicycles, firearms, and water. Nurses and parents can provide valuable teaching to adolescents and empower them to take necessary precautions to avoid injury. One of the most important ways in which parents can affect adolescent safety is to set a good example and be a positive role model.

DRIVING SAFELY. Since motor vehicle accidents occur so commonly and cause such significant injury, there needs to be a strong focus on injury prevention for this activity. Recommendations for parents to ensure safe driving include establishing limits, such as the number of passengers and restriction to daytime driving, enforcing penalties for unsafe driving practices, adult supervision of adolescents while driving, ensuring mechanical safety, and mandating the use of seat belts.

BICYCLE SAFETY. Another common area of injury in adolescence, and one that is not often discussed includes activities that involve bicycles, in-line skating, and skateboarding. Head injuries related to these activities are quite common in this age group. Approximately 50% of young adolescents hospitalized for a bicycle-related injury have some degree of brain injury. Behaviors that cause the majority of the injuries include riding into a street without yielding or stopping, swerving into traffic, and riding against the flow of traffic.

Box 4-4 Healthy Risk Alternatives for Adolescents

- Physical activities
 - Team sports
 - Horseback riding
 - Camping
 - Rock climbing (with supervision)
 - White water rafting (with supervision)
- Creative activities
 - Joining a band
 - Acting in a play
 - Photography
 - Dance
 - Producing a video
- Developing relationships
 - Talking openly about sex and relationships
 - Volunteering in the community
 - Participating in a student exchange program
- Learning responsibility
 - Getting a part-time job
 - Tutoring

Consistent use of a helmet is one of the best preventive strategies. It is essential that the helmet fit properly—it should not move around when the straps are fastened—and the straps should remain fastened when in use. When worn and used correctly, helmets can reduce the risk of a head injury by 85% and the risk of brain damage by 88%. All helmets should meet the standards established by the American National Standards Institute, the American Society for Testing and Materials, and the United States Consumer Product Safety Commission.

FIREARM SAFETY. Curiosity and impulse control remain important factors in firearm-related injuries and deaths among adolescents. Parents should consider the risks associated with storing a firearm in the home. In this age group, ready access to a firearm is the most frequent cause of the experimentation. If parents choose to keep a firearm in the home for protection or for hunting, it should be safely stored in a locked cabinet and all ammunition placed in a separate, locked location. A firearm safety class should be mandatory for adolescents who engage in the sport of hunting with parents or peers.

WATER SAFETY. Adolescents, who are in the process of developing formal operational thought, have an increased risk of drowning when swimming due to an overestimation of ability and skill, a lack of awareness of water depth and currents, and the use of alcohol and drugs. Safety measures include insisting that adolescents do not swim alone and teaching them never to dive into shallow water, above-ground pools, or the shallow end of an in-ground pool. In addition, adolescents riding in a boat should be required to wear personal flotation devices that are securely fastened. Parents and health care providers should routinely incorporate safety education into discussions with adolescents.

Now Can You— Provide safety education to adolescents?

1. Identify the three leading causes of death in adolescents?
2. Discuss methods for improving driving safety?
3. Identify the best method of preventing injury related to bicycle riding?
4. Describe methods to facilitate firearm safety?

REPRODUCTIVE HEALTH SAFETY Safety with regard to reproductive health can be positively impacted through proper, sensitive, and honest education on topics related to sexual activity. While the majority of parents indicate that they believe education on issues of sexual health should be taught in the family, most also agree that they do not feel prepared to do so alone. Many schools have subsequently incorporated education on sexuality into curricula in an effort to facilitate transfer of factual information.

Developmentally, adolescence is characterized by attempts to develop a personal identity, which includes sexual and gender identity. Young people are bombarded with sexual images from music, television, advertisements, and movies on a daily basis. Providing adolescents with correct information on issues of sexuality helps to empower them to make healthy decisions regarding their own sexual behavior. Whether taught by parents, health care providers, or classroom educators, educational content should

include human development, reproductive anatomy and physiology, relationships, personal coping skills and decision-making, sexual behavior, contraceptive use, condom use, sexual health, and gender role development.

It is also important that the information provided is appropriate to the age and sexual experience of the adolescent. For those who have not engaged in sexual intercourse, an approach that focuses on abstinence as the only absolute way to avoid pregnancy and sexually transmitted infections may be appropriate. Education that focuses on the avoidance of unprotected sex by the use of a condom with every sexual encounter may be an appropriate approach for adolescents who have begun to have sexual intercourse. Life-building skills that are necessary for adolescents, and which may facilitate appropriate decision-making, include negotiation skills, values clarification, goal setting, and interpersonal communication.

SUBSTANCE ABUSE. Experimentation and risk-taking behavior as a means of self-discovery and identity development are common during adolescence. Often this experimentation involves the use of drugs and alcohol. The reasons that adolescents give for trying drugs and alcohol include: to satisfy curiosity, to achieve a feeling of well-being while under the influence, to reduce stress, and to fit in with peers. Adolescents who are at an increased risk for developing dependency are those with low self-esteem, a family history of substance abuse, depression, and those who do not feel accepted by their peers.

Alcohol and marijuana are the most common drugs used by adolescents. On average, alcohol use begins at age 12 and marijuana use at age 14. Adolescent substance use is associated with school failure, an increased risk for accidents, violence, suicide, and unplanned and unsafe sexual activity.

There are many warning signs to alert parents to adolescent substance abuse. Physical signs include fatigue, red and glazed eyes, chronic cough, and health complaints. Emotional signs include personality changes, sudden mood swings, irritability, poor judgment and decision making, depression, and lack of interest in things that were of previous interest. As the substance abuse continues, adolescents may demonstrate a negative attitude, withdraw from the family or from previous friends, and become increasingly argumentative and secretive. Academic performance often drops and school officials report problems with truancy and discipline.

Parents need to be informed about the types of drugs that adolescents may use as well as the possible adverse consequences associated with each. Early and ongoing parent-adolescent education, open communication, appropriate role modeling and the early recognition of developing problems are the best strategies for prompt identification and interventions for substance use.

VIOLENCE AND ABUSE. Negative consequences are also seen in the rising degree of violence and abuse in the adolescent population. In a nationwide survey of high school students, 33% reported being involved in a physical fight one or more times in the preceding year, while 17% reported carrying a weapon one or more days in the preceding month (Centers for Disease Control and Prevention, 2004). It is estimated that 30% of all middle school students encounter some type of

bullying, either as the bully, as a victim of the bully, or both.

Violence is a learned behavior. Adolescents learn to solve problems through violence by watching parents, teachers, and others in the community and in the media and by role modeling their behavior. In order to engage in problem-solving behavior without violence, adolescents need to be taught how to assess the conflict, see the other person's point of view, and then redefine the conflict so that they and the others involved can negotiate to a decision without violence.

Parents need to allow the adolescent to develop social relationships outside of the family in order to mature and define their identity. At the same time, they need to continue to set limits to adolescent behavior, maintain open and honest communication on problem-solving, and allow the adolescent to evaluate options to conflict resolution in passive, yet assertive ways.

Successful conflict resolution strategies enable the adolescent to remain calm in a potentially violent situation and to understand that the aggressor is attempting to resolve the conflict in ways that are understood by him. If communication and respect are not facilitating conflict resolution, the adolescent should be taught to remove himself from the potentially dangerous situation.

Ethnocultural Considerations— Exploring differences in ethnicity and race in adolescent violence

- African Americans, Native Americans, and Hispanics are more likely to be victims or the persons responsible for fatal violence than Asians or Caucasians.
- These differences are more pronounced in adolescent aggression resulting in homicide than adolescent aggression not resulting in homicide.
- African Americans, Native Americans, and Hispanics are arrested more often for acts of interpersonal violence than Asians or Caucasians.
- Hispanic adolescent males are more likely to be victims of homicide than African Americans or Caucasians.
- African Americans account for the majority of all adolescents known to have committed murder.

Source: Center for the Study and Prevention of Violence (2004). *CSPV fact sheet: Ethnicity, race, class and adolescent violence*. Boulder, CO: Author.

Adolescents are particularly vulnerable to violence and abuse in dating relationships as well. Parents should be encouraged to discuss these issues openly before dating begins in order to prevent this type of abuse from occurring. Dating provides an opportunity to develop healthy love relationships that are built on mutual respect and trust. Similar to abusive situations, relationships can become coercive and escalate to physical abuse at a later time. Indicators of a coercive relationship include:

- Telling a partner what to wear
- Telling a partner where she is allowed to go
- Telling a partner who she can be friends with or talk to
- Making a partner do something she does not want to do

- Destroying the partner's personal property
- Threatening to hurt oneself if the partner breaks up with him
- Repeatedly contacting the partner after a break-up

Indications of abuse, which may be directed toward the male or female partner, can include rude and swearing talk, forcing sexual activity against the partner's will, humiliating one's partner in front of other people, and hitting or hurting one's partner in any way. If any of these behaviors are known by parents, it is the parents' responsibility to intervene, even to the point of legal action. Through interaction and communication, parents can have a lasting effect on helping their adolescent to develop future healthy relationships with others.

TATTOOING AND BODY PIERCING. Tattooing and body piercing are examples of adolescent risk-taking behavior (Roberts & Ryan, 2002; Stephens, 2003), and are associated with other high-risk activities, including smoking, alcohol use, use of smokeless tobacco, and riding in a vehicle driven by another individual who has been drinking. Health risks associated with tattooing and body piercing may be infectious or noninfectious.

Infectious health risks include viral, bacterial, and fungal diseases, most commonly infections caused by viruses and bacteria. The most common infections associated with tattooing and body piercing include hepatitis, human immunodeficiency virus (HIV), and human papilloma virus (HPV). Bacterial infections may be caused by *Staphylococcus*, *Streptococcus*, *Pseudomonas*, *Clostridium*, and *Mycobacterium* (Drifmeyer & Batis, 2007). These organisms have the potential to cause lifelong infection with adverse effects on various body systems or the progression to other diseases, such as cancer and tuberculosis. Allergic or hypersensitivity reactions are the most common noninfectious responses to tattooing and body piercing. Although these reactions may be transient, they can lead to the development of more serious lesions that require surgical intervention.

HEALTH PROMOTION

Although the majority of adolescents have not yet become sexually active, it is important that health care providers promote activities to prevent health problems from developing as they mature. Adolescents can be taught to perform breast self-examination (BSE) early in their development and to engage in activities to promote optimal bone health. Once adolescents become sexually active, they should be encouraged to have regular gynecological examinations.

Prevention of Osteoporosis

While adolescents are not at high risk for the development of **osteoporosis** (a condition characterized by loss of bone mass throughout the skeleton), it is essential that steps be taken at this early age to decrease the risk later in life. Strategies that are appropriate for adolescents include maintaining an adequate intake of calcium and vitamin D and engaging in regular exercise. Adolescents are at an increased risk for unhealthy eating behaviors that result in a calcium intake that falls far short of the amount needed for bone strengthening. Thus, nutritional intake during

the adolescent years becomes even more important. In addition, adequate amounts of vitamin D are necessary to facilitate the absorption of calcium. Regular exercise helps the adolescent to achieve peak bone density levels. Weight-bearing exercises, including walking, dancing, sports, and hiking, are the best activities for young people to develop strong muscles and bones.

Gynecological Examinations

Another aspect of developing health practices that continues into later years is the initiation of gynecological examinations during adolescence. It is important for parents and adolescents to understand that the first visit may not necessarily include an internal pelvic examination and collection of specimens.

The first visit, which should occur between the ages of 13 and 15, should be used as an introduction to reproductive health care. The health care provider should discuss issues of sexuality with the adolescent to help prepare her for making appropriate decisions. Information and reassurance can be provided regarding normal development and education on sexually transmitted infections and sexual behavior can empower the adolescent for informed sexual decision-making.

The first pelvic examination should be performed at age 21 or 3 years after the initiation of sexual activity, whichever comes first. Other reasons for pelvic examination include unexplained pain in the lower abdomen or pelvic region; vaginal discharge that causes itching, burning, or has an odor; delayed menstruation; prolonged menstruation lasting more than 10 days; dysmenorrhea; and missed periods.

PELVIC EXAMINATION. The frequency of pelvic examinations varies based on age. Females should have pelvic examinations once they become sexually active. Women ages 20 to 40 should undergo a pelvic examination at least every 3 years or annually if high risk. “High risk” includes those with abnormal findings on previous examinations, the presence of sexually transmitted infection, sexual activity before age 18, multiple sexual partners, or abnormal

Figure 4-3 Female external genitalia.

Figure 4-4 Using the thumb and index finger to separate the labia to assess the external genital structures.

mal spotting or bleeding. After the age of 40, pelvic examinations should be performed every 1 to 3 years, based on personal risk factors and history (Institute for Clinical Systems Improvement, 2005).

The nurse assists the patient with relaxation techniques before the pelvic examination, performed in a lithotomy position, is initiated. Anxiety is common, especially in women with a history of sexual abuse or assault. Deep breathing, a helpful relaxation strategy, is easy to perform. The patient is encouraged to take slow, deep breaths, in through the nose and out through the mouth. She should be observed for signs of hyperventilation and instructed to slow down her breathing if necessary. Visual imagery is another useful relaxation technique. Many health care providers place engaging pictures on the ceiling for the recumbent patient to view. Some women relax with conversation. Others prefer to quietly concentrate on deep breathing and visualization. It is important to ask the patient whether or not she prefers to talk during the examination.

EXTERNAL INSPECTION. The skin, including the labia majora, is inspected for color, bruising, erythema, lesions, and hair distribution (Fig. 4-3). Using a gloved hand, the examiner gently spreads the labia to assess the external genital structures (Fig. 4-4). The clitoris, labia minora, urethral opening, and vaginal opening are inspected for inflammation, lesions, and lumps. Bartholin's glands, which secrete fluid for lubrication, are palpated using the index finger and thumb, and are assessed for edema, pain, and discharge. The vaginal orifice is opened slightly, and the patient is asked to squeeze the vaginal muscles. This technique allows the examiner to inspect for cystocele, rectocele, uterine prolapse, and incontinence.

VULVAR SELF-EXAMINATION. Nurses can play a vital role in the early detection and treatment of vulvar and vaginal cancer by teaching patients about monthly self-examination. Routine self-examination frequently allows for the early identification and evaluation of abnormalities.

INTERNAL INSPECTION. The examiner uses a speculum for the internal inspection (Fig. 4-5). The speculum should be warmed or maintained at room temperature and moistened with water to avoid damage to cells that are collected for cytological analysis. Depending on the situation, specimens may be collected for cervical cancer screening (Papanicolaou test), gonorrhea, chlamydia, trichomoniasis, bacterial vaginosis, candidiasis, group B *Streptococcus*, and herpes

Family Teaching Guidelines... Performing Vulvar Self-Examination

To prepare for vulvar self-examination, the woman places a flashlight and mirror within easy reach. She washes her hands, removes clothing from the waist down and sits comfortably on the floor or bed, with a pillow support behind her back. The following steps should then be performed:

1. While bending her knees, she leans backward and allows her knees to fall slightly apart to expose the genital area. The mirror and flashlight should be positioned for optimal visualization.
2. External inspection of the genital area includes visualizing the labia, the clitoris, the urethral meatus, the vaginal opening, and the anal opening.
3. Using her fingers, the woman should gently spread the labia and inspect the vaginal vault. The vaginal walls should be pink and contain small folds or ridges, called rugae.
4. The vaginal discharge should be evaluated at this time as well. Normal vaginal discharge is clear to cloudy and white, with a slightly acidic odor; it may be thick or thin, depending on the timing of the examination with regard to the menstrual cycle.
5. Findings that need to be reported to the health care provider include the presence of sores or growths on the labia or vaginal walls, an unpleasant odor to the vaginal discharge, and tissue redness. Sores, redness, abnormal growths, malodorous or excessive vaginal discharge, and itching may indicate irritation or infection.

Source: Vulval Pain Society (2005). *How to perform a vulval self-exam*. Retrieved from <http://www.vulvalpainsociety.org/html/selfexam.htm>

simplex virus. The specimens for cervical cancer screening must be obtained first to avoid cell damage during the collection of additional specimens. Common sexually transmitted infections (STIs), symptoms, and methods of diagnosis are presented in Table 4-4 (CDC, 2006c). (See Chapters 9, 11, and 19 for further discussion.)

Once the speculum is inserted, the blades are opened fully to allow complete visualization of the cervix and cervical os (Fig. 4-6). The cervix should be pink, smooth, and absent of lesions or lacerations. It should be midline with no lateral displacement. The cervical os is rounded in nulliparous women and slit-shaped in multiparous women. Secretions in the cervical area may appear thin and watery

Figure 4-5 Inserting the speculum.

or thick and stringy, depending on the day of the menstrual cycle. The secretions should be clear to opaque and have no foul odor. Around the time of ovulation, the cervical secretions are more profuse, slippery, and stretchy to facilitate sperm transport through the cervical mucus. Once the specimens have been collected, the speculum is slowly removed and the vaginal vault is inspected for color and the presence of inflammation, edema, bleeding, and discharge. (See Chapter 9 for further discussion.)

PAPANICOLAOU TEST. The Papanicolaou test (Pap smear) is the microscopic examination of cells taken from the cervical area by various techniques. It is the most reliable method used to screen the patient for preinvasive cervical cancer. The U.S. Preventive Services Task Force (USPSTF) and the American Cancer Society (ACS) recommend that Pap tests should begin approximately 3 years after a woman becomes sexually active but not later than age 21. Yearly screening is recommended to age 30 (with the conventional Pap test; every 2 years with liquid-based Pap tests). After age 30 and three negative Pap tests, screening may be performed every 2 to 3 years, in consultation with the health care provider. Women ages 65 to 70 who have had no abnormal tests in the previous 10 years may choose to stop Pap screenings (ACS, 2006a; USPSTF, 2005). Women in high risk categories should have more frequent Pap tests.

The Papanicolaou test should not be performed if the woman is menstruating or has an infection. The best time to collect the specimen is at mid-cycle to ensure the absence of menstrual blood, which may distort results. The nurse should confirm that the woman has not had intercourse or douched within the 24 hours preceding the test. Using a spatula or an endocervical sampling device, cells are scraped from the cervical os and from around the cervical opening. With one cytological preparatory technique, the sample is smeared onto a slide, sprayed immediately with a fixative solution, and allowed to dry. With another method (e.g., the ThinPrep Pap Test), the specimen is placed directly into a prepared vial of preservative. Regardless of the method used, the sample is labeled and sent to a laboratory for cytological examination.

BIMANUAL PALPATION. The examiner lubricates the first and second (gloved) fingers with water-soluble lubricant. The vaginal canal is palpated for the presence of tenderness, lesions, and nodules (Fig. 4-7). The cervix is palpated for position, consistency, contour, and mobility. It should be soft and movable without tenderness. The uterus is palpated to determine if it is in a midposition, or retroverted or anteverted (Fig. 4-8). It should be soft, movable, and nontender. The uterine fundus (upper area above the openings of the fallopian tubes) should be rounded. The examiner then palpates the adnexa to assess for masses or tenderness. The ovaries may or not be palpable. If palpable, they should be mobile, smooth, and firm. Ovarian palpation may cause some slight discomfort (Fig. 4-9). Structures on each side of the uterus are palpated. As the examiner's fingers are removed, the patient is asked to tighten her vaginal muscles to facilitate assessment of pubococcygeal muscle strength. This component of the examination provides an opportune time to teach about Kegel exercises. (See Chapter 9 for further discussion.)

Table 4-4 Summary of Common Sexually Transmitted Infections

Infection	Symptoms (May Be Asymptomatic)	Detection
Gonorrhea	Yellow-green vaginal discharge	Endocervical culture
	Dyspareunia	Urine test
	Abdominal pain	
	Dysuria	
<i>Chlamydia</i>	Mucopurulent discharge	Endocervical culture
	Postcoital bleeding	Urine test
	Dyspareunia	
	Abdominal pain	
	Dysuria	
Trichomoniasis	Frothy malodorous vaginal discharge	Saline wet mount of vaginal discharge viewed under microscope
	Dyspareunia	
	Vaginal itching/irritation	
	Dysuria	
Hepatitis	Fatigue	Serological testing
	Dark urine	
	Clay-colored stool	
	Jaundice/abdominal pain	
Human papilloma virus (HPV)	Many subtypes exist, some associated with cervical dysplasia	Pap smear report
	Visible wartlike growths in genital area associated with subtypes 6, 11	Colposcopy/biopsy
Syphilis	Primary	Serological testing
	Chancre (painless raised ulcer)	Nontreponemal (RPR, VDRL)
	Secondary	<ul style="list-style-type: none"> • Reported quantitatively (titers)
	Skin rash, lymphadenopathy	<ul style="list-style-type: none"> • Fourfold change in titers clinically significant
	Latent	<ul style="list-style-type: none"> • Effective treatment will result in falling titers
	Lacking clinical manifestations	<ul style="list-style-type: none"> • False-positive possible; verify with treponemal test
HIV	Tertiary	Treponemal (FTA-ABS)
	Cardiac, ophthalmic, auditory involvement	<ul style="list-style-type: none"> • Reported as positive or negative
	Fever	Serological testing (Pretest and posttest counseling with informed consent required)
	Malaise	
	Lymphadenopathy	Positive screen must be confirmed by more specific test (Western blot)
Herpes simplex virus (HSV)	Skin rash	
	Painful, recurrent vesicular lesions	Viral culture with DNA probe
	Fever, malaise	
	Enlarged lymph nodes

RECTOVAGINAL PALPATION. The examiner changes gloves before this component of the examination. Following application of a water-based lubricant, the examiner inserts the index finger into the vagina and the middle finger into the rectum. To facilitate insertion and assessment of muscle strength, the patient is asked to bear down during the insertion. The procedures of the bimanual pal-

pation are repeated, allowing the examiner to palpate the rectovaginal wall, the posterior side of the uterus, and the area behind the adnexa. Palpation should reveal no tenderness or the presence of fissures or masses along the rectovaginal wall. The uterus and adnexa should be non tender, soft, movable and absent of masses (Figs. 4-10, 4-11, and 4-12).

Figure 4-6 Opening the speculum.

Now Can You— Discuss the pelvic examination process?

1. Discuss patient preparation for the procedure?
2. Identify the structures that are examined during the external assessment?
3. Identify the specimens collected during the internal inspection and explain their importance?
4. List the structures that are evaluated during the bimanual palpation?

MENSTRUAL DISORDERS

Various menstrual disorders may occur during adolescence. The most common conditions are menstrual cramps, **dysmenorrhea** (painful menstruation that interferes with daily activities), and premenstrual syndrome (PMS). Painful cramping in the uterus during menstruation occurs

from myometrial contractions induced by prostaglandins during the second phase of the menstrual cycle. **Prostaglandins** are chemical mediators that cause pain as part of the inflammatory response; during menstruation, the cramps are frequently accompanied by back pain and headache. Peaking levels of prostaglandins cause the symptoms to begin a day or two before the beginning of menstrual flow and continue until about the second or third day of menstrual flow.

Dysmenorrhea is painful menstruation that affects a woman's ability to perform daily activities for 2 or more days each month. Health care teaching for females experiencing dysmenorrhea should be holistic in nature and include relaxation and breathing techniques, the use of heat to reduce uterine contractions and increase blood flow to the uterine tissues, exercise or rest, and the use of nonsteroidal anti-inflammatory drugs to inhibit the synthesis of prostaglandin. For some women, dysmenorrhea is symptomatic of other conditions, including pelvic inflammatory disease and endometriosis. Severe pain and dysmenorrhea that disrupts a woman's life should be evaluated by a health care provider.

Premenstrual syndrome (PMS) is another commonly occurring disorder associated with menstruation that affects adolescents. Approximately 85% of all females experience some degree of symptoms related to PMS. Symptoms range from irritability and mood changes to fluid retention, heart palpitations, and visual disturbances. While the most common cause of PMS is the normal fluctuation of estrogen and progesterone during the menstrual cycle, other factors may be associated with PMS symptoms as well. For example, some PMS symptoms may result from the following: an imbalance in the levels of estrogen and progesterone; **hyperprolactinemia** (an excessive secretion of prolactin, the hormone responsible for stimulation of breast development); alterations in carbohydrate metabolism and hypoglycemia; and an excessive production of aldosterone resulting in sodium and water retention.

Recommendations for reducing the severity of the symptoms associated with PMS include the incorporation of simple lifestyle changes. Adolescents should be encouraged to exercise three to five times a week, eat a well-balanced diet, and get adequate sleep and rest. Dietary changes include increasing the daily intake of whole grains, vegetables, and fruits, while decreasing the intake of salt, sugar, and caffeine.

For more problematic symptoms, treatment may include the use of diuretics to reduce fluid retention, the administration of nonsteroidal anti-inflammatory drugs to inhibit synthesis of prostaglandins and provide pain relief, oral contraceptives to inhibit ovulation, central nervous depressants to promote relaxation, antidepressants, and vitamin supplements.

YOUNG ADULTHOOD HEALTH

Formal operational thought is completed as individuals move from adolescence into young adulthood (ages 19 to 34). The developmental stage during this time period is *intimacy versus isolation*. The individual no longer views the family as the primary source of identity and developmental tasks center on making a personal commitment to

another individual as a partner or spouse. With the increased independence associated with young adulthood and the concomitant increase in age, new challenges to health promotion and disease prevention arise. During young adulthood there is a focus on safety, sexual health, reproductive health promotion that includes monthly breast self-examination and yearly clinical breast examinations, and awareness of potential gynecological disorders common to this age group.

SAFETY

As young adults attempt to engage in dating relationships, the safety risks associated with substance use, sexual practices, and domestic violence become more evident. It is during this time, when young adults are developing relationships with members of the opposite or same sex in intimate ways, that nurses can provide education and counseling and empower women to care for themselves in healthy ways.

Substance Use

Once young adults reach the age of 21, they can legally purchase and consume alcoholic beverages. This "rite of passage" places them at an increased risk for problems associated with alcohol use. The newly gained independence that comes as the young adult moves out of the parent's home, combined with the social acceptance of drinking during this time, may coincide to place the young adult in situations where excessive and binge drinking can be common and frequent. Although formal operational thought has been developed by this age, the brain continues to mature during young adulthood. Heavy or binge drinking during this time of brain development and independent decision-making may cause serious health risks as well as risks to social growth.

In addition to alcohol consumption, young adults continue to be at risk for the use of illicit drugs. Peak use, similar to that of alcohol, occurs during the early 20s, declines in the late 20s, and tends to come to an end around age 30. The most reliable theory related to illicit substance use focuses on role development during young adulthood, specifically with regard to role normalization and role compatibility. As young adults take on more adult roles associated with employment, marriage, and parenting, the use of illicit drugs may decrease as performance is altered or the person is unable to meet role expectations. Similarly, when the adult roles are seen as being incompatible with illicit drug use and non-normative behavior, substance use declines.

SEXUAL HEALTH. While increased alcohol consumption and illicit drug use are associated with greater degrees of sexual freedom and loss of sexual inhibition, young adults are faced with sexual decision making regardless of substance use. Both males and females tend to have their sexual peak, with regard to interest, desire, ability, and performance in the mid- to late-20s, with sexual interest and ability beginning to decrease during the 30s. This is particularly true of males, as testosterone production and ejaculation decline later during young adulthood.

With regard to safe sex practices during young adulthood, it is essential for nurses to educate women regarding

the anatomy and physiology of their bodies in an effort to facilitate an understanding of the heightened risk of susceptibility to sexually transmitted infections. Physiological factors that predispose women to increased susceptibility include an increased genital mucosal surface area, retention of semen in the vagina for several hours following intercourse, and the pH of the vagina. During menstruation, women are more vulnerable to infection as the pH of the vagina becomes more alkaline, thereby becoming more hospitable to viral and bacterial transmission and growth.

During young adulthood, abstinence remains the only safe method for protection against sexually transmitted infections. However, as young adults begin to experiment with sexual activity, nurses must continue to educate them on the proper use of condoms, including the use of a water-based lubricant to prevent tears in the mucosa, use of a barrier during oral sex, and protection and cleaning of sexual toys that may be used. While some nurses may find these topics difficult to approach and discuss openly, it is only through open communication that young adults are likely to incorporate safe practices into their development and experimentation.

HEALTH PROMOTION

Health practices, both positive and negative, that were initiated during adolescence will likely continue into young adulthood. During this time, dietary and exercise behaviors are more likely to either protect from or increase the risk of developing obesity, hypertension, type 2 diabetes mellitus, and cardiovascular disease. Specifically, the chronic illnesses that are more likely to emerge during young adulthood include cancer, cardiovascular disease, type 2 diabetes mellitus, and autoimmune diseases such as lupus erythematosus and multiple sclerosis.

For women, stress-related disorders become more apparent during this time. Stress can trigger behaviors such as overindulgence in comfort foods, alcohol abuse, and the use of marijuana and other drugs to reduce tension. It is encouraging that women in young adulthood are more likely to experiment with alternative therapies to relieve stress. Herbal methods, homeopathic remedies, spiritual approaches, music and dance, and art therapy may be used. Nurses need to understand and support these positive, alternative methods for stress reduction to promote a holistic approach to health and wellness.

Complementary Care: Anxiety and depression

Herbal remedies for anxiety and depression include the use of kava kava, passionflower, valerian root, gotu kola, and St. John's wort. While these herbs are believed to reduce anxiety, stress, and muscle tension, the nurse should provide education on the potential side effects of these substances, which include gastrointestinal discomforts, nausea, and dizziness.

TESTICULAR CANCER SCREENING. Although considered rare, testicular cancer is the most common cancer found in young men 20 to 34 years of age. It is the second most

common cancer in men 35 to 39 years of age, and the third most common cancer in men between the ages of 15 and 19. Risk factors for testicular cancer include a positive family history and a personal history of undescended testes; congenital gonadal dysgenesis; and Klinefelter's syndrome, a sex-linked genetic disorder. Interestingly, the majority of testicular tumors are discovered during self-examination. The National Cancer Institute (2006) does not recommend routine screening, other than clinical palpation, for testicular cancer since treatment is effective at each state of diagnosis. However, all males should be taught to palpate the testes for abnormal lumps and masses on a regular basis.

Family Teaching Guidelines... Testicular Self-examination

The best time to perform a testicular self-examination is during or immediately following a hot shower or bath since the scrotum is more relaxed at this time. The following steps should be performed, examining one testicle at a time:

1. Examine the testicles. One should be slightly larger than the other, usually the right testicle.
2. Feel for lumps and bumps along the front and sides.
3. Using both hands, place your thumbs over the top of the testicle and your index fingers and middle fingers underneath the testicle. Gently roll the testicle, using slight pressure, between your fingers (Fig. 4-13).
4. The epididymis, which carries the sperm, can be felt at the top of the back part of each testicle. It should feel soft and rope-like and be slightly tender to pressure. This is a normal finding.
5. Notify your doctor if you notice any swelling, lumps, pain, or changes in color or size of either testicle.

Source: The Nemours Foundation (2007). *How to perform a testicular self-examination*. Retrieved from http://www.kidshealth.org/teen/sexual_health/guys/tse.html

Figure 4-13 Testicular self-examination.

GYNECOLOGICAL DISORDERS. Along with specific medical problems, certain gynecological disorders are more common during young adulthood as well. Endometriosis, cervical cancer, breast cancer, and urinary tract infections are more likely to occur during this time. Also, since young adulthood marks the time when most women try to begin a family, problems associated with infertility may be discovered at this time as well.

ENDOMETRIOSIS. **Endometriosis**, a benign disorder of the reproductive tract, is characterized by the presence and growth of endometrial tissue outside of the uterus. Women ages 30 to 40 are most likely to develop endometriosis. Endometrial tissue may implant on the fallopian tubes, ovaries, and the tissues surrounding and lining the pelvis. The endometrial tissue responds to hormonal influences during the secretory and proliferative stages of the menstrual cycle, where it grows and thickens, in a similar fashion to the endometrial tissue lining the uterus. However, during the ischemic and menstrual phases of the cycle, the misplaced endometrial tissue breaks down and bleeds into the surrounding tissue, causing inflammation. The blood becomes trapped in the surrounding tissues causing the development of blood-containing cysts. Recurring inflammation in the areas outside of the uterus eventually result in scarring, fibrosis, and the development of adhesions, scar tissue that binds the organs together causing increased abdominal pain and a risk of infertility.

Abdominal pain of varying intensity is the most common symptom associated with endometriosis. However, the degree of pain associated with endometriosis is not a reliable indicator of the extent of the disorder. Other symptoms may include pain during ovulation (**mittelschmerz**), heavy bleeding during menstruation, and episodes of diarrhea and constipation, which may be mistaken for irritable bowel syndrome. Women may also experience dyspareunia or pain during defecation.

Although the etiology of endometriosis is unknown, the most commonly held theory is “retrograde menstruation.” During menstruation, endometrial tissue is refluxed through the fallopian tubes and out into the peritoneal cavity where it implants on the ovaries and surrounding organs. While 90% of all women experience retrograde menstruation, only about 5% to 10% develop endometriosis, indicating a possible difference in immune function, genetic predisposition, or environmental influence.

The diagnosis of endometriosis may be made by pelvic examination although it is often impossible to palpate small areas of localized endometrial tissue. A vaginal ultrasound may be performed to provide imaging of the displaced endometrial tissue or cyst. The physician may also perform a laparoscopy to visualize the abdominal organs and locate signs of abnormally located endometrial tissue. Laparoscopy provides information concerning the location, size, extent of disease, and the presence of scars and adhesions.

Medical management includes pain control, the use of hormonal therapy to shrink the abnormal tissue, and, at times, surgery to remove the abnormal tissue. The pain associated with tissue inflammation may be managed with nonsteroidal anti-inflammatory drugs, such as ibuprofen, to inhibit the synthesis of prostaglandin and reduce the inflammation. If conservative treatment is not helpful, supplemental hormonal therapy may be introduced, with

the goal of stabilizing the release of estrogen and progesterone to decrease tissue swelling and bleeding.

When pregnancy is not an immediate goal, oral contraceptives with a low estrogen to progestin ratio may be used to inhibit the production of hormones and suppress ovulation. Gonadotropin-releasing hormone (Gn-RH) agonists and antagonists, such as leuprolide (Lupron) or nafarelin (Synarel), suppress the secretion of pituitary gonadotropins, decrease the release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH), and diminish ovarian function. Danazol (Danocrine), another medication that suppresses the release of FSH and LH, may be used. However, the side effects of acne and facial hair growth make danazol a less commonly prescribed medication. Medroxyprogesterone (Depo-Provera) is an injectable medication used to reduce the growth of the endometrial tissue, but its undesired side effects include weight gain and depression. Newer pharmacological modalities utilize aromatase inhibitors, including anastrozole (Arimidex), exemestane (Aromasin), and letrozole (Femara), chemicals that block the conversion of androgens to estrogen and suppress the production of estrogen from the abnormal endometrial tissue, thereby decreasing tissue growth.

When pharmacological approaches are not successful, or when pregnancy is desired, the endometrial tissue growths, scar tissue, and adhesions can be removed surgically through laparoscopy. When endometriosis is severe, however, radical surgery that includes removal of the uterus, fallopian tubes, and ovaries (bilateral salpingo-oophorectomy) may be indicated.

CERVICAL CANCER. Cervical cancer develops gradually as cells change their growth pattern. Pre-cancerous cellular changes, called **dysplasia**, eventually become cancerous. There are two types of cervical cancer: squamous cell carcinoma and adenocarcinoma. Approximately 80% to 90% of all cervical cancers are squamous cell carcinomas that cover the surface of the cervix.

While not all cervical dysplasia develops into carcinoma, screening and treatment of cervical dysplasia significantly reduces the chances that carcinoma will develop. This fact lends credence to the recommendation that screening through Papanicolaou testing be performed on all young adults. Furthermore, 50% of all women diagnosed with cervical cancer are diagnosed during the ages of young adulthood.

The primary risk factor for cervical cancer is human papilloma virus (HPV) infection. There is a strong correlation between infection with the high-risk types of HPV and the development of cervical cancer. Seventy percent of cervical cancers are caused by HPV-16 or HPV-18. Other types of HPV are associated with the development of **papillomas**, which are benign growths found primarily in the genital and anal regions. While there is no treatment for HPV, a new vaccine, Quadrivalent Human Papillomavirus (Types 6, 11, 16, 18) Recombinant Vaccine (Gardasil), has recently been marketed and is targeted for adolescent and young adult women. This vaccine is recommended for girls and women ages 9 through 26 years to protect against the development of cervical cancer; abnormal lesions of the cervix, vulva, and vagina; and genital papillomas (Merck & Co., Inc., 2006). It is important for nurses to remind patients receiving the vaccine to continue to have routine cervical cancer screenings.

The vaccine is given in three doses: the second dose is administered 2 months after the first dose, and the third dose is administered 6 months after the first dose.

Medical management is determined by biopsy and staging of the cancer. Following identification of an abnormal Pap smear, **colposcopy** (use of a stereoscopic binocular microscope to examine the cervix under magnification) is usually performed. An acetic acid solution applied to the cervix enhances visualization of the epithelium and helps to identify areas for biopsy. Cervical biopsies are then obtained and pathologically examined for the presence and extent of cancer. Several outpatient biopsy methods are available. The endocervical curettage (ECC) is an effective diagnostic method in about 90% of cases. The **cone biopsy** involves removal of a cone- or cylinder-shaped sample of tissue. **Loop electrosurgical excision procedure (LEEP)** is a newer method for cervical biopsy and the removal of abnormal cells. With this procedure, an electrically charged wire loop is inserted through a speculum and a thin layer of cells is removed from the cervix. The LEEP technique provides excision and cautery with minimal tissue damage. Patients should be instructed that vaginal drainage is normal and expected following the procedure and may last up to 3 weeks. The patient should refrain from using tampons or having sexual intercourse for the following 4 weeks to minimize the risk of infection. Nonsteroidal anti-inflammatory medications may be taken to reduce the mild cramping that may occur following the procedure.

Following the biopsy, further and more extensive treatment may be required if the cancer has spread to other areas of the cervix or beyond the cervix. The three primary methods of cervical cancer treatment include surgery, radiation, and chemotherapy. It is not uncommon for a combination of two treatment methods to be used.

case study Young Adult with Cervical Dysplasia

Vanessa, a 32-year-old woman, visits the women's health clinic in a small, rural community. She requests a gynecological examination, and states this is her first exam in 3 years. Vanessa has recently married and engages in normal sexual activity with her husband. Her medical history is positive for asthma, and she takes one Singular 10 mg tablet at bedtime and Flovent two puffs twice daily. Her Pap test reveals cervical dysplasia, and the physician recommends a LEEP procedure, with follow-up Pap tests every 3 months for 1 year.

1. Review the preceding information. List as many potential patient problems or risks as you can identify; prioritize your list.
2. Write a nursing diagnosis for each problem.
3. Develop a care plan for the top three nursing diagnoses. Include: (a) goals for the patient, (b) nursing interventions, (c) rationale(s) for each nursing intervention, and (d) how you would evaluate whether or not each goal was met.

Did you include *Deficient knowledge* or patient teaching in your care plan? Be sure to include the overall goal of your teaching, teaching strategies, content to be taught, and how you will evaluate patient learning.

- ◆ See Suggested Answers to Case Studies in the text on the Electronic Study Guide or DavisPlus.

URINARY TRACT INFECTIONS. Urinary tract infections (UTIs) can be very serious in young adults and may lead to major problems if not diagnosed or treated. Infections of the urinary tract are the second most common type of infection in adults, and young adults are more susceptible due, in most instances, to increased sexual activity during this time. Women tend to be more vulnerable than men because the short urethral length and the proximity of the urethral meatus to the anus allow for the easy ascension of bacteria. However, urinary tract infections in men can be more serious than in women. The majority of UTIs are caused by the microorganism *Escherichia coli* (*E. coli*), which is normally found in the colon. Once introduced into the urethra, the bacteria colonizes, causing urethritis. As the bacteria multiply and migrate into the bladder, cystitis develops. Left untreated, the infection can spread up the ureters and into the kidneys, causing pyelonephritis.

Symptoms of urinary tract infections include burning, urinary frequency, and urgency during urination, and a strong sensation of the need to void followed by passage of only a small amount of urine. Women often report a sensation of fullness noted above the symphysis pubis; in men, infection triggers a sensation of rectal fullness. Other clinical manifestations of infection include fever, general malaise and fatigue, elevated white blood cell count, and chills. The urine may appear cloudy due to the presence of white blood cells.

Medical management centers on the use of antibiotics. Trimethoprim/sulfamethoxazole (Bactrim, Septra) are the medications most commonly prescribed. Depending on the strain of bacteria and results from culture and sensitivity testing, other agents such as amoxicillin (Amoxil, Trimox) and ampicillin (Omnipen) may be used. Nitrofurantoin (Macrochantin) or ciprofloxacin (Cipro) may be prescribed for more complicated infections.

Patient education should focus on the prevention of urinary tract infections. Everyone should drink adequate water each day and urinate when the urge is felt. Following urination and defecation, women should wipe from front to back to prevent bacteria from entering the urethra from the colon, and encouraged to take showers instead of tub baths. Bath oils, perfume, and bubble baths should be avoided if tub baths are taken. Feminine hygiene sprays and scented douches should be avoided to prevent irritation, and cotton underwear should be worn to decrease perineal moistness and warmth that can enhance the growth of bacteria.

MIDDLE ADULTHOOD HEALTH

As the young adult matures into middle age, which includes ages 40 to 64, there is a decrease in the risk for some health problems and an increased risk for others. It is during this age group that mammography screenings should begin, along with colonoscopies, cholesterol and lipid screening, and osteoporosis screening. Most women begin to experience symptoms of perimenopause during middle age and need to make decisions on managing these symptoms. Certain gynecological disorders become more common during middle age, including fibroid tumors, ovarian cysts, ovarian cancer, and endometrial cancer.

HEALTH PROMOTION SCREENING

Health promotion screenings can be of great benefit to people in middle age as there are a variety of diseases that become more prevalent during this time. Breast cancer is the leading cause of death in women between the ages of 40 and 55. Breast cancer is the second leading cause of cancer death in U.S. women (American Cancer Society, 2006a), and there is a one in eight chance that a woman will develop breast cancer at some time during her lifetime.

The promotion of breast health encompasses several areas, including cancer screening, optimal nutrition, and physical activity. It is important for nurses to educate women throughout the life span about strategies for promoting breast health. Personal awareness of the normal appearance and feel of the breasts constitutes an essential first step in promoting and maintaining breast health (Box 4-5).

Box 4-5 Knowing and Understanding Your Breasts

- As you age, your breasts experience loss of milk glands and shrinkage of collagen. This causes an increase in the fat tissue and loosening of the breast tissue. Instead of getting larger with the increase in fat tissue, however, the breast tissue begins to sag, causing the breasts to drop.
- Breast tissue weighs less than most people think: an A-cup weighs 1/4 lb, a B-cup weighs 1/2 lb, a C-cup weighs 3/4 lb, and a D-cup weighs about 1 lb.
- The skin covering the breasts stretches as you grow, causing the skin to become thinner than the skin on other parts of the body.
- It is not uncommon for women to have some degree of hair surrounding their nipples. The darker the skin, the more hair there is likely to be.
- A woman's nipples may be different sizes and may be located in slightly different locations on each breast. This may cause the nipples to point in different directions, which is considered a normal finding.
- Fluctuating hormone levels during the monthly cycle cause changes in breast tissue. Following menstruation, when hormone levels are at their lowest, the breast tissue is smooth and nontender. As estrogen levels increase mid-cycle, breasts may become more sensitive. Also, just before menstruation, when progesterone is elevated, the breasts become swollen and tender, with palpable nodules.
- The health care provider should perform clinical breast examinations one week following menstruation, when the breast tissue is nontender and smooth.
- Breast implants still pose health risks, including deflation, leakage, and wrinkling. In addition, capsular contraction can occur, causing the scar tissue surrounding the implant to tighten and the breast to become hard.
- The area between the breasts has several oil and sweat glands, creating an atmosphere conducive to the growth of bacteria.
- Sleeping on your side, with a pillow to support your breasts, provides the best position for maintaining breast shape and contour over time.
- Regular exercise can strengthen the pectoral muscles, reducing sagging over time and creating a natural lift.
- It is not uncommon to have a third nipple, stemming from breast buds that form during early fetal development. These extra nipples, however, rarely contain milk glands.
- Pregnancy darkens the color of the nipple, which is an enhancement for the breastfeeding baby. This darker color does not disappear after pregnancy.
- The left breast is usually larger than the right breast.
- Breasts do not reach their full size until the early 20s.

Optimizing Outcomes— Teaching about fibrocystic breast changes

When teaching women about breast self-examination, nurses can include information about **fibrocystic changes**, palpable thickening in the breasts often associated with pain and tenderness that fluctuates with the menstrual cycle. Fibrocystic changes are common, benign, and tend to appear during the second and third decades of life. Treatment for the condition, which may be related to an imbalance in estrogen and progesterone, centers on relief of symptoms and may include analgesics, nonsteroidal anti-inflammatory drugs (e.g., ibuprofen), diuretics, use of a supportive bra, avoidance of tobacco and alcohol and the application of heat to the breasts.

Breast self-examination (BSE), clinical breast exams, and **mammography** (x-ray filming of the breasts) can assist in early detection and early treatment. The initiation and frequency of mammography depends on the woman's age and risk factors. Magnetic resonance imaging (MRI) appears to be more sensitive in detecting tumors in women with an inherited susceptibility to breast cancer, and recent findings suggest that this diagnostic method can detect cancer in the contralateral breast that was missed by mammography in women with recently diagnosed breast cancer (Lehman et al., 2007).

While breast cancer is more common in women, colon cancer is the fourth most common cancer in both men and women. In addition, risk for heart disease related to elevated cholesterol and lipids increases in both genders during middle age. Osteoporosis, which may also occur in men, becomes more common and debilitating in women in the latter years of middle age, as they move from perimenopause into menopause.

Ethnocultural Considerations— Breast cancer screening

There are notable differences in breast cancer screening practices between women of different ethnic backgrounds. Although African American women are at a lower risk for developing breast cancer than Caucasian women, they are more likely to die from breast cancer due to late diagnosis. According to Husaini et al. (2001), African American women are more likely to have mammogram screening if they are older, married, have a higher level of education, and believe that early detection could lead to a cure. A positive family history of breast cancer and church affiliation have no influence on the incidence of detection.

Asian American and Pacific Islander women have very low rates of breast cancer screening. Factors responsible for the low screening rates include lack of health insurance, low income, and lack of a primary care provider (Kagawa-Singer & Pourat, 2000).

Breast cancer causes a significant number of deaths in Filipino women. In a study by Wu and Bancroft (2006), researchers found that women were more likely to follow recommended screenings if there is support from physicians and family members, and if they had insurance. In addition, the presence of physical symptoms, family history of breast cancer, and health literacy promote adherence to recommendations.

Breast Self-examination

Familiarization with one's breasts facilitates the early detection of problems and allows for prompt evaluation. Breast self-examination (BSE) is a way for women to learn how their breasts normally feel. Routinely performing BSE is an approach that focuses on the importance of self-awareness and helps women to notice changes in breast tissue (ACS, 2003).

Family Teaching Guidelines... Breast Self-Examination

1. Visually inspect the breasts in front of a mirror. Assess for color, contour, shape, and size. Assess for dimpling or puckering of the skin; change in nipple direction; and redness, rash, or swelling.

2. Repeat first step with the arms slightly raised above the head.

3. Inspect and palpate the nipple. Gently squeeze the nipple between the thumb and forefinger, looking for discharge. Many women, especially those who have had children, are able to express some discharge by squeezing the nipples. Discharge that is of concern is most often spontaneous (ACS, 2007).

4. Palpate the breast and axillae. Recline on the bed and place a pillow under each shoulder during palpation. Use the left hand to palpate the right breast, and the right hand to palpate the left breast. Using the finger pads of the three middle fingers, palpate the entire surface of the breast. Use overlapping dime-sized circular motions and apply three different levels of pressure: *light pressure* is best to feel the tissue closest to the skin; *medium pressure* is best to feel a little deeper; and *firm pressure* is used to feel the tissue closest to the chest and ribs.

5. Repeat step 4 while standing or sitting. Many women find step 5 easier to complete if the skin is wet, and complete this step while in the shower. Move around the breast in an up and down pattern, checking the entire breast area until only the ribs are felt; repeat the entire technique on the opposite breast (ACS, 2007).

Clinical Breast Examination

All women should have a clinical breast examination performed at recommended intervals by a skilled health care provider. The clinical breast exam should be performed every 3 years for women aged 18 to 39, every 1 to 2 years for women aged 40 to 49, and annually for women age 50 and over (Michigan Quality Improvement Consortium, 2005a, 2005b).

Mammography

A mammography examination is used to aid in the early diagnosis of breast cancer. The examination, which requires exposure to small doses of ionizing radiation, allows for identification of small breast tissue abnormalities that may require further investigation. Two enhancements have been made to traditional mammography: digital mammography and computer-aided detection (CAD). Digital mammography, also called full-field digital mammography (FFDM), converts the x-rays to electrical signals, similar to those found in digital cameras. These signals produce images that can be viewed on a computer screen or printed

on special film. The images are stored for future comparison. Preliminary results from a clinical study sponsored by the National Cancer Institute indicate that digital mammography provides improved screening for women determined to be at high risk for developing breast cancer (Pisano et al., 2005). This latest technology is enhanced with the use of computer software that highlights areas of increased density, masses, and calcifications.

Lifestyle Choices and Breast Health

Lifestyle choices, including moderate alcohol consumption, weight maintenance, and avoidance of smoking can affect breast health as well. Alcohol consumption is known to be associated with an increased risk of breast cancer. The American Cancer Society (2006b) recommends limiting alcohol intake to one drink per day. The risk of breast cancer is increased 1.5 times in women who consume two to five drinks per day.

Routine exercise, which helps to maintain a healthy weight, is associated with a decreased risk of breast cancer. Maintenance of a healthy weight is recommended for optimum breast health. Obesity is associated with an increased risk of breast cancer, particularly in postmenopausal women. Following menopause, estrogen is produced in the fat cells. In combination with dietary fat, estrogen significantly increases the likelihood of breast cancer development. Smoking is associated with an increased risk of breast cancer, lung cancer and heart disease in women (National Women's Health Resource Centers, Inc., 2006).

BREAST CANCER. While the majority of lumps found in the breast and axillary tissue are not cancerous, discovery of a mass remains the most common sign of breast cancer. Other signs of breast cancer include a clear or bloody discharge from the nipple, retraction or indentation of the nipple, dimpling of the breast tissue, and change in the size or contour of the breast. While the exact etiology of breast cancer remains unclear, there are factors that place a woman at greater risk for developing breast cancer (Box 4-6).

Box 4-6 Risk Factors Associated with Breast Cancer

- Defects in breast cancer gene 1 (*BRCA1*) or breast cancer gene 2 (*BRCA2*)
- Gender: 100 times more likely to occur in females than in males
- Age: Increasing age, with 50% appearing by age 50
- Personal history of breast cancer in at least one breast
- Family history of breast cancer
- Exposure to radiation
- Excess weight
- Exposure to estrogen: early onset of menarche, late menopause, or use of hormonal therapy
- Race: Caucasians more likely to develop breast cancer than Hispanics or African-Americans
- Smoking
- Exposure to carcinogens
- Excessive use of alcohol
- Diagnosis of precancerous breast changes
- Increased breast density revealed on mammography

Source: American Cancer Society (2006).

Now Can You— Discuss ways to enhance breast health?

1. Identify the steps for performing breast self-examination?
2. Discuss recommendations regarding clinical breast examination and mammography?
3. Discuss risk factors associated with breast cancer?
4. Identify lifestyle choices that decrease the risk of developing breast cancer?

Optimizing Outcomes— Screening for breast cancer

Best outcome: Monthly breast-self examination, clinical breast examinations, and routine mammography allow health care practitioners to detect potentially cancerous tumors at the earliest stage possible. This multipronged screening approach facilitates early diagnosis and early treatment, providing the best outcome possible (National Comprehensive Cancer Network, 2006).

When breast self-examination, clinical breast examination, mammography, and MRI detect possible cancerous tumors in the breast or axillae, a biopsy procedure is performed to determine if cancer is indeed present. One type of biopsy procedure is the fine-needle biopsy, which is the simplest method. A thin, hollow needle is used to withdraw cells for histological analysis. Core needle biopsy may be performed to withdraw multiple (e.g., up to 15) tissue samples. This procedure is used when tissues, instead of cells, are necessary for diagnosis. A stereotactic procedure may be used for a nonpalpable lump that is detected by mammography. In this procedure, mammography is used as a placement guide for the core needle biopsy. In the unusual instance when a lump cannot be evaluated via a stereotactic procedure, the physician may use mammography to guide insertion of a thin wire into the breast lump. This procedure usually precedes a surgical biopsy and is used for localization of the problem area. Surgical biopsy, which involves removal of a part or all of a breast lump for analysis, is the most accurate method of breast biopsy.

Medical management of breast cancer is complicated and may require a multi-treatment approach, including surgery and adjunctive treatment, such as radiation, chemotherapy, and hormone therapy. The simplest surgical treatment option is a lumpectomy: the lump and an area of surrounding normal tissue are removed. The lumpectomy is usually followed by radiation treatment to remove any remaining cancerous cells. A partial or segmental mastectomy involves removal of the tumor, the surrounding breast tissue, a portion of the lining of the chest wall, and some of the axillary lymph nodes. This procedure is usually followed with radiation therapy as well. A simple mastectomy involves the removal of all of the breast tissue along with the area surrounding the nipple and areola. Radiation, chemotherapy, or hormone therapy may follow this surgical procedure. In a modified radical mastectomy, the entire breast and several axillary lymph nodes are removed, leaving the chest wall intact. While this procedure makes breast reconstruction easier for the patient, complications including lymphadenopathy and paresthesia are more likely to occur.

Many women choose to undergo breast reconstruction after a mastectomy. This surgical option, performed by a

plastic surgeon, is a personal decision that requires considerable individualized counseling and education. Since the reconstruction can be performed at the same time as the mastectomy, it is important to consider the options early. Breast reconstruction methods include use of a synthetic breast implant or reconstruction using one's own tissue. Synthetic implants typically are composed of a silicone shell filled with a saline solution. A tissue expander may be needed to cover the implant. To accomplish tissue expansion, an empty implant shell is placed under the skin and muscles and gradually filled with the saline solution over several months. Once the skin is stretched sufficiently, the expander is removed and replaced with a permanent implant. Recovery usually takes several weeks.

Women who choose to undergo breast reconstruction using their own tissue may have a transverse rectus abdominis myocutaneous (TRAM) flap procedure. The breast is reconstructed using fat and muscle tissue taken from the abdomen, back, and buttocks. Recovery following the procedure usually takes 6 to 8 weeks, and there is an increased risk of infection and tissue necrosis. Deep inferior epigastric perforator (DIEP) reconstruction is a slightly less complicated surgical procedure. This method is similar to the TRAM flap procedure, but the abdominal muscles are left intact. The DIEP procedure is associated with fewer complications and less postoperative pain. Following reconstruction of the breast tissue, the surgeon can reconstruct the nipple and areola using tissue from other areas of the body. A small mound is constructed to resemble a nipple, and tattooing may be used to create an areola; the areola may also be created by using a skin graft and slightly raising the skin, then tattooing the skin graft.

Adjuvant therapies may include radiation therapy, chemotherapy, or hormone therapy. Radiation is usually begun 3 to 4 weeks after surgery, and treatments are given 5 days per week for 5 to 6 weeks. Chemotherapy that includes a combination of two or more drugs may also be prescribed. Chemotherapeutics may be administered orally or intravenously, and usually require four to eight treatments over 3 to 6 months. Hormone therapy is most commonly used to treat advanced metastatic cancer or as an adjuvant treatment to prevent recurrence of cancer. Normally, estrogen and progesterone bind to receptor sites in the breast tissue and encourage growth of cancerous cells. Prescribed hormone medications bind to the sites instead, and prevent estrogen from reaching them. Medications used in hormone treatment include tamoxifen (Nolvadex), a selective estrogen receptor modulator (SERM), and aromatase inhibitors, which block the conversion of androgens into estrogen.

Colon Cancer Screening

A colonoscopy is the best method for identifying possible colon and rectal cancer. Since more than 90% of colon and rectal cancers are diagnosed after the age of 50, recommendations suggest having a colonoscopy at this age. Other tests that can be helpful in screening for colon cancer include:

- Fecal occult blood test (small amounts of blood can be detected in the stool)
- Sigmoidoscopy (detects polyps and cancer inside the rectum)

- Lower colon double-contrast barium enema (x-ray films are taken of the colon and rectum)
- Digital rectal exam (usually included as part of a routine physical exam)

A colonoscopy is an examination that involves insertion of a colonoscope (a thin catheter with a light and lens) into the rectum to allow the physician to visualize and photograph the tissues and, when indicated, remove specimens for pathological examination. Preparation for the procedure usually includes a clear liquid diet for 1 to 3 days before the examination and administration of a laxative or enema on the evening prior to the procedure. Patients who take anticoagulants, nonsteroidal anti-inflammatory drugs, or oral antidiabetic agents are instructed when to withhold their medications in preparation for the procedure.

Colonoscopy is performed under conscious sedation. The patient is placed on the left side and given an analgesic and a sedative. Once the patient is relaxed and the colonoscope is inserted into the rectum, the patient is asked to change positions several times to enhance visualization of the colon. Abnormal growths or tissue are removed for laboratory analysis. The procedure usually takes about 30 to 60 minutes and the patient may experience mild cramping and slight bleeding afterwards.

Cholesterol and Lipid Screening

Cholesterol is essential for cell membranes, synthesis of bile acids, and synthesis of steroid hormones. Included in the cholesterol are chylomicrons, very low density lipids (VLDLs), low-density lipids (LDLs), and high-density lipids (HDLs). **Chylomicrons** are lipoproteins that are present shortly after eating, then disappear within a couple of hours following a meal. HDLs are considered to exert a positive influence on prevention of heart disease: they carry cholesterol to the liver for excretion in the bile. Conversely, LDLs carry cholesterol into the bloodstream. Comparison of results with normal values provides the nurse with information to evaluate cardiac disease risk and provide patient education on healthy eating behaviors (Box 4-7).

THE CLIMACTERIC, MENOPAUSE, PERIMENOPAUSE, AND POSTMENOPAUSE

The **climacteric** is a transitional time in a woman's life marked by declining ovarian function and decreased hormone production. The climacteric begins at the onset of ovarian decline and ends with the cessation of postmenopausal symptoms. **Menopause**, a term derived from Latin *mensis* for month and Greek *pausis*, meaning to cease, refers to the last menstrual period and can be dated with certainty only 1 year after menstruation ceases. The average age at menopause in the United States is 51.4 years; the normal age at menopause ranges from 35 to 60 years.

Perimenopause is the period of time preceding menopause, usually between 2 and 8 years before menopause. The age at onset of perimenopause ranges from 39 to 51 years (Speroff & Fritz, 2005). Although perimenopause may last as few as 2 or as many as 10 years, on average, it lasts 4 years. During this time of transition, levels of estrogen and progesterone increase and decrease at uneven intervals, causing the menstrual cycle to become longer, shorter, and eventually absent. Ovulation is sporadic.

Box 4-7 Lipid Screening Results**GUIDELINES FOR INTERPRETING LIPID SCREENING RESULTS****Total Cholesterol**

Below 200 mg/dL:	Desirable
240 mg/dL and above:	High, increased risk of cardiac disease

LDL Cholesterol

Below 100 mg/dL:	Desirable; target goal for those with cardiac disease or multiple risk factors
100–129 mg/dL:	Elevated; target goal for those with two or more risk factors
130–160 mg/dL:	Borderline high; target goal for those with zero to one risk factor
Above 160 mg/dL:	Significantly elevated

HDL Cholesterol

Below 40 mg/dL:	Adds a risk factor for cardiac disease
60 mg/dL and above:	Desirable

Triglycerides

Below 150 mg/dL:	Desirable
200 mg/dL and above:	High

Source: Veterans Health Administration, Department of Defense (2006). *VHA/DoD clinical practice guideline for the management of dyslipidemia in primary care*. Washington, DC: Author.

Symptoms of perimenopause, including irregular menses, hot flashes, vaginal dryness, dyspareunia, and mood changes are associated with the fluctuation and decline in hormone levels.

During **postmenopause**, the time after menopause, estrogen is produced solely by the adrenal glands; the ovaries are no longer involved in estrogen production.

While there is no specific treatment for perimenopause, use of oral contraceptives may help to regulate menstrual periods and alleviate hot flashes and vaginal dryness. **Hormone replacement therapy** (HRT), provided as estrogen only or a combination of estrogen and progestin, is usually a consideration at this time. Estrogen-only HRT increases the risk of endometrial cancer and breast cancer. Estrogen–progestin therapy increases the risk of cardiovascular disease, stroke, and deep vein thrombosis by decreasing protective factors. In a recent position statement, the North American Menopause Society (NAMS) suggests that estrogen therapy (for women who have had hysterectomies) or the combination of estrogen and progesterone therapy offers the greatest benefit and smallest risk to women who are within 10 years of menopause (NAMS, 2007). (See Chapter 5 for further discussion.)

Be sure to— Provide patients with accurate information on menopausal hormone therapy

In 2002, the National Heart, Lung and Blood Institute of the National Institutes of Health halted a major landmark study, called the Women's Health Initiative. The study was intended to evaluate the risks and benefits of **menopausal hormonal therapy** (MHT). The study was immediately stopped when results indicated an increased risk of breast cancer and a lack of overall benefit for the relief of menopausal symptoms with the use of estrogen and pro-

gestin, known as hormonal replacement therapy (HRT) (Writing Group for the Women's Health Initiative Investigators, 2002). The findings also indicated an increased risk of heart attack, stroke, and blood clots; a reduced risk of colorectal cancer; fewer fractures; and no improvement in cognitive function.

The study component designed to investigate the use of **estrogen-only replacement therapy** (ERT) was allowed to continue. The findings from this branch of the study revealed no difference in the risk for heart attack or colorectal cancer; an increased risk of stroke and blood clots; an uncertain effect on breast cancer risk; and a reduced risk of fractures (The Women's Health Initiative Steering Committee, 2004).

Given the findings of this 15-year study, nurses should focus perimenopausal counseling on:

- Healthy lifestyle changes: Smoking cessation, consuming a variety of foods low in saturated fat and cholesterol, limiting salt and alcohol intake, maintaining a healthy weight, and being physically active
- Prevention of osteoporosis: consuming foods rich in vitamin D and calcium, obtaining moderate exposure to sunlight, engaging in weight-bearing exercises; smoking cessation; and limiting alcohol intake
- Treatment of menopausal symptoms: alternative therapies; antidepressants; stress reduction; avoidance of spicy foods, alcohol, and caffeine; getting adequate sleep; being physically active; and the use of selective estrogen receptor modulators (SERMs) for severe symptoms only

Complementary Care: Managing the symptoms of menopause

Dietary supplements and herbal therapies have long provided women with alternative treatments to alleviate some of the symptoms associated with menopause. These biologically based therapies include soy, vitamins, probiotics, and herbs such as black cohosh. However, research evidence does not support the ideas that they are efficacious in minimizing menopausal symptoms (Nedrow et al., 2006).

Complementary therapies that are currently being studied for their benefit in diminishing menopausal symptoms include:

- Mind–body therapy
- Energy therapy: Electromagnetic forces, life-force energy
- Manipulative and body-based therapy: Chiropractic, osteopathy, massage
- Traditional Chinese medicine

While there is no current evidence to support their effectiveness in minimizing the symptoms of menopause, these complementary methods are considered to be much safer than herbal and vitamin therapies.

Nursing Insight— Framing menopause as a celebration of midlife

Once considered by many to be a sign of “old age,” menopause has come to be viewed as a natural passage in a maturing woman's life. Through education and support, nurses can help empower women to embrace menopause and midlife as

a liberating time that brings freedom from the worry of an unplanned pregnancy; an end to childrearing responsibilities; and an opportunity to focus on hobbies, career, interpersonal relationships, and self-discovery.

GYNECOLOGICAL DISORDERS

During middle age, there is an increased incidence of certain gynecological disorders due to hormonal and environmental influences. Leiomyomas are present in about 20% of women during this age period. Ovarian cysts, which may occur at any age, are most common during the childbearing years up to the time of menopause. Endometrial cancer is the most common malignancy of the reproductive system. Ovarian cancer, the second most frequently occurring reproductive cancer in females, is the most common cause of death of all of the reproductive cancers due to its rapid growth and nonspecific symptomatology. Endometrial cancer is slow-growing and when detected at a localized stage, the survival rate is much greater than with ovarian cancer (ACS, 2006a).

Leiomyomas

Leiomyomas, or uterine fibroid tumors, are benign growths that arise from the smooth muscle in the uterus. They occur most often after age 50 and are more common in African American women and in women who have never been pregnant. While the exact cause is unknown, their growth is dependent on estrogen. Leiomyomas begin as small masses of tissue that spread into and throughout the myometrium. They rarely become malignant and shrink after menopause when levels of the ovarian hormones have declined.

Leiomyomas are often asymptomatic and may not be detected until there is evidence of infertility. Symptoms, if present, may include a sensation of fullness or pressure in the lower abdomen, increased pain and cramping with menstrual periods, abdominal distention, urinary frequency, or heavy menses. Uterine tumors may be identified during a pelvic examination through palpation of the uterus. A transvaginal ultrasound may be performed to confirm the diagnosis. If cancer is suspected, a laparoscopy may be indicated.

Medical management may include the use of nonsteroidal anti-inflammatory drugs for dysmenorrhea. Oral contraceptives may be prescribed to control heavy periods and decrease tumor growth. Leuprolide (Lupron), a medication that suppresses the production of estrogen and progesterone, may be used to shrink leiomyomas although patients may complain of menopausal symptoms such as vaginal dryness, hot flashes, and mood changes.

If the fibroid tumors are growing inside the uterus, a hysteroscopic uterine **ablation** (vaporization of tissue) may be performed under local or general anesthesia. In this procedure, a hysteroscope, a small camera, and surgical instruments are inserted through the vagina and into the uterus. After the procedure, scarring and adhesions that interfere with fertility may form in the uterine cavity.

Myomectomy (removal of the fibroid tumor) is an alternative surgical treatment that may be performed for women who wish to preserve their fertility. Myomectomy can be done through an abdominal incision, or through a laparoscopic or vaginal (hysteroscopic) approach.

Ovarian Cysts

Ovarian cysts are benign fluid-filled sacs that develop on the ovaries and cause pain and, at times, bleeding. The most common type of ovarian cyst is a functional, or “simple” cyst in which fluid is contained within a thin wall inside the ovary. Functional ovarian cysts result when the ovarian follicle fails to rupture and release an oocyte. Instead, the fluid remains in the follicle and develops into a cyst. This type of cyst occurs most often during a woman’s childbearing years and disappears without treatment.

There are, however, other types of ovarian cysts. A follicular cyst develops when ovulation does not occur or when an immature follicle does not reabsorb fluid following ovulation. Follicular cysts are usually asymptomatic and shrink after two or three menstrual cycles. However, rupture of the cyst causes severe pelvic pain.

A corpus luteum cyst occurs after ovulation. Under normal circumstances, if fertilization does not occur, the corpus luteum shrinks and disappears. When the corpus luteum persists, it can become filled with fluid or blood and remain on the ovary. Symptoms associated with a corpus luteum cyst include abdominal pain, ovarian tenderness, and delayed or irregular menses. If bleeding occurs within the cyst, it is known as a hemorrhagic cyst. Rupture can cause an intraperitoneal hemorrhage. Corpus luteum cysts typically resolve spontaneously within one or two menstrual cycles.

A dermoid cyst is a germ cell tumor that usually affects women at an earlier age. This type of ovarian cyst may grow to 6 inches in diameter, and can contain fat, teeth, bone, hair, and cartilage. Dermoid cysts can develop bilaterally and may cause lower abdominal pain or complications related to torsion. Surgical removal is the usual treatment.

Endometrioid cysts result from the growth of endometrial tissue in the ovaries. They are often filled with dark blood and may cause chronic pelvic pain. Treatment involves removal to prevent rupture and the development of a hemoperitoneum.

Ovarian Cancer

Cancer of the ovary is the second most frequently occurring reproductive cancer and causes more deaths than any other genital tract cancer (ACS, 2006a). While the cause is unknown, there are identified risk factors, including nulliparity, pregnancy later in life, presence of *BRCA1* and *BRCA2* genes, a personal history of breast cancer, and a family history of breast or ovarian cancer. Associative causes include the use of fertility medications, exposure to asbestos, genital exposure to talc, a high-fat diet, and childhood mumps infection. Older women are at increased risk as compared to younger women. Approximately two-thirds of the deaths associated with ovarian cancer occur in women who are age 55 and older, while approximately 25% occur in women between the ages of 35 and 54. Pregnancy and oral contraceptive use provide some protection against ovarian cancer, and the use of postmenopausal estrogen may increase the risk (ACS, 2006a).

Symptoms are usually vague and nonspecific, and include pelvic fullness, lower abdominal pain, weight gain, irregular menstrual cycles, back pain, abdominal distention and increased abdominal girth (related to

ovarian enlargement or ascites), urinary urgency, urinary frequency, indigestion, lack of appetite, feeling full after eating only a little bit and bloating (Goff et al., 2007). Since ovarian cancer is a rapidly growing neoplasm, the diagnosis is usually not made until the cancer has metastasized, giving rise to the nickname for ovarian cancer as “the silent killer.”

The diagnosis is made via transvaginal ultrasonography, CA-125 antigen (a tumor-associated antigen) testing, or laparotomy. The preferred treatment for ovarian cancer is surgical removal, and usually requires a hysterectomy with bilateral salpingo-oophorectomy. After surgery, chemotherapy is used to treat any remaining cancer. Radiation therapy may be used as a palliative measure although it is not typically used as a treatment option for ovarian cancer.

Older Adulthood Health

As individuals move into the later stages of life, physiological changes as well as psychological changes alter their health and increase their risk of disease. During these years, health promotion and disease prevention is imperative in order to maintain quality of life and encourage empowerment in managing health and daily activities. Health care management focuses on gynecological health and mental and emotional health.

HEALTH PROMOTION

Health promotion is complex and challenging in older adults as they are experiencing changes in sexual functioning, exercise and activity, cognition, and function. Many considerations must be incorporated into patient education during older age.

Sexual Functioning

Intimacy and sexual activity during the later years remain important in fulfilling relationships that can positively affect one’s physical and emotional health. However, physical and psychological changes that occur in the body can affect intimacy as one ages. Testosterone, the hormone that regulates the sex drive, does not decrease significantly as one ages. Instead, other changes exert a more immediate impact on intimacy and sexual functioning.

For women, the most significant change is the decrease in estrogen that accompanies menopause. Low levels of estrogen are associated with decreased vaginal lubrication and a slowed response to sexual stimulation. In addition, the vaginal tissue loses elasticity, resulting in increased dryness and dyspareunia. Prolonged foreplay and use of a water-soluble lubricant or an estrogen cream that can be applied directly to the vagina can facilitate lubrication and help in maintaining elasticity.

For men, it may take longer to achieve an erection. Once achieved, the erection may not be as firm or last as long as in previous years. To help with this problem, the health care provider can make recommendations including medications, a penile vacuum pump, or vascular surgery.

For both genders, changes in physical appearance can adversely affect one’s emotional ability to develop an intimate relationship with another. The presence of gray hair,

wrinkles, and increased body fat may cause the older adult to feel less attractive and experience a reduced libido. Talking to one’s partner about these feelings and emotions can stimulate intimacy and help the couple connect on a more comfortable level with one other.

For those who are single, it is imperative that health providers address sexually transmitted infections and safe sex practices. About 20% of all adults with HIV infection are older adults, and the risk increases for women due to the increased dryness and loss of elasticity of the vaginal mucosa. Barriers should be used for sexual intercourse as well as for oral sex for all sexually active adults.

Exercise and Activity

Maintaining exercise and activity during the later years can improve an adult’s strength, balance, flexibility, and endurance, which can combine for healthier living and increased independence. Strength exercises build muscles, increase metabolism, and help with maintaining healthy body weight and blood sugar levels. Exercises that can be performed safely by older adults to help in strength building include arm raises, bicep curls, triceps extensions, and knee flexion. Balance exercises help adults to build leg muscles, which can help to prevent falls. Included in the balance exercises are side leg raises, hip flexion, and hip extension. Stretching exercises improve movement and allow one to be more physically active during the later years. Included in the stretching exercises are triceps stretches and double hip rotations. Endurance exercises include cardiovascular exercises that increase the heart rate and respiratory rate and help to build up endurance gradually. The activities can include any activity that builds cardiovascular health in this way, from walking to jogging to swimming and biking. Older adults who have not engaged in endurance exercises should begin slowly, with only about 5 minutes of activity per day.

Cognitive Functioning

While cognition includes memory and knowledge, there are other factors incorporated into cognitive ability. Cognition is a combination of acquiring knowledge, perceiving events that surround us, using language, making decisions, using judgment, and executing motor skills. As cognitive changes occur due to the aging process, older adults begin to notice changes in memory and the ability to execute normal daily functions.

Most of the decline seen in cognitive functioning due to the aging process is irreversible. However, there are some factors that can slow the decline. Stress management and coping strategies can lessen depression and increase concentration and memory. Medical management of physical illnesses can control renal disease, liver disease, endocrine disorders, and electrolyte imbalances that can contribute to diminishing cognitive functioning. Good nutritional intake, including folate, riboflavin, and thiamine can improve cognition. Finally, moderation or elimination of alcohol use can reduce cognitive impairment.

A simple cognitive assessment that can be performed on all adults includes the use of clock drawing, box copying, and narrative writing to describe a pictured scene. These activities allow the health care provider to gather

information regarding cognitive function in a relatively quick fashion. A Mini-Mental Status Examination can be performed to provide a better gauge of cognitive difficulty. The specific components in the Mini-Mental Status Examination are time orientation, place orientation, registration of three words, serial 7's as a test of attention and calculation, recall of three words, naming, repetition, comprehension, reading, writing, and drawing (Tufts New England Medical Center, 2007).

Functional Ability

Functional ability may also decrease with aging, especially if the older adult has any disability or does not engage in physical activity and exercise. When assessing functional ability, it is important to consider how a person manages her day-to-day activities, the impact of any disease on the daily activities, and the overall quality of life being experienced by the individual. To gain this information, the health care provider should perform a functional assessment.

The functional assessment needs to incorporate physical, social, psychological, demographic, financial, and legal issues. Questions asked should be designed to provide answers regarding self-concept and self-esteem, occupation, activity and exercise, sleep and rest, nutrition and elimination, interpersonal relationships and resources, coping and stress management, and environmental hazards.

Across Care Settings: Optimizing senior health

Older adults should be encouraged to become more involved in activities that can improve health, endurance, and the enjoyment of life. Whether the individual is at home, in the workplace, in the community, or residing in a senior living environment, regular activity needs to be promoted. Physical activities may include walking, exercise classes, strength training, or swimming. In addition, cognitive functioning can be improved through conversation, puzzles, board games, and card games. Many communities have organizations that provide activities to promote healthy living for seniors, and nurses can play an integral role in encouraging and providing information on available resources.

Immunizations

Recommended immunizations for the older adult focus on disease prevention related to highly communicable illnesses (CDC, 2006a). An influenza vaccination should be administered annually to prevent infection from influenza, and this is particularly important in older adults with chronic respiratory and cardiac diseases. Other older adults at high risk for infection are those who reside in assisted living or long-term care facilities. The pneumococcal vaccine, which provides protection against pneumococcal pneumonia, should be administered to all adults around the age of 65. Individuals at higher risk for infection and complications related to infection are those who reside in assisted living or long-term care facilities as well as older adults with chronic respiratory, cardiac, renal, and hepatic disease.

COMMON HEALTH PROBLEMS IN WOMEN

Health problems that frequently develop in women during older age include osteoporosis, endometrial cancer, and pelvic floor dysfunction. Medical management of each of these disorders can prolong life and, in many cases, provide for a healthier ability to engage in daily activities.

Osteoporosis

As individuals age, there is a progressive decrease in bone density. **Osteoporosis** is a generalized, metabolic disease characterized by decreased bone mass and an increased incidence of bone fractures. Although osteoporosis occurs primarily in older women, it can also occur in older men, in persons with decreased levels of calcium and phosphorus, and in conjunction with increased corticosteroid release or administration. The most common problem associated with osteoporosis is the increased risk of bone fracture, primarily in the spine, hip, or wrist. While normal changes in bone density occur with aging, there are a number of risk factors that are associated with the development of osteoporosis (Box 4-8).

SCREENING. Screening for osteoporosis through measurement of bone density should begin for all women at age 65, and initiated between ages 60 and 64 for women at increased risk for developing osteoporosis.

A variety of tests are available for osteoporosis screening. Dual-energy x-ray absorptiometry (DXA), measured at the femoral head of the hip, spine, and wrist, is the best indicator of an increased risk for hip fracture, although measurements at different areas can be used to determine the presence and degree of osteoporosis. Peripheral sites can also be used for screening purposes, through quantitative ultrasonography, radiographic absorptiometry, single-energy x-ray absorptiometry, peripheral dual-energy x-ray absorptiometry, and peripheral quantitative computed tomography (Nelson, Helfand, Woolf, & Allan, 2002).

Medical management of osteoporosis is usually pharmacological, and focuses on the goals of preventing increased bone density loss and, if possible, increasing bone density over time. Bisphosphonates, the most common group of medications used, inhibit osteoclast activity,

Box 4-8 Risk Factors for Developing Osteoporosis

Risk factors for developing osteoporosis include:

- Age, due to decreased estrogen following menopause
- Slender build and small frame
- Low body weight (150 lb [<70 kg])
- Shortened exposure to estrogen, through late menarche or early menopause
- Family history of osteoporosis
- Smoking
- Decreased physical activity or sedentary lifestyle
- Excessive caffeine or alcohol use
- Low calcium and vitamin D intake
- Southeast Asian and Caucasian ethnicity
- Use of corticosteroids, commonly used to treat chronic respiratory disorders and arthritis

preserve bone mass, and increase bone density. The most common bisphosphonates are alendronate (Fosamax), ibandronate (Boniva), and risedronate (Actonel), which can be taken on a weekly or monthly basis. Raloxifene, a selective estrogen receptor modulator, can also be used for women with osteoporosis since this medication reduces loss of bone density without increasing the risk of breast or endometrial cancer.

Prevention is the best strategy for reducing the risk of fractures associated with osteoporosis. Health-promoting activities that facilitate prevention include adequate amounts of calcium and vitamin D, moderate exposure to sunlight, strength training exercises, endurance exercises, adding soy, which contains plant estrogens, to the diet, cessation of smoking and the avoidance of excess caffeine and alcohol.

Pelvic Floor Dysfunction

The pelvic muscles atrophy after menopause, becoming weak and unable to adequately support the pelvic structures and organs. As the pelvic organs shift position, they begin to press against the vagina, resulting in prolapse, usually of the vagina or bladder. The most common cause of pelvic muscle weakness results from damage to the muscles during vaginal birth, particularly if the baby was large or if the labor was difficult. Other factors related to weakening of the pelvic floor include obesity, chronic cough, chronic constipation, and strenuous exercise. A prolapse can result in pain during intercourse and urinary incontinence. In severe cases, the vagina may prolapse and protrude through the vaginal orifice.

Different types of prolapse can occur, depending upon the muscles and organs that are affected. A **cystocele** results when the bladder herniates into the vagina. Symptoms include difficulty in voiding, incontinence, and dyspareunia. A **rectocele** occurs when the muscles behind the vagina are damaged, allowing the rectum to press into the vagina. When the muscle damage occurs in a higher location in the colon, it is referred to as an **enterocele**. Symptoms associated with both of these types of prolapse include constipation, difficulty in completing a bowel movement, and dyspareunia. Uterine and vaginal vault prolapses occur when the uterus and cervix press downward, resulting in a sensation of pressure in the abdomen and vagina, dyspareunia, and back pain.

Exercise can strengthen the muscles; however, muscle damage cannot be reversed. Surgery is the primary treatment for pelvic prolapse; the timing of the surgery depends upon the woman's symptoms and their effect on her daily activities.

Some symptoms can be medically managed until surgery is appropriate. Many treatment options are available for urinary incontinence, especially if it is not accompanied by a cystocele. Exercises to strengthen the pelvic muscles, including Kegel exercises, can be beneficial in decreasing the incidence of urinary incontinence (see Chapter 10 for more information). Vaginal cones, which may also be vaginal weights, can be used to strengthen the vaginal muscles as well. These tampon-shaped cones are inserted into the vagina, beginning with the lightest weight. Once inserted, the patient should contract the pelvic muscles in an effort to keep the cone in place for minutes. As the muscles strengthen, the patient then

transitions, one at a time, to the next heaviest cone. It is helpful to use the cone while doing Kegel exercises as well. As the pelvic muscles strengthen, patients can use the cones while engaging in exercise.

Electrical stimulation during Kegel exercises stimulates and contracts the pelvic muscles in a manner similar to the Kegels. This approach, conducted in the health care practitioner's office, may be helpful for women who have difficulty contracting the pelvic muscles voluntarily. With biofeedback, the patient is taught to voluntarily control the pelvic muscles and bladder. With an electrode attached to the skin, biofeedback machines measure the electrical signals elicited when the pelvic muscles and urinary sphincter are contracted. Through the visual cues from the graph shown on the monitor, patients can learn to control these muscles voluntarily.

Some women choose to use a **pessary**, which is a device inserted into the vagina to support the prolapsed bladder or uterus. This device must be fitted by a health care practitioner, and needs to be removed and cleaned regularly with soap and water to reduce the risk of infection.

Pharmacological management of incontinence is aimed at relaxing the involuntary contractions that occur in the bladder. For overactive bladder, common medications include tolterodine (Detrol), oxybutynin (Ditropan), and imipramine (Tofranil). Common side effects associated with these medications include dry mouth, nausea, dizziness, drowsiness, and constipation. For **urinary stress incontinence** (USI), in which there is an involuntary loss of urine during sneezing, coughing, or laughing, the goal of treatment is to increase muscle tone in the urinary sphincter. Postmenopausal women may choose to use estrogen replacement therapy following careful consideration of the risks and benefits. For weak or underactive bladder problems, bethanechol (Urecholine) is the usual medication of choice.

Surgical interventions include laparoscopic or abdominal procedures to support the bladder and urethra in the correct anatomical position or methods to tighten the sphincter muscles. In one type of procedure, the surgeon sutures the vaginal wall to the tissue near the pubic bone. Another involves the creation of a sling using synthetic material or tissue taken from the abdomen or from beneath the thigh. The sling is then positioned beneath the urethra to provide support and prevent urine leakage. A newer procedure uses a mesh-like tape, called tension free transvaginal tape (TVT), which is surgically inserted through the vagina and positioned to support the neck of the urethra and the bladder. This procedure is performed under local anesthesia and intravenous sedation. A final procedure involves injections of collagen or silicone into the lining of the urethra. The injected substance increases the bulk of the surrounding tissues, allowing the urethra to close tightly and prevent leakage of urine. This technique usually requires two to three injections before symptom improvement is noticed.

Following either type of surgical repair, the patient should not engage in exercise for 2 weeks and avoid lifting objects weighing more than 10 pounds for 3 months after the surgery. At that time, exercises to protect and strengthen the pelvic muscles are initiated.

Endometrial Cancer

Endometrial cancer occurs most often in women between the ages of 60 and 70, and is the most common malignancy of the reproductive system. Endometrial cancer is slow growing and most women are symptomatic in the early stages, factors that lead to early diagnosis and, frequently, successful treatment. For postmenopausal women, the cardinal symptom is vaginal bleeding; perimenopausal women may have heavy or prolonged menstruation or spotting or bleeding between menses. Other symptoms for all women with endometrial cancer include pelvic pain, dyspareunia, and/or weight loss.

An increased estrogen level, which stimulates growth of the endometrium during the menstrual cycle, is the most common cause of endometrial cancer. However, several additional risk factors have been identified: early age of menarche (before the age of 12), combined with late menopause; nulliparity; irregular ovulation, which may result from obesity or polycystic ovarian syndrome; a high-fat diet, which increases the levels of circulating estrogen; diabetes (a condition closely related to obesity and a high-fat dietary intake); estrogen-only replacement therapy; ovarian tumors that produce estrogen; age greater than 40 years; a personal history of breast cancer or ovarian cancer; breast cancer treatment with tamoxifen; Caucasian race; and hereditary nonpolyposis colorectal cancer (HNPCC), a specific type caused by a gene that inhibits DNA repair.

The diagnosis is made by histologic examination. Most often, tissue is obtained by endometrial biopsy, an outpatient procedure performed using local anesthesia. A suction-type curette is used to remove the tissue for laboratory analysis. Dilatation and curettage (D and C), a surgical procedure performed under general anesthesia, may also be used to obtain endometrial tissue for sampling. If endometrial cancer is present, staging, which may include chest radiography, abdominal CT scan, and serum testing for the presence of cancer antigen 125 (CA 125, released by some endometrial and ovarian cancers), is done to determine the degree of metastasis.

Hysterectomy (surgical removal of the uterus) is the most common treatment for endometrial cancer. In most cases, a bilateral salpingo-oophorectomy is also performed, along with removal of local lymph nodes. If metastasis has occurred, adjunctive treatment may be needed. Radiation therapy may be recommended if the cancer has metastasized or if there is a high risk for recurrence. Hormone therapy involving synthetic progestin may be used for those premenopausal patients or for those who wish to preserve fertility. Chemotherapy may also be used to reduce the tumor size or prevent recurrence.

PROSTATE CANCER SCREENING

Prostate cancer is the most common cancer diagnosed in men. Risk factors include a positive family history, environmental exposure to carcinogens, hormonal influences, especially elevated levels of androgens, and advancing age. Currently, prostate cancer is the leading cause of cancer in men, regardless of race. Benign hypertrophy of the prostate (BPH) is associated with prostate cancer. However, there is no evidence that a causative link exists. While BPH does not usually cause symptoms in men

before the age of 40, more than 50% of men in their 60s and 90% of men in their 70s and 80s have some symptoms of BPH, including difficulty voiding, dribbling, and urinary retention.

Prostate screening should be initiated at age 50. Two screening tests are used to determine the need for prostate biopsy: the digital rectal examination (DRE) and the serum prostate specific antigen (PSA). To perform a DRE, the examiner inserts a gloved and lubricated finger into the rectum and carefully palpates the prostate gland. The examination is considered normal when palpation reveals a prostate that is smooth, absent of nodules, and of normal size and shape.

When the DRE is determined to be normal, there may be other findings (i.e., changes in the texture of the prostate over time or the presence of cysts that cannot be differentiated from a tumor) that signal a need for further screening. If the DRE reveals the presence of enlargement, nodules or an abnormal glandular shape, a blood test measuring the serum tumor marker prostate-specific antigen (PSA) is obtained. The total PSA and free PSA ratio are used to determine the risk of prostate cancer in men whose total PSA is greater than 4 ng/mL. A total PSA between 4 and 10 ng/mL indicates a 25% risk of prostate cancer; a total PSA greater than 10 ng/mL indicates a 67% risk of prostate cancer. Men whose total PSA is greater than 4 ng/mL benefit from the inclusion of a free PSA test, which is the ratio of free-circulating PSA and total PSA. Men who have a free PSA of 20% or less should have a prostate biopsy performed to determine if cancer is present.

A prostate biopsy is typically performed with the assistance of transrectal ultrasonography. During the procedure, an ultrasound probe is inserted into the rectum and ultrasonographic pictures are transmitted for viewing. This procedure allows the physician to determine the size and shape of the prostate and location of abnormal growths. A fine needle is then inserted into the gland and several samples of prostate tissue are removed for pathological examination.

Preparation for Prostate Biopsy

Patients are provided with the necessary information for biopsy preparation at least 2 weeks before the procedure. Although men who have a history of cardiac valvular disease must receive antibiotic prophylaxis before the procedure, many physicians prescribe prophylactic antibiotic therapy for all patients prior to the procedure to decrease the incidence of postprocedure infection. Patients who are taking coagulation-modifier agents or anti-inflammatory agents are instructed to discontinue the use of these medications 7 to 10 days before the procedure, and blood tests, including prothrombin time (PT) and international normalized ratio (INR), are performed before the procedure on the day of the biopsy to determine if bleeding times are normal. The patient is also instructed to administer an enema for bowel cleansing the day before the scheduled procedure.

After the procedure, the patient is instructed to refrain from taking coagulation-modifier agents and anti-inflammatory agents for 3 days, and to drink plenty of water. A sitz bath or warm soak is recommended for rectal tenderness. Antibiotics are prescribed for all postprocedure patients to prevent infection.

MENTAL AND EMOTIONAL HEALTH

Some older adults may experience declines in health and cognitive ability, which can lead to behavioral and emotional problems and physical complaints. Signs of altered mental and emotional health may begin with subtle changes in personality or with dramatic alterations that require immediate intervention from a health care professional. Symptoms that require immediate intervention include hallucinations, paranoia, incoherent thinking or language, extreme lack of motivation or flat affect, and expression of suicidal thoughts or actions. Less serious symptoms that also require intervention include changes in sleeping or eating patterns, loss of interest in activities, neglect of grooming and personal hygiene, changes in sexual habits, and refusal to take prescribed medications.

Treatment for alterations in mental and emotional health requires a collaborative approach. Psychologists and neurologists may be involved in initial testing and diagnosis, while psychiatrists and nurses become an integral part of the treatment and management team. Pharmacists are an important part of the team as they have specialized knowledge in drugs and drug interactions. Psychologists provide psychotherapy treatment and counseling for the patient and the family. Social workers are essential in coordinating care with regard to medical care, benefits, and housing. Occupational therapists are experts that evaluate and restructure a person's physical environment as well as provide mental activities to enhance independent functioning. Community health nurses visit the home to assess the patient and family and to gauge understanding and acceptance of the treatment plan.

Collaboration in Caring— *Culturally sensitive community approaches to enhanced health care for older citizens*

Organizations, groups, and health care facilities recognize the importance of culturally sensitive approaches to meet the health needs of older citizens. Information gained from these collaborative endeavors benefits diverse communities by generating new knowledge and understanding and by providing insights for further investigation. Examples of successful projects include the following:

- The National Asian Pacific Center on Aging (NAPCA) organized community forums to share assessment results with participants. Three translators were available throughout the forums. Working groups were then developed to implement interventions to meet the identified needs.
- An advisory committee was used to evaluate the methodology and language used for a breast cancer study in Vietnamese women conducted by the University of California at San Francisco. Vietnamese women were hired to conduct the interventions in the study to improve accuracy of the results.
- The American Society on Aging conducted a study to determine the drinking habits of elders in the Chinese community. The written survey was translated into Chinese, and included alcoholic beverages specific to that culture, including plum wine. The researchers were able to acquire more accurate results by using culturally appropriate content (American Society on Aging, 2006).

Advancing age raises issues related to death and dying for most individuals. As they age, individuals may lose a spouse, family member, or close friend, which can significantly alter their living situation and their emotional health. As with persons of any age, the patient needs to be encouraged to grieve. However, it is essential for the nurse to be sensitive to the specific issues that frequently arise following the loss of the loved one: fear about living arrangements; preoccupation with one's own death; agitation and an inability to perform daily activities; and an overwhelming sadness or withdrawal. Counseling, support groups, and antidepressant medications are often beneficial for individuals who are experiencing difficulty with coping.

Another issue related to emotional and mental health concerns the older person's ability to remain connected to other people. Declines in health, physical mobility, and cognitive function may contribute to problems of isolation for the older adult. Family members should be encouraged to maintain frequent contact and engage the elderly in a variety of social activities to keep their loved ones involved in life and socially connected. Many community health agencies or elder day care facilities offer programs with supervised stimulation for adults experiencing difficulty in these areas. Respite care, which allows family members an opportunity for time away from the care-giving situation, may also be beneficial.

summary points

- ◆ Health promotion screening can provide early detection and treatment of health disorders, including reproductive cancers, hyperlipidemia, osteoporosis, and gynecological disorders
- ◆ Nurses play a key role in collaborative care for all patients, at each stage of the lifespan, from infancy to older age
- ◆ A holistic approach to health promotion includes focusing on nutrition, dental care, safety, injury prevention, screening for early diagnosis and treatment, and other strategies to facilitate healthy development
- ◆ Cultural and ethnic differences must be taken into consideration when providing anticipatory guidance and health promotion education to patients

review questions

Multiple Choice

1. The outpatient clinic nurse correctly makes a recommendation that Henry, a 65-year-old patient, schedule a health maintenance examination every:
 - A. Year
 - B. 2 years
 - C. 3 years
 - D. 5 years
2. The pediatric clinic nurse correctly identifies the most appropriate milk to introduce to the child at 1 year of age as:
 - A. Whole milk
 - B. 1% milk
 - C. 2% milk
 - D. Skim milk

3. The clinic nurse teaches new parents that the most normal time for children to ask about “where babies come from” is approximately:
 - A. 2 to 3 years of age
 - B. 3 to 5 years of age
 - C. 5 to 7 years of age
 - D. 7 to 9 years of age
4. The clinic nurse assesses Tom’s risk for obesity by reviewing his parent’s health records. Both of his parents have a BMI (body mass index) of 32. This finding gives Tom a risk of obesity of:
 - A. 25%
 - B. 50%
 - C. 75%
 - D. 90%

Select All that Apply

5. The clinic nurse teaches the new mother about feeding readiness that she may see in her infant:
 - A. Reaching 4 to 6 months of age
 - B. A doubling of the infant’s birth weight
 - C. An ability to hold up the head
 - D. Hunger after five or six breast feeds per day or 30 ounces of formula
6. Julie, a mother of a 9-month old infant, asks about appropriate finger foods for her baby. The clinic nurse could suggest:
 - A. Small pieces of ripe banana
 - B. Teething crackers
 - C. Cooked spiral pasta
 - D. Bite-size orange sections
7. The clinic nurse recognizes that adolescents have an increased risk of injury and disease due to:
 - A. The importance placed on peer relationships
 - B. An increased level of sex hormones
 - C. A developmental need to learn to trust
 - D. The natural development of primary sexual characteristics

Fill-in-the-Blank

8. The clinic nurse is aware that water safety is an important health promotion topic to discuss with adolescents and their parents. Teens have an increased risk of drowning due to an overestimation of their _____ and _____ in the water.
9. The clinic nurse is aware that the greatest effect on _____ is the media. Teens watch approximately 3 to 4 hours of television a day which increases the likelihood for decreased exercise and adds to their risk for _____.
10. As a component of health promotion, the clinic nurse screens all overweight teens in the clinic for _____ because of their increased risk for this condition.

The Process of Human Reproduction

Reproductive Anatomy and Physiology

chapter 5

Since you are like no other being ever created since the beginning of time, you are incomparable.

— Brenda Ueland

LEARNING TARGETS *At the completion of this chapter the student will be able to:*

- ◆ Describe gender differentiation and differences in male and female embryos including timing of anatomical sexual differences.
- ◆ Identify anatomy of the female and male reproductive systems.
- ◆ Explain physiological functions of the reproductive organs.
- ◆ Analyze the actions and interactions of hormones from the hypothalamus, pituitary, gonads, and other hormones that affect the reproductive system.
- ◆ Describe the process of sexual maturation.
- ◆ Discuss various physiological events that accompany the menstrual cycle.
- ◆ Develop an understanding of physiological changes that occur during the menopause years.
- ◆ Identify several age-related issues for men.

moving toward evidence-based practice Menstrual Cycle Variability

Fehring, R.J., Schneider, M., & Raviele, K. (2006). Variability in the phases of the menstrual cycle. *JOGNN*, 35(3), 376–384.

The purpose of this study was to determine the variability in the phases of the menstrual cycle among 165 healthy, regularly menstruating women. The sample consisted of 21- to 44-year-old women from four major U.S. cities. All participants reported having regular menstrual cycles that occurred every 21–42 days. None of the women had used depot medroxyprogesterone acetate (Depo-Provera) for the previous 12 months or oral or subdermal contraceptives for 3 months before the study. None of the women had known fertility problems. To be included in the study, breastfeeding mothers must have experienced at least three menstrual cycles after infant weaning.

The participants were taught how to monitor fertility by the use of the Clearblue Easy Fertility Monitor, a handheld electronic device designed to read wick-type urine test strips. The monitor notes “low,” “high,” or “peak” fertility status based on urine hormone levels. According to the manufacturer, the Clearblue Easy Fertility Monitor is accurate in detecting a hormone surge

98.8% of the time. The participants were also taught how to record monitor readings and the days of menstruation on a fertility chart. The fertility charts were reviewed with each participant at 1, 2, 6, and 12 months.

This prospective descriptive study utilized a data set with biological markers to estimate menstrual cycle parameters:

- Length of the follicular, fertile, luteal, and menstrual phases
- The estimated day of ovulation based on the “peak fertility” monitor reading (determined by the urinary luteinizing hormone surge)
- The cycle length, determined by counting the number of days beginning with the 1st day of menses to the beginning of the next menses
- The fertile phase, defined as a 6-day interval beginning with the 5 days preceding and including the second “peak fertility” day (the estimated day of ovulation)

(continued)

moving toward evidence-based practice (continued)

- The follicular phase, defined as the interval from the first day of menses up to and including the estimated day of ovulation
- The luteal phase, defined as the interval from the first day after the estimated day of ovulation up to and including the day before the next menstrual cycle
- The menses phase, defined as the interval beginning with the first day of bleeding through the last day of bleeding

Data analysis revealed the following:

- Mean age = 29.0 years; average number of children = 1.3
- Average number of menstrual cycles per 12 months = 5.2 (range 3–13)
- Mean frequency of menstrual cycles = 28.9 days; (range 22–36 days)
- Mean frequency of menstrual cycles in women over 35 years of age = 27.2 days
- On average, the fertile phase began on cycle day 13 and lasted for 6 days

- On average, the menstrual phase lasted for 5.8 days (range 3–8 days)
- On average, the follicular phase lasted 16.5 days (range 10–22 days)
- On average, the luteal phase lasted 12.4 days (range 9–16 days)

The study findings confirmed and expanded known information about the norms of menstrual cycle variability. There is considerable normal variability in the phases of the menstrual cycle among regularly menstruating women; the greatest amount of variability occurs in the follicular phase.

1. What might be considered as limitations to this study?
 2. How is this information useful to clinical nursing practice?
- See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

This chapter provides an overview of the anatomy and physiology of the male and female reproductive systems. Growth and development over the lifespan is explored with a primary focus on females, and special issues related to male development. The menstrual cycle and events that occur in the absence of fertilization as well as those that take place soon after conception are explored. A discussion of key hormones that impact the menstrual cycle enhances understanding of the symphony of cyclic events during the reproductive years.

Sexual Differentiation in the Embryo

In humans, the course of gender maturation is quite lengthy, extending from embryonic development to full maturation in later adolescence. Although the gender of an individual is determined at the moment of conception, it takes about 8 weeks of development before the reproductive system becomes differentiated as male or female. Before 8 weeks' gestation, the embryo displays no distinguishing sexual characteristics. At 5 weeks after conception, the first reproductive tissue arises from the **mesoderm**, the embryo's middle layer. The first structure formed is a **gonad** (sex gland), which is composed of an internal portion called a medulla and an external portion known as the cortex. During the next few weeks, the gonad undergoes various developmental changes. Primitive reproductive ducts form during this undifferentiated period, and include a pair of mesonephric ducts and a pair of paramesonephric ducts. The mesonephric ducts are dominant in males and the paramesonephric ducts are dominant in females (Blackburn, 2003). Depending on the gender of the embryo, one ductal pair becomes dominant in genital development while the

other genital pair regresses. Differing male/female developmental changes in the embryonic mesonephric/paramesonephric duct structure are the first gender changes that occur.

Male Gender

In a male embryo, the cortex of the gonad regresses and the medulla develops into a testis at around the 7th to 8th week of gestation. The mesonephric ducts evolve into the efferent ductule, vas deferens, epididymis, seminal vesicle, and ejaculatory duct. Collectively, these structures become the male genital tract. This process is stimulated by the production of testosterone in the testes. The testes also secrete Müllerian regression factor, which suppresses the paramesonephric ducts. The testes do not produce **spermatozoa** (sperm) until puberty. Beginning in the 12th developmental week, androgens begin to stimulate the growth of the external genitalia (Blackburn, 2003).

Female Gender

In a female embryo, the medulla of the first primitive gonad regresses while the cortex develops into an ovary at approximately 10 weeks. During fetal life, underdeveloped egg cells, **oogonia**, develop to become **oocytes**, (primitive eggs). At the time of birth, there are 2 to 4 million oocytes present in the ovary. The process of oocyte development that results in maturation of human ova is called **oogenesis**. External female genitalia develop in the absence of androgens. At approximately 12 weeks, the clitoris is formed and the labia majora and minora develop from the surrounding connective tissue. By 16 weeks, the paramesonephric ducts have evolved into the fallopian tubes, uterus, and vagina.

Female Reproductive System

EXTERNAL STRUCTURES (PUDENDUM MULIEBRE)

The external genital structures include the mons pubis, labia majora, labia minora, clitoris, vestibule of the vagina, urethral (urinary) meatus, Skene's glands, Bartholin's glands, vaginal introitus (opening), hymen, and the perineum (Fig. 5-1).

The **vulva** (pudendum femininum) is the portion of the female external genitalia that lies posterior to the mons pubis. It consists of the labia majora, labia minora, clitoris, vestibule of the vagina, vaginal opening, and Bartholin's glands (Venes, 2009).

Mons Pubis

The mons pubis, or mons veneris, is a layer of subcutaneous tissue anterior to the genitalia in front of the symphysis pubis. It is located in the lowest portion of the abdomen and typically is covered with pubic hair that grows in a transverse pattern. The texture and amount of pubic hair vary ethnically. In Asian women, the hair is fine and sparse. In women of African descent, the hair is thick and curly. The mons pubis is essentially a fatty pad that cushions and protects the pelvic bones, especially during intercourse.

Labia

The **labia majora** are the two folds of tissue that lie lateral to the genitalia and serve to protect the delicate tissues between them. The external labia are covered with pubic hair while the medial surfaces, which are moist and pink, are without pubic hair. During pregnancy, the labia majora are highly vascular due to hormonal influences. The labia majora share an extensive lymphatic network with other vulvar structures, leading to an enhanced capacity to spread diseases such as malignant carcinomas. The labia majora become less prominent after each pregnancy.

The **labia minora** are two folds of tissue that lie within the labia majora and converge near the anus to form the **fourchette** (a tense fold of mucous membrane at the pos-

terior opening of the vagina). Similar to but smaller than the labia majora, these structures are moist and absent of hair follicles and resemble mucous membrane. The labia minora contain a number of sebaceous glands that provide lubrication and protective bacteriocidal secretions. During puberty the labia minora enlarge. After menopause they become smaller due to declining hormonal levels. The mons, labia majora, and labia minora all function to protect the clitoris and vestibule.

Clitoris

The clitoris is located at the upper junction of the labia minora. The **prepuce**, or clitoral hood, is a small fold of skin that partially covers the glans (head) of the clitoris. Composed of erectile tissue, the clitoris is primarily the organ of sexual pleasure and orgasm in women. The clitoris contains a rich blood and nerve supply, and is extremely sensitive. Sensory receptors located in the clitoris send information to the sexual response area in the brain. This message prompts the clitoris to secrete a cheese-like fatty substance with a distinctive odor called **smegma**. It is believed that smegma is a pheromone (chemical signal sent between individuals). Anatomically, the clitoral shape is similar to that of the urinary meatus, and the structural similarity of the two organs sometimes results in misguided and painful catheterization attempts. Some cultures remove the clitoris and other external genitalia in a ritualistic process called **female circumcision**.

Vestibule

The vestibule is essentially an oval-shaped space enclosed by the labia minora. It contains openings to the urethra and vagina, the Skene's glands, and the Bartholin's glands. This area of a woman's anatomy is extremely sensitive to chemical irritants. Nurses should be prepared to educate women about the potential discomforts associated with the use of dyes and perfumes found in soaps, detergents, and feminine hygiene products, and encourage their discontinuation if symptoms develop.

Urethral (Urinary) Meatus

The urethral or urinary **meatus** (opening) is located in the midline of the vestibule, approximately 0.4 to 1 inch (1 to 2.5 cm) below the clitoris. The small opening is often shaped like an inverted "V." The vaginal orifice or introitus lies in the lower portion of the vestibule posterior to the urethral meatus. It is essentially a boundary between the internal and external genitals. The **hymen**, a connective tissue membrane, encircles the vaginal introitus.

Skene's Glands and Bartholin's Glands

The Skene's glands (paraurethral glands), located on each side of the urethra, produce mucus that helps to lubricate the vagina. The Skene's glands are not readily visible. To facilitate examination, the margins of the urethra are drawn apart and the mucous membrane gently everted to reveal the small glandular opening on each side of the floor of the urethra (Venes, 2009).

The Bartholin's glands, also known as the greater vestibular or vulvovaginal glands, are located deep within the posterior portion of the vestibule near the posterior vaginal introitus. These glands secrete a clear mucus that moistens and lubricates the vagina during sexual arousal.

Figure 5-1 Female external genitalia.

Hymen

Surrounding the opening of the vagina is a small portion of tissue called the hymen. The hymen typically forms a border around the entrance of the vagina in premenstrual girls. Hymenal tissue does not completely cover or occlude the vagina. Ultimately the hymen becomes widened, sometimes by tearing, which may be accompanied by bleeding. Widening of the hymen may also occur following a vulvar injury, tampon insertion, or at the time of the first sexual intercourse. It is a societal myth that the hymen must be intact for a female to be considered a virgin.

Perineum

The perineum, an anatomical landmark, is the skin-covered region between the vagina and the anus. The perineal body consists of fibromuscular tissue located between the lower part of the vagina and the anus. During the labor process, as the fetus descends through the vagina, the perineum stretches and becomes very thin, sometimes tearing as the baby is born. An **episiotomy** (incision made to enlarge the perineal opening to allow delivery of a fetus) may be performed to widen the external passage (see Chapter 12 for further discussion).

Now Can You—Discuss aspects of development of the reproductive system and identify components of the female reproductive tract?

1. Identify the developmental week when differentiation of the embryo's reproductive system occurs?
2. Name three structures that arise from the mesonephric ducts?
3. Describe the anatomical locations and functions of the labia, Skene's glands, and Bartholin's glands?

PELVIC FLOOR

The bony pelvis contains a pelvic floor of soft tissues that provides support and stability for surrounding structures. Most of the perineal support comes from the pelvic diaphragm (musculofascial layer forming the lower boundary of the abdominopelvic cavity) and the urogenital diaphragm (musculofascial sheath lying between the ischiopubic rami

surrounding the female vagina). The pelvic diaphragm includes fascia and the levator ani and coccygeus muscles (Cunningham et al., 2005).

Above the pelvic diaphragm lies the pelvic cavity; below and behind is the perineum. The urogenital diaphragm includes fascia, deep transverse perineal muscles, and the urethral constrictor (Cunningham et al., 2005). The muscles of the pelvic floor include the levator ani (consists of the iliococcygeal, pubococcygeal [pubovaginal], puborectal muscles) and the coccygeus. These structures create a “sling” that provides support for internal pelvic structures and the pelvic floor. The ischiocavernosus muscle extends from the clitoris to the ischial tuberosities on each side of the lower bony pelvis. Two transverse perineal muscles extend from fibrous tissue of the perineum to the ischial tuberosities to stabilize the perineum (Fig. 5-2).

INTERNAL STRUCTURES

The internal female reproductive structures consist of the ovaries, fallopian tubes (oviducts, or uterine tubes), uterus, adjacent structures (**adnexa**), and vagina (Figs. 5-3 and 5-4). The ureters, bladder, and urethra are structures of the internal urinary system.

Ovaries

The ovaries are sometimes referred to as the essential female organ because they produce **ova** (female gametes or eggs) that are required for reproduction. They are a pair of oval structures, each measuring approximately 1.5 inches (4 cm) long, located on each side of the uterus below and behind the fallopian tubes. The ovarian ligament extends from the medial side of each ovary to the uterine wall; the broad ligament is a fold of the peritoneum that provides a covering for the ovaries. These two ligaments help to keep the ovaries in place.

The ovaries are responsible for the production of ova and the secretion of female sex hormones. Both of these functions become activated at the time of puberty. **Oogenesis** (the process of meiosis for egg cell formation) results in the formation of mature eggs within the ovary. Oogenesis is a process that occurs at regular (usually monthly) intervals. The ovaries also secrete the female sex hormones estrogen

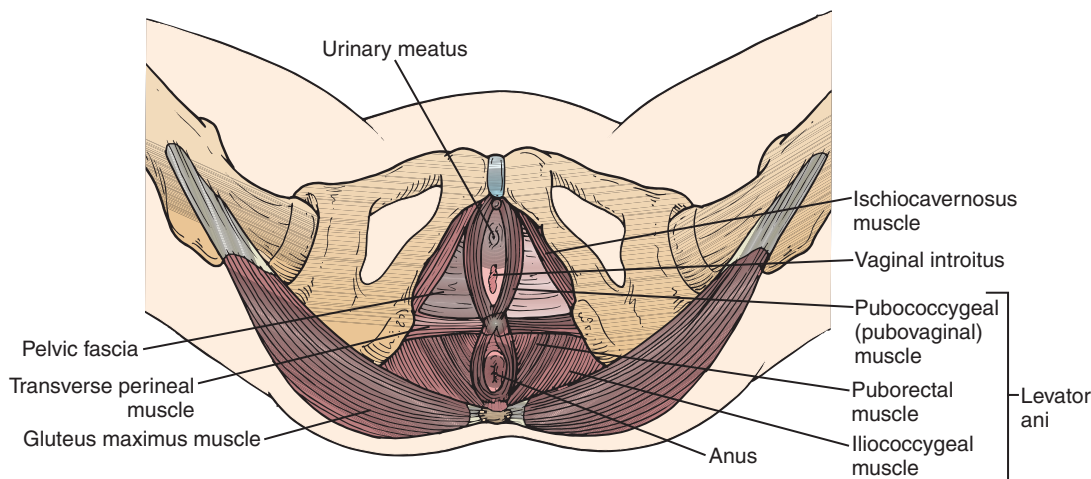

Figure 5-2 The muscles of the female pelvic floor.

Figure 5-3 Internal female genitalia and cross section of the rectum.

and progesterone. This important endocrine function helps to regulate the menstrual cycle.

A & P review Oogenesis

Oogenesis begins in the ovaries and is regulated by follicle stimulating hormone (FSH), which initiates the growth of ovarian follicles. Each follicle contains an **oogonium**, or egg-generating cell (Fig. 5-5). FSH also stimulates the follicle cells to secrete estrogen, which promotes maturation of the ovum. For each primary oocyte that undergoes the process of meiosis, only one functional egg cell is

produced. The remaining three cells, termed polar bodies, have no function and deteriorate. A mature ovarian follicle, also called a **graafian follicle**, contains the secondary oocyte and if the egg is fertilized, the second meiotic division occurs and the ovum nucleus becomes the female pronucleus. ♦

Microscopically, the ovarian surface is termed the germinal epithelium. Each ovary has hundreds of thousands of follicles that contain immature female sex cells. All of the follicles in a woman's ovaries develop in utero and are present at birth. During a postpubertal woman's monthly

Figure 5-4 Internal structures of the adnexa.

Figure 5-5 Oogenesis is the processes of mitosis and meiosis. For each primary oocyte that undergoes meiosis, only one functional ovum is formed.

menstrual cycle, one follicle develops and releases a mature ovum. (Please refer to the menstrual cycle discussion later in this chapter for additional information.) Throughout a woman's reproductive years, only 300 to 400 follicles develop into mature ova and are released for potential fertilization by a sperm.

The ovaries are supported in their position in the pelvis by three important ligaments: the mesovarium, the ovarian ligament, and the infundibular pelvic ligament or suspensory ligament. The ovarian ligament positions the fimbriae (finger-like projections) of the fallopian tube in contact with the lower pole of the ovary to enhance “pick-up” of the ovum following ovulation.

ACCESSORY ORGANS

Fallopian Tubes

The (two) fallopian tubes are also called the **uterine tubes** or **oviducts**. Measuring approximately 4 inches (10 cm) in length, the lateral end of each fallopian tube encloses an ovary; the medial end opens into the uterus. Anatomically, the fallopian tubes are composed of four layers. Beginning with the external layer and progressing inward to the internal layer, these include the peritoneal (serous), which is covered by the peritoneum, the subserous (adventitial), the muscular, and the mucous layers. The blood and nerve supplies are housed in the subserous layer. The muscular layer has an inner circular and an outer longitudinal layer of smooth muscle. It provides peristalsis that assists in transporting the ovum toward the uterus for potential implantation. The mucosal layer contains **cilia** (hairlike projections) that also assist in directing the ovum toward the uterus (Venes, 2009).

The fallopian tubes are attached at the upper outer angles of the uterus, and then extend upward and outward (Fig. 5-6). The diameter of each tube is approximately 6 mm. Anatomically, the tubes consist of three divisions: infundibulum, ampulla, and isthmus. The infundibulum is the funnel-shaped portion located at the distal end of the fallopian tube. The ovum enters the fallopian tube through a small opening (ostium) located at the bottom of the infundibulum. Several finger-like processes (fimbriae) surround each ostium and extend toward the ovary. The longest fimbria, the fimbria ovarica, is attached to the ovary. The ampulla, which is the second division of the fallopian tube, is two-thirds the length of the tube and is most often

the site of ovum fertilization. The third division of the fallopian tube, the isthmus, is nearest the uterus and is typically the site for **tubal ligation** (permanent sterilization).

A patent fallopian tube is able to convey the ovum from the ovary to the uterus and the spermatozoa from the uterus toward the ovary. Fertilization usually occurs in the outer one third of the fallopian tube, which provides a safe, nourishing environment for the ovum and sperm. If fertilization occurs, the fertilized ovum (termed a **zygote** until the first cell division) is slowly and gently swept into the uterus by fallopian peristalsis and cilia movement, where implantation takes place. If fertilization does not occur, the ovum dies within 24 to 48 hours and disintegrates, either in the tube or in the uterus.

Internally, each tube connects laterally with its corresponding ovary and medially with the uterus. Thus, there is a continuous route that passes from the vagina into the uterus and then on out to the tubes and ovaries. If the vagina is infected by a pathogen, the potential exists for retrograde transmission to the ovaries. Although most vaginal infections can be readily treated and cured, residual scarring from the inflammatory process can cause tubal narrowing leading to an increased risk for tubal pregnancies or infertility resulting from blockage.

Uterus

The uterus, centrally located in the pelvic cavity between the bladder (anteriorly) and rectum (posteriorly), is approximately 3 inches long by 2 inches wide (7.5 cm × 5 cm). It is a pear-shaped organ with the narrower end positioned closest to the vagina (Fig. 5-7). The uterine interior is hollow and forms a path from the vagina to the fallopian tubes. Because the uterine walls are very thick and collapsed upon each other, the interior cavity is, in actuality, a “potential space.”

Two major functions of the uterus are to permit sperm to ascend toward the fallopian tubes and to provide a nourishing environment for the zygote until placental function begins. In addition, it provides a safe environment that protects and nurtures the growing embryo/fetus until the pregnancy has been completed. In the absence of conception, the uterus sheds the outermost layers of the inside of the endometrium (menstruation) in order to prepare for another menstrual cycle by regeneration of the endometrium.

The arteries of the uterus are the uterine, from the hypogastric arteries, and the ovarian, from the abdominal

Figure 5-6 Fallopian tube and ovary.

Figure 5-7 Uterus and surrounding structures of the female genitourinary system shown in a midsagittal section through the pelvic cavity.

aorta. This rich blood supply helps to ensure ample oxygenation and nutrition to facilitate the growing uterus and fetus during pregnancy. The uterine veins drain into the internal iliac veins. The vasculature of the uterus is twisted and tortuous and as the **gravid** (pregnant) uterus expands, these vessels straighten out, allowing a continued rich blood supply throughout pregnancy.

The uterus receives its nerve supply via the afferent (sensory) and efferent (motor) autonomic nervous systems. These two systems are important in regulating both vasoconstriction and muscle contractions. The uterus also has an innate intrinsic motility as well. Thus, a patient with a spinal cord injury above level T6 may still have adequate enough uterine contractions to deliver a fetus vaginally.

Uterine pain nerve fibers reach the spinal cord at levels T11 and T12. Because of this location and the presence of other pain receptors there, pain from the ovaries, ureters, and uterus may all be similar and may be reported by a woman who identifies pain in the flank, inguinal, or vulvar areas. Several sensory nerve fibers that contribute to **dysmenorrhea** (painful menstruation) are housed in the uterosacral ligaments.

Uterine Anatomy

The uterus is divided into three sections: the corpus, the isthmus, and the cervix.

The corpus of the uterus is the upper two-thirds of the uterine body and contains the cornua portion, where the fallopian tubes enter, and the fundus or uppermost section superior to the cornua (Fig. 5-8).

CORPUS

The layers of the corpus of the uterus include the perimetrium, the myometrium, and the endometrium. The perimetrium is the outer, incomplete layer of the parietal peritoneum (the serous membrane that lines the abdominal wall). The **myometrium**, or middle layer, is composed of layers of smooth muscle that extend in three directions—longitudinal, transverse, and oblique—and are continuous with the supportive ligaments of the uterus (Fig. 5-9). The tridirectional formation of the muscular layers is important in facilitating effective uterine contractions during labor and birth. The endometrium is the third and innermost uterine layer. It is composed of three layers, and of these, two are shed with each menses.

ISTHMUS

The isthmus is a slight constriction on the surface of the uterus midway between the uterine body (the corpus, or upper two-thirds), and the **cervix**, or “neck.” During pregnancy, the isthmus becomes incorporated into the lower uterine segment and acts as a passive or noncontractile part of the uterus during the labor process. The isthmus is the site for the uterine incision when a low-transverse cesarean section is performed.

CERVIX

The cervix is the lower, narrow end of the uterus. It is similar to a neck or tube and extends from the inside of the uterus, opening into the vagina. The cervix secretes

Figure 5-8 Female reproductive system shown in anterior view. The left ovary has been sectioned to show the developing follicles. The left fallopian tube has been sectioned to show fertilization. The uterus and vagina have been sectioned to show internal structures. Arrows indicate the movement of the ovum toward the uterus and the movement of sperm from the vagina toward the fallopian tube.

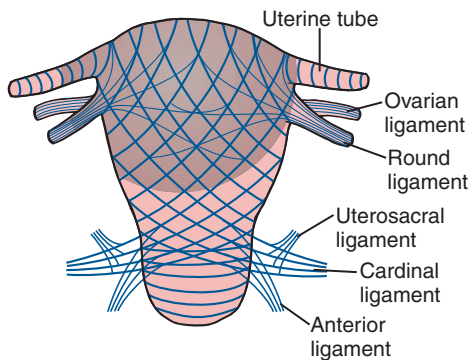

Figure 5-9 Arrangement of the directions of the smooth muscles of the myometrium. The uterine muscle fibers are continuous with the supportive ligaments of the uterus.

mucus, which serves several functions: (1) lubricates the vaginal canal, (2) forms a barrier to sperm penetration into the uterus during nonfertile periods, (3) provides an easy flowing pathway to facilitate sperm passage into the uterus during fertile periods, (4) provides an alkaline environment to facilitate the viability of sperm that have been deposited in the acidic vagina, (5) forms a solid plug called an **operculum** to protect a pregnancy from outside pathogens, and (6) functions as a bacteriostatic agent. The composition of cervical mucus changes during the menstrual cycle and these changes are important in the fertility assessment. During pregnancy, the cervical mucus forms a thick plug that creates a safe barrier between the developing embryo/fetus and the outside environment.

The vaginal portion of the cervix is composed of squamous (epithelial) cells. This portion of the cervix is fleshy pink in color. The canal portion of the cervix that leads into the uterine epithelium is composed of columnar cells. This tissue is bright red in color. The juncture of these two cell types is called the **squamocolumnar junction**. After puberty, this junction is active with cellular growth activity and cell turnover and it is the site where dysplasia (abnormal tissue development) may occur.

Uterine Support Structures

Uterine position in the body varies with age, pregnancy, and distention of related pelvic viscera. Typically, the uterus lies over the urinary bladder. The cervix points down and backward and enters the apex (the pointed extremity portion) of the vagina at a right angle. Several ligaments hold the uterus in place, but also allow for some movement.

The uterus is supported in the pelvis by several ligaments and muscles. These include the broad, round, cardinal, pubocervical, and uterosacral ligaments and the pelvic muscles (Fig. 5-10). The broad and round ligaments support the upper portion of the uterus, while the cardinal, pubocervical, and uterosacral ligaments provide support for the middle portion. The lower portion of the uterus is supported by the muscles of the pelvic floor.

The broad ligaments are supportive stretches of peritoneum that extend from the lateral pelvic sidewalls to the uterus. Within these structures are the fallopian tubes, arteries and veins, ligaments, ureters, and other tissues.

Figure 5-10 Uterine ligaments.

The round ligaments expand both in diameter and in length during pregnancy and this normal physiological change may be associated with maternal discomfort termed “round ligament pain.” As the uterus expands, the round ligaments become stretched tight and sudden movements such as position changes, coughing or stretching may result in sharp pains that can be quite concerning until the woman understands the physiology for the discomfort. The round ligaments also play an important role during labor by pulling the uterus forward and downward, thereby holding it steady to facilitate the movement of the fetal presenting part toward the cervix. The cardinal ligaments prevent uterine prolapse and are the major support structures for the uterus and cervix.

Vagina

The vagina is a tubular organ approximately 4 inches (10 cm) in length that internally extends between the uterus and perineal opening. It is located between the rectum, urethra, and bladder. The collapsible vagina is composed of smooth muscle lined with mucous membrane arranged in **rugae** (small ridges), which allow distention during childbirth. The vagina has five functions: (1) to provide lubrication to facilitate intercourse, (2) to stimulate the penis during intercourse, (3) to act as a receptacle for semen, (4) to transport tissue and blood during menses to the outside, and (5) to function as the lower portion of the birth canal during childbirth.

The apex of the vagina, also termed the vaginal vault or fornix, is the upper, recessed area around the cervix. Following intercourse, sperm pool in the fornix, where they have close contact with the cervix and its alkaline pH. The vaginal pH is typically acidic (4.5 to 5.5) during the reproductive years. The acid environment, though harmful to sperm, helps to protect the genital tract from pathogens.

Ureters, Bladder, and Urethra

The ureters, bladder, and urethra and its external opening or meatus are part of the urinary system and are not reproductive organs. The urethra is a mucous membrane-lined

tube that passes from the bladder to outside of the body to allow micturition. Its position is posterior to the symphysis pubis and anterior to the vagina. The urethra is approximately 1.2 inches (3 cm) in length.

Now Can You— Discuss various aspects of the female reproductive system?

1. Identify the location of the perineum and describe its importance during childbirth?
2. Describe three functions of the uterus?
3. Name the five functions of the cervix?

Bony Pelvis

The pelvis forms a bony ring that transmits body weight to the lower extremities. In women, the bony pelvis is structured to adapt to the demands of childbearing. The pelvis functions to support and protect the pelvic contents and to form a relatively fixed axis for the birth passage (Cunningham et al., 2005).

The pelvis is composed of four bones: the sacrum, the coccyx, and two innominate (hip) bones. The bilateral innominate bones are formed by the fusion of the ilium, ischium, and pubis bones (Fig. 5-11).

True/False Pelves

The pelvis consists of two sections known as the “false pelvis” and the “true pelvis.” These sections are divided by the **linea terminalis**, or pelvic brim. The false pelvis is superior to the linea terminalis. Its anterior boundary is the abdominal wall, its posterior boundary is the lumbar vertebra, and the lateral boundary is the iliac fossa. The false pelvis helps to support the gravid uterus and direct the fetal presenting part down toward the true pelvis.

The true pelvis, located below the linea terminalis, is important for childbearing. Its size and structure direct the fetus downward for delivery and its dimensions must be large enough to deliver the fetus for a vaginal birth. Its boundaries are partly bony and partly ligamentous. Superiorly, the true pelvis is bounded by the sacral promontory

Figure 5-11 Female bony pelvis.

(anterior projecting portion of the base of the sacrum) and the sacral alae (broad bilateral projections from the base of the sacrum), the linea terminalis, and the upper margins of the pubic bones. Inferiorly, the lowest portion of the true pelvis is termed the **pelvic outlet**. The anterior landmarks of the true pelvis consist of the pubic bones, the ascending superior rami of the ischial bones, and the obturator foramen. The sacrum serves as the posterior landmark. Bilaterally, the true pelvis is bordered by the ischial bones and the sacrosciatic notches and ligaments. The true pelvis is divided into three sections: the inlet, the midpelvis, and the outlet, and each of these three components are important during the labor process.

Pelvic Diameters and Planes

In order to assess the adequacy of a woman's pelvis for delivery of a fetus of average size, health care providers may use **pelvimetry** (measurement of the pelvis to predict the feasibility of a vaginal birth). (See Chapter 9 for further discussion.) Measurements of the pelvis are approximate for two reasons: an inability to measure it directly and the presence of soft tissue covering the pelvis that can distort the actual size. Despite findings from clinical pelvimetry, in most situations, women in labor are allowed to experi-

ence a **trial of labor** (allowing uterine contractions in order to evaluate labor progress, e.g., cervical dilation and fetal descent) to assess the feasibility of vaginal birth.

Three portions of the true pelvis are measured during pelvimetry: the pelvic inlet, the midpelvis, and the pelvic outlet. The narrowest portion of the pelvic inlet is the line between the sacral promontory and the inner pelvic arch including the symphysis pubis. It is termed the **obstetrical conjugate** and should measure at least 4.5 inches (11.5 cm). Once the fetus passes this landmark, the presenting part is "engaged" in the pelvis. The midpelvis, which constitutes the area between the ischial spines, is the narrowest lateral portion of the female pelvis. This measurement needs to be at least 4.7 inches (12 cm) to allow for a vaginal birth. During labor, the ischial spines serve as a landmark for assessing the level of the fetal presenting part into the pelvis. At the pelvic outlet, two measurements are assessed: the angle of the ascending rami (pubic arch), which should be at least 90 to 100 degrees and the distance between the ischial tuberosities, which should be at least 3.9 inches (10 cm). These are the minimal measurements deemed necessary to allow the fetus to descend through the pelvis for birth. During pregnancy the joints of the pelvis soften and become more mobile due to effects of the hormone relaxin. This important physiological change creates additional space to accommodate childbirth (see Chapter 12 for further discussion).

Pelvic Types

There are four basic bony pelvic types that have a distinct shape that has distinct implications for childbirth (Caldwell & Moloy, 1933) (Fig. 5-12):

- **Gynecoid:** The gynecoid pelvic type is the typical, traditional female pelvis (present in 50% of women) that is best suited for childbirth. The anterior/posterior and lateral measurements in the inlet, midpelvis, and outlet of the true pelvis are largest in the gynecoid pelvis. The inlet is round to oval-shaped laterally, a characteristic that improves its adequacy for childbirth. In addition, the ischial spines are less prominent, the shortened sacrum has a deep, wide curve and the subpubic arch is wide and round. All of these characteristics enhance the feasibility for a vaginal birth. The other pelvic structures can pose problems for vaginal birth.
- **Android:** The android pelvis (found in 23% of women) resembles a typical male pelvis. The inlet is triangular or heart-shaped, and laterally narrow. The subpubic arch is narrow; there are more bony prominences, including the ischial spines, which are also prominent and narrow. These characteristics can cause difficulty during fetal descent.
- **Anthropoid:** The anthropoid pelvis (occurs in 24% of women) resembles the pelvis of the anthropoid ape. Similar to the gynecoid pelvis, the anthropoid pelvis is oval-shaped at the inlet, but in the anterior–posterior, rather than lateral, plane. The subpubic arch may be slightly narrowed. Fetal descent through an anthropoid pelvis is more likely to be in a posterior (facing the woman’s front) rather than anterior (facing the woman’s back) presentation (see Chapter 12 for further discussion).
- **Platypelloid:** The platypelloid pelvis (found in 3% of women) is broad and flat and bears no resemblance to a lower mammal form. The pelvic inlet is wide

laterally with a flattened anterior–posterior plane and the sacrum and ischial spines are prominent. The subpubic arch is generally wide. Fetal descent through a platypelloid pelvis is usually in a transverse presentation and will not allow for a vaginal birth (see Chapter 12 for further discussion).

Now Can You—Discuss aspects of the female bony pelvis?

1. Differentiate between the true and false pelvis?
2. Name the three components of the true pelvis that are measured during pelvimetry?
3. Identify characteristics of the gynecoid pelvis and explain why this type is best suited for vaginal birth?

Breasts

The female breasts or mammary glands are considered to be accessory organs of the reproductive system (Fig. 5-13). The two breasts lie over the pectoral and anterior serratus muscles. Breast tissue consists primarily of glandular, fibrous, and adipose tissue suspended within the conical-shaped breasts by Cooper’s ligaments that extend from the deep fascia.

The glandular tissue contains 15 to 24 lobes that are separated by fibrous and adipose tissue. Each lobe contains several lobules composed of numerous alveoli clustered around tiny ducts that are layered with secretory cuboidal epithelium called alveoli or acini. The epithelial lining of the ducts secretes various components of milk. The ducts from several lobules come together to form the lactiferous ducts, which are larger ducts that open on the surface of the nipple.

The wide variation in breast size among women is related to the differing amounts of adipose tissue that surrounds the mammary glands. At puberty, development of an adolescent’s breasts is controlled by the hormones estrogen and

Figure 5-12 Comparison of the four Caldwell–Moloy pelvic types. The average woman has a gynecoid pelvis; others may have a variation or a mixture of types. Few women have pure android, anthropoid, or platypelloid types.

Figure 5-13 Mammary gland shown in a midsagittal section

progesterone. Interestingly, in most women, the left breast is often larger than the right.

The primary function of the breasts is to provide nutrition to offspring through the process known as lactation. Preparation for milk production takes place during pregnancy as the ovaries and placenta produce hormones (estrogen and progesterone) to prepare the breasts structurally for lactation by promoting growth of the ducts and secretory cells. After birth and delivery of the placenta, there is an abrupt decrease in estrogen. This event triggers an increased secretion of prolactin (the hormone that stimulates milk production) by the anterior pituitary gland. The posterior pituitary and hypothalamus play a role in the production and secretion of oxytocin, a hormone that causes release of milk from the alveoli.

PARTS OF THE BREAST

Nipples

Centrally located on the breast, the nipples contain several pores that secrete colostrum (breast fluid that precedes breast milk) and breast milk during lactation. The nipples consist primarily of erectile tissue to assist with infant latch-on during suckling (see Chapter 15 for further discussion).

Areola

The areola is a more deeply pigmented area that surrounds the nipple. Its diameter ranges from 1 to 3.9 inches (2.5 to 10 cm).

Montgomery Tubercles

The Montgomery tubercles are papillae located on the surface of the nipple and the areola. The Montgomery tubercles secrete a fatty substance that lubricates and protects the nipple and areola during breastfeeding.

Now Can You— Discuss anatomy of the female breast?

1. Name three types of tissue that comprise the breast?
2. Identify the pituitary hormone responsible for initiation of lactation?
3. Explain the function of the Montgomery tubercles?

The Interplay of Hormones and Reproduction

Knowledge of the functions of key hormones associated with reproduction is essential to an understanding of the female menstrual cycle. The following discussion centers on hormones that play a major role in the process of human reproduction.

HORMONES RELEASED BY THE HYPOTHALAMUS

Since hormones released by the hypothalamus stimulate the release of other hormones, they are termed “releasing factors.” Factor hormones act on the anterior pituitary and stimulate the release of hormones from the pituitary. Releasing factors from the hypothalamus include the following:

- *Gonadotropin-releasing hormone* (GnRH): Stimulates the release of the gonadotropins follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the anterior pituitary. These hormones are released when a decrease in ovarian hormones (estrogen and progesterone) is detected by the hypothalamus. In the premenopausal female, GnRH exerts an ovarian influence: it affects the cyclic process of follicular growth, ovulation, and maintenance of the corpus luteum. In the male, GnRH affects **spermatogenesis**, the process of meiosis in the testes to produce sperm cells.
- *Corticotropin-releasing hormone* (CRH): Regulates adrenocorticotropic-stimulating hormone (ACTH) secretion by the anterior pituitary to activate the sympathetic nervous system. CRH is also released by the pregnant woman and her embryo soon after implantation. CRH appears to provide a protective action by minimizing a maternal immunological rejection that could result in a miscarriage. Other effects of CRH relate to the woman’s response to stress.
- *Growth hormone-releasing hormone* (GH-RH): Stimulates the production and release of growth hormone (GH) by the anterior pituitary.
- *Growth hormone-inhibiting hormone* (GH-IH), also known as somatostatin: Inhibits the release of GH.
- *Thyrotropin-releasing hormone* (TRH): Regulates thyroid hormones (T_3 and T_4) by stimulating the anterior pituitary to release thyroid-stimulating hormone (TSH). TRH also stimulates the release of prolactin.
- *Prolactin-inhibiting factor* (PIF), also known as prolactostatin: Inhibits the synthesis and release of prolactin by the pituitary gland. Dopamine, another hormone released by the hypothalamus, also inhibits prolactin.

HORMONES RELEASED BY THE PITUITARY GLAND

The anterior pituitary produces the following hormones:

- *Thyroid-stimulating hormone* (TSH), also known as thyrotropin: Regulates the endocrine function of the thyroid gland.
- *Adrenocorticotropic hormone* (ACTH), also known as corticotropin: Controls the development and functioning of

the adrenal cortex, including its secretion of glucocorticoids and androgens (Venes, 2009).

- **Prolactin (PRL):** Stimulates the maturation of the mammary glands during pregnancy; initiates milk production and provides some inhibition to the stimulation of FSH and LH.
- **Growth hormone (GH),** also known as somatotropin: Stimulates growth and cell reproduction (e.g., height growth during childhood) in humans. Growth hormone is also responsible for increased muscle mass, calcium retention and bone mineralization, the growth of various organ systems, protein synthesis, stimulation of the immune system, reduced uptake of glucose in the liver, and the promotion of lipolysis.
- **Gonadotropins** (gonad-stimulating hormones): Follicle-stimulating hormone (FSH) and luteinizing hormone (LH) stimulate and inhibit the ovaries. These two hormones help to regulate the menstrual cycle by producing a positive and negative feedback of estrogen and progesterone by the ovaries. The feedback systems stimulate the hypothalamic secretion of releasing hormones that act on the anterior pituitary gland.

The posterior pituitary releases oxytocin. Oxytocin stimulates uterine contractions and the release of milk from milk ducts in the breasts during lactation. A synthetic form of oxytocin can be administered during labor to enhance uterine contractions and after birth to promote expulsion of the placenta and minimize uterine bleeding.

Collectively, the pituitary hormones are essential in the regulation of gonadal, thyroid, and adrenal function, lactation, body growth, and somatic development (Moskosky, 1995; Venes, 2009).

A & P review Hormonally Mediated Events and the Menstrual Cycle

The menstrual cycle is hormonally mediated through events that take place in the hypothalamus, anterior pituitary gland, and the ovaries. The hypothalamus stimulates the anterior pituitary gland to produce gonadotropin. FSH, one of these hormones, stimulates the growth and development of the graafian follicle, which secretes estrogen. Estrogen stimulates proliferation of the endometrial lining of the uterus. After ovulation, the anterior pituitary gland secretes LH, which stimulates development of the corpus luteum. Progesterone secreted by the corpus luteum prompts further development of the lining of the uterus in preparation for the fertilized ovum. When pregnancy does not occur, the corpus luteum degenerates, and the levels of estrogen and progesterone decline. The decreased levels of estrogen and progesterone cause the uterus to shed its lining during menstruation. The decrease in estrogen and progesterone triggers a positive feedback to the hypothalamus, which stimulates the anterior pituitary gland to secrete FSH once again. A schema depicting the hormonal feedback mechanisms that regulate the menstrual cycle is presented in Figure 5-14. The interrelationships between the levels of hormone secretion, development of ovarian follicles, and changes in the uterine endometrium are presented in Figure 5-15. ♦

Figure 5-14 Hormonal feedback mechanisms that regulate the female menstrual cycle.

HORMONES RELEASED BY THE GONADS

The gonadal hormones are estrogen, progesterone, and testosterone. Estrogen and progesterone are primarily female hormones; testosterone is primarily a male hormone. These hormones are produced chiefly by the gonads (ovaries and testes) and have important influences on sexual characteristics and the menstrual cycle. Fluctuating levels of estrogen and progesterone stimulate or suppress the hypothalamus or pituitary gland to release or cease releasing their hormones in a complex orchestration of events that regulate the menstrual cycle.

Estrogen

Estrogen, the primary female sex hormone, is present in high levels in women of childbearing age, and is also present in much smaller levels in men. In females, estrogen is responsible for development of the secondary sex characteristics (i.e., breast development, widening of the hips, deposition of fat in the buttocks and mons pubis). It also helps to regulate the menstrual cycle by stimulating proliferation of the endometrial lining in preparation for a pregnancy.

Progesterone

Progesterone also plays a role in regulation of the menstrual cycle. It decreases uterine motility and contractility (caused by estrogen) and prepares the uterus for implantation after fertilization. During pregnancy, progesterone readies the breasts for lactation.

Figure 5-15 The female reproductive cycle. Levels of the hormones secreted from the anterior pituitary are shown relative to one another and throughout the cycle. Changes in the ovarian follicle are depicted. The relative thickness of the endometrium is also shown.

Testosterone

Testosterone, the primary male hormone, is produced by the testes (in men) and the ovaries (in women). Testosterone is responsible for the development of the male genital tract and the secondary sex characteristics (body hair distribution, growth and strength of the long bones, increase in muscle mass, deepening of the voice through enlargement of the vocal cords). In both genders, testosterone enhances the libido, increases energy, boosts immune function, and helps protect against osteoporosis.

HUMAN CHORIONIC GONADOTROPIN, PROSTAGLANDINS, AND RELAXIN

Human chorionic gonadotropin (hCG) is an important hormone during early pregnancy. It is produced by the **trophoblast** (outermost layer of the developing blastocyst) and maintains the ovarian **corpus luteum** (remainder of ovarian follicle after ovulation) by keeping levels of progesterone and estrogen elevated until the placenta has sufficiently developed to assume that function. Human chorionic gonadotropin may also play a role in limiting the maternal immune response to the pregnancy. Serum or urine hCG levels are measured to diagnose pregnancy.

Prostaglandins are unsaturated, oxygenated fatty acids classified as hormones. Prostaglandins are found in many body tissues, occurring in high concentrations in the

female reproductive tract. Prostaglandins modulate hormonal activity and have an effect on ovulation, fertility, and cervical mucus viscosity. Premenstrually, the release of prostaglandins in the uterus causes vasoconstriction and muscle contractions that lead to the tissue ischemia and pain associated with premenstrual syndrome (PMS). During pregnancy, prostaglandins are believed to help maintain a reduced placental vascular resistance and most likely are involved in the biochemical process that initiates labor.

Relaxin is a hormone primarily produced by the corpus luteum, although the uterine decidua and the placenta are also believed to produce small amounts. Relaxin may be detected in maternal serum by the time of the first missed menstrual period. Although its role in pregnancy is not fully understood, relaxin aids in the softening and lengthening of the uterine cervix and works on the myometrial smooth muscle to promote uterine relaxation.

Now Can You— Discuss key hormones involved in reproduction?

1. Name two gonadotropins and describe their functions?
2. Explain the primary action of human chorionic gonadotropin (hCG)?
3. Identify one action of prostaglandins during pregnancy?

Sexual Maturation

PUBERTY

Puberty is the biological time frame between childhood and adulthood characterized by physical body changes that lead to sexual maturity. During this period, adolescents experience a growth spurt, develop secondary sexual characteristics, and achieve reproductive maturity. The timing of puberty onset and its progress are variable between individuals and are influenced primarily by genetics. However, other factors such as geographical location, exposure to light, nutritional status, and general health all influence the timing of puberty. It is known that the initiation of puberty is triggered by events that lead to the production of gonadotropin-releasing hormone (GnRH) in the hypothalamus. GnRH stimulates the manufacture of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) in the anterior pituitary. The increasing levels of FSH and LH initiate a gonadal response, and this response varies between males and females.

In females, sexual maturation begins with **thelarche**, the appearance of breast buds. Thelarche, which occurs at approximately 9 to 11 years, is the first signal that ovarian function has begun. It is followed by the growth of pubic hair. During thelarche, the “growth spurt,” or period of peak height velocity occurs. **Menarche**, the first menstrual period, begins approximately 1 year after the peak height velocity. It usually occurs between the ages of 9 and 15 years; the average age is 12.4 years (Chumlea et al., 2003).

Major hormonal events surrounding menarche involve the secretion of follicle stimulating hormone (FSH) from the pituitary gland. FSH stimulates the ovaries to begin follicular maturation and to produce estrogen. After maturation of an ovum, LH stimulates release of the ovum from the ovary (**ovulation**). Left behind is the **corpus luteum** (“yellow body” that remains in the ovary following ovulation), a structure that produces progesterone.

In males, LH stimulates the Leydig cells in the testicles to mature the testes and begin testosterone production. FSH and LH stimulate sperm production. Increasing levels of estrogen, progesterone, testosterone, and other circulating androgens stimulate the hypothalamus to continue to release GnRH, which perpetuates the cycle. As puberty progresses, the gonads become increasingly sensitive to hormone stimulation and begin to function. Testosterone secretion causes testicular enlargement, which is the first sign of pubertal changes in males.

Development of the secondary sexual characteristics begins around age 11 to 13 and puberty is completed when a young person reaches sexual maturity at approximately 18 to 20 years of age. The time frame from the first stages of puberty to full sexual maturation ranges from 1.5 to 9 years. In females, puberty is generally initiated about 2 years earlier in the lifespan than in males. Throughout the process of puberty, both genders experience a myriad of physical, psychological, and emotional changes. Alterations in body image and social interactions typically accompany these changes.

FEMALE SECONDARY SEXUAL CHARACTERISTICS

At birth, oocytes are present in the ovary as primary follicles in a state of suspended meiosis. With the onset of puberty, hormonal stimulation prompts the ovaries to secrete small amounts of estrogen. As the process of puberty progresses, estrogen levels rise and menarche occurs. However, estrogen levels at this time are usually insufficient to stimulate ovulation and the menstrual periods are generally unpredictable and irregular. As the gonadotropin cycles continue, the ovaries mature from sustained hormonal stimulation and eventually become capable of follicular maturation with increasing numbers of cycles. Over time, regular cyclic ovulation is established and each menstrual period becomes increasingly more predictable. Once a female reaches a weight of 105 pounds (47.8 kg) and 16% to 23.5% body fat, there is a high correlation with menarche (Garibaldi, 2004).

In addition to the cyclic hormonal changes associated with ovulation, sexual physical changes (secondary sexual characteristics) also occur during puberty. Hormones of the hypothalamic–pituitary–ovarian axis trigger most of the changes that take place in the young woman’s body during this time. (Please see the menstrual cycle discussion). Examples of some of the pubertal changes that occur in the female are presented in Table 5-1.

Other female secondary sexual characteristic changes include growth and development of the vagina, uterus, and fallopian tubes, darkening and growth of the skin on the areola, and external genitals and widening of the hips. Appearance of the secondary sexual characteristics precedes menarche. Estrogen is primarily responsible for changes in the breasts although progesterone, thyroxine, cortisol, insulin, and prolactin also affect glandular development. Guidelines of secondary sexual characteristic

Table 5-1 Female Body Changes Associated with Puberty

Type of Body Change	Body Change	Definition	Average Age Initiated	Average Age Completed
Growth spurt	Adolescent growth spurt	Height increase 2.4–4.3 inches (6–11 cm) in 1 year	10	11.8
Secondary	Thelarche	Breast budding	9.8	14.6
	Adrenarche	↑ Adrenal androgen secretion → axillary and pubic hair	10.5	
Primary	Menarche	First menstrual period	12.8	

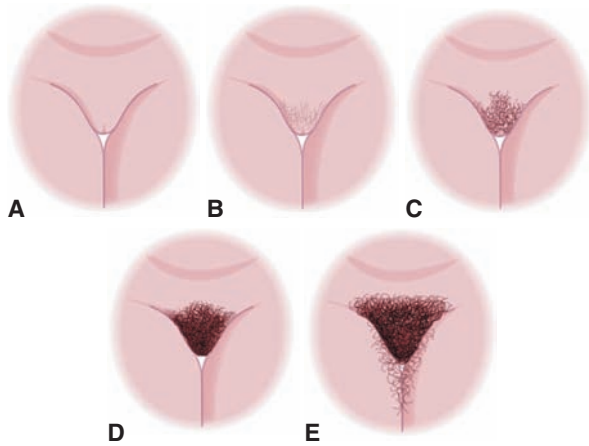

Figure 5-16 Maturation states in females.

A, Preadolescent. No pubic hair, just fine body hair similar to hair on abdomen. **B, Sparse growth** of long, downy hair, straight or slightly curled mainly along labia. **C, Darker, courser, curlier hair** that spreads over pubic symphysis. **D, Hair is course and curly** and covers more area. **E, Adult.** Hair may spread over medial surfaces of thighs, but not over abdomen.

development, termed “Tanner stages” measure the predictable stages of pubertal body changes in both genders (Tanner, 1962). A sexual maturity rating concerning development of pubic hair in the female is presented in Figure 5-16.

Now Can You— Discuss concepts related to puberty?

1. Trace the hormonal events associated with the onset of puberty in females?
2. Explain why the first few menstrual periods are often irregular?
3. Identify six female secondary sex characteristics that precede menarche?

The Menstrual Cycle and Reproduction

Menstruation is the periodic discharge of bloody fluid from the vagina that women experience during reproductive years. Menstrual flow begins at puberty and continues for approximately three to four decades. The **menstrual cycle** refers to the changes that occur in the uterus, cervix, and vagina associated with menstruation and during the interval between each menstruation, termed the “intermenstrual period.” The average time for a menstrual cycle is 28 to 32 days, although there is considerable variation among women and monthly cycles. Factors such as stress, nutritional status, excessive exercise, fatigue, and illness can alter an individual’s cycle intervals and length.

Menstruation and ovulation, key elements in the reproductive cycle, are controlled by positive and negative feedback systems associated with hormones released by the hypothalamus, pituitary, and ovaries. In synchrony, the hormones coordinate the complex biochemical events that result in the monthly menstrual cycle. Regulation of the menstrual cycle involves an overlapping of the uterine (endometrial), hypothalamic-pituitary and ovarian cycles (see Figs. 5-14 and 5-15).

Uterine (Endometrial) Cycle

The uterine, or endometrial, cycle has four phases: menstrual, proliferative, secretory, and ischemic.

MENSTRUAL PHASE

The menstrual phase is time of vaginal bleeding (approximately days 1 to 6). The onset of menses signals the beginning of the follicular phase of the ovarian cycle. Menstruation is triggered by declining levels of estrogen and progesterone produced by the corpus luteum. The decrease in hormones results in poor endometrial support and constriction of the endometrial blood vessels. These changes lead to a decreased supply of oxygen and nutrients to the endometrium. Disintegration and sloughing of the endometrial tissue occurs. During menstruation, constriction of the endometrial blood vessels limits the likelihood of hemorrhage.

Prostaglandins also play a role in menstruation. The uterus releases prostaglandins that cause contractions of the smooth muscle and decrease the risk of hemorrhage. Prostaglandin-induced uterine contractions often produce **dysmenorrhea** (painful menstruation) in the days surrounding the onset of menstrual flow. Other systemic effects of prostaglandins include headache and nausea. Over-the-counter medications that inhibit prostaglandin synthesis such as nonsteroidal anti-inflammatory agents can be used to control the discomfort associated with dysmenorrhea and premenstrual syndrome.

Menstrual fluid is composed of endometrial tissue, blood, cervical and vaginal secretions, bacteria, mucus, leukocytes, prostaglandins, and other debris. The color of menstrual fluid is dark red, but variable throughout the days of menses. The amount of discharge is typically 30 to 40 mL and the duration of bleeding is 4 to 6 days \pm 2 days.

PROLIFERATIVE PHASE

The proliferative phase is the end of menses through ovulation (approximately days 7 to 14). At the beginning of the proliferative phase, the endometrial lining is 1 to 2 mm thick. Circulating estrogen levels are low. Gradually increasing levels of estrogen, enlarging endometrial glands, and the growth of uterine smooth muscle characterize the proliferative phase. Endometrial receptor sites for progesterone are developed during this time. Systemic effects of the increasing amounts of estrogen include an increased secretion of thyroxine-binding globulin (TBG) by the liver, an increase in the breast mammary duct cells, thickening of the vaginal mucosa, and changes in cervical mucus (i.e., increased amount and elasticity) to facilitate sperm penetration at midcycle.

SECRETORY PHASE

The secretory phase is the time of ovulation to the period just prior to menses (approximately days 15 to 26). This phase of the endometrial cycle is characterized by changes induced by increasing amounts of progesterone. Progesterone functions to create a highly vascular secretory endometrium that is suitable for implantation of a fertilized ovum. Glycogen-producing glands secrete endometrial fluid in preparation for a fertilized ovum. At this time, endometrial growth ceases and the number of estrogen and progester-

one receptors decrease. Other progesterone effects during the secretory phase include increased glandular growth of the breasts, thinning of the vaginal mucosa, and increased thickness and stickiness of the cervical mucus.

ISCHEMIC PHASE

The ischemic phase is from the end of the secretory phase to the onset of menstruation (approximately days 27 to 28). During the ischemic phase, estrogen and progesterone levels are low and the uterine spiral arteries constrict. The endometrium becomes pale in color due to a limited blood supply and the blood vessels ultimately rupture. Rupture of the endometrial blood vessels leads to the onset of menses (this event marks day 1 of the next cycle) and initiation of the menstrual phase of the cycle.

HYPOTHALAMIC–PITUITARY–OVARIAN CYCLE

The menstrual cycle is controlled by complex interactions between hormones secreted by the hypothalamus, anterior pituitary, and ovaries (see Fig. 5-14). Hormones from the hypothalamic–pituitary–gonadal (ovarian) axis interact with one another and influence the secretion of hormones from other sites. The hypothalamus and anterior pituitary communicate through the hypophyseal portal system (a system of venous capillary blood vessels that supplies blood and endocrine communication between the hypothalamus and pituitary). The major interacting hormones include GnRH (hypothalamus), LH, and FSH (pituitary), and estrogen and progesterone (ovaries).

HYPOTHALAMIC–PITUITARY COMPONENT

The pituitary receives GnRH input from the hypothalamus. GnRH stimulates the secretion of FSH and LH. FSH prompts the ovaries to secrete estrogen and progesterone and these hormones inhibit the continued secretion of hypothalamic GnRH. FSH also induces the proliferation of ovarian granulosa cells. LH stimulates the growth of the ovarian follicles and prompts ovulation and luteinization (formation of the corpus luteum) of the dominant follicle. The corpus luteum produces high levels of progesterone along with small amounts of estrogen.

OVARIAN COMPONENT

The ovarian portion of the hypothalamic–pituitary–ovarian axis occurs in two phases: the follicular phase and the luteal phase. The phases are distinguished by events in the ovarian cycle, especially those related to ovulation.

FOLLICULAR PHASE

Day 1 of the menstrual cycle begins with the onset of bleeding (menstruation). This event marks the beginning of the follicular phase, which lasts about 14 days, but can vary from 7 to 22 days. This variance often accounts for the irregularity in menstrual cycles in some women (Fehring, Schneider, & Raviele, 2006). The follicular phase is characterized by dominance in estrogen, follicle-stimulating hormone (FSH), and leutinizing hormone (LH). (Please refer to the earlier discussion concerning the role of estrogen and the endometrial cycle.)

FSH stimulates the ovary to prepare a mature ovum for release at ovulation. LH stimulates the theca cells of the

ovary to produce androgens which convert to estrogen in the granulosa cells of the ovary. Immediately before ovulation, the hypothalamus secretes gonadotropin-releasing hormone (GnRH). This action prompts the anterior pituitary to release LH and FSH. The surge of LH stimulates the release of the ovum and ovulation generally occurs within 10 to 16 hours after the LH surge.

Ovulation signifies the end of the follicular phase of the ovarian follicular cycle. The ovum is capable of fertilization by a sperm cell for approximately 12 to 24 hours after ovulation. The follicle that contained the mature ovum remains in the ovary and becomes the corpus luteum, a structure that plays a major role during the second half, or luteal phase, of the ovarian cycle.

LUTEAL PHASE

The luteal phase of the ovarian cycle begins at ovulation and ends with the onset of menses. When pregnancy is not achieved following ovulation, the corpus luteum dominates over the second half of the menstrual cycle. In the absence of fertilization, the life span of the corpus luteum is 14 days. Thus, the luteal phase of the uterine cycle is predictable in length and lasts for 14 days. The corpus luteum secretes estrogen and progesterone, producing a negative feedback that signals the anterior pituitary gland to decrease production of FSH and LH. As the end of the luteal phase nears (approximately 8 to 10 days), low levels of FSH and LH cause regression of the corpus luteum. Degeneration of the corpus luteum is associated with declining levels of estrogen and progesterone. The resultant low progesterone levels stimulate the hypothalamus to secrete GnRH, while the decreased levels of estrogen and progesterone trigger endometrial sloughing. The corpus albicans (“white body”) forms from the remnants of the corpus luteum and eventually disappears.

Body Changes Related to the Menstrual Cycle and Ovulation

Before ovulation, several events occur to indicate that the woman’s body is preparing for fertilization of the released ovum. Increased estrogen secretion by the ovaries produces changes in the cervical mucus that assist the sperm in successfully locating the ovum. There is a dramatic increase in the amount and quality of the cervical mucus. It becomes watery and clear, creating a pathway for sperm to readily swim through the cervix. The elasticity (**spinnbarkeit**) of the cervical mucus increases and the woman can assess this change by stretching the mucus between her fingers (Fig. 5-17). Another method of assessment involves stretching the cervical mucus between two glass slides. At the time of ovulation, the cervical mucus can be stretched to 8 to 10 cm or longer. If the mucus is thin, watery, and stretchable the woman is ready to conceive.

There is also an increase in the **ferning** capacity (crystallization) of the cervical mucus (Fig. 5-18). Ferning, an indirect indicator of estrogen production, results from a decrease in the levels of salt and water that interact with glycoproteins in the mucus during midcycle. The clinician assesses for the presence of ferning by placing a sample of cervical mucus on a glass slide, allowing it to air dry and examining it under a microscope for a fernlike pattern.

Figure 5-17 Spinnbarkeit (elasticity).

Physiological changes also accompany ovulation. The basal body temperature (BBT) increases 0.3 to 0.6°C approximately 24 to 48 hours after ovulation and some women experience *mittelschmerz* (abdominal pain that occurs at the time of ovulation, typically described as a cramping sensation) and midcycle spotting. It is still possible to become pregnant at this point in the menstrual cycle, even when spotting is present.

Natural Cessation of Menses

CLIMACTERIC PHASE

The **climacteric** is a phase characterized by the decline in ovarian function and the associated loss of estrogen and progesterone production.

PERIMENOPAUSAL PHASE

Perimenopause, the time preceding menopause, is the period associated with declining fertility for two reasons: the number of ovarian follicles responsive to gonadotropins is decreased; and the responsive follicles do not develop as quickly as before. Because of these normal changes, many cycles during perimenopause are **anovulatory** (no ova are released from ovary). Anovulatory menstrual cycles are irregular and often variable in the amount of blood flow. Fewer functioning follicles are associated

Figure 5-18 A fern-like pattern of cervical mucus occurs with high estrogen levels.

with lower estradiol (estrogen, E_2) levels. Decreased circulating estrogen levels prompt the anterior pituitary to secrete follicle-stimulating hormone (FSH). Elevated serum FSH levels combined with low estradiol levels are usually indicative of perimenopause/menopause.

The peri-/postmenopausal period is characterized by greatly decreased amounts of endogenous estrogen. During this time, estrone (E_1), created from the peripheral conversion of androstenedione, becomes the predominant form of estrogen. A number of physical changes may accompany the estrogen depletion. These include vasomotor instability (hot flashes/flushes/night sweats), atrophy of the urogenital sites (vaginal dryness, urinary disturbances), amenorrhea (cessation of menses), skin changes (hyper/hypopigmentation, decreased sweat and sebaceous gland activity, thinning of the epidermal and dermal skin layers, decrease in hair distribution), musculoskeletal changes (bone thinning and osteoporosis), and psychological changes (anxiety, depression, irritability, libido changes, insomnia).

The hot flashes associated with perimenopause usually occur at night and result from vasodilation associated with decreased estrogen levels. Vaginal atrophy, also related to estrogen deficiency, results in vaginal dryness and increased sensitivity and pain, particularly during sexual intercourse. Atrophy of the urinary tissues may cause urinary incontinence. Alterations in mood, such as depression, mood swings, and tiredness also result from decreased estrogen levels.

A number of long-term effects occur with the diminishing hormone levels during menopause. Decreased estrogen, associated with lower levels of high-density lipids and elevated levels of low-density lipids, increases the risk for cardiovascular disease. As estrogen diminishes, there is a loss in skeletal bone mass, which results in more brittle bones, and leads to the development of osteoporosis and a loss of spinal flexibility.

MENOPAUSE

Menopause simply refers to the last menstrual period.

POSTMENOPAUSAL PHASE

Postmenopause, the time after menopause, is characterized by estrogen production solely by the adrenal glands. Although controversial, hormone replacement therapy, prescribed on a highly individual basis, may be used to minimize the symptoms and improve quality of life. HRT

can be provided as estrogen only or estrogen and progestin. Estrogen-only HRT reduces the symptoms of menopause. However, the continuous administration of estrogen with no progesterone to facilitate shedding of the endometrial lining should be used only after hysterectomy or after menopause is complete to reduce the risk of endometrial cancer. Estrogen-only HRT also increases the risk of breast cancer. Estrogen-progestin therapy increases the risk of cardiovascular disease, stroke and deep vein thrombosis by decreasing protective factors.

Selective serotonin reuptake inhibitors may be prescribed for alleviation of symptoms. These medications decrease hot flashes in approximately half of the women who take them, and are also useful in managing the mood changes that occur during perimenopause. Gabapentin (Neurontin) and clonidine (Catapres) reportedly reduce hot flashes, but are associated with side effects including drowsiness, dizziness, and sexual dysfunction. Selective estrogen receptor modulators (SERMs) such as raloxifene (Evista) mimic the effects of estrogen without increasing the risk of breast cancer and endometrial cancer; however, hot flashes are a common side effect of SERMs.

Now Can You— Discuss characteristics of the uterine cycle?

1. Outline the four phases of the uterine cycle and describe the major physiological events that occur during each phase?
2. Trace the hormonal interplays that characterize the hypothalamic–pituitary–ovarian cycle?
3. Describe four physiological changes that occur in the female body around the time of ovulation?
4. Discuss the hormonal events that accompany perimenopause?

Male Reproductive System

EXTERNAL STRUCTURES

The external structures consist of the perineum, penis, and scrotum (Fig. 5-19).

Perineum

The male perineum is a roughly diamond-shaped area that extends from the symphysis pubis anteriorly to the coccyx posteriorly and laterally to the ischial tuberosity.

Penis

The penis is composed of three cylindrical masses of erectile tissue that surround the urethra. The function of the penis is to contain the urethra and serve as the terminal duct for the urinary and reproductive tracts by excreting urine and semen. During sexual arousal, the penis becomes erect to allow penetration for sexual intercourse.

The glans penis is the tip of the penis. It contains many nerve endings, is very sensitive and important in sexual arousal. The urethra is approximately 8 inches (20 cm) long and serves as a passageway for both urine and ejaculated semen. It extends from the urinary bladder to the urethral meatus at the tip of the penis. **Circumcision** is a surgical procedure in which the prepuce (epithelial layer covering the penis; foreskin) is separated from the glans penis and excised. (See Chapter 18 for further discussion.)

Scrotum

The scrotum is a two-compartment pouch covered by skin. It is suspended from the perineum and contains two testes, the epididymis, and the lower portion of the spermatic

Figure 5-19 The male reproductive system shown in a midsagittal section through the pelvic cavity.

cord. The scrotum functions to enclose and protect the two testes. A large component of the protection occurs through temperature regulation of the testes (maintained at about 5 degrees F below core body temperature), which is accomplished by the cremaster and dartos scrotal muscles. These muscles control elevation of the scrotal sac to help maintain the testes in a controlled temperature environment. When exposed to cold, the scrotal muscles contract, causing the testes to be elevated closer to the body to preserve warmth.

INTERNAL STRUCTURES

The internal male reproductive structures include the testes, epididymis, ducts (vas deferens, ejaculatory duct), urethra, spermatic cords, and accessory glands (seminal vesicles, prostate, bulbourethral glands and urethral glands) (Fig. 5-20).

Testicles/Testes

The male testes are considered “essential organs” because they manufacture sperm, which are necessary for reproduction. The two testicles are composed of several lobules, seminiferous tubules, and interstitial cells separated by septa. They are encased in the tunica albuginea capsule. The seminiferous tubules open into a plexus (rete testis) drained by efferent ductules located on the top of the testicle that enters the head of the epididymis. The seminiferous tubules contain spermatogonia, or sperm-generating cells that divide first by the process of mitosis to produce primary spermatocytes (Figs. 5-20 and 5-21).

One testicle is housed in each compartment of the scrotum. The function of the testicle is twofold and includes spermatogenesis and the production and secretion of the male hormone testosterone by the interstitial cells of Leydig.

A & P review Spermatogenesis

Spermatogenesis, the formation of mature sperm within the seminiferous tubules, is a process that occurs in the following four stages:

1. Spermatogonia, the primary germinal epithelial cells, grow and develop into primary spermatocytes. Spermatogonia and primary spermatocytes both contain 46 chromosomes; these consist of 44 autosomes and the two sex chromosomes, X and Y.
2. The primary spermatocytes divide to form secondary spermatocytes. In this stage no new chromosomes are formed; instead, the pairs only divide. Each secondary spermatocyte contains half the number of autosomes—22—and one secondary spermatocyte contains an X chromosome and the other contains a Y chromosome.
3. Each secondary spermatocyte then undergoes another division to form spermatids.
4. In the final stage, the spermatids undergo a series of structural changes that transform them into mature spermatozoa (sperm), each containing a head, neck, body, and tail. The head houses the nucleus; the tail contains a large amount of adenosine triphosphate (ATP), which provides energy for sperm motility (Dillon, 2007). ♦

Epididymis

There are two epididymi, which are tightly coiled tubes positioned on the top of each testis. The epididymi store maturing sperm cells and convey sperm to the vas deferens. They also secrete seminal fluid and serve as the site where sperm become motile.

Ducts

There are two vas deferens/ductus deferens and two ejaculatory ducts. The vas deferens are two tubes that extend beyond the epididymis through the inguinal canal into the abdomen and over and behind the bladder. They serve as an excretory duct for seminal fluid. The vas deferens also connect the epididymis with the ejaculatory duct. The two ejaculatory ducts serve as the connection between the vas deferens and the seminal vesicle ducts. The ejaculatory ducts pass through the prostate gland and terminate in the urethra.

Urethra

The urethra is a mucus membrane-lined tube that passes from the bladder to the exterior of the body. It joins with the two ejaculatory ducts in the prostate gland. Its length is approximately 7.9 inches (20 cm). In males, the urethra functions in both the urinary and reproductive systems.

Spermatic Cords

The two spermatic cords are fibrous cylinders located in the inguinal canals. They enclose the seminal ducts, blood and lymphatic vessels, and nerves.

Accessory Glands

The accessory glands include the seminal vesicles, the prostate, the bulbourethral glands, and the urethral (Littre's) glands.

The two seminal vesicles are pouches located on the posterior surface of the bladder. They secrete the viscous nutrient-rich component of seminal fluid. This fluid, which accounts for 60% of semen volume, contains alkaline prostaglandin to help neutralize semen pH.

The prostate, located inferiorly to the bladder, is a donut-shaped structure that encircles the urethra. It secretes a thin, milky, alkaline fluid that is rich in zinc, citric acid, acid phosphatase, and calcium. Prostatic fluid helps protect sperm from the acidic environments of the vagina and male urethra and accounts for 30% of the semen volume.

Each of the two bulbourethral glands is a small pea-shaped organ that contains a 1-inch (2.5-cm) long duct leading into the urethra. These glands are located below the prostate gland and they function to secrete fluid to lubricate the end of the penis. This fluid makes up 5% of the semen volume.

The urethral or Littre's glands are multiple glands located along the urethra, especially in the penile section. They secrete mucus that is incorporated into the semen.

Characteristics of Semen and Sperm

Seminal fluid consists of secretions from the testes, the epididymi, the seminal vesicles, the prostate, the bulbourethral glands, and the urethral glands. Seminal fluid is

Figure 5-20 A, Midsagittal section of portion of a testis; the epididymis is on the posterior side of the testis. B, Cross section through a seminiferous tubule showing development of sperm.

Figure 5-21 Spermatogenesis. The processes of mitosis and meiosis are shown. For each primary spermatocyte that undergoes meiosis, four functional sperm cells are formed. The structure of a mature sperm cell is also shown.

secreted during ejaculation and is slightly alkaline with a pH of about 7.5. The typical amount present in one ejaculate is 2 to 5 mL. There are approximately 120 million sperm cells in each milliliter of ejaculate and, typically, around 40% of the sperm are motile. There are also about 5 million white blood cells in each milliliter of semen along with secretions from the testes, epididymi, seminal vesicles, prostate and bulbourethral glands. The following pathway traces the events from the formation of sperm to the ejaculation of semen:

1. The testes produce sperm that are transported to the epididymis.
2. Move to the vas deferens
3. From there the seminal fluid moves to the ejaculatory duct before exiting the body through the urethra.

Sperm are capable of surviving in optimal favorable alkaline conditions for up to 72 hours postejaculation in a woman's body. The average length of time for sperm to locate from the cervix to the fallopian tubes is approximately 5 minutes under favorable conditions.

Male Hormonal Influences

TESTOSTERONE

The testes produce androgens, the male sex hormones. Testosterone is the dominant male hormone. At the time of puberty, testosterone stimulates enlargement of the testes and accessory organs and prompts development of the secondary sex characteristics. The male secondary sex characteristics include changes in body hair (coarse hair on face, chest, and pubic area and sometimes decreased hair on the head), a deepening of the voice, thickened skin, increased upper body musculature and narrow waist, and a thickening and straightening of bone (Shier, Butler, & Lewis, 2003). Testosterone also prompts a linear growth spurt.

Fertility

Male fertility is related to overall sperm number, size, shape, and motility. Decreased fertility is associated with insufficient sperm counts affected by active contact sports; smoking; and tight, constrictive clothing. Decreased fertility is also associated with an autoimmune disorder that results in the manufacture of antibodies to one's own sperm. The presence of varicose veins on the scrotum (varicocele) can cause testicular warming and adversely affect the life span of the sperm. Decreased sperm motility or "slow swimming" caused by an ineffective flagella also affects male fertility.

Age-related Development of the Male Reproductive System

Similar to embryological development in the female, the male genital organs develop in the abdomen of the fetus, but are immature. The testes develop near the kidneys and

descend into the scrotum through the inguinal canal after 35 weeks' gestation. Scrotal examination is an important component of the male neonate's physical assessment to ensure that the testes have descended and do not remain in the inguinal canal. **Cryptorchidism** is the condition in which the testes fail to descend; sterility results unless the testes are surgically placed in the scrotum (Scanlon & Sanders, 2003) (See Chapter 18 for further discussion). It is important to locate both testes in a newborn as testicular failure to descend may indicate gonadal malgenesis, which can lead to testicular cancer and fertility issues in young adulthood.

The reproductive functions of the testes begin at the time of puberty. Once critical hormone levels have been reached, the final stages of reproductive system development take place. A gradual decline in hormone production normally occurs during late adulthood. Although the hormonal decline may be associated with a decrease in sexual desire and fertility, most men maintain the ability to reproduce into old age.

Now Can You— Discuss aspects of the male reproductive system?

1. Identify the three external structures of the male reproductive system and describe one function for two of them?
2. Discuss the functions of the testicles, epididymis, vas deferens and prostate gland?
3. Trace the pathway from sperm production to semen ejaculation?
4. Name five male secondary sex characteristics that result from the influence of testosterone?

summary points

- ◆ Gender is determined at the moment of conception. Identifiable sexual characteristics are apparent in the embryo at 8 weeks of gestation.
- ◆ Gender maturation is a lengthy process that begins during embryonic development and reaches full maturity during late adolescence.
- ◆ External structures of the female reproductive system include the mons pubis, labia, clitoris, vestibule, urethral meatus, Skene's and Bartholin's glands, vaginal introitus, hymen and perineum.
- ◆ Internal structures of the female reproductive system include the ovaries, fallopian tubes, uterus, and vagina.
- ◆ The female bony pelvis supports and protects the contents of the pelvis and provides a fixed axis for the process of childbirth.
- ◆ The breasts or mammary glands are considered to be accessory organs of the female reproductive system.
- ◆ Hormones secreted by the pituitary gland are essential in the regulation of gonadal, thyroid and adrenal function, lactation, body growth, and somatic development.
- ◆ Menstruation and ovulation are controlled by a complex interplay of positive and negative feedback systems associated with hormones released by the hypothalamus, pituitary, and ovaries.

- ◆ The male reproductive system consists of the testes, where spermatogonia and male sex hormones are formed; a series of continuous ducts that allow spermatozoa to be transported outside the body; accessory glands that produce secretions to foster sperm nutrition, survival, and transport; and the penis, which functions as the reproductive organ of intercourse.
- ◆ Testosterone, the dominant male hormone, is responsible for the development of secondary sex characteristics in the male.

review questions

Multiple Choice

1. The perinatal nurse explains to the new nurse that a female fetus has a developed ovary by
 - A. 8 weeks
 - B. 10 weeks
 - C. 12 weeks
 - D. 16 weeks
2. The perinatal nurse describes to the prenatal class attendees that an incision for a Cesarean birth is normally made in the uterine segment known as the:
 - A. Isthmus
 - B. Cervix
 - C. Apex
 - D. Corpus
3. The perinatal nurse knows that ova are produced and estrogen secreted at the time of:
 - A. Puberty
 - B. Birth
 - C. The climacteric
 - D. Pregnancy
4. The perinatal nurse teaches the new nurse that the assessment landmark for the fetal presenting part is the:
 - A. Ischial spines
 - B. Sacral promontory
 - C. Sacral alae
 - D. True pelvis

Fill-in-the-Blank

5. The clinic nurse teaches the new nurse that the fallopian tubes or _____ measure about _____ inches (_____cm) and are vulnerable to infection which can cause _____ and increase the risk of _____ pregnancy.
6. The perinatal nurse knows that uterine circulation is supplied by the _____ and _____ arteries, which are _____ until the uterus expands during pregnancy.
7. The clinic nurse is aware that when a woman is undergoing a PAP test and physical examination, it is not always possible to visualize the _____ glands located on either side of the _____. These glands are responsible for mucus production that _____ the vagina.

True or False

8. The perinatal nurse knows that beginning at the 12th gestational week, a male fetus produces androgens that stimulate growth of the external genitalia.

Select All that Apply

9. The perinatal nurse describes the multiple functions of the uterus as:
 - A. Providing a safe environment for a growing embryo
 - B. Providing a passageway for sperm
 - C. Providing nourishment for the zygote
 - D. Providing a blood supply for the accessory organs
10. The perinatal nurse knows that the internal urinary system is composed of:
 - A. Ureters
 - B. Urethra
 - C. Vagina
 - D. Bladder

CONCEPT MAP

Human Sexuality and Fertility

chapter 6

Cherish your human connections: Your relationships with friends and family.

—Barbara Bush

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Discuss the nurse's role in providing sexual and reproductive health care.
- ◆ Identify advantages and disadvantages of barrier and hormonal contraceptive methods, intrauterine devices and permanent sterilization.
- ◆ Teach patients how to use various methods of contraception.
- ◆ Assess a patient for short-term complications after an induced abortion.
- ◆ Analyze the nurse's role in infertility care.
- ◆ Differentiate among the various advanced reproductive technologies.
- ◆ Identify potential alternatives to childbearing for the infertile couple.

moving toward evidence-based practice Therapy for Unexplained Infertility

Harrison, E.C., & Taylor, J.S. (2006). IVF therapy for unexplained infertility [Electronic version]. *American Family Physician, 73*(1), 63–66.

The purpose of this review was to determine whether in vitro fertilization (IVF) improves the probability of live births in the context of unexplained infertility, compared to alternative management approaches. Unexplained infertility was defined as failure to conceive after 1 year in couples in whom no abnormalities were found during an infertility work-up. IVF is a process that involves stimulation of the ovaries with gonadotropins, egg retrieval, and fertilization in the laboratory. Pregnancy rates achieved with IVF therapy have been reported to reach 30%.

Alternative management approaches to achieve live births included: (1) expectant management, (2) the administration of clomiphene citrate (Clomid), (3) intrauterine insemination (IUI) with or without controlled ovarian stimulation, and (4) gamete intrafallopian transfer (GIFT).

Of the ten randomized controlled trials (RCT) reviewed, six met the study criteria and were included in the meta-analysis. Significant variations among study outcomes and therapies were found; the live-birth rate per patient was considered to be the outcome of interest.

Data analysis revealed the following: (1) IVF was found to be significantly better than expectant management in two studies; (2) there were no significant differences in live birth rates among patients who received IVF and those who received intrauterine insemination; and (3) one study reported a greater live birth rate associated with IVF as compared with GIFT. The use of clomiphene citrate (Clomid) was not compared with other infertility therapies in any of the studies.

The researchers concluded that there were insufficient data to allow for the comparison of IVF with other methods of infertility treatment and recommended larger randomized trials.

It was noted that the cost of a single cycle of IVF reportedly exceeds \$10,000.00. Insurance coverage for IVF varies from zero to 100% reimbursement.

Risks associated with infertility therapies include psychological stress (e.g., anxiety and depression), multiple gestations, operative risks, and ovarian hyperstimulation syndrome. Approximately 25% of IVF pregnancies involve multiple gestations, which are frequently associated with maternal–fetal complications.

(continued)

moving toward evidence-based practice (continued)

Operative risks associated with egg retrieval include a potential for bleeding and infection.

1. Does this study provide sufficient evidence to suggest that IVF therapy is more effective than other forms of infertility

management, when compared to the risks associated with this treatment modality?

2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

Sexuality is a multidimensional concept that encompasses one's sexual nature, activity, and interest. Influenced by ethical, spiritual, cultural, and moral factors, sexuality constitutes an important component of women's health. A central role for nurses involves helping women to understand their sexual health and assist them with reproductive life planning. This chapter explores the nurse's roles in various aspects of reproductive health care and concludes with a brief overview of some of the legal and ethical issues that surround methods of advanced reproductive technology.

Sexuality and Reproductive Health Care

Women's health care is a broad term that encompasses the provision of holistic care to women within the context of their day-to-day lives. This approach to health recognizes that a woman's physical, mental, and spiritual states are interdependent and all affect the present level of wellness. In any therapeutic setting, eliciting the woman's view of her situation, and assessing her needs, values, beliefs, and supports constitute essential components in formulating an appropriate plan of care.

Nurses have an opportunity to work with women in a variety of settings. Teaching about health promotion can take place at community centers, schools, clinics, private offices, and senior centers. The majority of women's health care is delivered outside of the acute care setting. Approaching women's health from a community-based perspective enables nurses to recognize each person's autonomy and provide holistic care that is sensitive to physical, emotional, sociocultural, and situational needs.

Sexuality and its reproductive implications are woven into the fabric of human behavior. Because it is such an emotion-laden aspect of life, people have many concerns, problems, and questions about sex roles, behaviors, inhibitions, education, morality, and related components such as contraception. The reproductive implications of sexual behavior must also be considered. Some people desire pregnancy; others wish to avoid it. Health concerns constitute yet another issue that must be addressed. The rising incidence of sexually transmitted infections, especially HIV/AIDS and herpes virus, has prompted many individuals to modify their sexual practices. Women often ask questions and voice concerns about these issues to the

nurse in the ambulatory care setting. Hence, the nurse may need to assume the role of educator, counselor, or care provider when dealing with sexual and reproductive health matters.

It is essential that nurses who practice in reproductive care settings develop an awareness and understanding of personal feelings, values, and attitudes about sexuality. These insights allow the nurse to provide sensitive, individualized care to women who have their own set of values and beliefs. Nurses must have current, evidence-based information about anatomy and physiology and about topics related to sexuality and reproductive health. Nurses must also be sensitive to the relationship dynamics they may observe when women arrive for care accompanied by their partners.

THE HUMAN SEXUAL RESPONSE

In the 1960s, the research work of Masters and Johnson (1966) helped to define sexuality as a natural component of a healthy human personality. Before that time, human sexuality was often viewed as a negative or nonexistent, sometimes shameful, aspect that needed to be shrouded in secrecy. The work of the two sexuality researchers gave new insights into the physical components of human pleasure during sexual response and orgasm.

Masters and Johnson described four human sexual response phases: excitement, plateau, orgasmic, and resolution. The *excitement phase* is characterized by physiological responses to internal and/or external cues. Women experience vaginal lubrication, breast and pelvic engorgement, and increased heart rate, respiratory rate, and blood pressure. Clitoral and labial tissues become swollen, the nipples become erect, and the vagina becomes distended and elongated. Men experience penile engorgement with an increase in circumference and length (erection) along with scrotal thickening and elevation.

During the *plateau phase*, women experience the most heightened sense of sexual tension. The labia become more congested, the vagina becomes more fully expanded and the uterus rises out of the pelvis in preparation for intercourse. Most women also experience sexual flushing, tachycardia, and hyperventilation. In men, the testicles enlarge and become elevated and the coronal circumference of the penis increases. Both genders experience a generalized muscular tension.

The *orgasmic phase* is characterized by an intense desire for sexual release due to congestion of the blood vessels. Tachycardia, blood pressure, and hyperventilation are intensified. These sensations build until orgasm is reached.

Muscular contractions occur in the man's accessory reproductive organs (vas deferens, seminal vesicles, and ejaculatory duct). There is a relaxation of the bladder sphincter muscles along with contractions of the urethra and perirectal muscles followed by ejaculation as orgasm occurs.

An overall release of muscular tension takes place during the *resolution phase*. Both genders experience a feeling of warmth and relaxation and women may experience a brief refractory period or "rest time" before they are interested in sexual intercourse again. Women are capable of experiencing multiple orgasms.

Masters and Johnson were instrumental in opening the topic of human sexual response for discussion and study in the United States. The media often send the message that sexuality involves only a physical expression such as the act of sexual intercourse. In actuality, human sexuality is a multidimensional phenomenon that touches and permeates many aspects of human behavior.

EXPLORING DIMENSIONS OF SEXUALITY

Sexual Orientations

Even though it constitutes an integral and normal dimension of every human being, sexuality evokes controversy when it involves alternative sexual orientation or sexual expression at either end of the age spectrum. **Heterosexual** sexual orientation is the sexual attraction to or sexual activity with a person of the opposite sex or gender. Heterosexuality is often considered the norm in America, and any other form of sexual expression is viewed as being outside the realm of "normal."

Homosexuality is the sexual attraction to or sexual activity of a person with another individual belonging to the same sex or gender. The term "gay" is often used for homosexual males; "lesbian" is used for females. An estimated 2.3 million women in the United States presently identify themselves as lesbians (Marrazzo, 2004). Although a genetic factor has been linked with male homosexuality, no such etiology has been identified for lesbians (Ridley, 2000). Thus, the origin of this sexual orientation in women remains basically unknown.

Masters and Johnson (1966) refuted the idea that homosexuality is a mental health disorder. Yet lesbians and bisexuals (individuals who are sexually active with others of both sexes) are more likely to report that they experience poor physical and mental health (Mays, Yancey, Cochran, Weber, & Fielding, 2002). Although the exact etiology of diminished health status among this population is not clear, one factor may relate to homosexual/bisexual women's hesitancy in seeking health care. The mental and physical discomforts associated with seeking medical attention may translate into a failure to obtain timely professional help for health concerns or illnesses. Some lesbians may be reluctant to disclose their sexual orientation to their health care provider owing to fears related to hostility, inadequate health care, or breach of confidentiality. Also, in many health care settings, patient heterosexuality is assumed and interview questions are structured toward a heterosexual orientation.

Lesbians who decide to bear a child often must undergo a number of medical procedures in order to conceive. In general, lesbian women who choose to have children are firmly committed to their decision, for they must work

harder at achieving conception than other women. Significant health issues also exist for this population. Women who are lesbians are more at risk for breast cancer due to their lower rates of breastfeeding. They are also at risk for sexually transmitted infections (including HIV) and cervical cancer. However, woman-to-woman transmission of sexually transmitted infections is much lower than in heterosexual relationships. Since not all gynecological cancers are related to sexual activity, lesbian women who have never had children may be at an increased risk for endometrial and ovarian cancer. Further, their risk for other cancers (e.g., lung and colon) and heart disease is not different from that of heterosexual women. It is essential that health care providers give correct advice and conduct appropriate cancer and other disease screening for these women. The nurse should develop an approach that does not assume that all patients are heterosexual (Martinez, 2007; Stevens & Hall, 2001). As is true with any group, homosexual women deserve to have their healthcare concerns addressed by compassionate, non-judgmental healthcare providers who are knowledgeable about the healthcare needs of women with alternative sexual preferences.

A Nursing Framework for Promoting Women's Sexual and Reproductive Health

Nurses who work with women in reproductive care settings must understand what is meant by healthy sexual function before they can begin to recognize and understand how a behavior becomes dysfunctional. A newer vision of sexuality in women (Basson, 2002; Katz, 2007) takes into account relationships for women by including emotional intimacy, sexual stimuli, and relationship satisfaction as a model of sexual response. Thus, women's sexual response is far more complex and complicated than the achievement of an orgasm with intercourse. Sexuality for women encompasses much more than the physical dimension of the sex act.

Sexual dysfunction for women is defined as any sexual situation that causes distress for the woman herself. If the woman is comfortable with a situation, there is no dysfunction. If she is distressed by any physical, emotional, or relationship aspect of her sexuality, she may be experiencing a dysfunction (Hicks, 2004). Dysfunction can be manifested in the form of pain, arousal disorder, orgasmic disorder, or desire disorder (American Psychiatric Association [APA], 2000).

ASSESSMENT

A first step in the sexual and reproductive health assessment involves the establishment of a trusting relationship where the patient feels safe asking questions and sharing concerns. Discussion of sexual issues can be embarrassing for women. Nurses need to be aware of their own sexual biases and beliefs and educate themselves about the many aspects of sexuality. When assessing women for sexual concerns, it is important not to make assumptions about partner preferences or sexual

activity. Misguided assumptions can bring an abrupt ending to any therapeutic communications. For example, speaking with a woman about contraceptive choices may halt further dialogue with the patient who is lesbian and has sexual concerns unrelated to a heterosexual relationship (Martinez, 2007).

When working with very young patients, the nurse must avoid communicating personal views that adolescent sexual behavior is wrong or shameful. Regardless of involvement in sexual activity, teenagers need a reliable source of education and information. They must first feel accepted before they can ask questions and share concerns about sexuality and sexual behavior.

Assessing women for current or past problems that may interfere with or contraindicate pregnancy or the use of certain types of **contraception** (products that prevent pregnancy) is an important nursing role in reproductive health care. For example, women with chronic health problems such as diabetes, stroke, multiple sclerosis, cancer, or pain may be taking medications that are contraindicated with certain contraceptives or are associated with fetal anomalies (Table 6-1). Individualized counseling, guidance, and reliable information helps empower them to make informed, realistic choices about reproductive planning. Other chronic conditions, including endometriosis and polycystic ovarian disease, may interfere with fertility and create a sense of powerlessness in those who desire pregnancy. Nurses are in a unique position to listen generously to these women, make appropriate referrals, and assist them in resolving their grief and feelings of loss (Katz, 2007; Martinez, 2007).

Women also need to be counseled about the ideal age for childbearing and the implications of delaying pregnancy too long. Those who have not conceived by the mid- to late 30s may remain childless and burdened with guilt. Outside pressures exerted by cultural influences and family expectations often compound the feelings of remorse. Providing all women with current, factual information about the natural aging process and its influence on fertility empowers women of all ages to make informed decisions that best suit their needs.

Obtaining the Sexual History

The sexual history elicits information concerning prior treatment for sexually transmitted infections (STIs), pain with intercourse (**dyspareunia**), postcoital spotting or bleeding, and frequency of intercourse. Women who have intercourse more frequently and on a regular basis are more likely to become pregnant. The probability for pregnancy with each unprotected intercourse is about 20% (Nelson & Marshall, 2004). An important component of holistic reproductive care centers on helping women to understand their body's natural functioning in relation to the menstrual cycle, so that they can problem-solve about the timing of intercourse to achieve pregnancy, if desired.

The nurse also inquires about the number of past sexual partners. This information is useful in developing an estimate of the patient's risk for STIs and guides the nurse in providing appropriate education about safe sex practices. It is estimated that 4 out of 10 Americans between 18 and 59 years of age have had five or more partners (Haffner & Stayton, 2004). Since the risk of contracting a sexually transmitted infection increases with

each sexual partner, this information is very important for women whose reproductive life plan includes future pregnancy. Sexual health promotion includes providing correct information about the implications of multiple sexual partners; this information empowers women to make knowledgeable, informed choices. Depending on the situation and purpose of the visit, other appropriate components of the patient assessment may include a physical examination and diagnostic testing.

Now Can You—Discuss the nurse's role in reproductive health care?

1. Explain why nurses who work in a reproductive health care setting must be comfortable with their own sexuality?
2. Develop six questions that will assist with taking a patient's sexual history?
3. Analyze the nurse's role in the reproductive health assessment?

NURSING DIAGNOSES FOR PATIENTS SEEKING CONTRACEPTIVE CARE

Depending on the purpose of the visit and analysis of the assessment findings, a number of nursing diagnoses may be appropriate. For women seeking contraception, diagnoses may include decisional conflict regarding choice of birth control because of a health concern, contraceptive alternatives, or the partner's willingness to agree on the contraceptive method. Other possible nursing diagnoses are listed in Box 6-1.

PLANNING AND IMPLEMENTATION OF CARE

Regardless of the patient's age and contraceptive method selected, the nurse must first seek the woman's confirmation that she truly wants contraception. Birth control is always an individual choice. Feelings of helplessness and manipulation may result when the woman believes that someone else has decided what is "best" for her or coerces her into contraceptive use.

One of the primary goals during the contraceptive care visit is to determine and provide the contraceptive method of "best fit" for the woman or couple. Obtaining the medical, social, and cultural history helps to safeguard the

Box 6-1 Possible Nursing Diagnoses for Reproductive Care

- Ineffective Sexuality patterns related to fear of pregnancy
- Knowledge Deficit related to new use of the contraceptive method of choice
- Effective Therapeutic Management related to birth control method of choice
- Risk for Spiritual Distress related to discrepancy between religious or cultural beliefs and choice of contraception
- Risk for Infection related to use of contraceptive method or unprotected sexual intercourse
- Broken skin or mucous membrane after surgery or intrauterine device (IUD) insertion
- Fear related to contraceptive method side effects

Table 6-1 Drugs that Adversely Affect the Female Reproductive System		
Drug Class	Drug	Possible Adverse Reactions
Androgens	Danazol	Vaginitis, with itching, dryness, burning, or bleeding; amenorrhea
	Fluoxymesterone, methyltestosterone, testosterone	Amenorrhea and other menstrual irregularities; virilization, including clitoral enlargement
Antidepressants	Tricyclic antidepressants	Changed libido, menstrual irregularity
	Selective serotonin reuptake inhibitors	Decreased libido, anorgasmia
Antihypertensives	Clonidine, reserpine	Decreased libido
	Methyldopa	Decreased libido, amenorrhea
Antipsychotics	Chlorpromazine, perphenazine, prochlorperazine, thioridazine, trifluoperazine, haloperidol	Inhibition of ovulation (chlorpromazine only), menstrual irregularities, amenorrhea, change in libido
Beta blockers	Atenolol, labetalol hydrochloride, nadolol, propranolol hydrochloride, metoprolol	Decreased libido
Cardiac glycosides	Digoxin	Changes in cellular layer of vaginal walls in postmenopausal women
Corticosteroids	Dexamethasone, hydrocortisone, prednisone	Amenorrhea and menstrual irregularities
Cytotoxics	Busulfan	Amenorrhea with menopausal symptoms in premenopausal women, ovarian suppression, ovarian fibrosis and atrophy
	Chlorambucil	Amenorrhea
	Cyclophosphamide	Gonadal suppression (possibly irreversible), amenorrhea, ovarian fibrosis
	Methotrexate	Menstrual dysfunction, infertility
	Tamoxifen	Vaginal discharge or bleeding, menstrual irregularities, pruritus vulvae (intense itching of the female external genitalia)
Estrogens	Conjugated estrogens, esterified estrogens, estradiol, estrone, ethinyl estradiol	Altered menstrual flow, dysmenorrhea, amenorrhea, cervical erosion or abnormal secretions, enlargement of uterine fibromas, vaginal candidiasis
	Dienestrol	Vaginal discharge, uterine bleeding with excessive use
Progestins	Medroxyprogesterone acetate, norethindrone, norgestrel, progesterone	Breakthrough bleeding, dysmenorrhea, amenorrhea, cervical erosion, and abnormal secretions
Thyroid hormones	Levothyroxine, sodium, thyroid USP, and others	Menstrual irregularities with excessive doses
Miscellaneous	Lithium carbonate	Decreased libido
	L-tryptophan	Decreased libido
	Spironolactone	Menstrual irregularities, amenorrhea, possible polycystic ovarian syndrome

patient's health and guide discussion of the contraceptive choices available to her. Patients often come for care with a specific birth control method in mind. However, it is essential that the nurse explore the woman's knowledge and understanding of contraceptive choices, her motiva-

tions for using a method, and her level of commitment to use the method consistently. On occasion, the desired contraceptive method is contraindicated or associated with side effects that outweigh the personal benefits. Open, honest discussion where appropriate information

can be provided in a nonthreatening environment empowers the patient to make an informed choice of a birth control method that is best suited to her lifestyle (Fig. 6-1).

Across Care Settings: Enhancing contraceptive decision making

The choice of a contraceptive method usually rests with the individual, although certain types of birth control may not be the best fit for special populations. Methods that require planning ahead, visiting a restroom for insertion, or are considered “messy” may not be the best choice for adolescents. Combination hormonal methods may be contraindicated in women with a history of breast cancer or diabetes, and these patients need assistance in finding another method that safely suits their lifestyle and health needs. An essential nursing role centers on obtaining a comprehensive history and educating patients about options, special considerations, and side effects. Often the nurse enlists the assistance of other health professionals such as health educators, social workers, translators, and home health workers in teaching about contraception and in managing appropriate follow-up care.

EVALUATION

When obtaining contraception is the purpose of the reproductive health visit, an immediate evaluation may take place at the conclusion of the patient encounter. This evaluation centers on mutually agreed upon outcomes that reflect the patient’s understanding of, and comfort level with, the chosen method. Examples of possible outcomes are listed below.

The patient:

- Voices understanding about the selected contraceptive method.
- Voices an understanding of all information necessary to provide informed consent.
- Voices a comfort level with use of the contraceptive method selected.

Intermediate and long-term evaluation of outcomes is especially important in the area of contraceptive care because patients who discontinue use of a birth control

Figure 6-1 Teaching about contraception is an essential component of reproductive health care.

method are at risk for pregnancy. Ideally, patients should be reassessed within a few weeks after initiating a new method. At this time, appropriate outcomes may include the following.

The patient:

- Has used the contraceptive method correctly and consistently.
- Has experienced no adverse side effects from use of the contraceptive method.
- Voices continued satisfaction with the selected contraceptive method.
- Consistently uses the contraceptive method without pregnancy for the following year.

Toward Achieving the National Goals for Reproductive Life Planning

The *Healthy People 2010* national initiative includes a number of goals that directly address reproductive health (Box 6-2). Individuals and couples who seek assistance with this aspect of their lives may need counseling about fertility and methods of contraception. Seeking guidance and making decisions about contraception are prompted by a number of influences but generally center on a desire to take control over one’s reproductive life.

Nurses can be instrumental in helping the nation to achieve the objectives by assisting women who want to practice safe sex and providing effective contraception when they do not desire to be pregnant. Women of all ages are capable of responsible sexual behavior when given enough education, motivation, and opportunity. One of the challenges for nurses in the community concerns poor women who are unable to afford contraception as well as those with fertility problems who cannot afford special treatments to achieve pregnancy. Nurses must advocate for all women to ensure that reproductive care is available to all persons, regardless of socioeconomic status.

Box 6-2 *Healthy People 2010* National Goals Related to Reproductive Life Planning

Several of the National Health Goals are related to reproductive life planning. These include the following:

- Reduce the proportion of women experiencing pregnancy despite use of a reversible contraceptive method from a baseline of 13% to a target of 7%.
- Increase the proportion of pregnancies that are intended from a baseline of 51% to a target of 70%.
- Decrease the proportion of births occurring within 24 months of a previous birth from a baseline of 11% to a target of 6%.
- Increase the proportion of females at risk for unintended pregnancy (and their partners) who use contraception from a baseline of 93% to a target of 100%.
- Increase the number of health care providers who provide emergency contraception.
- Increase male involvement in pregnancy prevention and family planning efforts (new goal; baseline to be determined).

Source: Department of Health and Human Services (DHHS). (2000). *Healthy People 2010*. Washington, DC: DHHS.

Although the rate of unintended pregnancies in the United States has declined, the rate of unintentional pregnancy remains highest among young, less educated women with low income (American Medical Women's Association, 2005). These individuals, who may be less likely to afford birth control or reach a health care clinic, must be a major focus for education and support from nurses in the community. All women deserve holistic health care along with culturally, educationally, and developmentally appropriate information to empower them to make realistic decisions about reproductive life planning.

Providing Contraceptive Care: Methods of Contraception

MEDICATION-FREE CONTRACEPTION

- *Natural Family Planning* (NFP) is a contraceptive method that involves identifying the fertile time period and avoiding intercourse during that time every cycle. It is the only method of contraception acceptable to the Roman Catholic Church.
- *Fertility Awareness Methods* (FAMs) identify the fertile time during the cycle and use abstinence or other contraceptive methods during the fertile periods. These methods require motivation and considerable counseling to be used effectively. They may interfere with sexual spontaneity and require several months of symptom/cycle charting before they may be used effectively.

Effectiveness

The effectiveness in preventing pregnancy depends on the exact method used, but it is generally around 75% effective.

Optimizing Outcomes—When teaching about NFP and FAMs of contraception

The patient and her partner need to be fully committed to use these methods successfully. There are several variations: (1) the calendar, or rhythm method in which the fertile days are calculated; (2) the standard days method in which color-coded strung beads are used to track infertile days; (3) the cervical mucus method (also called the “ovulation detection method” or the “Billings method”) where the changes in cervical mucus are used to track fertile periods; (4) the basal body temperature (BBT) method in which body temperature changes are used to detect the fertile period (Fig. 6-2; Box 6-3); and the symptothermal method that combines the BBT and cervical mucus methods and involves recording various symptoms such as changes in cervical mucus, mittelschmerz (abdominal pain at midcycle), abdominal bloating, and the BBT to recognize signs of ovulation (Hatcher et al., 2005). The woman needs to realize that stress or illness can affect her cycle and cause a variation in the fertile days. These methods are not best suited for adolescents or couples who would be devastated by an unplanned pregnancy. Since the “natural” methods identify fertile periods, couples who are attempting to conceive may also wish to use them.

Ovulation predictor kits detect the surge in luteinizing hormone (LH) that occurs 24–36 hours before ovulation.

The kits vary in price and procedure but most are similar to home pregnancy tests and are performed on the woman's urine. Intercourse can then be timed to avoid or achieve pregnancy.

COITUS INTERRUPTUS

Coitus interruptus or the “withdrawal method” involves the man withdrawing his penis from the vagina before ejaculation. However, ejaculation may occur before withdrawal is complete and spermatozoa may be present in the pre-ejaculation fluid. Men with unpredictable or premature ejaculation have difficulty using this method successfully.

Effectiveness

The typical effectiveness rate for this method is about 71%.

LACTATIONAL AMENORRHEA METHOD (BREASTFEEDING)

Breastfeeding can be a form of contraception, although it is used more effectively in underdeveloped countries where mothers breastfeed their infants exclusively. Some lactating mothers may ovulate but not menstruate. It is difficult to determine when fertility is restored. This

Figure 6-2 A basal body temperature chart.

Box 6-3 Basal Body Temperature as an Indicator of Ovulation

During the preovulatory phase, the basal temperature is usually below 98°F (36.7°C). As ovulation approaches, estrogen production increases. At its peak, estrogen may cause a slight drop, then a rise, in the basal temperature. Before ovulation, a surge in luteinizing hormone (LH) stimulates the production of progesterone. The LH surge causes a 0.5°F–1°F (0.3°C–0.6°C) rise in the basal temperature. These changes in the basal temperature create the biphasic pattern consistent with ovulation. Progesterone, a thermogenic, or heat-producing hormone, maintains the temperature increase during the second half of the menstrual cycle. Although the temperature elevation does not predict the exact day of ovulation, it does provide evidence of ovulation about one day after it has occurred. Release of the ovum probably occurs 24–36 hours before the first temperature elevation.

method works best when the mother exclusively breast-feeds, has had no menstrual period since giving birth, and whose infant is younger than 6 months of age.

Effectiveness

When the above conditions are met, the effectiveness rate for this method is about 98% (Hatcher et al., 2005).

ABSTINENCE

Abstinence is the only contraceptive method with a 100% effectiveness rate. If a couple chooses to be **abstinent** (refrain from vaginal intercourse), intimacy and sexuality may be expressed in many other ways. Abstinence requires commitment and self-control, but success with this method can lead to increased self-esteem and enhanced communication about emotions and feelings. Abstinence can help adolescents learn negotiation skills (Hatcher et al., 2005).

BARRIER METHODS

Barrier methods are relatively inexpensive and some types can be used more than once. Although less effective than certain other forms of contraception, barrier methods have gained in popularity as a protective measure against the spread of STIs. If the woman is under 30 years of age, uses alcohol or recreational drugs, or has intercourse three or more times weekly, barrier methods are usually not as effective because of a decreased likelihood to use them consistently (Cates & Stewart, 2004).

Many women dislike barrier methods because they must be inserted or applied before intercourse. Most require a water-based lubricant and these should never be used with an oil-based lubricant (i.e., baby oil, petroleum jelly, vegetable oil) or vaginal yeast cream as these products cause latex deterioration. Barrier methods have few side effects, although latex allergy may lead to life-threatening anaphylaxis. There is evidence that consistent use of latex condoms reduces the rate of HIV transmission, and both condoms and diaphragms can reduce the risk of cervical STIs (Hatcher et al., 2005). Each of the barrier methods must be applied or inserted with clean hands. The key to success with these contraceptives is consistent and correct use, and the nurse must ensure that women know how to use their barrier method correctly and that they are satisfied with their choice.

Diaphragm

The **diaphragm** is a latex dome-shaped barrier device with a spring rim that resembles half a tennis ball. It is filled with spermicide and inserted up into the vagina to cover the cervix. Diaphragms are available in several sizes and types and must be fitted by a trained health care professional.

Use of the diaphragm requires some planning ahead, so this method may not be the best choice for adolescents. The diaphragm is inserted by the woman using her fingers or an inserter up to 6 hours before intercourse, and it must be filled with a spermicide applied inside and along the rim before insertion (Fig. 6-3). The diaphragm must remain in place for 6 hours after intercourse. If intercourse occurs again before 6 hours have elapsed, the diaphragm should be left undisturbed and another applicator-full of spermicide should be inserted into the vagina. The diaphragm should remain in place for 6 hours after the last act of intercourse. To ensure continued protection, the

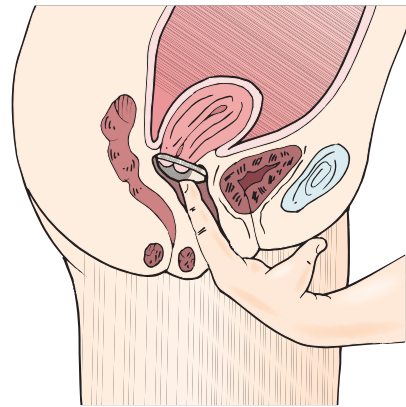

Figure 6-3 Diaphragm insertion.

diaphragm should be replaced every 2 years, and it may need to be refitted after weight loss or weight gain, term birth or second trimester abortion (Hatcher et al., 2005).

SIDE EFFECTS. Other than occasional allergic reactions to the diaphragm or spermicide, there are no side effects from a well-fitted device. There is an increased risk of urinary tract infections due to pressure of the diaphragm against the urethra, which may interfere with complete emptying of the bladder. Thus, women with a history of frequent urinary tract infections (UTIs) should avoid this method. The diaphragm should not be used during menses due to the risk of **toxic shock syndrome** (TSS), a rare, sometimes fatal disease caused by toxins produced by certain strains of the bacterium *Staphylococcus aureus*. Women with pelvic relaxation syndrome or a large cystocele are not suitable candidates for the diaphragm.

EFFECTIVENESS. The effectiveness in preventing pregnancy for typical use is 84% (Bachmann, 2007). For this reason, the diaphragm may not be the best choice for a woman who would consider pregnancy a disaster in her life or for a woman who feels uncomfortable touching her genital area. Since it is made of latex, the diaphragm is contraindicated in women with latex allergies.

Optimizing Outcomes— When teaching patients about use of the diaphragm

The diaphragm must be in the correct position for it to be comfortable and work effectively as a contraceptive. The patient should practice insertion and removal of the diaphragm before leaving the clinic, and be instructed to return with it in place for a recheck of proper fit 1 week later. Before each use, the diaphragm is carefully inspected for tears, holes, or damage. After removal, the device is cleaned with mild soap and water, dried thoroughly, and stored in its case in a cool place. Oil-based vaginal medications or lubricants should never be used with the diaphragm (Hatcher et al., 2005).

Cervical Cap

The **cervical cap** is a thimble-shaped latex device that fits firmly around the base of the cervix close to the junction of the cervix and vaginal fornices (Hatcher et al., 2005, Fig. 6-4). The device has a pliable rim and is available in

Figure 6-4 Cervical cap insertion.

four sizes. It is somewhat more difficult to use than the diaphragm because it must be placed exactly over the cervix where it is held in place by suction. The seal provides a physical barrier to sperm and the spermicide placed inside the cap provides a chemical barrier. Women who choose the cervical cap should practice insertion and removal after the fitting and return in 1 week with the cap inserted to check for proper placement.

Nursing Insight— When counseling patients about the cervical cap

Certain women are not suitable candidates for the cervical cap. Patients who have a history of toxic shock syndrome, pelvic inflammatory disease (PID), cervicitis, papillomavirus infection, a previous abnormal Pap smear or cervical cancer, and undiagnosed vaginal bleeding should choose another contraceptive method. Also, women who have an abnormally short or long cervix may not be able to use a cervical cap satisfactorily.

SIDE EFFECTS. There is evidence that the cervical cap can cause cervical irritation and erosion and it is not recommended for women who are at high risk for HIV (Hatcher et al., 2005). Because the device is made of latex, it is contraindicated in women with latex allergies. Since the cervical cap is associated with a high failure rate, women who choose this method should also be given emergency contraception pills.

EFFECTIVENESS. With typical use, the FemCap cervical cap is about 74% effective in preventing pregnancy (Trussell, 2004), so it may not be the best choice for the woman who would consider a pregnancy to be a disaster in her life. It is not as effective for contraception in women who have had a pregnancy (Bachmann, 2007). Since proper use of the cervical cap requires planning ahead and strong motivation, it may not be the best contraceptive method for adolescents.

Optimizing Outcomes— When teaching patients about use of the cervical cap

Before insertion, approximately one-third of the cap is filled with spermicide. Taking care not to spill the spermicide, the woman inserts the cap into the vagina and places it

directly over the cervix. The woman is taught to use her finger to trace around the rim of the cap to make certain the entire cervix is covered. The cervical cap can be inserted up to 6 hours before intercourse and should remain in place for 6 hours after the last intercourse. No additional spermicide is necessary with repeated intercourse. The cap should never remain in place longer than 48 hours and it should never be used during menses or when a vaginal infection is present. To remove the cap, the woman pushes against the rim with her finger to dislodge it from the cervix, gently hooks her finger over the rim and removes it. The cap is then washed with mild soap and water. The cap should be dried thoroughly and stored in a cool, dry place. Oil-based vaginal medications or lubricants should never be used with the cervical cap (Hatcher et al., 2005).

Be sure to— Inquire about latex allergy

Before dispensing diaphragms, cervical caps, or male condoms, ask all patients about a personal or partner history of allergy to latex. Use of latex contraceptive devices is contraindicated in patients with latex sensitivity.

Condoms

Condoms are generally considered to be a male contraceptive device although the female condom (vaginal sheath) is also available. Male condoms may be made of latex rubber, polyurethane, or natural membranes. Latex male condoms are widely recognized for their role in preventing HIV infection and sexually transmitted infections (STIs). Natural skin condoms do not offer protection against HIV and STIs because they contain small pores that may permit the passage of viruses including HIV, hepatitis B, and herpes simplex. Although previous recommendations included combining condom use with the spermicide nonoxynol-9, recent data suggest that the spermicidal coating does not provide additional protection from pregnancy or STIs (Nelson & Le, 2007). Also, frequent use of condoms coated with nonoxynol-9 may increase the transmission of HIV and can cause genital lesions (Centers for Disease Control and Prevention [CDC], 2007; Warner, Hatcher, & Steiner, 2004). Condoms are non-reusable and act as a mechanical barrier between the female and male genitalia.

MALE CONDOMS. Male condoms are one of the oldest known methods of contraception. When used correctly, male condoms are placed over the erect penis before any genital, oral, or anal contact. Condoms are inexpensive, require no prescription, and are available in a variety sizes, shapes, and colors. To prevent pregnancy and the spread of STIs, they must be used correctly at every act of intercourse.

SIDE EFFECTS. Condoms may cause an anaphylactic reaction in patients who are allergic to latex. Individuals with latex allergies must choose condoms made of other materials.

EFFECTIVENESS. With typical use, male condoms are about 85% effective in preventing pregnancy.

Optimizing Outcomes— When teaching patients about use of the male condom

It is important to choose and use the correct size of condom. The condom is rolled onto the erect penis and should fit snugly. The reservoir tip should be left unobstructed or extra space at the end (of a condom with no reservoir tip) should be provided for collection of the semen. Care must be taken not to tear the condom or spill its contents during removal. When possible, patients should practice placing a condom on a penile model to enhance understanding of the proper technique. Immediately after intercourse, the man should hold the condom at the base of the penis and withdraw the penis while still erect, then check the condom for the presence of tears after removal. Expiration dates should be checked often and out-of-date condoms discarded. Condoms should always be stored in a cool, dry place and latex condoms only used with water-based lubricants (Nelson & Le, 2007).

FEMALE CONDOMS. Made of polyurethane in a “one size fits all,” the female condom or vaginal sheath (Fig. 6-5) is less widely used than the male condom. The female condom resembles a sheath with a ring on each end: the closed end is inserted into the vagina and anchored around the cervix; the open end is placed at the vaginal introitus. Although no prescription is needed, female condoms are often difficult to find, and they are more expensive than male condoms. Because they contain no latex, female condoms are safe for use in individuals with latex allergies.

Optimizing Outcomes— When teaching patients about use of the female condom

Female condoms cannot be used at the same time as male condoms. The man must carefully direct his penis into the condom to keep from inserting it between the condom and the vaginal wall. The female condom can be used during oral sex. Some individuals complain that female condoms generate “noise” during intercourse, but lubricant seems to help alleviate this problem.

Figure 6-5 Insertion of a female condom.

Spermicides

Spermicides are available in the form of gels, creams, films, and suppositories. All are inserted into the vagina or used with diaphragms or cervical caps. Spermicidal condoms are no longer recommended for use. Spermicides act as chemical barriers that cause death of the spermatozoa before they can enter the cervix. Although spermicides can be messy, the lubrication afforded by the spermicide-based methods may improve sexual satisfaction for both partners.

Women who are at risk for HIV should not use spermicides as their only method of birth control (Hatcher et al., 2005). Since spermicidal suppositories and films require 15 minutes to become effective, women who feel they cannot comply with this time constraint may wish to use a spermicidal foam, cream, or gel instead. Because of the low effectiveness rates associated with spermicides, the woman who believes that pregnancy would be personally disastrous may wish to choose another contraceptive method.

SIDE EFFECTS. Spermicides should not be used in women with acute cervicitis because of the potential for further cervical irritation. Rarely, topical irritation may develop from contact with spermicides. When this occurs, the product should be discontinued and another contraceptive method selected.

EFFECTIVENESS. The typical use effectiveness of spermicides in preventing pregnancy is 71%.

Optimizing Outcomes— When teaching patients about the use of spermicides

The woman should wash her hands before inserting any spermicide. Spermicides are most effective when used with a diaphragm or cervical cap. Most contraceptive films and suppositories require a period of 15 minutes to elapse after insertion to become effective and they should be inserted no longer than one hour before intercourse. The spermicide should be inserted deep into the vagina so that it makes contact with the cervix. Although douching is never recommended, it should be avoided for 6 hours after intercourse to avoid washing the spermicide away (Hatcher et al., 2004). Douching in and of itself is not a reliable form of birth control.

Contraceptive Sponge

The contraceptive sponge was recently returned to the U.S. market. It is a soft, round disposable polyurethane device that fits over the cervix (one size fits all). The sponge is permeated with the spermicide nonoxynol-9. One side is concave to enhance fit over the cervix; the other side contains a woven polyester loop to facilitate removal.

SIDE EFFECTS. The contraceptive sponge is contraindicated in women who are allergic to the spermicide nonoxynol-9. The sponge should not be left in place for more than 30 hours (which includes the 6-hour waiting period after the last act of intercourse) due to the risk of toxic shock syndrome. It should not be used during menstruation or immediately after abortion or childbirth or if a woman has a history of toxic shock syndrome.

EFFECTIVENESS. The typical use effectiveness of the contraceptive sponge in preventing pregnancy is 84% to 87%.

Optimizing Outcomes— When teaching patients about use of the contraceptive sponge

The patient should wash her hands before inserting the sponge. The sponge is moistened thoroughly with tap water and inserted into the vagina prior to intercourse. It provides up to 24 hours of protection for repeated sexual intercourse. The sponge must remain in the vagina for at least 6 hours after the last act of intercourse. The contraceptive sponge offers no protection against STIs or HIV.

Be sure to— Teach about toxic shock syndrome

Women who use the diaphragm, cervical cap, or contraceptive sponge should be aware of the possible association between these devices and toxic shock syndrome (TSS). Common signs of TSS include fever of sudden onset greater than 101.1°F (38.4°C), rash, and hypotension with a systolic blood pressure less than 90 mm Hg.

HORMONAL METHODS

Hormonal contraceptive methods include oral medications, the transdermal patch, the vaginal ring, long-acting injectables, the subdermal implant, and the progestin-releasing intrauterine device. Estrogen and progestins decrease the pituitary's release of follicle-stimulating hormone and luteinizing hormone to prevent ovulation. Progestins also thicken cervical mucus to prevent sperm penetration.

Oral Contraceptives

This method, known as “the pill,” or oral contraceptive pill (OCP), has been available for more than 40 years. Throughout that time, the dose of estrogen has significantly decreased and newer generation progestins have become safer with fewer side effects. It was once recommended that patients occasionally “take a break” from the pill because of the high hormonal dosages they contained. With today's formulations however, patients can continue to take oral contraceptives into the perimenopausal years. Oral contraceptives are the most extensively studied medications in history (Hatcher, 2004).

Hormonal contraceptives contain estrogen in the form of ethinyl estradiol or mestranol; ethinyl estradiol is the most common estrogen used. Estrogens work by preventing the release of follicle-stimulating hormone (FSH) from the anterior pituitary. When FSH levels are kept low, the ovarian follicle is unable to form and ovulation is prevented (Rice & Thompson, 2006).

Progestins provide effective contraception when used alone or in combination with estrogen. When combined with an estrogen, progestins inhibit the luteinizing hormone (LH) surge, which is required for ovulation. When used alone, progestins are believed to inhibit ovulation inconsistently. Progestin-only contraceptives are thought to func-

tion primarily by creating a thickened cervical mucus (which produces a hostile environment for sperm penetration) and by causing endometrial atrophy. These alterations inhibit egg implantation and decrease the penetration of sperm and ovum transport (Rice & Thompson, 2006).

In the United States, oral contraceptives are available in monophasic, biphasic, and triphasic preparations. Monophasic formulas provide fixed doses of estrogen and progestin throughout a 21-day cycle. Biphasic preparations provide a constant amount of estrogen throughout the cycle but there is an increased amount of progestin during the last 11 days. Triphasic formulas, designed to more closely mimic a natural cycle, provide varied levels of estrogen and progestin throughout the cycle. Triphasic preparations reduce the incidence of breakthrough bleeding (bleeding that occurs outside of menstruation) in many women.

Women who wish to use oral contraceptives are examined before the medication is prescribed and then yearly thereafter. The mandatory examination includes a history, weight, blood pressure, general physical and pelvic examination, and Pap smear. Most providers schedule women for a return visit approximately 3 months after initiating the medication to confirm patient acceptance and correct use of the method and to detect any complications.

Optimizing Outcomes— Counseling about medications that decrease the effectiveness of oral contraceptives

It is essential for the nurse to take a thorough history on any patient who wishes to use oral contraceptives for birth control. Certain medications such as rifampin (Rifadin, Rimactane), isoniazid, barbiturates, and griseofulvin (Fulvicin-U/F, Gris-PEG, Grifulvin V) can decrease the effectiveness of oral contraceptives, and higher doses of estrogen must be used. Vomiting and diarrhea affect the absorption of oral contraceptives, thus patients who experience these symptoms should use a back-up method such as condoms. Recent research indicates that antibiotics do not affect the effectiveness of oral contraceptives (Hatcher et al., 2005). Interactions with certain drugs such as acetaminophen, anticoagulants, and some anticonvulsants (e.g., phenytoin sodium, carbamazepine, primidone, topiramate), may reduce efficacy of the OCP.

Many noncontraceptive benefits are associated with OCPs (Box 6-4). Perimenopausal women who do not smoke, who maintain a normal blood pressure and who have a normal well-woman annual exam can safely use oral contraceptives. Oral contraceptives can moderate the irregular bleeding that often occurs during the perimenopausal period and provide contraception as well. When used on an extended cycle basis, hot flashes and vaginal dryness may also be alleviated (Clark & Burkman, 2006). The onset of menopause in women who use hormonal contraception may be difficult to detect.

CONTRAINDICATIONS. There are several absolute and relative contraindications to the use of combined oral contraceptive pills and the nurse must be fully aware of

Box 6-4 Noncontraceptive Benefits of Oral Contraceptive Pills

Oral contraceptive pills are associated with a decreased incidence of:

- Fibrocystic breast disease
- Iron-deficiency anemia, due to a reduced amount of menstrual flow
- Colorectal, endometrial, and ovarian cancer and the formation of ovarian cysts
- Mittelschmerz and dysmenorrhea, due to the lack of ovulation
- Premenstrual dysphoric syndrome, due to increased progesterone levels
- Acute pelvic inflammatory disease (PID) and scarring of the fallopian tubes
- Ectopic pregnancy
- Osteopenia and osteoporosis

them. Relative contraindications include hypertension, migraine headaches, epilepsy, obstructive jaundice in pregnancy, gallbladder disease, surgery with prolonged immobilization, and sickle cell disease (Rice & Thompson, 2006).

SIDE EFFECTS. A number of unpleasant and often troublesome side effects may accompany OCP use, especially during the first 3 months after initiation of the method. Nurses should teach patients that they might experience scanty periods, bleeding between periods (breakthrough bleeding), nausea, breast tenderness, headaches, and cyclic weight gain from fluid retention. If patients understand that these side effects may occur, they are more likely to seek health care provider advice before arbitrarily discontinuing use of the OCP. The symptoms often subside after a few months of use or they may be diminished with a change in routine or in the brand of contraceptive.

EFFECTIVENESS. The typical user effectiveness of combined oral contraceptives is 95% (Family Health International, 2006).

Optimizing Outcomes— When teaching patients about use of oral contraceptive pills

The woman should identify a convenient and obvious place to keep her pills so that she will remember to take one every day. Ovulation suppressants work only when they are taken consistently and conscientiously. OCPs are not effective for the first 7 days, so a second form of contraception should be used during the first 7 days that the initial package of pills is taken. OCPs should be taken at approximately the same time each day. Many OCPs are available. Most are taken daily for 21 days, beginning on the Sunday after the first day of the menstrual cycle. Withdrawal bleeding usually occurs within 1–4 days after the last pill is taken. This schedule was developed on the assumption that women would desire to have monthly periods (Dominguez, Moore, & Wysocki, 2005). Seven days after taking the last pill, the woman begins a new package (she always begins a new pack on the same day). Some OCP packages contain seven inert or iron pills during the fourth week so that the woman never stops taking a pill. In addition to the nurse's verbal

instructions, it is imperative that all women receive written information to take home with them and encouraged to call if they have questions or experience any problems. Oral contraceptive pills offer no protection against STIs or HIV.

critical nursing action Recognizing Contraindications to Oral Contraceptive Use

When counseling patients about oral contraceptive pills, the nurse must be aware of the following *absolute* contraindications to use:

- Smoking and age greater than 35 years
- Moderate to severe hypertension (BP 160/100)
- Undiagnosed uterine bleeding
- Diabetes of more than 20 years' duration or with vascular complications
- History of pulmonary embolism or deep venous thrombosis
- Ischemic heart disease or stroke
- Severe migraine headaches
- Known or suspected breast cancer
- Marked liver function impairment
- Pregnancy
- Major immobilizing surgery within the past month
- Cholecystitis

A major emphasis in patient teaching concerns warning signs that must be immediately reported to the health care provider. The acronym “ACHES” can prompt the health care provider and patient to remember the warning signs. “ACHES” uses the first letter of each sign of cardiovascular, liver, gallbladder, or thromboembolic complications that are side effects of estrogen use and can be life-threatening. If patients experience any of these signs, they must stop taking the pill and promptly contact the health care provider. In addition to the “ACHES” signs, patients who become depressed or jaundiced, or who develop a breast lump should notify their health care provider.

Be sure to— Teach the patient taking oral contraceptives to report ACHES

- Abdominal pain (problem with liver or gall bladder)
- Chest pain or shortness of breath (blood clot in lungs or heart)
- Headaches: Sudden or persistent (hypertension, cardiovascular accident)
- Eye problems (hypertension, vascular accident)
- Severe leg pain (thromboembolism)

Nursing Insight— Postponing initiation of OCPs in adolescents

Adolescent girls should have well-established menstrual cycles before beginning OCPs. Waiting until 2 years of monthly cycles have occurred reduces the chance that the oral contraceptive will cause permanent suppression of the pituitary-regulating center. In addition, estrogen prompts closure of the long bone epiphyses; postponing initiation of OCPs ensures that the preadolescent growth spurt will not be prematurely halted.

Low-Dose Progestin-Only Contraceptive Pills

Low-dose progestin-only contraceptive pills are often referred to as the “mini pill” because they contain no estrogen. Although ovulation may occur, the progestins cause thickening of the cervical mucus and endometrial atrophy. These changes inhibit implantation and decrease the penetration of sperm and ovum transport (Rice & Thompson, 2006). The minipill is used primarily by women who have a contraindication to the estrogen component of the combination OCP. It must be taken at the same time every day. The minipill may be used during breastfeeding because it does not interfere with milk production.

SIDE EFFECTS. Irregular menses frequently occur with the progestin-only pills. Also, this type of oral contraceptive may be associated with an increased number of persistent ovarian follicles (Hatcher et al., 2005). Women with a history of functional ovarian cysts, a history of ectopic pregnancy or those with unexplained vaginal bleeding should not take the progestin-only oral contraceptive pills.

EFFECTIVENESS. The progestin-only contraceptive pills are 92% effective in preventing pregnancy (Hatcher et al., 2005).

case study Young Woman Who Believes She Is Infertile

Jana, who is 16 years old, arrives at the family planning clinic with her 17-year-old girlfriend who has brought her in for a “check up.” During the health history, she tells the nurse that she believes she cannot have children. She confides that she has been having occasional unprotected sex with different boyfriends for the past year, and has never gotten pregnant. But she believes she should use “something,” just in case.

1. What are the major teaching needs for Jana?
2. The nurse determines that this will be Jana’s first gynecological examination. What are some teaching needs and strategies?
3. In addition to specific instruction about the prescribed oral contraceptive, what other information should be emphasized?

◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

Transdermal Contraceptive Patch

The transdermal contraceptive patch is applied to the abdomen, buttock, upper outer arm, or upper torso once weekly for 3 weeks, followed by one patch-free week. It should not be placed on the breasts. During the patch-free week, withdrawal bleeding occurs. The patch delivers low levels of estrogen and a progestin (norelgestromin) that are readily absorbed into the skin on a daily basis. The contraceptive patch costs slightly more than combined oral contraceptive pills.

SIDE EFFECTS. The side effects and contraindications and warning signs for the patch are the same as for the oral contraceptive pills. However, the patch exposes patients to higher steady-state concentrations and lower peak concen-

trations of ethinyl estradiol (the estrogen component). There is a potential for increased adverse events in women using the patch (Rice & Thompson, 2006).

EFFECTIVENESS. The patch is about 99% effective in preventing pregnancy. Due to concerns that excessive adipose tissue may be associated with inconsistent levels of hormonal absorption, it is not recommended for women who weigh more than 198 pounds. In general, patient compliance is enhanced because of the once-weekly administration (Potts & Lobo, 2005).

Optimizing Outcomes—When teaching patients about use of the transdermal contraceptive patch

The patch can cause skin irritation, particularly if it is placed on damp skin or in the same location every time. Thus, rotating the application site is recommended. Hypopigmentation at the site of the patch placement has been reported (Hatcher et al., 2005). Some women have complained that the patch adhesive catches fibers from their clothing; placing the patch on the buttock under the underpants may be desirable. Bathing and swimming should not interfere with the patch. If the patch becomes detached for more than 24 hours, a new one should be applied and another form of contraception used for the following 7 days (Burki, 2005). The transdermal contraceptive patch offers no protection against STIs or HIV.

Vaginal Contraceptive Ring

The vaginal contraceptive ring contains estrogen and etonogestrel, a progestin. It is a flexible ring that is inserted deep into the vagina by the fifth day of the menstrual cycle, and left in place for 3 weeks. It is removed during the fourth week to allow withdrawal bleeding and a new ring is inserted at approximately the same time of day that the old ring was removed.

SIDE EFFECTS. The vaginal contraceptive ring is associated with a higher incidence of vaginitis, vaginal discomfort, and vaginal infections when compared to other forms of hormonal contraception. It is not recommended for patients with cystocele, rectocele, or uterine prolapse (Rice & Thompson, 2006).

EFFECTIVENESS. The ring slowly releases estrogen and progestin. Its effectiveness in preventing pregnancy is about 98% (Rice & Thompson, 2006).

Optimizing Outcomes—When teaching patients about use of the vaginal contraceptive ring

The contraceptive ring should not be removed before, during, or after intercourse. The patient should not douche. If the contraceptive ring comes out of the vagina, it should be washed with plain hand soap and warm water before reinsertion. If the woman has a supply of more than four rings, they should be stored in the refrigerator (Hatcher et al., 2005). Before discarding a used contraceptive ring, the patient should take care to protect the environment by sealing the used ring in a closed plastic bag. If the ring is removed for more than 3 hours, it should be reinserted and

another method of contraception should be used for the following 7 days (Burki, 2005). Unopened vaginal rings must be protected from sunlight and high temperatures. The vaginal contraceptive ring offers no protection against STIs or HIV.

Emergency Postcoital Contraception

Emergency contraception (EC) is available to women whose birth control methods fail or who have been the victims of sexual assault. Two forms of emergency postcoital contraception are available: hormonal methods, which include estrogen and progestin or progestin-only oral contraceptive pills; and the insertion of a copper releasing intrauterine device (IUD). Emergency contraception is available by prescription, office visit or, in some states, over the counter.

HORMONAL METHOD. Often referred-to as “the morning after pill,” or the “emergency contraceptive pill” (ECP), there are two FDA-approved OC products specifically packaged for emergency contraception. Preven is a kit that contains four combination estrogen/progestin tablets and a pregnancy test. Plan B contains two progestin-only tablets. The hormonal preparations are most effective when taken as soon as possible after unprotected intercourse. The first dose should be taken within 72 hours (after intercourse); the second dose 12 hours later. Nausea and vomiting is a common side effect with both products and may be minimized by taking an antiemetic 1 hour before the first EC dose (Burki, 2005; Lever, 2005). Although regular OCPs can be taken for emergency contraception, the dose varies with the brand and may require taking a large number of tablets. The risk of pregnancy is reduced by 75% after completion of the EC dose.

IUD METHOD. The copper IUD can be inserted within 5 days of unprotected intercourse. Because of the product’s cost and the need for insertion by a trained professional, the IUD is used less frequently than the ECPs. The IUD is not recommended for women who have been raped or are at risk for STIs and pelvic infections (Burki, 2005).

SIDE EFFECTS. Fewer side effects are associated with oral emergency contraceptive pills than with continuous oral contraceptives. Side effects include nausea and vomiting and bleeding within a few days after administration. The side effects for the IUD are the same whether it is being used as an emergency contraception method or as a long-term contraceptive. (See later discussion in this chapter.)

EFFECTIVENESS. Emergency contraceptive pills are 98.9% effective in preventing pregnancy if used correctly and the IUD is 99% to 100% effective (Hatcher et al., 2005).

Optimizing Outcomes— When teaching patients about postcoital emergency contraception

Emergency contraception in either form (pills or IUD) does not cause abortion although it is often confused with the medical abortion procedure. The high hormone levels in the oral contraceptive pills prevent or delay ovulation,

thicken cervical mucus, alter sperm transport to prevent fertilization, and interfere with normal endometrial development. Emergency contraception is ineffective if implantation has already occurred and it does not harm a developing embryo (Smith, 2007).

The IUD is suitable for women who wish to have the benefit of long-term contraception. Insertion of the IUD within 5 days after intercourse causes an alteration in the endometrium to prevent implantation. Patients should contact their health care providers if no period occurs within 3 weeks after insertion (Lever, 2005). Emergency contraception offers no protection against STIs or HIV.

INJECTABLE HORMONAL CONTRACEPTIVE METHODS

Depo-Provera (DMPA), Depo-SubQ Provera 104 (Depot Medroxyprogesterone)

Depo-Provera (medroxyprogesterone acetate) is a progestin-only long-term contraceptive. Its effects last about 3 months, and it is injected either intramuscularly (150 mg) or subcutaneously (104 mg). The first injection should be given within the first 5 days of menstruation to ensure the patient is not pregnant. Medroxyprogesterone 150 mg is injected into the deltoid or gluteal muscle and functions by suppressing ovulation and altering the cervical environment (Rice & Thompson, 2006). The administration site should not be massaged after injection, as it may reduce the effectiveness of DMPA.

Depo-SubQProvera 104 was the first subcutaneous hormonal contraceptive product available. It is administered into the anterior thigh or the abdomen and functions by preventing ovulation and producing thinning of the endometrium. On average, ovulation is restored within 10 months after discontinuation of the medication (both dosages).

SIDE EFFECTS. Irregular bleeding is the most common side effect of Depo-Provera. Most women who use this method experience spotting during the first few months, usually until the second injection. Amenorrhea often occurs after about 6 months of use. Other side effects include weight gain, depression, headache, and breast tenderness. Although Depo-Provera may reduce bone mineral density, the subcutaneous injectable form may not be associated with a loss in bone density (Hatcher et al., 2005).

EFFECTIVENESS. The typical effectiveness for the 150-mg intramuscular dose of Depo-Provera is 98% to 99%. The typical effectiveness rate of the subcutaneous 104-mg Depo-Provera injection appears to be greater than 99% (Hatcher et al., 2005).

Optimizing Outcomes— When teaching patients about injectable hormonal contraception

Women who desire pregnancy within the next year may wish to choose another contraceptive method that is more easily reversible. Depo-Provera is associated with weight gain and a reduction in bone mineral density. Patients who use DMPA should include adequate calcium in their diet

(1200 mg/day) and perform daily weight-bearing exercise to enhance bone density maintenance and to offset weight gain. Clinic visits must be scheduled every 3 months for the contraceptive injection. Providing a reminder card that includes the date of the next injection is helpful, and some women set their PDA calendars or cell phones to alarm on the date. Since DMPA is injected, it cannot be reversed or stopped abruptly. Women who wish to hide their use of contraception from a partner or others may find this method to be particularly appealing. Because it contains no estrogen, DMPA can be safely given to breastfeeding mothers. Injectable hormonal contraception offers no protection against STIs or HIV.

where research and practice meet: Detrimental Effects of Depo-Provera on Bone Mineral Density in Adolescents

Findings from a 2005 prospective cohort trial established that adolescents are at increased risk for detrimental effects of Depo-Provera on bone mineral density (BMD). Study participants included 14- to 18-year-old women, in whom bone density is expected to increase due to continued bone growth and development. Those who used Depo-Provera experienced significant losses in bone mineral density at both the hip and spine in comparison to participants not using Depo-Provera, whose bone mineral density increased. After discontinuation of Depo-Provera, BMD significantly improved (Scholes et al., 2005). These findings suggest that the adverse effect is reversible in adolescents if therapy is withdrawn. Recommendations from professional organizations including the American College of Obstetricians and Gynecologists (ACOG), the Society for Adolescent Medicine (SAM), and the World Health Organization (WHO) state that for the majority of adolescents, the benefits of DMPA use outweigh the potential risks (Arias, Kaunitz, & McClung, 2007). During contraceptive counseling, nurses must empower young patients with information about decreased bone mineral density and Depo-Provera and assist them in making appropriate contraceptive choices (Rice & Thompson, 2006).

SUBDERMAL HORMONAL IMPLANT

Implanon

Implanon is a subdermal contraceptive that is effective for 3 years. The single-rod implant, which is inserted on the inner side of the woman's upper arm, contains etonogestrel (ENG), a progestin. It is simpler to insert and remove than the previously available six-capsule levonorgestrel implant (Norplant) (Schulman, 2007). Implanon functions to prevent pregnancy by suppressing ovulation and by creating a thickened cervical mucus that hinders sperm penetration. Etonogestrel is metabolized by the liver. Hepatic-enzyme inducers, including certain antiepileptic agents, may interfere with absorption and contraceptive effectiveness (*Clinician Reviews*, 2006; Darney & Mishell, 2006).

SIDE EFFECTS. Bleeding irregularities frequently occur during the first several months after insertion; amenorrhea becomes more common with increasing duration of use. Other symptoms include emotional lability,

weight increase, headache, depression, dysmenorrhea, and acne.

EFFECTIVENESS. Effectiveness rates approach 100%.

Optimizing Outcomes— When teaching patients about the contraceptive implant

The Implanon contraceptive is appropriate for women who desire long-term reversible contraception and who have no objections to the insertion/removal procedures or to palpating the implant when it is in place. It must be removed and replaced every 3 years if continued contraception is desired. After removal, ovulation occurs within 3 to 6 weeks. Contraceptive efficacy in obese women (>130% of ideal body weight) has not been studied (Darney & Mishell, 2006). The contraceptive implant offers no protection against STIs or HIV.

INTRAUTERINE DEVICES

The intrauterine device (IUD) is a small plastic device that is inserted into the uterus and left in place for an extended period of time, providing continuous contraception. The exact mechanism of action is not fully understood although it is believed that the IUD causes a sterile inflammatory response that results in a spermicidal intrauterine environment. Few sperm are able to reach the fallopian tubes and if fertilization does occur, the intrauterine environment is unfavorable for implantation (Epsey, 2005).

Two types of intrauterine devices (IUDs) are currently available in the United States: the levonorgestrel-releasing intrauterine system (LNG-IUS) (Mirena), which releases a progestin, and the copper T380A (ParaGard) (Fig. 6-6). The Dalkon Shield IUD was removed from the market in the 1970s due to pelvic infections associated with it. Today's IUD manufacturers have corrected the design problem that accompanied the Dalkon Shield, and IUDs are once again safe to use.

LNG-IUS (Mirena) slowly releases a small amount of levonorgestrel, a progestin, on a constant basis. It must be replaced every 5 years. The ParaGard IUD has copper wire

Figure 6-6 Intrauterine device (IUD) properly positioned in the uterus.

wrapped around it and this device may remain in place for 10 years. Both types of IUDs are shaped like the letter “T.” They are inserted in a collapsed position and then expand into shape in the uterus once the inserter is withdrawn. The IUD is contained wholly within the uterus and the attached plastic string, or “tail,” extends through the cervix and into the vagina. Both are impregnated with barium sulfate for radiopacity. The IUD is inserted during menses to ensure that pregnancy has not occurred; it may also be inserted immediately after childbirth or first trimester abortion (Clark & Arias, 2007; Hatcher et al., 2005).

Once in place, the IUD has several advantages over other methods of contraception. There is no continued expense, no daily attention is required and the device does not interfere with sexual enjoyment. The IUD may decrease the incidence of endometrial cancer. The IUD is appropriate for women who are at risk for developing complications related to OCPs or who desire to avoid the systemic effects of hormonal preparations. When pregnancy is desired, the IUD is removed by the health care provider.

SIDE EFFECTS. Irregular bleeding and/or spotting may occur about 3 months following insertion. The Mirena IUD may produce amenorrhea (Rice & Thompson, 2006). Pelvic infections may occur and the likelihood of occurrence is greatest during the first month after insertion (Epsey, 2005). Contraindications to IUDs include pregnancy, current sexually transmitted diseases, abnormal vaginal bleeding, cancer of the genital tract, known uterine anomalies or fibroid tumors (which may make insertion difficult), or allergy to any of the IUD components.

EFFECTIVENESS. Both types of IUDs have a failure rate of 1% to 2% (Hatcher et al., 2005).

Optimizing Outcomes— When teaching patients about the IUD

The IUD should be considered a long-term form of contraception—it is relatively expensive if used for only a short period of time. Sharp cramping may occur at the time of insertion. The IUD offers no protection against STIs or HIV. Women who use the IUD may experience irregular bleeding, **menorrhagia** (heavy menstrual flow), or dysmenorrhea (painful menstruation) for several months following insertion. The progestin releasing IUD can decrease menstrual bleeding and dysmenorrhea; the copper-bearing IUD can increase menstrual flow and cramping (Clark & Arias, 2007). Women who become pregnant using the IUD are more likely to have an ectopic pregnancy or spontaneous abortion. All IUD patients must understand warning signs (“PAINS”) that may indicate infection or ectopic pregnancy. A vaginal “string check” should be performed each month to ensure that the IUD remains in place. If the strings are not felt or if they seem to be longer or shorter than they were previously, the woman should return to her health care provider for evaluation. If pregnancy occurs with the IUD in place, the device is usually removed vaginally to decrease the possibility of infection or spontaneous abortion. IUD users should obtain a yearly pelvic examination and Pap smear.

critical nursing action Teach “PAINS” Warning Signs to IUD Users

Period late (pregnancy)
Abdominal pain, pain with intercourse (infection)
Infection exposure or vaginal discharge
Not feeling well, fever, or chills (infection)
String missing, shorter or longer (IUD expelled)

Optimizing Outcomes— With the IUD as a contraceptive choice

Appropriate candidates for intrauterine contraception include nulliparas; women with previous ectopic pregnancies; women receiving treatment for pelvic inflammatory disease; lactating women; women testing positive for human immunodeficiency virus; and women immediately postpartum or postabortion (World Health Organization, 2004). Before insertion, patients should have a negative pregnancy test, treatment for dysplasia if present, cervical cultures to rule out STIs and a consent form that has been signed.

STERILIZATION

Sterilization should be considered a permanent and irreversible form of birth control. Although both the male and female procedures are theoretically reversible, the permanency of the method should be emphasized. An essential nursing role centers on counseling to empower the couple to make an informed decision. The nurse must also ensure that informed consent documentation has been obtained and is attached to the patient’s chart.

Female Sterilization

Bilateral tubal ligation (BTL) or “tying the tubes” causes interruption in the patency of the fallopian tubes. This permanent birth control method is most easily performed during cesarean birth or in the first 48 hours following a vaginal birth because at this time, the uterine fundus is located near the umbilicus and the fallopian tubes are immediately below the abdominal wall. At other times, the procedure is performed in an outpatient surgery clinic, usually under general anesthesia.

Tubal ligation may be accomplished in various ways. In the postpartum period, a minilaparotomy incision is made near the umbilicus or just above the symphysis pubis at other times. The fallopian tubes are brought through the incision and a small segment is removed. The remaining ends are cauterized or tied, or both. Another method of tubal ligation is accomplished with a laparoscope. The surgeon locates the fallopian tubes and obstructs them with clips or rings or destroys a portion of them with electrocoagulation.

A nonincisional method, called a hysteroscopic tubal ligation, is also available. This procedure is performed in the physician’s office or as an outpatient procedure with a local anesthetic to the cervix. Microinserts are placed into the openings of the fallopian tubes. During the following months, scar tissue grows into the inserts, causing tubal

blockage. A **hysterosalpingogram** (dye test to evaluate tubal patency) is performed at 3 months to ensure that both tubes have been blocked. Patients are instructed to use an alternate form of contraception until bilateral tubal blockage has been confirmed (Holloway, Moredich, & Aduddell, 2006).

SIDE EFFECTS. As with any surgery, complications include infection, hemorrhage and blood vessel injury, damage to adjacent organs, and complications from anesthesia (Hatcher et al., 2005; Holloway et al., 2006).

EFFECTIVENESS. The effectiveness depends on the type of procedure used and ranges from 96.3% with the clip procedure to better than 99% with the postpartum procedure (Hatcher et al., 2005).

Male Sterilization

Vasectomy is a surgical procedure that involves a small incision in the scrotum. The vas deferens is cauterized, clipped, or cut to interrupt the passage of sperm into the seminal fluid. Following vasectomy, the semen no longer contains sperm. Vasectomy should be considered a permanent method.

SIDE EFFECTS. Complications following vasectomy include infection, hematoma, and excessive pain and swelling.

EFFECTIVENESS. Vasectomy is greater than 99% effective in preventing pregnancy.

Optimizing Outcomes— When teaching patients about permanent sterilization

There is a high rate of ectopic pregnancies in tubal ligation procedures that fail. BTL has been found to decrease the risk of ovarian cancer and ovarian cancer mortality (Schulman & Westhoff, 2006). Menstruation and menopause are unaffected. After vasectomy, the man should rest, apply ice to the scrotum, and wear snug underwear for scrotal support. Complete sterilization has not occurred until all sperm have left the system. This process may take several weeks. The man will need to submit semen specimens for analysis until two specimens show no sperm present; he should also plan to have periodic sperm counts every few years (Hatcher et al., 2005). Permanent sterilization methods offer no protection against STIs or HIV.

Now Can You— Teach about contraception?

1. Explain what is meant by “natural family planning”?
2. Compare and contrast barrier and hormonal methods of contraception?
3. Identify five danger signs associated with OCPs and intrauterine devices?

Clinical Termination of Pregnancy

A clinical termination of pregnancy, or abortion, is a procedure performed to deliberately end a pregnancy before the fetus reaches a viable age. The legal definition of

viability (usually 20 to 24 weeks) varies from state to state. Abortion has been legal in the United States since the 1973 Supreme Court decision in *Roe v. Wade*.

An abortion performed at the patient’s request is termed an **elective abortion**; when performed for reasons of maternal or fetal health or disease, the term **therapeutic abortion** applies. Abortions performed during the first trimester are technically easier and safer than abortions performed during the second trimester. Methods for performing early elective abortion include vacuum aspiration and medical methods. Second-trimester abortion is associated with increased complications and costs and involves cervical dilation and removal of the fetus and placenta.

NURSING CARE RELATED TO ELECTIVE PREGNANCY TERMINATION

Holistic nursing care for women who are considering abortion includes guidance for pregnancy testing, ultrasonography to accurately determine the weeks of gestation, and individualized counseling about the available options. Any woman who is unsure of her decision deserves emotional support and time to allow her to make the choice that she feels is the appropriate one for her. The decision for nearly every woman is difficult and complicated. Once a decision has been made for an abortion, a medical history and physical examination with appropriate screening tests (e.g., complete blood count [CBC], blood typing and Rh, gonococcal smear, serological test for syphilis (STS), urinalysis, and Pap smear) are obtained. Informed consent documents are signed and placed on the patient’s chart. The nurse counsels the patient about potential complications such as excessive bleeding and infection, reinforces information about follow-up visits, and offers strategies for self-care. The nurse must ensure that the patient understands how to contact a health care provider if needed. Women who are Rh₀D-negative should receive Rh₀(D) immune globulin (RhoGAM) if they do not have a preexisting sensitivity to Rh-positive blood. Since fertility returns quickly after a pregnancy termination, the nurse should also provide information about contraception.

SURGICAL TERMINATION OF PREGNANCY

Vacuum Aspiration

Vacuum aspiration is the most common method for surgical abortion for pregnancies up to 12 weeks’ gestation. Very early (5 to 7 weeks after the LMP) procedures, called menstrual extraction and endometrial aspiration, can be done with a small flexible plastic cannula with no cervical dilation or anesthesia. **Laminaria**, dried seaweed that swells as it absorbs moisture and mechanically dilates the cervix, may be inserted 4 to 24 hours before the pregnancy termination. Upon removal, the cervix has usually dilated two to three times its original diameter and further instrumental dilation is unnecessary.

Abortions performed between 8 and 12 weeks’ gestation require mechanical cervical dilation after injection of a local anesthetic. A plastic cannula is then inserted into the uterine cavity. The contents are aspirated with negative pressure and the uterine cavity is often scraped with

a curet to ensure that the uterus is empty. Patients may experience cramping for 20 to 30 minutes following the procedure. Complications include uterine perforation, cervical lacerations, hemorrhage, infection, and adverse reactions to the anesthetic agent.

Abortion during the second trimester involves cervical dilation with removal of the fetus and placenta. This procedure is termed “dilation and evacuation” (D & E). Similar to vacuum curettage, greater cervical dilation and use of a larger cannula are required because of the increased volume in the products of conception. Laminaria are inserted 24 hours before the procedure to dilate the cervix. D & E may be associated with long-term adverse effects from cervical trauma.

Nursing care during surgical abortion includes continued patient assessment and emotional support. The woman should be informed about what to expect: abdominal cramping and sounds emitted by the suction machine. After the procedure, the patient rests in a recovery area for 1 to 3 hours to ensure that no excessive cramping or bleeding occurs. The aspirated uterine contents are inspected to ascertain that all fetal parts and adequate placental tissue have been aspirated.

Although check-up visits are usually scheduled between 2 weeks and 6 weeks postabortion, serum levels of human chorionic gonadotrophin (hCG) may remain elevated even if the abortion successfully ended the pregnancy. Women whose hCG levels are still present in the urine (at the follow-up appointment) should be encouraged to return for urine hCG levels every 2 weeks until the test is negative. Persistently elevated hCG levels are associated with a delay in the return of menses.

clinical alert

Signs of short-term complications after clinical termination of pregnancy

- Fever of 40°C (104°F)
- Abdominal pain or tenderness in the abdomen
- Prolonged or heavy bleeding or passing large clots
- Foul vaginal discharge
- No menstrual period within 6 weeks

Source: Hatcher et al. (2004).

MEDICAL TERMINATION OF PREGNANCY

“Medical abortion” is an alternative for the surgical form of abortion, and for some women this method is more “natural” and more closely resembles a miscarriage (Stewart et al., 2004). A medical abortion can be performed for up to 63 days of gestation. The woman who considers medical abortion should be carefully educated about what to expect. Specific medications are used to induce uterine contractions to end the pregnancy. These include mifepristone (Mifeprex, originally called RU-486), an abortifacient, and methotrexate (amethopterin, Folex, Rheumatrex, Trexall), an antimetabolite used to treat certain types of cancer. Both medications may be followed by a vaginal administration of misoprostol (Cytotec), a prostaglandin

analogue that promotes expulsion of the pregnancy. Misoprostol is commonly associated with nausea, vomiting, and cramping.

Uterine bleeding begins several days after medication administration, and most patients experience a period of painless heavy bleeding along with the expulsion of tissue (the products of conception). This experience may trigger strong emotions. The nurse should advise the patient that she would most likely benefit from the presence of a caring, trusted close friend, or relative who can help her through the experience and lend emotional and physical support (Stewart et al., 2004). Follow-up visits include ultrasonography (to confirm that the uterus is empty) and assessment of hCG levels. A surgical abortion procedure may be necessary if medical attempts are unsuccessful.

Medical termination of pregnancy is probably not the ideal choice for adolescents, and for this reason, some clinics offer this method of abortion only to women 18 years of age or older. Interestingly, this method has been proven useful in evacuating pregnancies that occur in the fallopian tubes. Medical termination of a tubal pregnancy has enabled many women to avoid surgery and preserve the fallopian tubes for future pregnancy conceptions.

Medical termination during the second trimester most often includes an administration of prostaglandins via vaginal suppository, gel, or by intrauterine injection. Repeated doses are often needed and side effects including nausea, vomiting, diarrhea, and cramping usually occur. Rarely used methods include the intrauterine instillation of hypertonic solutions such as saline or urea and uterotonics agents (e.g., misoprostol and dinoprostone).

Complications

Legal abortion is actually safer than pregnancy, especially when performed early in pregnancy. All patients should be told to expect cramping and some bleeding after an abortion. Some of the rare complications associated with abortion include infection, incomplete abortion, hemorrhage, **Asherman syndrome** (condition characterized by the presence of endometrial adhesions or scar tissue), and postabortal syndrome (severe abdominal cramping and pain from intrauterine blood clots) (Hatcher et al., 2005). Patients should be cautioned to call the office should any signs of short-term complications (i.e., excessive bleeding, pain, fever) occur. Most complications develop within the first few days after the abortion. All patients should return in 2 weeks for a follow-up examination.

The Nurse’s Role in Infertility Care

THE INITIAL ASSESSMENT

Fertility requires that the sperm and the ovum can meet, that the sperm is viable, normal, and able to penetrate a viable, normal egg, and that the lining of the uterus can support the implanted embryo. **Sterility** is the term applied when there is an absolute factor that prevents reproduction. **Infertility** is diagnosed if a woman has not conceived within 12 months of actively attempting pregnancy. At present, 10% to 15% of heterosexual couples in

the United States are infertile (Nelson & Marshall, 2004). Approximately 40% of cases of infertility can be attributed to female problems, 40% can be attributed to male causes, and the remaining cases of infertility are attributable to a combination of male and female factors, or are undeterminable (Mooney, 2005). Delays in childbearing and increased consumer awareness of reproductive technology have prompted more heterosexual couples, single women, and same-sex couples to seek fertility assistance than ever before. The nurse's role in infertility care begins with education and counseling during the initial assessment.

 **Nursing Insight**— *Toward meeting the Healthy People 2010 national goals*

The *Healthy People 2010* goal that directly addresses infertility states: “Reduce the proportion of married couples whose ability to conceive or maintain a pregnancy is impaired from a baseline of 13% to a target of 10%” (DHHS, 2000). To help achieve this goal, nurses must be proactive in health promotion strategies for all childbearing aged individuals. Empowering young adults with knowledge about nutrition, exercise, stress reduction, and safe sex practices helps them to make lifestyle choices that foster optimal health and preservation of fertility.

Before extensive testing for infertility, it is important to establish that the timing of intercourse and length of coital exposure are adequate. The nurse assesses the couple's understanding about the most fertile times to have intercourse during the menstrual cycle. Teaching about the signs and timing of ovulation, the most effective times for intercourse (every 48 hours around ovulation) and positions to enhance sperm retention is an important nursing intervention during the initial evaluation.

 **Ethnocultural Considerations**— *Obtaining a sexual history for infertility care*

Culturally influenced practices and taboos may create feelings of discomfort for couples when asked specific details of their intimate lives during the infertility care interview. Nurses must be sensitive to these issues and aware of cultural variations. For example, Orthodox Jewish law forbids a couple from engaging in sexual intercourse for 7 days after the menstrual period. This tenet can create an infertility problem if ovulation occurs during the early days after menstruation.

Providing an overview of what to expect during the initial and subsequent visits empowers the couple to make an informed decision about their level of commitment to the evaluation and possible treatment and affords them some sense of control over their situation. The nurse explains what is involved in the basic infertility work-up in a sensitive, unhurried manner that conveys caring and promotes a trusting, therapeutic relationship. Depending on findings from the history and physical examination, the evaluation will most likely include an assessment of

ovarian function, cervical mucus (amount and receptivity to sperm), sperm adequacy, tubal patency, and the general condition of the pelvic organs.

Instructions about recording the basal body temperature are usually provided at the initial visit. An in-depth interview, preferably with both partners, may reveal medical problems (i.e., chronic illness), lifestyle patterns (i.e., substance abuse, sexual orientation) or other factors such as advanced age that can adversely affect fertility. The physical examination includes evaluation of the pelvis (bimanual and rectovaginal assessment) and laboratory testing.

LATER METHODS OF ASSESSMENT

A thyroid function test, glucose tolerance test, serum prolactin levels, and specific hormonal assays (i.e., estradiol, LH, progesterone, dehydroepiandrosterone [DHEA], androstenedione, testosterone, 17 alpha-hydroxy progesterone [17-OHP]) may also be ordered along with ultrasonography (abdominal or transvaginal) to visualize the pelvic structures. Other diagnostic tests may include an endometrial biopsy to assess the endometrial response to progesterone, a hysterosalpingography (transcervical instillation of a radiopaque dye to provide visualization of the interior dimensions of the uterine cavity and fallopian tubes), and a laparoscopy to allow direct visualization of the internal pelvic structures. Selected methods of fertility evaluation in the female along with nursing implications are presented in Table 6-2.

Evaluation of the man begins with a semen analysis to assess the quality and quantity of sperm. The nurse explains the purpose of the test and advises the man to collect the semen specimen by masturbation following a 2- to 3-day abstinence. He is instructed to note the time the specimen was obtained. This information allows the laboratory to evaluate liquefaction of the semen. The specimen should be transported near the body (to preserve warmth) and should arrive at the laboratory within 1 hour after collection. Additional testing may include serum samples for evaluation of endocrine function (testosterone, estradiol, LH, FSH), ultrasonography, testicular biopsy, and sperm penetration assay. Referral to a urologist may be indicated. A post coital test (PCT) may be ordered to assess the cervical mucus, sperm, and degree of sperm penetration through the cervical mucus. The test is performed on a sample of cervical mucus obtained several hours after intercourse.

 Labs: Basic Infertility Evaluation and Workup		
	Woman:	Man:
CBC		Semen analysis: sperm count should be
Urinalysis		Volume of 2–6 mL of semen
Pap smear and wet mount		
Serology		>20 million sperm per 1 mL of semen
Luteinizing-hormone-surge ovulation predictor kit		>50% forward moving sperm
FSH cycle day 3 if >35 years old		>30% normal sperm
Rh factor, blood grouping		< 1 million WBCs per mL of semen
Hysterosalpingogram (to reveal uterine or tubal obstruction or abnormalities)		

Table 6-2 Common Diagnostic Methods Used in the Evaluation of Female Infertility

Type/Name of Test	Role of the Nurse
<p>Prediction of Ovulation</p> <p>To identify the LH surge – precedes ovulation by 24–36 hours. Also identifies the absence of ovulation. Tests include basal body temperature, commercial ovulation predictor kits, and assessment of cervical mucus.</p>	Teach the couple how the information helps to determine timing of intercourse to coincide with ovulation. Instruct the woman about recording the BBT and assessing cervical mucus; reinforce directions for using commercial ovulation predictor kits.
<p>Postcoital Test (PCT); Huhner Test</p> <p>Assessment of the quality and quantity of cervical mucus and sperm function at the time of ovulation.</p>	Instruct the patient to arrange to come in 6–12 hours after intercourse for evaluation of the cervical mucus.
<p>Ultrasound Examination</p> <p>To evaluate structure of the pelvic organs; identify maturing ovarian follicles and the timing of ovulation.</p>	Reassure the patient that sonography uses sound waves, not radiation, to evaluate the pelvic structures. The examination may be conducted transabdominally or transvaginally and specific instructions are given, depending on method.
<p>Hysterosalpingogram (see Diagnostic Tools)</p>	
<p>Tests of Endocrine Function</p> <p>To evaluate the hypothalamus, pituitary gland and ovaries. Various assays determine levels of FSH, LH, estrogen, and progesterone. Depending on the history and physical findings, additional testing may be indicated.</p>	Inform the patient that testing is performed on serum samples and timing is an important consideration in interpretation of the results. Explain that FSH and LH stimulate ovulation; and estrogen and progesterone make the endometrium receptive for implantation of the fertilized ovum.
<p>Endometrial Biopsy</p> <p>Involves the removal of a sample of the endometrium with a small pipette attached to suction. Provides information about the effects of progesterone (produced by the corpus luteum after ovulation) on the endometrium.</p>	Teach the patient about the purpose and appropriate timing of the test: it should be performed not earlier than 10–12 days after ovulation (2–3 days before menstruation is expected). Cramping, pelvic discomfort, and vaginal spotting may occur; a mild analgesic (i.e., ibuprofen) may be used to alleviate the discomfort.
<p>Hysteroscopy and Laparoscopy</p> <p>Procedures that involve the use of an endoscope to examine the interior of the uterus and the pelvic organs under general anesthesia. Hysteroscopy may be performed without general anesthesia in the office. Abnormalities such as polyps, myomata (fibroid tumors) and endometrial adhesions are identified.</p>	Explain the purpose of the test and other procedures that may be done at the same time. When general anesthesia is to be used, the patient should take nothing by mouth for several hours before the planned procedure. Advise her that since carbon dioxide gas will be instilled in the abdomen to enhance organ visibility, she may experience post-operative cramping and referred shoulder pain, which can be relieved with a mild analgesic.

diagnostic tools: Hysterosalpingography (HSG)

During hysterosalpingography, radiopaque dye is injected through the cervix. The dye enters the uterus and fallopian tubes and through x-ray examination, any abnormalities in the uterine structure or tubal patency can be identified.

- It is performed during the follicular phase of the menstrual cycle to avoid interrupting an early pregnancy. It may exert a therapeutic effect as well: instillation of the water-based dye may flush out debris or adhesions in the uterine cavity.
- Moderate to severe cramping and shoulder pain “referred” from the subdiaphragmatic collection of gas may occur. All patients should be warned about the possibility of pain during the test.
- The patient should be given a nonsteroidal anti-inflammatory drug (NSAID) (i.e., ibuprofen) 30 minutes to 1 hour before the procedure.
- Recurrence of pelvic inflammatory disease may result from the test; prophylactic antibiotics are recommended to prevent infection.
- The patient is instructed to report severe cramping, bleeding, fever or malodorous discharge that develops within a week following the procedure, although spotting and slight cramping for a few days may occur. She should be advised to take an NSAID after the procedure for these symptoms.

Treatment Options for Infertility

MEDICATIONS

Depending on the cause of infertility, a number of pharmacological methods are used to induce ovulation, supplement the woman’s levels of follicle-stimulating hormone (FSH) and luteinizing hormone (LH), prepare the uterine endometrium for implantation, and support the pregnancy following conception and implantation (Table 6-3).

Induction of Ovulation

Medications are commonly used to stimulate follicle development in women who are anovulatory or who ovulate infrequently. Clomiphene citrate (Clomid) is frequently prescribed. It is an antiestrogenic agent that binds to hypothalamic estrogen receptors to trigger the release of FSH and LH. Patients who will be undergoing assisted

Table 6-3 Selected Medications Used in the Treatment of Infertility

Medication	Actions	Nursing Considerations and Side Effects
Clomiphene citrate (Clomid)	Antiestrogen that binds with estrogen receptors to trigger FSH and LH release.	Contraindicated with hepatic impairment. Patients may experience ovarian enlargement, vasomotor flushes, abdominal distention, nausea and vomiting, breast tenderness, blurred vision, headache, pelvic pain, abnormal uterine bleeding. May cause multiple ovulation.
Bromocriptine mesylate (Parlodel)	Reduces elevated prolactin secretion by the anterior pituitary, which improves gonadotropin-releasing hormone secretion and normalizes follicle-stimulating hormone and luteinizing hormone release. Ovulation is restored and increased progesterone by the corpus luteum supports early pregnancy.	Patients may experience nausea and vomiting, headache, dizziness, orthostatic hypotension, blurred vision, diarrhea, metallic taste, dry mouth, urticaria, rash.
GnRH agonists (gonadorelin); goserelin [Zoladex], leuprolide [Lupron], nafarelin [Synarel]	Stimulates release of pituitary FSH and LH in patients with deficient hypothalamic GnRH secretion. FSH and LH stimulate ovulation (female) and testosterone and spermatogenesis (male).	Advise patients of potential side effects: headache, depression, nasal irritation (Synarel), vaginal dryness, breast swelling and tenderness, hot flashes, vaginal spotting, decreased libido, and impotence.
GnRH antagonists; cetrorelix [Cetrotide], ganirelix [Antagon], abarelix [Plenaxis], histrelin [Supprelin]	Reduces extent of endometriosis; used with medications that stimulate ovulation by suppressing LH and FSH.	Patients are closely monitored for ovarian hyperstimulation (ascites with or without pain, pleural effusion, ruptured ovarian cysts, multiple births), headache, nausea.
Human chorionic gonadotropin (hCG) (Profasi HP, Pregnyl, Chorex)	Used after failure to respond to therapy with clomiphene citrate, induces ovulation; used in conjunction with gonadotropins (FSH and LH [Pergonal], [Repronex], [Humegon]); ovulation usually occurs within 18 hours. Also stimulates production of progesterone by the corpus luteum.	When used with menotropins, risk for ovarian hyperstimulation, and arterial thromboembolism; other side effects include headache, irritability, restlessness, and depression.
Progesterone (IM, intravaginal)	Provides luteal phase support—prepares the endometrial lining to promote implantation of the embryo.	Common side effects include nausea, weight gain, and fluid retention.

reproductive techniques including in vitro fertilization, gamete intrafallopian transfer, and tubal embryo transfer may also receive agents to induce superovulation, or the release of several ova. After adequate follicular stimulation, human chorionic gonadotropin (hCG) is administered to prompt ovulation.

Induction of ovulation increases the risk of multiple births because many ova may be released and fertilized. Depending on the medications used, daily ultrasound examinations and serum estrogen levels may be obtained to monitor ovarian response. **Ovarian hyperstimulation** is a serious complication that may result from ovulation induction. It is characterized by marked ovarian enlargement, ascites with or without pain, and pleural effusion. When detected, hCG is not given, and ovulation will not occur. The patient undergoes a “rest” period and postponement of the infertility treatment until the following cycle. Careful monitoring and medication titration are usually successful in preventing this complication as well as high-order (triplets or more) multifetal pregnancy. Throughout therapy, which often requires repeated office visits and testing, nursing interventions center on continued education and patient support. Emotional instability, anxiety, and depression are common reactions to the dramatic hormonal alterations and need for frequent surveillance.

SURGICAL OPTIONS

Surgical interventions using endoscopic techniques may be useful in correcting obstructions. Laparoscopic ablation (destruction) of endometrial implants may help patients with endometriosis achieve pregnancy, especially during the first few months immediately following the procedure. Newer laser surgical techniques are minimally invasive and useful in reducing adhesions that have resulted from infection, prior surgical procedures, and endometriosis. Microsurgical techniques may be successful in correcting obstructions in the fallopian tubes or in the male tubal structures. Transcervical tuboplasty (surgery for correction of fallopian tube abnormalities) is a minimally invasive technique that involves insertion of a catheter through the cervix, into the uterus and the fallopian tube. A balloon is inflated to clear any blockage.

THERAPEUTIC INSEMINATION

Therapeutic insemination (previously termed “artificial insemination”) involves the placement of semen at the cervical os or directly in the uterus (intrauterine insemination [IUI]) by mechanical means. Partner sperm (termed “therapeutic husband insemination” [THI]) or donor sperm (termed “therapeutic donor insemination” [TDI])

is used. Clomiphene citrate and ultrasound monitoring for follicle development are frequently used to ensure timing of the insemination with ovulation. Fertilization most often occurs in the fallopian tube. The technique involves the insertion of a small catheter into the vagina and through the cervix to facilitate the deposition of sperm directly into the uterus. Since seminal fluid is rich in prostaglandins, IUI prevents the nausea, cramping, abdominal pain, and diarrhea that can result from the absorption of prostaglandins by the cervical lining.

Before the IUI, the sperm are “washed”: they are removed from the seminal fluid and placed in a special solution that enhances motility and improves the chances for fertilization. An added advantage of washing sperm concerns sperm antibodies. After infection or surgery, a woman’s immune system may produce antibodies that cause sperm clumping and adversely affect motility and ovum penetration. Sperm washing may correct the clumping, increase sperm motility and improve the likelihood of fertilization (Mooney, 2005).

ADVANCED REPRODUCTIVE TECHNOLOGIES

Gamete Intrafallopian Transfer

Advanced reproductive technologies (ARTs) are procedures intended to achieve pregnancy by placing gametes together to promote fertilization. Although assisted reproductive methods are more common today than in the past, they are very expensive, and are often unavailable to women of lower socioeconomic status. **Gamete intrafallopian transfer (GIFT)** is a technique that involves laparoscopy and ovulation induction. The patient must have at least one patent fallopian tube. Three to five oocytes are harvested from the ovary and immediately placed into a catheter along with washed, motile donor or partner sperm. The sperm and oocytes are injected into the fimbriated ends of the fallopian tube(s) through a laparoscope. Since fertilization normally takes place in the fallopian tube, this technique increases the likelihood of conception in situations where the sperm and ovum may be prevented from uniting. Supplemental progesterone is given to promote implantation and provide support for the early pregnancy.

Zygote Intrafallopian Transfer

Zygote intrafallopian transfer (ZIFT) is a procedure that evolved from the GIFT procedure. Following ovulation induction, retrieved oocytes are fertilized outside the woman’s body and the subsequent zygotes are placed in the distal fallopian tube(s).

Tubal Embryo Transfer

Tubal embryo transfer (TET) involves placement at the embryo stage. The patient must have at least one patent fallopian tube. Exogenous progesterone is used to enhance endometrial preparation.

In Vitro Fertilization

In vitro fertilization (IVF) involves retrieval of the oocytes from the ovaries, usually via an intra-abdominal approach or a transvaginal approach under ultrasound guidance. The oocytes are then combined with partner or donor sperm in the laboratory. After fertilization,

the normally developing embryos are placed in the uterus (Fig. 6-7). Success with IVF is dependent upon many factors, such as the woman’s age and the indication for the procedure. On average, women who undergo three IVF cycles have a good chance of achieving pregnancy.

Embryo Cryopreservation

Cryopreservation, or freezing, is used in some instances to store sperm or ovarian tissue for future use or to freeze excess embryos that have resulted from an in vitro fertilization procedure. If no pregnancy results, the frozen embryos can be processed and replaced in the uterus. This option allows the couple to attempt another pregnancy without the need for ovarian stimulation and egg retrieval.

An initial fee is charged for the freezing process; additional fees are incurred for the continued preservation of the frozen reproductive tissues. One of the ethical and sociocultural issues involved with cryopreservation arises when excess embryos are no longer needed or desired by the woman or couple. In most situations, the embryos are destroyed although a social debate presently concerns an alternate use of the embryos for research.

Micromanipulation

Micromanipulation is a process that involves the use of micromanipulators—fine, specialized instruments—to handle individual sperm and ova. Intracytoplasmic sperm injection (ICSI) allows a sperm cell to be directly injected into an ovum. Assisted embryo hatching is used as an IVF adjunct for women in whom the normal “hatching process” is impeded because of a thickening of the zona pellucida. A small opening created in the zona pellucida facilitates the hatching process by allowing the embryo to escape from the zona pellucida to interact with the endometrium for implantation. Blastomere analysis allows for chromosomal analysis using a single cell from the six-to-eight-cell embryo before implantation.

Figure 6-7 The process of in vitro fertilization. A, Ovulation. B, Intra-abdominal retrieval of the ova. C, Ova fertilization and growth in culture medium. D, Fertilized ova is placed in the uterus.

ART and Legal Considerations

Before any ART procedure, patients must be given current, factual information about the advantages and limitations of techniques that involve the use of donor sperm or eggs for the purpose of conception. Informed consent must be obtained and documented in the patient record. Advanced reproductive technology is expensive (approximately \$10,000.00 a cycle) and available only in specialized centers. Unfortunately, there is never a guarantee of a viable pregnancy that will result in a healthy child. Nursing responsibilities include ensuring that patients and their partners have ample opportunity to ask questions, thoughtfully explore available options, and freely express concerns. They must be able to verbalize an understanding of the chosen procedure(s), including the risks and potential complications. Ongoing support includes education, counseling, and strategies for continued follow-up.

When donor ova or sperm are to be used, patients and their partners require additional information. They need to be reassured that all gamete donors have undergone psychological and physical examinations and screening for medical and genetic disease. Clinical findings from potential donors are made available to the woman or couple to allow them to make an informed decision. The donor's and the recipient's confidentiality are closely guarded, and in most instances, their identities are not revealed without their specific permission.

Infertility, ART, and Potential Effects on the Couple's Relationship

Infertility produces a great amount of emotional stress for most couples. Societal and cultural influences may intensify the feelings of disappointment and failure. It is not unusual for the woman and her partner to experience a sense of loss: loss of perceived good health, loss of self-esteem, loss of a "normal" relationship with the spouse, loss of security and self-confidence, and loss of the potential child. Affected individuals often move through the stages of grieving identified by Kubler-Ross: surprise, denial, anger, isolation, guilt, grief and resolution.

For heterosexual couples, intercourse can transition from a shared loving, intimate moment into a clinical, goal-oriented procedure. Unfortunately, some relationships do not survive the stress of infertility. Even under the best of circumstances, infertile couples are subjected to a loss of privacy and often a lack of spontaneity. During treatment for infertility, menstrual periods become a regular and repeated reminder of failure. Patients are asked to share with others their most personal and emotionally laden information concerning sexual preferences and sexual practices. It is imperative that the nurse and other members of the health care team maintain confidentiality and privacy for these patients as much as possible. The nurse's caring demeanor and expressions of genuine concern are essential qualities when dealing with the sensitive and emotional circumstances that surround infertility testing and treatment. Depending on the patient's unique situation, a number of nursing diagnoses may be appropriate (Box 6-5).

Box 6-5 Potential Nursing Diagnoses for the Patient Experiencing Infertility

- Risk for ineffective coping related to infertility
- Risk for posttrauma response related to infertility
- Risk for spiritual distress related to infertility
- Risk for situational low self-esteem related to infertility

Family Teaching Guidelines... Fostering Relationships During Evaluation and Treatment for Infertility

Couples should be encouraged to spend quality time with one another and enjoy sexual intimacy outside of the "fertile times." Professional counseling may be appropriate if one member of a couple becomes depressed or obsessed with conceiving while the other remains less involved. The nurse may suggest involvement with infertility community support groups and contact with RESOLVE, a national education/support organization that is readily available at <http://www.resolve.org/>.

LIFESTYLE CHOICES AND INFERTILITY

Regular physical activity, adequate rest, stress reduction and balanced nutrition, essential strategies for health promotion, are especially important during the infertility work-up and treatment. Many seek holistic and complementary alternatives to enhance therapeutic regimens or promote a sense of personal control and well-being. Yoga is an example of a lifestyle choice that combines meditation, spirituality, exercise, and relaxation to promote balance and harmony. In addition, a number of herbal alternatives to fertility medications are available (Table 6-4) and this information may be shared with infertile couples.

Complementary Care: Herbal supplements and infertility

Chaste berry tree is believed to promote ovulation; false unicorn root powder has been used to enhance fertility and prevent miscarriage. However, little research has been conducted to confirm the safety or effectiveness of these herbs and patients should be warned about the lack of scientific data about herbal preparations. Certain herbs, including blue or black cohosh, goldenseal, poke root, pennyroyal, and maloe can be detrimental to a pregnancy and should be avoided by couples who are attempting to conceive (see Table 6-4).

ADDITIONAL OPTIONS FOR THE INFERTILE COUPLE

For patients for whom advanced reproductive technologies are unsuccessful or undesirable, surrogacy, use of a gestational carrier or adoption may be the best option. Surrogate mothers contract to carry pregnancies for women who are unable to carry a pregnancy due to an

absent or anomalous uterus or medical condition that would be life threatening during pregnancy. A gestational carrier contracts to carry a pregnancy that is not genetically her own offspring. Adoption may be considered after repeated attempts for pregnancy. Today, there are fewer infants and children available for adoption. Consequently, the adoptive process is often prolonged and difficult unless the couple considers a foreign-born or physically or cognitively challenged child.

Surrogacy and the use of gestational carriers involve legal as well as ethical considerations. Financial resources, personal values, and religious beliefs are all factors that may prohibit these options from being viable alternatives to a traditional pregnancy. Individuals and couples who consider these options should be advised to see an attorney to ensure that their rights, the surrogate's/carrier's rights, and the rights of the child are protected. This very important visit for legal counsel may avoid later heart-break and legal entanglements for the patient and her family. If the surrogate/carrier changes her mind or the parents change their minds, safeguards must be in place for all parties, including the child.

Remaining childless is another option for fertile and infertile couples. Many advantages, such as opportunity for career fulfillment, travel, and continued education make a child-free lifestyle the right choice for many couples. When working with couples who are exploring these alternative options, the nurse's role centers on education, advocacy, and empowerment. Using a framework that encompasses the cultural, spiritual, and environmental domains, the nurse provides information and guidance to community and national resources to assist the couple in dealing with these important issues.

Now Can You— Provide sensitive, appropriate care for the infertile couple?

1. Discuss emotions and stressors frequently experienced during infertility treatment?
2. Analyze the nurse's role in infertility care?
3. Create a teaching plan that describes the various reproductive technologies available?

summary points

- ◆ Sexuality is a multidimensional concept that is influenced by ethical, spiritual, cultural, and moral factors.
- ◆ A variety of contraceptives are available; contraceptive care should empower the patient to choose the method best suited for her.
- ◆ Tubal ligation and vasectomy are permanent sterilization procedures that have become increasingly popular.
- ◆ Infertility is the inability to conceive and carry a child when the couple wishes to do so.
- ◆ Abortion performed during the first trimester is safer than abortion performed during the second trimester.
- ◆ Reproductive alternatives include IVF, GIFT, ZIFT, oocyte/embryo donation, TDI, surrogate motherhood, and adoption.

review questions

Multiple Choice

- The clinic nurse understands that according to Masters and Johnson's research about the four human sexual response phases, women experience the highest sense of sexual tension in the:
 - Excitement phase
 - Plateau phase
 - Orgasmic phase
 - Resolution phase
- The Family Planning clinic nurse describes the contraceptive options for Janeen, an 18-year-old who has had a sexual partner who tested positive for HIV. Janeen has also been treated for gonorrhea. Janeen's best option for contraception would be:
 - Spermicide
 - Cervical cap
 - Latex male condom
 - Progestin-only pill
- The clinic nurse schedules Tina for her initial dose of Depo-Provera (medroxyprogesterone acetate) within:
 - 24 hours of menstruation
 - 48 hours of menstruation
 - 3–4 days of menstruation
 - 5 days of menstruation

True or False

- The contemporary perinatal nurse must become aware of personal feelings, values, and attitudes about sexuality in order to sensitively practice woman-centered care.
- The clinic nurse explains to the new nurse that an intrauterine device (IUD) is believed to cause a sterile inflammatory response that results in a spermicidal intrauterine environment.

Fill-in-the-Blank

- The first step that the clinic nurse takes when initiating the interview and sexual history from a woman is to form a _____ with her.
- During discussion about pregnancy options, the clinic nurse explains to a young couple that _____ is the term used after 12 months of unprotected intercourse with no pregnancy.
- A young woman who is concerned about the possibility of an unwanted pregnancy inquires about emergency contraception. The nurse explains that with Plan B, _____ progestin-only pills are taken immediately with an _____ medication to minimize side effects.

Select All that Apply

- When assisting a woman who is choosing a method of contraception, it is important for the clinic nurse to:
 - Assess the woman's knowledge of options.
 - Assess her motivation for different options.
 - Determine her level of commitment.
 - Ask about methods she has used in the past.

- As a part of health promotion, the clinic nurse reviews the diet and activity levels of every woman who is using Depo-Provera (medroxyprogesterone acetate) as a contraceptive method. The clinic nurse recommends:
 - Daily weight bearing exercise
 - 500 mg calcium daily
 - 1200 mg calcium daily
 - 1200 mg calcium daily with vitamin D

chapter 7

Conception and Development of the Embryo and Fetus

You are a child of the universe no less than the trees and the stars; you have a right to be here.

And whether or not it is clear to you, no doubt the universe is unfolding as it should.

—From the poem “Desiderata”

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Explain the basic concepts of inheritance.
- ◆ Outline the process of germ cell formation.
- ◆ Outline the process of fertilization, implantation, and placental development.
- ◆ Discuss the structure and function of the placenta and umbilical cord.
- ◆ Trace a drop of blood through the fetal circulatory system.
- ◆ Explain the origin and purpose of the fetal membranes and amniotic fluid.
- ◆ Identify the time intervals and major events of the pre-embryonic, embryonic, and fetal stages of development.
- ◆ Discuss threats to embryo/fetal well-being and development.
- ◆ Explain the nurse’s role in minimizing threats to the developing fetus.

moving toward evidence-based practice Vitamin E and Fetal Growth

Scholl, T.O., Chen, X., Sims, M., & Stein, T.P. (2006). Vitamin E: Maternal concentrations are associated with fetal growth. *American Journal of Clinical Nutrition*, 84(6), 1442–1448.

The purpose of this study was to examine the relationship between vitamin E and fetal growth. The researchers theorized that antioxidants such as vitamin E may decrease adverse maternal–fetal outcomes, such as preeclampsia, preterm birth, and low birth weight (LBW) by reducing oxidative damage to the mother and the fetus. Antioxidants are naturally produced by the body or are consumed in the diet. Naturally occurring vitamin E (α -tocopherol) and dietary-consumed vitamin E (γ -tocopherol) levels were examined.

The sample consisted of 1231 pregnant women from Camden, NJ who entered the study at approximately 16 weeks of gestation. Vitamin E plasma concentrations were measured at the time of entry into the study, at 20 weeks’ gestation, and again at 28 weeks’ gestation. The participants included women ≤ 18 years to 45 years of age who received prenatal care

through local area clinics. Forty-nine percent of the participants were Hispanic and 39.7% were African American. Women with serious nonobstetric problems were excluded from the study.

Data collection methods included interviews and 24-hour dietary recalls along with serum concentration levels of vitamin E.

Multiple linear regression was used to examine the relationships among the plasma concentrations of vitamin E, the maternal diet, and the use of prenatal multivitamins.

Findings:

1. Women with the highest concentrations of naturally occurring and dietary vitamin E were generally older, multiparous, and tended to have a higher body mass index (BMI).
2. Obese women had lower concentrations of α -tocopherol and higher concentrations of γ -tocopherol.

(continued)

moving toward evidence-based practice (continued)

3. African American women had the lowest concentration of α -tocopherol compared to Hispanic, Asian, and Caucasian women.
4. Hispanic women had lower concentrations of γ -tocopherol compared to the other ethnic groups.
5. The concentration of α -tocopherol was lower in women who smoked; the serum levels rose with increasing age, intake of dietary vitamin E, and use of prenatal multivitamins.

The researchers found that: (1) plasma concentrations for the vitamin E isomers at the time of entry into the study and again at 28 weeks' gestation were positively associated with increased fetal growth, a decreased risk of small for gestational age infants, and an increased risk for large for gestational age infants. (2) Concentration of α -tocopherol was

positively associated with the maternal intake of prenatal multivitamins and a dietary intake of vitamin E. (3) The concentration of γ -tocopherol was positively associated with dietary fat intake and negatively associated with the use of multivitamins. (4) An early and late circulating concentration of α -tocopherol is positively associated with fetal growth.

1. This investigation was conducted in one of the poorest cities in the United States, and approximately 90% of the study participants were from minority populations. Do you believe that the study findings could be generalized to other populations?
2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

The beginnings of human life occur when a female gamete (ovum) unites with a male gamete (spermatozoa). The birth of a newborn signals the completion of a successful process that begins with conception (the union of a single egg and sperm) and continues throughout a remarkable period of fetal growth and development. During this time, many complex events take place. Fertilization of an ovum by a sperm creates a zygote, which must successfully implant into the hormonally prepared uterus for continued survival. The placenta plays an essential role in the ongoing transfer of oxygen and nutrients to the developing embryo and fetus. The umbilical cord that connects the developing fetus to the placenta is another key structure that facilitates the transfer of maternal oxygen and nutrients, and the removal of fetal waste products. The fetal circulatory system follows a unique pathway that allows the delivery of oxygen-rich blood from the placenta to all major organ systems while bypassing the lungs. The membranes and amniotic fluid are other important elements that are essential for successful fetal growth and development. During the gestational period, drugs, infections, and environmental hazards can have a negative impact on the developing embryo and fetus. This chapter examines the key events that take place during conception and fetal development. Threats to the embryo/fetus, influences of heredity and genetics, and the basics of multifetal pregnancy are also explored.

Basic Concepts of Inheritance

THE HUMAN GENOME PROJECT

The Human Genome Project began in 1990 with an overarching goal to identify the exact **DNA** (deoxyribonucleic acid) sequences and **genes** (segments of DNA that contain information needed to make protein) that occur in humans. The information obtained from the Human Genome Project has enabled scientists to read

the complete genetic blueprint of a human being. It is anticipated that the project findings will lead to new methods of diagnosing, treating, and perhaps even preventing a host of diverse human diseases and disorders. Additional information about the Human Genome Project can be found at <http://www.genome.gov/10001772> and in Chapter 2.

Nursing Insight— Differentiating between “genetics” and “genomics”

Genetics is the study of single genes and their effects. Genomics is the study of the functions and interactions of all genes in the **genome** (a complete copy of the genetic material in an organism) (Guttmacher & Collins, 2005). The shift from genetics to genomics may be viewed as a continuum that ranges from the concept of disease in genetics to the concept of genetic information in genomics (Khoury, 2003).

CHROMOSOMES, DNA, AND GENES

Before our present understanding of DNA, scientists noticed that traits were passed down from preceding generations. In the 19th century, Gregor Mendel proposed that the “strength” of some characteristics explains the variations in patterns of inheritance. Later in the 19th century, scientists identified **chromosomes** (threadlike packages of genes and other DNA) in the nucleus of the cell and found that one half of each pair was derived from the maternal **gamete** (mature germ cell) and one half from the paternal gamete. A number of influences help to determine who we are. These include heredity, the process of cellular division, and environmental factors.

The fundamental unit of heredity in humans is a linear sequence of working subunits of DNA called genes. DNA carries the instructions that allow cells to make proteins and transmit hereditary information from one cell to another. Most genes are located on chromosomes found in the nucleus of cells. Genes occupy a specific location

along each chromosome, known as a locus. Genes come in pairs, with one copy inherited from each parent. Many genes come in a number of variant forms, known as alleles. Different alleles produce different characteristics such as hair color or blood type. One form of the allele (the dominant one) may be more greatly expressed than another form (the recessive one).

All normal somatic (body) cells contain 46 chromosomes that are arranged as 23 pairs of **homologous** or matched chromosomes. One chromosome of each pair is inherited from each parent. Twenty-two of the pairs are **autosomes** (nonsex chromosomes that are common to both males and females) and there is one pair of the sex chromosomes that determines gender (Fig. 7-1). The autosomes are involved in the transmission of all genetic traits and conditions other than those associated with the sex-linked chromosomes. The large **X chromosome** is the female chromosome; the small male chromosome is the **Y chromosome**. The presence of a Y chromosome causes the embryo to develop as a male; in the absence of a Y chromosome, the embryo develops as a female. Thus, a normal female has a 46 XX chromosome constitution; a normal male has a 46 XY chromosome constitution. The two distinct sex chromosomes carry the genes that transmit sex-linked traits and conditions. Because the chromosomes are paired, there are two copies of each gene. If the gene pairs are identical, they are **homozygous**; if they are different, they are **heterozygous**. In the heterozygous state, if one allele is expressed over the other, this allele is considered dominant. Recessive traits can be expressed when the allele responsible for the trait is found on both chromosomes.

Figure 7-1 The sex chromosomes. (Courtesy of National Human Genome Research Institute.)

Nursing Insight— Differentiating genotype from phenotype

Although “**genotype**” refers to the genetic makeup of an individual when referring to a specific gene pair, it is sometimes used to refer to an individual’s entire genetic makeup or all of the genes that a person can pass on to future generations. An individual’s **genome** is the complete set of genes present (about 50,000 to 100,000). The term “**phenotype**” refers to the *observable* expression of a person’s genotype: physical features, a biochemical or molecular trait, or a psychological trait. A trait or disorder is *dominant* if it is phenotypically apparent when only one copy of an allele associated with the trait is present. It is *recessive* if it is phenotypically apparent only when two copies of the alleles associated with the trait are present. Consider, for example, the inheritance of eye color. Although eye color is determined by many pairs of genes, with many possible phenotypes, one pair is considered the principal pair, with brown eyes dominant over blue eyes. A Punnett square (diagram drawn to determine the possible combinations of alleles in the offspring of a particular set of parents) may be used to illustrate inheritance of eye color (Fig. 7-2). Both parents are heterozygous for eye color; their genotype consists of a gene for brown eyes and a gene for blue eyes but their phenotype is brown eyes (Scanlon & Sanders, 2007).

The sex of the embryo is determined at fertilization and is dependent on the sperm (X or Y) that fertilizes the ovum (Fig. 7-3). The union of these highly specialized cells marks the beginning of the development of each unique human being. Clinical practice is based on a calculation of pregnancy weeks, beginning with the first day of the last normal menstrual period (LNMP). However, fertilization usually occurs approximately 2 weeks after

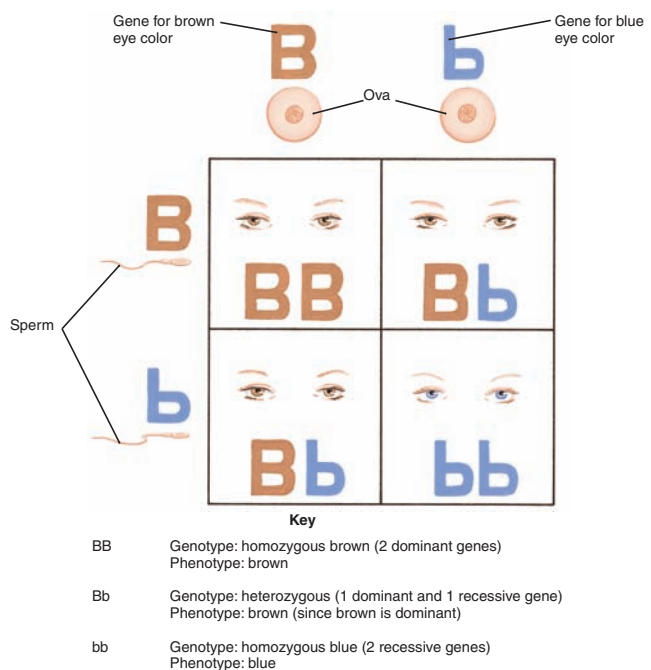

Figure 7-2 Use of a Punnett square to demonstrate inheritance of eye color.

the beginning of the woman's LNMP. **Gestation** is defined as the length of time from conception to birth. The gestational period in humans ranges from 259 to 287 days. In this chapter, the weeks of gestation are calculated from the time of fertilization.

Nursing Insight— Understanding abnormalities in sex chromosomes

Turner syndrome, the most common sex chromosome deviation in females, is characterized by a chromosomal constitution of 45X: one X chromosome is missing (**monosomy X**). Affected females usually exhibit juvenile external genitalia, undeveloped ovaries, short stature, and webbing of the neck. Intelligence may be impaired. In males, *Klinefelter syndrome*, or trisomy XXY, is the most common sex chromosome deviation. The presence of the extra X chromosome results in poorly developed male secondary sexual characteristics, small testes, and infertility. Intelligence may be impaired as well.

Inheritance of Disease

Heritable characteristics describe those that can be passed on to offspring. The manner in which genetic material is transmitted to the next generation is dependent on the number of genes involved in the expression of the trait. A number of phenotypic characteristics can result when two or more genes on different chromosomes act together (known as multifactorial inheritance). A trait or disorder may also be controlled by a single gene (referred to as unifactorial inheritance). A family pedigree, or map of family relationships, is useful for assessing the incidence of inherited disorders.

MULTIFACTORIAL INHERITANCE

The majority of congenital malformations result from multifactorial inheritance, a combination of genetic and environmental factors. Examples include malformations such as cleft lip, cleft palate, neural tube defects, pyloric stenosis,

Figure 7-3 Inheritance of gender.

and congenital heart disease that may range from mild to severe, depending on the number of genes for the particular defect and the amount of the environmental influence.

UNIFACTORIAL INHERITANCE

Unifactorial mendelian or single-gene inheritance describes a pattern of inheritance that results when a specific trait or disorder is controlled by a single gene. There are many more single-gene disorders than chromosomal abnormalities. Patterns of inheritance for single-gene disorders include autosomal dominant, autosomal recessive, and X-linked dominant and recessive modes of inheritance.

Autosomal Dominant Inheritance

Autosomal dominant inheritance disorders are caused by a single altered gene along one of the autosomes. In most situations, the affected individual comes from a family of multiple generations that have the disorder. The variant allele may also arise from a **mutation** (a spontaneous, permanent change in the normal gene structure). In this situation, the disorder occurs for the first time in the family. An affected parent who is heterozygous for the trait (e.g., has a corresponding healthy recessive gene for the trait) has a 50% chance of passing the variant allele to each offspring. Examples of autosomal dominant disorders include neurofibromatosis (a progressive disorder of the nervous system that causes the formation of nerve tumors throughout the body), Marfan syndrome (a connective tissue disorder in which the child is taller and thinner than normal and has associated heart defects), Factor V Leiden mutation (a disorder that significantly increases the individual's risk for deep venous thrombosis and pulmonary emboli) (Foster, 2007; Moll, 2006), achondroplasia (dwarfism), Huntington's disease (a progressive disease of the central nervous system characterized by involuntary writhing, ballistic or dance-like movements), and facioscapulohumeral muscular dystrophy (a form of osteogenesis imperfecta, a disorder in which the bones are extremely brittle). A typical pedigree of a family with neurofibromatosis, a dominantly inherited autosomal disorder, is shown in Figure 7-4. Several human genetic diseases, with their patterns of inheritance, are described in Table 7-1.

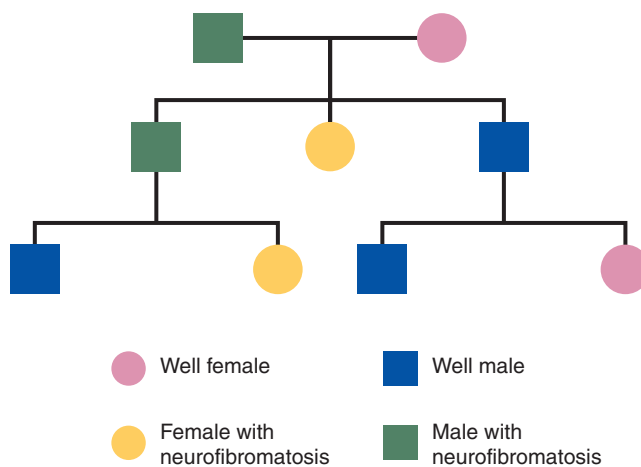

Figure 7-4 Family pedigree for neurofibromatosis, an autosomal dominant disorder.

Table 7-1 Human Genetic Diseases	
Disease (Pattern of Inheritance)	Description
Sickle-cell anemia (R)	The most common genetic disease among people of African ancestry. Sickle cell hemoglobin forms rigid crystals that distort and disrupt red blood cells; oxygen-carrying capacity of the blood is diminished.
Cystic fibrosis (R)	The most common genetic disease among people of European ancestry. Production of thick mucus clogs the bronchial tree and pancreatic ducts. Most severe effects are chronic respiratory infections and pulmonary failure.
Tay–Sachs disease (R)	The most common genetic disease among people of Jewish ancestry. Degeneration of neurons and the nervous system results in death by the age of 2 years.
Phenylketonuria of PKU (R)	Lack of an enzyme to metabolize the amino acid phenylalanine leads to severe mental and physical retardation. These effects may be prevented by the use of a diet (beginning at birth) that limits phenylalanine.
Huntington’s disease (D)	Uncontrollable muscle contractions begin between the ages of 30 and 50 years, followed by loss of memory and personality. There is no treatment that can delay mental deterioration.
Hemophilia (X-linked)	Lack of Factor 8 impairs chemical clotting; may be controlled with Factor 8 from donated blood.
Duchenne’s muscular dystrophy (X-linked)	Replacement of muscle by adipose or scar tissue, with progressive loss of muscle function; often fatal before age 20 years due to involvement of cardiac muscle.

R = recessive; D = dominant.

Source: Scanlon, V.C. and Sanders, T. (2007). *Essentials of anatomy and physiology* (5th ed., p. 490). Philadelphia: F.A. Davis.

Autosomal Recessive Inheritance

Autosomal recessive inheritance disorders are expressed in an individual when both members of an autosomal gene pair are altered. Although each parent carries the recessive altered gene, neither is affected by the disorder because each is heterozygous for the trait and the altered gene is not expressed. When two individuals carrying the same recessive altered gene reproduce, both may pass the altered gene to their offspring. Each parent, or **carrier**, of the autosomal recessive disorder, has a 25% risk of passing the disorder to each offspring, who will then have no normal gene to carry out the necessary function. Because parents must pass the same altered gene for expression of the disorder to occur in their children, an increased incidence of the disorder occurs in consanguineous matings (closely related parents). In addition, specific populations may have a greater frequency of recessive disorders than other populations. For example, sickle cell anemia occurs more frequently in black populations than in white populations. A Punnett square illustrating the inheritance pattern of sickle cell anemia is presented in Figure 7-5. Other examples of autosomal dominant inheritance disorders include galactosemia, phenylketonuria (PKU), maple syrup urine disease, Tay–Sachs disease, and cystic fibrosis (CF).

X-Linked Dominant Inheritance

X-linked dominant inheritance disorders are the result of an alteration in a gene located along an X chromosome (Fig. 7-6). Since females have two X chromosomes, these disorders occur twice as frequently in females as in males. When the gene is dominant, it need be present on only one of the X chromosomes for symptoms of the disorder to be expressed. X-linked dominant disorders are passed from an affected male to all of his daughters, because the daughters receive the father’s altered X chromosome. Conversely, none of the sons are affected because they receive only the father’s Y chromosome.

Figure 7-5 Inheritance of sickle cell anemia, an autosomal recessive disorder.

A female with an X-linked dominant disorder has a 50% chance of passing the altered genes to her offspring. Each child of a female with the X-linked dominant disorder has a 1 in 2 chance of expressing the disorder. Examples of X-linked dominant disorders include hypophosphatemia (vitamin D-resistant rickets) and cervico-oculo-acoustic syndrome.

X-Linked Recessive Inheritance

X-linked recessive inheritance disorders are more common than X-linked dominant disorders and occur more frequently in males because males have a single X chromosome and the single X chromosome carries the altered

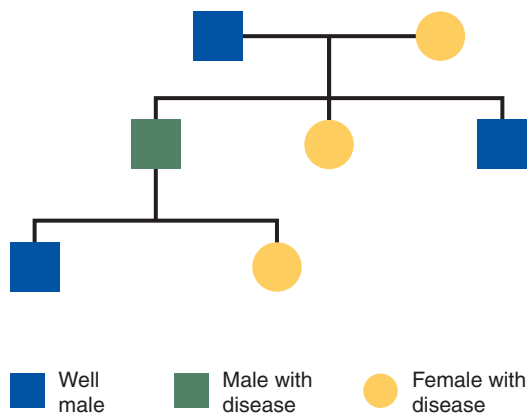

Figure 7-6 Family pedigree for X-linked dominant inheritance.

gene. Thus, when the male receives a “single dose” of the altered gene, the disorder is expressed. For the disorder to be expressed in the female, the altered gene must be present on both X chromosomes.

A female who is a carrier of a gene that causes an X-linked recessive disorder has a 50% risk of passing the abnormal gene to her male offspring. Each son has a 1 in 2 chance of expressing the disorder. The female carrier also has a 50% chance of passing the altered gene to her female offspring, who will have a 1 in 2 chance of becoming carriers of the altered gene. A son who is affected by an X-linked disorder has a 100% chance of passing the variant X to his daughters since the affected father has only one X to pass on. Fathers cannot transmit the altered gene to their male offspring because they transmit the Y instead of the X chromosome to their sons. The Punnett square in Figure 7-7 illustrates the inheritance pattern for red-green color blindness, an X-linked recessive inheritance disorder. Other X-linked recessive inheritance disorders include hemophilia A, Duchenne (pseudohypertrophic) muscular dystrophy and Christmas disease, a blood-factor deficiency (Lashley, 2005).

Now Can You— Discuss aspects of patterns of inheritance?

1. Differentiate between unifactorial and multifactorial patterns of inheritance?
2. Compare and contrast autosomal dominant, autosomal recessive, and X-linked inheritance disorders?
3. Construct a Punnett square to illustrate inheritance patterns for a dominant trait?

Cellular Division

Human cells can be categorized into either gametes (sperm and egg cells) or somatic cells (any body cell that contains 46 chromosomes in its nucleus). Gametes are haploid cells. They have only one member of each chromosome pair and contain 23 chromosomes. Somatic cells are diploid, which means that they contain chromosome pairs (a total of 46 chromosomes). One member of each pair comes from the mother, and one member

Figure 7-7 Inheritance of red-green color blindness.

comes from the father. Cells reproduce through either meiosis or mitosis. **Meiosis** is a process of cell division that leads to the development of sperm and ova, each containing half the number (haploid) of chromosomes as normal cells. **Mitosis** is the process of the formation of two identical cells that are exactly the same as the original cell and have the normal (diploid) amount of chromosomes.

Meiosis occurs during gametogenesis, the process in which germ cells, or gametes, are produced. During cell division, the genetic complement of the cells is reduced by one half. During meiosis, a sex cell containing 46 chromosomes (the diploid number of chromosomes) divides into two, and then four cells, each containing 23 chromosomes (a haploid number of chromosomes). The resulting “daughter cells” are exactly alike, but they are all different from the original cell. The process of meiosis includes two completely different cell divisions. During the first cell division, the chromosomes replicate each of the 46 chromosomes (diploid number of chromosomes). The chromosomes then become closely intertwined and the sharing of genetic material occurs. New combinations are produced, and this process accounts for the variations of traits in individuals. Next, the chromosomes separate and the cell divides and forms two daughter cells, each containing 23 double structured chromosomes (the same amount of DNA as a normal somatic cell).

In the second division, each chromosome divides and each half (or chromatid) moves to opposite sides of the cell. The cells divide and form four cells containing 23 single chromosomes each, a haploid number of chromosomes, or half the number of chromosomes present in the somatic cell. Gametes must contain the haploid number of chromosomes. When the female and male gametes unite to form a fertilized ovum (zygote), the normal (diploid) number of 46 chromosomes is reestablished. The entire process results

in the creation of four haploid gamete cells from one diploid sex cell.

Mitosis is the phase in the cell cycle that permits duplication of two genetically identical daughter cells each containing the diploid number of chromosomes. The process of mitosis allows each daughter cell to inherit the exact human genome.

The Process of Fertilization

Fertilization is a complex series of events. Transportation of gametes must occur to allow the oocyte and the sperm to meet. Most often, this meeting takes place in the ampulla of the uterine (fallopian) tube (Fig. 7-8).

After completion of the first meiotic division, the secondary oocyte is expelled from the ovary during ovulation. The oocyte then makes its way to the infundibulum (funnel-shaped passage) at the end of the fallopian tube and passes into the ampulla of the tube. At the time of ejaculation, about 200 to 600 million sperm are deposited around the external cervical os and in the fornix of the vagina. During ovulation, the amount of cervical mucus increases and it becomes less viscous and more favorable for sperm penetration. Propelled by the flagellar movement of their tails, sperm travel into the uterus and upward through the fallopian tubes. Muscular contractions of the tubal walls, believed to be enhanced by prostaglandins in the semen, facilitate the sperm movement. The fallopian tubes are lined with **cilia**, hairlike projections from the epithelial cells that

serve a dual action: movement of the ovum toward the uterus and movement of the sperm from the uterus toward the ovary. Of the 200 to 600 million sperm deposited, approximately 200 actually reach the fertilization site.

Sperm must undergo a process called capacitation, whereby a glycoprotein coat and seminal proteins are removed from the surface of the sperm's acrosome (the caplike structure surrounding the head of the sperm). The sperm become more active during this process of capacitation, which takes about 7 hours and usually occurs in the fallopian tube but may begin in the uterus. An acrosome reaction occurs when the capacitated sperm comes into contact with the zona pellucida surrounding the secondary oocyte. During the acrosome reaction, enzymes from the sperm's head are released. This helps to create a pathway through the zona pellucida, allowing the sperm to reach the egg and fertilization to occur.

Once a sperm penetrates through the zona pellucida, a reaction takes place to prevent fertilization by other sperm. The oocyte then undergoes its second meiotic division and forms a mature oocyte and secondary polar body. The nucleus of the mature oocyte becomes the female pronucleus. The sperm loses its tail within the cytoplasm of the oocyte, and then enlarges to become the male pronucleus. Fusion of pronuclei of both the oocyte and sperm create a single zygote containing the diploid number of chromosomes. The zygote is genetically unique in that it contains half of its chromosomes from the mother and half from the father.

Figure 7-8 Ovulation, fertilization, and early embryonic development.

Collaboration in Caring— Impaired fecundity

According to the National Center for Health Statistics (NCHS), in 2002, 7.3 million women between the ages of 15 and 44 had “impaired fecundity,” meaning it was difficult or impossible to get pregnant or carry a fetus to term (NCHS, 2006). Infertility is a widespread problem and treatment may include referrals to internal medicine, endocrinology, obstetrics, urology, and psychiatry. Infertility is usually first identified by the gynecologist/obstetrician. A referral to internal medicine may be recommended to optimize the health status of both partners. A reproductive endocrinologist specializes in infertility. Treatments offered by an endocrinologist include fertility drugs, infertility surgery, and assisted reproductive therapy. Routine screening (including laboratory tests) is conducted on both partners to identify the possible cause of infertility. Abnormalities identified in the male partner may involve the care of the urologist.

The Process of Implantation and Placental Development

After conception, the fertilized ovum, or zygote, remains in the ampulla for 24 hours and then, propelled by ciliary action, travels toward the uterus. During this time, cleavage (mitotic cell division of the zygote) occurs. By 3 to 4 days after fertilization, there are approximately 16 cells. The zygote is now called a **morula**, and enters the uterus. Once the morula enters the uterus, fluid passes through the zona pellucida, into the intercellular spaces of the inner cell mass and forms a large fluid-filled cavity. The morula is now called a **blastocyst** and contains an inner mass of cells called the embryoblast. The embryo develops from the embryoblast, and contains an outer cell layer called the trophoblast. The chorion and placenta develop from the trophoblast.

Nursing Insight— Understanding the origin of embryonic stem cells

The cells of the inner cell mass are termed embryonic stem cells. In these cells, all of the DNA has the potential to develop into any of the 200 kinds of human cells that will be present at birth. As the cells continue to divide and increase in number, some DNA will be “switched off” in each cell, the genes will become inactive and the possibilities for specialization of each cell will decrease (Scanlon & Sanders, 2007).

The uterus secretes a mixture of lipids, mucopolysaccharides, and glycogen that nourishes the blastocyst. The zona pellucida degenerates approximately 5 to 6 days after fertilization. This process allows the blastocyst to adhere to the endometrial surface of the uterus (usually in the upper posterior portion) to obtain nutrients. Implantation begins as the trophoblast cells invade the endometrium. By the tenth day after fertilization, **nidation** (implantation of the

fertilized ovum into the endometrium) has occurred and the blastocyst is buried beneath the endometrial surface.

The placenta develops from the trophoblast cells at the site of implantation. This important organ is essential for the transfer of nutrients and oxygen to the fetus and the removal of waste products from the fetus, and any alteration in its function can adversely affect growth and development. As the trophoblast cells invade the endometrium, spaces termed lacunae develop. The lacunae fill with fluid from ruptured maternal capillaries and endometrial glands. This fluid nourishes the embryoblast by the process of diffusion. The lacunae later become the intervillous spaces of the placenta. At about the same time, the trophoblast cells form primary **chorionic villi**, small non-vascular processes that absorb nutritive materials for growth. Blood vessels begin to develop in the chorionic villi around the third week and a primitive fetoplacental circulation is established.

The trophoblast cells continue to invade the endometrium until 25 to 35 days after fertilization, when they reach the maternal spiral arterioles. spurts of maternal blood form hollows around the villi, creating **intervillous spaces** containing reservoirs of blood that supply the developing embryo and fetus with oxygen and nutrients. The placenta has become well established by 8 to 10 weeks after conception. By 4 months, the placenta has reached maximal thickness although circumferential growth progresses as the fetus continues to grow. The placenta is responsible for providing oxygenation, nutrition, waste elimination, and hormones necessary to maintain the pregnancy (Fig. 7-9).

The placenta is a metabolic organ with its own substrate needs. Metabolic activities of the placenta include glycolysis, gluconeogenesis, glycogenesis, oxidation, protein synthesis, amino acid interconversion, triglyceride synthesis, and lengthening or shortening of fatty acid chains. The placenta uptakes glucose, synthesizes estrogens and progesterone from cholesterol, and uses fatty acids for oxidation and membrane formation. Placental transport of gases, nutrients, wastes, and other substances occurs in a bidirectional movement from maternal to fetal circulation, and from fetal to maternal circulation. Transport across the placenta increases with gestation due to the decreased distance between the fetal and maternal blood, increased blood flow, and increased needs of the developing fetus.

There are several mechanisms by which substances are transported across the placenta. These include simple (passive) diffusion, facilitated diffusion, active diffusion, pinocytosis and endocytosis, bulk flow, accidental capillary breaks, and independent movement. Pinocytosis is the process by which cells absorb or ingest nutrients and fluid; endocytosis is a method of ingestion of a foreign substance by a cell wall (Venes, 2009).

- Simple diffusion: Substances transported via this mechanism include water, electrolytes, oxygen, carbon dioxide, urea, simple amines, fatty acids, steroids, fat-soluble vitamins, narcotics, antibiotics, barbiturates, and anesthetics.
- Facilitated diffusion: Substances transported are glucose and oxygen.

Figure 7-9 Placenta and umbilical cord.

- Active transport: Substances transported via this mechanism include amino acids, water-soluble vitamins, calcium, iron, and iodine.
- Pinocytosis and endocytosis: Globulins, phospholipids, lipoproteins, antibodies, and viruses use these mechanisms of transport.
- Bulk flow and solvent drag: Water and electrolytes use these mechanisms of transport.
- Accidental capillary breaks: Facilitate the transport of intact blood cells.
- Independent movement: Maternal leukocytes and microorganisms such as *Treponema pallidum* use this mechanism of transport.

Placental endocrine activity plays a crucial role in maintaining the pregnancy. The four main hormones produced by the placenta are human chorionic gonadotrophin (hCG), human placental lactogen (hPL), progesterone, and estrogens. Human chorionic gonadotropin maintains the corpus luteum (a structure that secretes progesterone) during early pregnancy until the placenta has sufficiently developed to produce adequate amounts of progesterone. Human placental lactogen regulates glucose availability for the fetus and promotes fetal growth by altering maternal protein, carbohydrate, and fat metabolism. Progesterone helps to suppress maternal immunological responses to fetal antigens, thereby preventing maternal rejection of the fetus. Progesterone has a number of additional functions: decreases myometrial activity and irritability, constricts myometrial vessels, decreases maternal sensitivity to carbon dioxide, inhibits prolactin secretion, relaxes smooth muscle in the gastrointestinal and urinary systems, increases basal body temperature, and increases maternal sodium and chloride secretion.

Estrogen production increases significantly during pregnancy. This essential hormone enhances myometrial activity, promotes myometrial vasodilation, increases maternal respiratory center sensitivity to carbon dioxide, softens

fibers in the cervical collagen tissue, increases the pituitary secretion of prolactin, increases serum binding proteins and fibrinogen, decreases plasma proteins, and increases sensitivity of the uterus to progesterone in late pregnancy.

The placenta also plays an important role in protecting the fetus from pathogens and in preventing maternal rejection of the pregnancy. Although many bacteria are too large to pass through the placenta, most viruses and some bacteria are able to cross the placenta. Maternal antibodies (i.e., all subclasses of IgG) transit the placenta primarily by pinocytosis; others cross by the process of diffusion. Although the fetus has a unique genetic makeup that is different from the mother's, maternal rejection of the fetus usually does not occur. The exact reason for this phenomenon is not known.

Development of the Embryo and Fetus

THE YOLK SAC

Early in the pregnancy, the embryo is a flattened disc that is situated between the **amnion** (thick membrane that forms the amniotic sac that surrounds the embryo and fetus) and the yolk sac. The yolk sac is a structure that develops in the embryo's inner cell mass around day 8 or 9 after conception. It is essential for the transfer of nutrients to the embryo during the second and third weeks of gestation when development of the uteroplacental circulation is underway. **Hematopoiesis** (formation and development of red blood cells) occurs in the wall of the yolk sac beginning in the third week. This function gradually declines after the eighth gestational week when the fetal liver begins to take over this process. As the pregnancy progresses, the yolk sac atrophies and is incorporated into the umbilical cord. Key events that take place during early development of the embryo are shown in Figure 7-10.

Figure 7-10 Key events during early development of the embryo.

ORIGIN AND FUNCTION OF THE UMBILICAL CORD

During the time of placental development, the umbilical cord is also being formed. The body stalk connects the embryo to the yolk sac that contains blood vessels connecting to the chorionic villi. The vessels contract to form two arteries and one vein as the body stalk elongates and develops into the umbilical cord. Maternal blood flows through the uterine arteries and into the intervillous spaces of the placenta. The blood returns through the uterine veins and into the maternal circulation. Fetal blood flows through the umbilical arteries and into the villous capillaries of the placenta. The blood returns through the umbilical vein and into the fetal circulation. **Wharton's jelly** is a specialized connective tissue that surrounds the two arteries and one vein in the umbilical cord. This tissue, in addition to the high volume and pressure in the blood vessels, is important because it helps to protect the umbilical cord from compression. Most umbilical cords have a central insertion site into the placenta and at term are approximately 21 inches (55 cm) long with a diameter that ranges from 0.38 to 0.77 inch (1 to 2 cm).

Now Can You— Discuss characteristics of growth in the embryo/fetus?

1. Identify where the developing embryo obtains nutrients prior to development of the feto-maternal circulatory placental unit?

2. Describe seven mechanisms used for the transport of nutrients across the placenta?
3. Discuss how human placental lactogen (hPL) promotes fetal growth?

THE FETAL CIRCULATORY SYSTEM

The embryo receives nutrition from maternal blood by diffusion through the extraembryonic coelom (fluid-filled cavity surrounding the amnion and yolk sac) and the yolk sac by the end of the second week. Blood vessels begin to develop in the yolk sac during the beginning of the third week and embryonic blood vessels begin to develop about two days later. A primordial heart tube joins with blood vessels in the embryo, connecting the body stalk, chorion, and yolk sac to form a primitive cardiovascular system. The heart begins to beat and blood begins to circulate by the end of the third week.

During the third week, capillaries develop in the chorionic villi and become connected to the embryonic heart through vessels in the chorion and the connecting stalk. By the end of the third week, embryonic blood begins to flow through capillaries in the chorionic villi. Oxygen and nutrients from maternal blood diffuse through the walls in the villi and enter the embryo's blood. Carbon dioxide and waste products diffuse from blood in the embryo's capillaries through the wall of the chorionic villi and into the maternal blood. The umbilical cord is formed from the connecting stalk during the fourth week.

Blood travels through the fetus in a unique way. The umbilical cord contains three vessels: two arteries and one vein. Blood flows through the vein from the placenta to the fetus. A small amount of blood flows through the liver and then empties into the inferior vena cava. Most of the blood bypasses the liver and then enters the inferior vena cava by way of the **ductus venosus**, a vascular channel that connects the umbilical vein to the inferior vena cava. The blood then empties into the right atrium, passes through the **foramen ovale** (an opening in the septum between the right and left atrium) into the left atrium, then moves into the right ventricle and on into the aorta. From the aorta, blood travels to the head, upper extremities, and lower extremities. Blood returning from the head enters the superior vena cava, then the right atrium and the right ventricle before entering the pulmonary artery. Most of the blood that enters the pulmonary artery bypasses the lungs and enters the aorta through the **ductus arteriosus**, a vascular channel between the pulmonary artery and descending aorta. The remaining blood flows to the pulmonary circulation to support lung development. The blood then returns through the pulmonary vein to the left atrium, the left ventricle, to the aorta, and returns to the placenta through the two arteries. Most of the blood in the lower extremities enters the internal iliac artery and the umbilical arteries to the placenta to be re-oxygenated and re-circulated. Some of the blood in the lower extremities passes back to the ascending vena cava and is mixed with oxygenated blood from the placenta without being oxygenated.

The placenta is the site of oxygenation and waste elimination. Blood travels through the umbilical vein from the placenta to the fetus (Fig. 7-11). There are three shunts unique to fetal circulation:

1. Some blood circulates through the liver, but most bypasses the liver through the *ductus venosus* and enters the inferior vena cava.
2. Blood from the superior vena cava enters the right atrium, passes through the *foramen ovale*, through the right ventricle and into the aorta, supplying blood to the head and upper and lower extremities.
3. Blood returning from the head enters the right atrium, and then flows through the right ventricle and into the pulmonary artery. Most of this blood bypasses the lungs through the *ductus arteriosus*. A small amount of blood flows through the pulmonary circulation, back into the right atrium, right ventricle, and then into the aorta.

The arterial PO_2 of the fetus is about one-fourth of the maternal PO_2 because of the structure and function of the placenta (i.e., oxygenation of fetal blood takes place at a low PO_2), and because arterial blood in the fetal circulation is formed by the mixing of maternal oxygenated blood with fetal deoxygenated blood. Fetal hemoglobin has a lower oxygen content than that of the adult. The highest oxygen concentration ($PO_2 = 30$ to 35 mm Hg) is found in the blood returning from the placenta via the umbilical vein; the lowest oxygen concentration occurs in blood shunted to the placenta where re-oxygenation takes place. The blood with the highest oxygen content is delivered to the fetal heart, head, neck, and upper limbs, while the blood with the lowest oxygen content is shunted

Figure 7-11 Fetal circulation.

toward the placenta. The low PO_2 level is important in maintaining fetal circulation, as it keeps the ductus arteriosus open and the pulmonary vascular bed constricted. Fetal hemoglobin enables the fetus to adapt to the lowered PO_2 . This unique type of hemoglobin has a high affinity for oxygen at low tensions, which improves saturation and facilitates oxygen transport to the fetal tissues. The increased perfusion rate (as compared to the adult) also helps to compensate for the lower oxygen saturations and increased oxygen-hemoglobin affinity.

Now Can You— Discuss unique aspects of the fetal circulatory system?

1. Name the three shunts found in the fetal circulatory system?
2. Identify where the highest and lowest fetal oxygen concentrations are found?
3. Explain how fetal hemoglobin is unique?

FETAL MEMBRANES AND AMNIOTIC FLUID

The embryonic membranes (chorion and amnion) are early protective structures that begin to form at the time of implantation. The thick **chorion**, or outer membrane, forms first. It develops from the trophoblast and encloses the amnion, embryo, and yolk sac. The chorion contains fingerlike projections (chorionic villi) that may be used for genetic testing (chorionic villus sampling) during the first

trimester. The villi beneath the embryo grow and branch out into depressions in the wall of the uterus, and from this structure, the fetal portion of the placenta is formed.

The amnion arises from the ectoderm during early embryonic development. This membrane is a thin, protective structure that contains the amniotic fluid. The amniotic cavity, or space between the amnion and the embryo, houses the embryo and yolk sac, except in the area where the developing embryo attaches to the trophoblast via the umbilical cord. With embryonic growth, the amnion expands and comes into contact with the chorion. The two fetal membranes are slightly adherent and form the amniotic fluid-filled sac (the **amniotic sac**), also called the bag of waters. The fetal membranes provide a barrier of protection from ascending infection.

Amniotic fluid is vital for fetal growth and development. It cushions the fetus and protects against mechanical injury, helps the fetus to maintain a normal body temperature, allows for symmetrical fetal growth, prevents adherence of the amnion to the fetus, and aids in fetal musculoskeletal development by providing freedom of movement. It is essential for normal fetal lung development. Amniotic fluid volume is dynamic, constantly changing as the fluid moves back and forth across the placental membrane.

Amniotic fluid first appears at about 3 weeks. Approximately 30 mL of amniotic fluid are present at 10 weeks' gestation, and this amount increases to approximately 800 mL at 24 weeks' gestation. After that time, the total fluid volume remains fairly stable until it begins to decrease slightly as the pregnancy reaches term.

During late gestation, fetal urine and fetal lung secretions are the primary contributors to the total amniotic fluid volume. Fetal swallowing and absorption through the placenta are the primary pathways for amniotic fluid clearance. The fetus swallows approximately 600 mL every 4 hours and up to 400 mL of amniotic fluid flows from the fetal lungs every 24 hours. Amniotic fluid is slightly alkaline and contains antibacterial and other protective substances similar to those found in maternal breast milk (e.g., transferrin, beta-lysin, peroxidase, fatty acids, immunoglobulins [IgG and IgA], and lysozyme). It also contains albumin, uric acid, creatinine, lecithin, sphingomyelin, bilirubin, vernix, leukocytes, epithelial cells, and **lanugo** (fine, downy hair).

Now Can You— Discuss aspects of the amniotic sac and amniotic fluid?

1. Identify the origins of the embryonic membranes?
2. Name five functions of the amniotic fluid?
3. Discuss where amniotic fluid originates?

Human Growth and Development

Major organs are formed (organogenesis) during the first 8 weeks after fertilization. During this time, the developing organism is called an **embryo**. By the end of eight weeks, the embryo has sufficiently developed to be called a **fetus**. Human development proceeds in a cephalocaudal pattern of maturation: motor development, control, and coordination progress from the head to the feet.

The loss of a fetus before 20 to 22 weeks' gestation (less than 500 grams) is referred to as an abortion because the fetus is considered too immature to survive the **extrauterine** (outside of the uterus) environment. A fetus born before the completion of 37 weeks is considered to be preterm or premature.

PRE-EMBRYONIC PERIOD

The pre-embryonic period refers to the first 2 weeks of human development after conception. Rapid cellular multiplication, cell differentiation, and establishment of the embryonic membranes and primary germ layers occur during this time. Development takes place in a pattern that is cephalocaudal, proximal to distal and general to specific.

EMBRYONIC PERIOD

Critical development that occurs during the embryonic period involves cleavage of the zygote, blastogenesis (early development characterized by cleavage and formation of three germ layers that later develop into tissues and organs), and the early development of the nervous system, cardiovascular system, and all major internal and external structures. The pre-embryonic period refers to the first 2 weeks beginning at fertilization, which for most is approximately 2 weeks after the last normal menstrual period. The embryonic period is the time period beginning with the third week after fertilization and continuing until the end of the eighth week. This period is known as the organogenetic period that denotes the formation and differentiation of organs and organ systems.

Week 1

Fertilization usually occurs in the outer third portion of the uterine tube. The zygote then travels toward the uterus, while undergoing cleavage (series of mitotic cell division) and forming blastomeres (cells formed from the first mitotic division). Approximately 3 days after fertilization, a morula (a ball of 12 or more blastomeres) enters the uterus. A cavity forms within the morula, creating a blastocyst that consists of a trophoblast that encloses both the embryoblast (gives rise to the embryo and some extraembryonic tissues) and the blastocystic cavity (fluid-filled space). The trophoblast begins to invade the uterus and the blastocyst is superficially implanted by the end of the first week.

Week 2

The trophoblast undergoes rapid proliferation and differentiation as the blastocyst continues the process of uterine implantation. The yolk sac develops, the amniotic cavity appears, and the embryoblast differentiates into the bilaminar embryonic disc. Implantation of the blastocyst is completed by the end of the second week.

Week 3

The third week is characterized by the appearance of a primitive streak (proliferation and migration of cells to the central posterior region of the embryonic disc), the development of the notochord (cellular rod along the dorsal surface that will later be surrounded by vertebrae), and differentiation of the three germ layers: embryonic **ectoderm** (outer layer, gives rise to skin, teeth, and glands of the mouth and nervous system), **endoderm**

(inner layer, gives rise to epithelium of the respiratory, digestive and genitourinary tracts), and **mesoderm** (lies between the ectoderm and endoderm; gives rise to the connective tissue) (Table 7-2).

A & P review Formation of the Primary Germ Layers

Implantation of the blastocyst occurs at approximately 7 to 8 days after conception. At this time, the cells of the embryonic disc are separated from the amnion by a fluid-filled space. The syncytiotrophoblast continue to erode the endometrium and implantation is completed by the ninth day. The extraembryonic mesoderm forms a discrete layer beneath the cytotrophoblast. By the 16th day, all three germ layers are present, along with a yolk sac and the allantois, an outpouching of the yolk sac that forms the structural basis of the body stalk, or umbilical cord. The chorion arises from the cytotrophoblast and associated mesoderm and contains many fingerlike projections (chorionic villi) on its surface. ♦

Week 4

At the beginning of the fourth week, the flat trilaminar embryonic disc folds into a C-shaped, cylindrical embryo. Development continues as the three germ layers differentiate into various organs and tissues. By 28 postovulatory days, four limb buds and a closed otic vesicle (later develops into labyrinth of inner ear) are present (Fig. 7-12).

During the third and fourth weeks, development of the nervous system is well underway. A thickened portion of the ectoderm develops into the neural plate. The top portion will differentiate into the **neural tube**, which forms the central nervous system (brain and spinal cord) and the neural crest, which will develop into the peripheral nervous system. Later, the eye and inner ear develop as projections of the original neural tube. During the early period of development, the embryo's nervous system is particularly vulnerable to environmental insults.

Table 7-2 Derivatives of the Three Germ Layers

Ectoderm	Mesoderm	Endoderm
Epidermis Epithelium of mouth, oral glands, teeth, and organs of special sense.	Smooth muscle coats, connective tissues, and vessels associated with tissues and organs.	Epithelium of the pharynx, thyroid, thymus, parathyroid, respiratory passages, gastrointestinal tract, liver and pancreas
Central nervous system	Blood	
Peripheral nervous system	Bone marrow	
Hypophysis	Muscular tissues	
Suprarenal medulla	Skeletal tissues	
	Suprarenal cortex	

Figure 7-12 Embryo at 4 weeks' gestation (28 postovulatory days). All four limb buds are present. (Smith, B.R. (2008). The multidimensional human embryo, Carnegie Stages. Retrieved from <http://embryo.soad.umich.edu/carnstages/>)

Optimizing Outcomes— Preventing neural tube defects

Defective closure of the neural tube during the fourth week of development results in a condition known as a **neural tube defect** (NTD). This is a malformation that involves defects in the skull and spinal column and is primarily caused by failure of the neural tube to close. Tissues overlying the spinal cord including the meninges, vertebral arches, muscles, and skin may be affected as well. Neural tube defects include rachischisis (spina bifida), myelocele, myelomeningocele, and meningocele. Immediate surgical repair is often necessary after birth. NTDs are the second most frequent structural fetal malformation and occur in 1 to 2 per 1000 live births (Cunningham et al., 2005). Folic acid supplementation has been found to decrease the incidence of NTDs (Evans, Llorba, Landsberger, O'Brien, & Harrison, 2004). Currently, the United States Public Health Service recommends that all women of childbearing age who are capable of becoming pregnant consume 0.4 mg of folic acid daily to reduce the incidence of neural tube defects.

Week 8

By the end of the eighth week, there is a clear distinction between the upper and lower limbs, the external genitals are well developed, although not always well enough to distinguish the gender, and the embryo has a human appearance (Fig. 7-13). The main organ systems have also begun to develop by the end of 8 weeks. Except for the cardiovascular system, however, there is minimal function of most of the organ systems.

Now Can You— Discuss the pre-embryonic and embryonic periods of development?

1. Define the pre-embryonic period and identify the pattern of human development that occurs?
2. Identify what time frame is encompassed in the embryonic period?
3. Describe the major developmental events that have occurred by the end of the eighth week?

THE FETAL PERIOD

The beginning of the ninth week marks the beginning of the fetal period when the embryo has now developed into a recognizable human being. The fetal period is character-

Figure 7-13 The embryo at 8 weeks (56 to 57 postovulatory days) has a human appearance. (Smith, B.R. (2008). The multidimensional human embryo, Carnegie Stages. Retrieved from <http://embryo.soad.umich.edu/carnstages/>)

ized by rapid body growth and differentiation of tissues, organs, and systems. The rate of head growth during this period of time slows down as compared to the rate of body growth. During the last 12 weeks of pregnancy there is a substantial increase in fetal size: the weight triples and the body length doubles.

Weeks 9 to 12

The fetal head is half the length of the crown–rump length at the beginning of the ninth week. The face is recognizably human at 10 weeks. Body growth increases, and as a result, the crown–rump length more than doubles by the twelfth week. Head growth does not keep pace with body growth and slows considerably by the twelfth week but remains proportionately large as compared to the rest of the body. Ossification centers appear in the skeleton. The intestines leave the umbilical cord and enter the abdomen. The external genitalia differentiate and are distinguishable by week 12. At 9 weeks, the liver serves as the major site for red blood cell production (erythropoiesis). However, by 12 weeks, the spleen begins to take over this process. Urine production commences between 9 and 12 weeks.

Weeks 13 to 16

There is very rapid growth during this period. Although coordinated movements of the limbs occur by the fourteenth week, they are too small to be felt by the mother. Ossification of the skeleton takes place and the bones become clearly visible on ultrasound examination. The external genitalia are recognizable by 12 to 14 weeks, the ovaries are differentiated, and the primordial (primitive) ovarian follicles are present by 16 weeks.

Weeks 17 to 20

Growth continues but slows during this period. Maternal awareness of fetal movements (**quickening**) is frequently reported during this time. The skin is now covered with a thick, cheese-like material called **vernix caseosa** that protects the fetal skin from exposure to the amniotic fluid. By 20 weeks, hair appears on the eyebrows and head. Fine downy hair (lanugo) is usually present by 20 weeks and covers all parts of the body except the palms, soles, or areas where other types of hair are usually found. Subcutaneous deposits of **brown fat**, used by the newborn for heat production, help to make the skin less transparent in appearance. The fetal

uterus is formed at 18 weeks in females, and in males, the testes have begun to descend but are still located in the abdominal wall. By 20 weeks, the fetus weighs about 300 grams and is approximately 7.3 inches (19 cm) long.

Weeks 21 to 25

The fetus gains much weight during this time. The skin appears pink or red as blood is now visible in the capillaries. Rapid eye movements begin at 21 weeks. By 24 weeks, the fetus has fingernails and the lungs have begun to secrete **surfactant**, a substance that decreases surface tension in the alveoli and is necessary for survival following birth.

Weeks 26 to 29

A fetus may survive if born during this time because the lungs can breathe air, and the central nervous system can regulate body temperature and direct rhythmic breathing. The eyelids are open, the toenails are evident, and subcutaneous fat is present under the skin. Erythropoiesis occurs in the spleen but ends at 28 weeks when the bone marrow takes over that function.

Weeks 30 to 34

At 30 weeks, the pupillary light reflex is present.

Weeks 35 to 40

At 35 weeks, the fetus has a strong hand grasp reflex and orientation to light. At 38 to 40 weeks, the average fetus weighs 3000 to 3800 grams, and is 17.3 to 19.2 inches (45 to 50 cm) long (Table 7-3).

Across Care Settings: Empowering through education

The nurse who works in any perinatal setting can help to promote self-care and empowerment by increasing the pregnant woman's understanding of the prenatal journey and by encouraging her active involvement in safeguarding her pregnancy. Providing information regarding normal fetal growth and development constitutes an important component of the early and ongoing bonding process for many women. Displaying fetal growth charts in visible areas and discussing developmental landmarks throughout gestation facilitate discussion and enhance understanding for the patient and her family. Other professional resources including the nutritionist, social worker, and home health worker can be instrumental in helping to ensure healthy fetal growth and development.

Nursing Insight— Preterm birth at less than 38 weeks' gestation

It is important to understand fetal growth and development so that the nurse can anticipate specific types of problems that may occur when infants are born prematurely. An infant born at 28 weeks will have significantly different needs from an infant born at 38 weeks' gestation.

Table 7-3 Embryonic and Fetal Growth and Development

Weeks	Weight	Length (crown to rump)	Characteristics
2 weeks	?	2 mm	Blastocyst implanted in uterus
4 weeks	0.4 g	4 mm	Embryo is curved, tail prominent. Upper limb buds and otic pits present. Heart prominence evident.
8 weeks	2 g	3 cm	Head rounded with human characteristics. Unable to determine sex. Intestines still present in umbilical cord. Ovaries and testes distinguishable.
12 weeks	19 g	8 cm	Resembles human being, with disproportionately large head. Eyes fused. Skin pink and delicate. Upper limbs almost reached final length. Intestines in the stomach. Sex distinguishable externally.
16 weeks	100 g	13.5 cm	Scalp hair appears. External ears present. Lower limbs well developed. Arm to leg ratio proportionate. Fetus active.
20 weeks	300 g	18.5 cm	Head and body hair (lanugo) present. Vernix covers skin. Quickening felt by the woman.
24 weeks	600 g	23 cm	Skin reddish and wrinkled. Some subcutaneous fat present. Some respiratory-like movements. Fingernails present. Lean body.
28 weeks	1100 g	27 cm	Eyes open with eyelashes present. Much hair present. Skin slightly wrinkled, more fat now present.
32 weeks	1800 g	31 cm	Skin is smooth. Increase in weight gain more than length. Toenails present. Testes descending.
36 weeks	2200 g	34 cm	Skin pale, body plump. Body lanugo almost gone. Able to flex arm and form grasp. Umbilicus in center of body. Testes in inguinal canal, scrotum small with few rugae. Some sole creases present.
40 weeks	3200+ g	40 cm	Skin smooth and pink. Lanugo on upper back and shoulders. Ear lobes formed and firm. Chest prominent and breasts often protrude slightly. Testes with well defined rugae. Labia majora well developed. Creases cover soles of feet.

Now Can You— Discuss major events of the fetal period?

1. Identify the developmental week when the fetal face becomes human in appearance?
2. Name the cheese-like substance that covers and protects the skin?
3. List three developmental events that occur from 26 to 29 weeks?

Factors that May Adversely Affect Embryonic and Fetal Development

Damage to the developing embryo/fetus may result from genetic factors or from maternal exposure to various environmental hazards. In most circumstances, the uterus provides a safe and peaceful environment for the developing embryo and fetus. However, teratogens (drugs, radiation, and infectious agents that can cause developmental or structural abnormalities in an embryo) and a variety of internal and external developmental events may cause structural and functional defects.

CHROMOSOMES AND TERATOGENS

Genetic defects and congenital anomalies usually result from genetic factors, environmental hazards (e.g., drugs and viruses), or a combination of both (multifactorial inheritance). However, the exact cause of anomalies

is unknown in approximately 50% to 60% of cases. Congenital anomalies may occur singularly or in combination with other defects (multiple anomalies) and they may be of little or of great clinical significance. Single, minor anomalies occur in approximately 14% of newborns. The greater the number of anomalies present, the greater the risk of a major anomaly. Statistically, 90% of infants with three or more minor anomalies will also have one or more major anomaly. Major developmental defects are more common in early embryos that are usually spontaneously aborted. It has been estimated that approximately one-third of all birth defects are caused by genetic factors.

Before fertilization, damage may have already occurred to the chromosomes of one or both parents, or they may carry defective genes inherited from their own parents. Alterations in the development of sperm or an ovum may also cause alterations in the development of the embryo. Teratogens or environmental factors may adversely affect the process of implantation and result in loss of the zygote. Teratogens may have specific effects associated with congenital anomalies (e.g., alcohol: fetal alcohol syndrome; rubella: cataracts; tetracycline: stained teeth) or they may produce dysmorphic (damage to the structure and form) features. The extent of the teratogenic effect depends on the developmental timing, duration, and dosage of exposure as well as the maternal genetic susceptibility. Greater exposure during early gestation is associated with more severe effects.

Teratogen Exposure During Organogenesis

The period of organogenesis lasts from approximately the second until the eighth week of gestation, during which time the embryo undergoes rapid growth and differentiation. During organogenesis the embryo is extremely vulnerable to teratogens such as medications, alcohol, tobacco, caffeine, illegal drugs, radiation, heavy metals, and maternal (TORCH) infections. Structural defects are most likely to occur during this period because exposure to teratogens either before or during a critical period of development of an organ can cause a malformation.

After 11 weeks, the fetus becomes more resistant to damage from teratogens because the organ systems have been established. However, organ function can still be adversely affected. Insults that occur later in fetal life or during early infancy may cause mental retardation, blindness, hearing loss, deafness, stillbirth, or malignancy.

The most critical time for brain development is between 3 and 16 weeks of gestation. However, the brain continues to differentiate and grow rapidly until at least the first 2 years of life. Diet and nutrition are important during this time because amino acids, glucose, and fatty acids are considered to be the primary dietary factors in brain growth.

Medications and Other Substances

It is estimated that approximately 82% of women between the ages of 18 and 44 regularly use at least one medication (prescription or over-the-counter) or vitamins, minerals, herbal supplements, topical medications, or eye drops. Forty-six percent take a prescription medication and the most commonly used drugs used include acetaminophen, ibuprofen, estrogen, pseudoephedrine, and aspirin (National Center for Health Statistics, 2006). Many women unintentionally take medications during early pregnancy when they do not yet know they are pregnant and approximately 59% of pregnant women receive a prescription for a medication other than a vitamin or mineral supplement. To identify drugs that are unsafe for maternal ingestion due to their teratogenic potential, the U.S. Food and Drug Administration (FDA) has established five categories of safety (Table 7-4).

A small number of medications and other substances are known or are strongly suspected to be human teratogens. These include fat-soluble vitamins, alcohol, tobacco, caffeine, cocaine, opiates, anticonvulsants, warfarin (Coumadin), cardiovascular agents (e.g., Lipitor, Mevacor, Pravachol), retinoids (e.g., Soriatane, Tegison, Accutane, Avage), certain hormones (e.g., Depo-Provera, Android, Androlone-D, Pitressin), antineoplastic agents (e.g., Targretin, Casodex, Emcyt), certain anti-infective agents (e.g., Penetrex, Novo quinine, Virazole), thalidomide, and methyl mercury.

FAT-SOLUBLE VITAMINS. Both high and low doses of vitamin A (Retinol) can cause fetal malformations that include anomalies of the central nervous system, microtia (deformity of the outer ear), and clefts (a fissure or elongated opening that originates in the embryo, such as a branchial or facial cleft). Vitamin D deficiency may cause poor fetal growth, neonatal hypocalcemia, rickets, and poor tooth enamel. High doses of vitamin E (α -tocopherol) may increase the risk for bleeding problems, but neither deficiency nor excess has been associated with maternal or fetal complications during pregnancy (Tillett et al., 2003).

Table 7-4 FDA Pregnancy Categories

Category	Interpretation
A	Adequate, well-controlled studies in pregnant women have not shown an increased risk of fetal abnormalities to the fetus in any trimester of pregnancy.
B	Animal studies have revealed no evidence of harm to the fetus; however, there are no adequate and well-controlled studies in pregnant women.
	OR
	Animal studies have shown as adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester.
C	Animal studies have shown an adverse effect and there are no adequate and well-controlled studies in pregnant women.
	OR
	No animal studies have been conducted and there are no adequate and well-controlled studies in pregnant women.
D	Adequate well-controlled or observational studies in pregnant women have demonstrated a risk to the fetus.
	However, the benefits of therapy may outweigh the potential risk. For example, the drug may be acceptable if needed in a life-threatening situation or serious disease for which safer drugs cannot be used or are ineffective.
X	Adequate well-controlled or observational studies in animals or pregnant women have demonstrated positive evidence of fetal abnormalities or risks.
	The use of the product is contraindicated in women who are or may become pregnant.

ALCOHOL. Ethyl alcohol is one of the most potent teratogens known. The Surgeon General's advisory on alcohol use (February, 2005) found that in 2003, approximately 10% of pregnant women reported drinking, and of those, 4% reported having engaged in binge drinking (U.S. Department of Health and Human Services [USDHHS], 2005).

A safe threshold level for the use of alcohol during pregnancy has never been established. Current data suggest that children of mothers who chronically ingested large amounts of alcohol or who engaged in binge drinking (five or more drinks on one occasion) during pregnancy are at greatest risk for permanent damage. (See Chapter 10 for further discussion.)

TOBACCO. Approximately 25% of women smoke while pregnant. Cigarette smoking during pregnancy is associated with an overall reduction in fetal growth, cleft lip anomalies, impaired infant neurobehavior, and decreased babbling in infants (Chiriboga, 2003). Nicotine causes

vasoconstriction of the uterine blood vessels, resulting in a decreased blood flow and supply of nutrients and oxygen to the fetus. Cigarette smoking doubles the risk of low birth weight and increases the likelihood of giving birth to a small for gestational age (SGA) infant (Reed, Aranda, & Hales, 2006). Cessation of smoking during pregnancy is beneficial to the developing fetus, and infants born to women who stop smoking during the first trimester have birth weights similar to those of infants born to nonsmoking women. (See Chapter 10 for further discussion.)

CAFFEINE. Caffeine, present in many beverages (sodas, coffee, tea, hot cocoa) and other substances including chocolate, cold remedies, and analgesics, is the most popular drug in the United States. Caffeine stimulates central nervous system and cardiac function and produces vasoconstriction and mild diuresis. The half-life of caffeine is tripled during pregnancy. Although caffeine readily crosses the placenta and stimulates the fetus, it is not known to be a teratogen. However, there is no assurance that maternal consumption of large quantities of caffeine is safe for the developing fetus. (See Chapter 10 for further discussion.)

COCAINE AND CRACK. Cocaine and crack (a form of free-base cocaine that can be smoked) use during pregnancy causes vasoconstriction of the uterine vessels and adversely affects blood flow to the fetus. Cocaine use in pregnancy is associated with spontaneous abortion, abruptio placentae, stillbirth, intrauterine growth restriction (IUGR), fetal distress, meconium staining, and preterm birth. Problems manifested in children born to women who use cocaine during pregnancy include altered neurological and behavior patterns, neonatal strokes and seizures, and congenital malformations (genitourinary anomalies, limb reduction deformities, intestinal atresia, and heart defects) (Chiriboga, 2003). (See Chapters 9 and 10 for further discussion.)

OPIATES. Morphine, heroin, and methadone are opiates sometimes used by pregnant women. Maternal effects from these substances include spontaneous abortion, premature rupture of the membranes, preterm labor, an increased incidence of sexually transmitted infections, hepatitis, an increased potential for HIV exposure, and malnutrition. Methadone is a habit-forming synthetic analgesic drug with a potency equal to that of morphine but with a weaker narcotic action. It is frequently given to pregnant women who enter drug addiction programs. Fetal death, intrauterine growth restriction, perinatal asphyxia, prematurity, intellectual impairment, and neonatal infection are associated with maternal opiate use. Neonatal withdrawal syndrome, characterized by hyperirritability, gastrointestinal dysfunction, respiratory distress, and autonomic disturbances, has been reported in 50 to 80% of infants born to opiate-dependent mothers (Chiriboga, 2003). (See Chapters 9 and 19 for further discussion.)

SEDATIVES. Barbiturates and tranquilizers produce maternal lethargy, drowsiness, and CNS depression. In the neonate, these substances are associated with withdrawal syndrome, seizures and delayed lung maturity.

AMPHETAMINES. Amphetamines are also known as “speed,” “crystal,” and “ice”; use of these substances during pregnancy is associated with maternal malnutrition, tachycardia, and withdrawal symptoms that include lethargy and

depression. The fetus is at an increased risk for intrauterine growth restriction, prematurity, cardiac anomalies, cleft palate, and placental abruption. Following birth, affected neonates may exhibit hypoglycemia, sweating, poor visual tracking, lethargy, and difficulty feeding. (See Chapter 9 for further discussion.)

MARIJUANA. Δ -9-Tetrahydrocannabinol (THC), the active component in marijuana, passes through the placenta and may remain in the fetus for up to 30 days. The carbon monoxide levels produced with marijuana smoking are five times higher than amounts produced with cigarette smoking. Marijuana may cause intrauterine growth restriction, and research has indicated that maternal use of marijuana during pregnancy has adverse effects on neonatal neurobehavior (e.g., hyperirritability, tremors, photosensitivity) and can affect cognitive and language development in infants up to 48 months of age (Chiriboga, 2003). In addition, maternal marijuana use is often combined with other drugs such as cocaine and alcohol. Repeated marijuana use during pregnancy may increase the incidence of maternal anemia and low weight gain. (See Chapters 9 and 10 for further discussion.)

RADIATION. High levels of radiation during pregnancy may cause damage to chromosomes and embryonic cells. Radiation can adversely affect fetal physical growth and cause mental retardation. Unborn babies are particularly at risk to damage from radiation exposure during the first trimester. Consequences of radiation exposure during this time include stunted growth, deformities, abnormal brain function, or cancer that may develop sometime later in life (Centers for Disease Control and Prevention [CDC], 2005).

LEAD. Lead passes through the placenta and has been found to be associated with spontaneous abortion, fetal anomalies, and preterm birth. The nervous system is the most sensitive target of lead exposure. Fetuses and young children are especially vulnerable to the neurological effects of lead because their brains and nervous systems are still developing and the blood–brain barrier is incomplete (USDHHS, 1999). Fetal anomalies associated with lead exposure include hemangiomas, lymphangiomas, hydrocele, minor skin abnormalities (e.g., skin tags and papillae), and undescended testes (Gardella, 2001).

Optimizing Outcomes— Prenatal screening and questions regarding drug use

Due to the teratogenic effects of drugs and other substances on the developing embryo/fetus, prenatal screening for maternal drug use is an important component of the prenatal interview. The nurse should ask questions regarding maternal drug use in a nonjudgmental manner that conveys caring and concern. Questions should be specific, and begin with inquiries that concern innocuous drug use and then progress to the most harmful substances. Examples of questions to ask include the following:

Do you drink any caffeinated beverages? How many in a day?

Do you smoke cigarettes? How many in a day?

Do you drink alcohol? What kind, and how much in a day?

Do you use substances such as marijuana, cocaine, crack, or heroin? Which ones, and how often?

Are you currently, or have you ever been enrolled in a substance abuse program?

 **Now Can You**—Discuss substances that may adversely affect embryo/fetal growth and development?

1. Explain why the embryo is particularly vulnerable to teratogens during organogenesis?
2. Name two vitamins that are associated with fetal malformations?
3. List one fetal effect associated with maternal use of each of the following: tobacco, cocaine, heroin, and marijuana?

TORCH INFECTIONS

TORCH infections are a group of agents that can infect the fetus or newborn. These include **Toxoplasmosis**, **Other infections**, **Rubella virus**, **Cytomegalovirus**, and the **Herpes simplex virus**. The fetal risks associated with the various TORCH infections are listed in Box 7-1. (See Chapters 4, 9, and 11 for further discussion about TORCH infections.)

Toxoplasmosis

Toxoplasma gondii, a single-celled parasite, is responsible for toxoplasmosis. This parasite is found throughout the world, and although more than 60 million people in the United States may be infected, most are unaware of the disease (CDC, 2004a). The majority of individuals who become infected with toxoplasmosis are asymptomatic, although when present, symptoms are described as “flu-like” and include glandular pain and enlargement (lymphadenopathy) and myalgia. Severe infection may cause damage to the brain, eyes, or organs. Toxoplasmosis is usually acquired by eating raw or poorly cooked meat contaminated with *Toxoplasma gondii*. This disease may also be acquired through close contact with feces from an infected animal (usually a cat) or from contact with soil that has been contaminated with *Toxoplasma gondii*.

Once maternal infection occurs, the *Toxoplasma gondii* organism crosses the placental membrane and infects the fetus, causing damage to the eyes and brain. If the infection is acquired early in the gestation, there is an increased risk of fetal death. To minimize the risk of infection, pregnant women should avoid raw or poorly cooled meats and contact with animals that may be infected with the toxoplasmosis parasite.

Other Infections

Other infections recognized as teratogens include varicella-zoster virus (chickenpox), human immunodeficiency virus (HIV), and syphilis. The varicella-zoster virus, a member of the herpes family, causes chickenpox and shingles. Infection with the varicella virus during the first 4 months of pregnancy is associated with a number of congenital anomalies including muscle atrophy, limb hypoplasia (underdevelopment), damage to the eyes and brain, and mental retardation. No proven teratogenic risks have

Box 7-1 TORCH Infections

TORCH infections can cause serious harm to the embryo-fetus, especially during the first 12 weeks when developmental anomalies may occur.

TOXOPLASMOSIS

Associated with consumption of infested undercooked meat and poor hand washing after handling cat litter. Fetal infection occurs if the mother acquires toxoplasmosis after conception and passes it to the fetus via the placenta. Most infants are asymptomatic at birth, but develop symptoms later.

Maternal Effects

Flu-like symptoms in the acute phase.

Fetal/Neonatal Effects

Miscarriage likely in early pregnancy. In neonates, CNS lesions can result in hydrocephaly, microcephaly, chronic retinitis, and seizures. Retincho-roiditis may appear in adolescence or adulthood.

OTHER INFECTIONS

Most commonly includes the hepatitis virus. Hepatitis A virus is spread by droplets or hands; transmission is rare but can occur. Hepatitis B virus can be transmitted via placenta, but transmission usually occurs when the infant is exposed to blood and genital secretions during labor and birth.

Maternal Effects

Fever, malaise, nausea, abdominal discomfort, may be associated with liver failure.

Fetal/Neonatal Effects

Preterm birth, hepatitis infection, intrauterine death.

RUBELLA (GERMAN MEASLES)

Spread by respiratory droplets.

Maternal Effects

Fever, rash, mild lymphedema.

Fetal/Neonatal Effects

Miscarriage, IUGR, cataracts, congenital anomalies, hepatosplenomegaly, hyperbilirubinemia, mental retardation, and death. Other symptoms may develop later. Infants born with congenital rubella are contagious and should be isolated. Patients are instructed not to become pregnant for 1 month after receiving the immunization; a signed consent form must be obtained before administration of the vaccine.

CYTOMEGALOVIRUS (CMV)

Respiratory droplets, semen, cervical and vaginal secretions, breast milk, placental tissue, urine, feces, and banked blood (nearly 50% of adults in United States have antibodies for this virus).

Maternal Effects

Asymptomatic illness, cervical discharge, and mononucleosis-like syndrome.

Fetal/Neonatal Effects

Fetal death or severe generalized disease with hemolytic anemia and jaundice, hydrocephaly or microcephaly, pneumonitis, hepatosplenomegaly, mental retardation, cerebral palsy, and deafness. The organs/tissues affected most often are blood, brain, and liver.

HERPES SIMPLEX VIRUS (HSV)

HSV II is sexually transmitted, infant usually infected during exposure to lesion in birth canal, most at risk during a primary infection in the mother (50% born vaginally will develop some form of herpes; 60% will die; half of survivors develop problems).

Maternal Effects

Blisters, rash, fever, malaise, nausea, and headache.

Fetal/Neonatal Effects

Miscarriage, preterm birth, stillbirth, transplacental infection is rare but can cause skin lesions, IUGR, mental retardation, microcephaly, seizures, coma.

been associated with varicella infection that occurs after 20 weeks' gestation (Moore & Persaud, 2003) although approximately 25% of infants born to mothers who become infected with varicella in the last 3 weeks of pregnancy will develop clinical varicella (Gershon, 2006).

The human immunodeficiency virus may be transplacentally transmitted to the fetus in utero. Infection may also occur intrapartally (during labor and birth) from exposure to maternal blood and body fluids, and postpartally (after birth), through breast milk. Without medical intervention, the risk of perinatal transmission of HIV is approximately 25%; with appropriate treatment, the rate of perinatal transmission can be reduced to 2% (Havens & Walters, 2004). (See Chapter 11 for further discussion.)

Treponema pallidum, the microorganism that causes syphilis, readily crosses the placenta. The fetus may become infected during any time of gestation. Serious fetal infection and congenital anomalies are almost always associated with primary maternal infections that occur during pregnancy. However, *Treponema pallidum* can be destroyed with adequate treatment that will prevent placental transmission and fetal infection. Secondary infections acquired before pregnancy rarely result in fetal disease and anomalies. Left untreated, only 20% of pregnant women with primary syphilis infections will give birth to a normal term infant. Neonatal manifestations of congenital syphilis infection include prematurity, skin rash, hydrops fetalis, failure to thrive, hepatosplenomegaly, lymphadenopathy, and bone lesions (osteochondritis, osteomyelitis, and periostitis). Late-onset manifestations of congenital syphilis infection include keratitis (inflammation of the cornea), deafness, and bowing of the shins (Woods, 2005).

Rubella

The virus that causes rubella (also known as German measles) can cause damage to the developing embryo/fetus. The earlier in the pregnancy that the disease is contracted, the greater the risk to the developing embryo. If the pregnant woman experiences a primary rubella infection during the first trimester, there is a 20% risk that the fetus will also become infected. When maternal rubella infection occurs during the first 4 to 5 weeks after fertilization, the majority of infants will demonstrate congenital anomalies. If rubella is contracted during the second and third trimesters, the risk of congenital anomalies is decreased to 10%, but mental retardation and hearing loss may result from infection that occurs late in the gestation. Birth defects associated with congenital rubella syndrome include hearing loss, eye defects causing vision loss or blindness, heart defects, and mental retardation.

Cytomegalovirus (CMV)

Approximately 50% to 80% of adults have antibodies to the cytomegalovirus (CMV) (Yudkin & Gonik, 2006). CMV produces no signs or symptoms of infection in the majority of affected individuals. However, CMV can cause disease in unborn babies or in persons with weakened immune systems. The cytomegalovirus is a member of the herpesvirus family, and is the most common viral infection in the fetus.

Spontaneous abortion (miscarriage) may result from maternal CMV infection during the first trimester. Infection

that occurs later in the pregnancy may result in fetal intrauterine growth restriction, microphthalmia, chorioretinitis, blindness, microcephaly, cerebral calcification, mental retardation, deafness, cerebral palsy, and hepatosplenomegaly. In the neonate, asymptomatic CMV infections are often associated with audiological, neurological, and neurobehavioral disturbances.

Herpes Simplex Virus (HSV)

Spontaneous abortion is increased threefold if maternal infection from herpes simplex virus occurs in early pregnancy. Infection after the twentieth gestational week is associated with an increased rate of prematurity. The transmission of the herpes virus occurs at the time of delivery during passage through the birth canal, but may also occur transplacentally via ascending infection before labor or rupture of the membranes. Congenital anomalies associated with the herpes simplex virus include extensive dermatological scarring or bullae, microencephaly, hydranencephaly, encephalitis, microphthalmia, chorioretinitis, and hepatosplenomegaly (Pan, Cole, & Weintrub, 2005). (See Chapter 19 for further discussion.)

Now Can You— Discuss TORCH infections?

1. Identify the components of the acronym "TORCH"?
2. Describe a teaching need for pregnant women who have indoor cats?
3. Explain why pregnant women should avoid individuals infected with chickenpox and rubella?

The Nurse's Role in Prenatal Evaluation

The clinical gestational period is divided into three trimesters that each last for 3 months. By the end of the first trimester, all major organs are developed. During the second trimester, the fetus continues to grow in size and most fetal anomalies can be detected using high-resolution real-time ultrasound. By the beginning of the third trimester the fetus has a chance for survival and most survive if born at or after 35 weeks' gestation.

At the initial prenatal visit, the nurse performs an assessment that includes careful consideration of cultural, emotional, physical, and physiological factors that may signal a need for genetics counseling and comprehensive fetal evaluation.

Optimizing Outcomes— Expanding nursing roles in genetics health care

Roles for maternity, women's health, and pediatrics nurses in genetics health care have expanded significantly over the past few years as genetics education and counseling has become standard of care. Today, nurses may provide preconception counseling for women at risk for the transmission of a genetic disorder (Klipstein, 2005), prenatal care for women with genetically linked psychiatric disorders (Lamberg, 2005) or other conditions (e.g. congenital heart disease) that require specialized care (Khairy et al., 2006),

or infant screening (Kenner & Moran, 2005). Nurses may also be involved in caring for families who have children with genetic conditions (Gallo, Angst, Knafl, Hadley, & Smith, 2005; Kenner, Gallo, & Bryant, 2005) or those who have lost a fetus or child affected by a genetic condition (Korenromp, 2005). In 2005, nursing leaders developed the document *Essential Nursing Competencies and Curricula Guidelines for Genetics and Genomics*. This publication, which presents minimal genetic and genomic competencies for all nurses, may be accessed at <http://www.nursingworld.org/>.

Prenatal care involves ongoing medical and psychosocial support. (See Chapter 9 for further discussion.) Common prenatal screening includes blood testing and ultrasound examination. Depending on maternal and familial risk factors, advanced screening tests may be indicated. Amniocentesis, chorionic villus sampling, and percutaneous umbilical blood sampling (PUBS) are examples of specialized prenatal diagnostic methods. (See Chapters 9 and 11 for further discussion.)

Nursing Insight— Specific methods for gene identification and testing

Gene identification and testing involves the analysis of human DNA, RNA (ribonucleic acid), chromosomes, or certain proteins to identify abnormalities related to an inherited condition. Through direct or molecular testing, the DNA and RNA that make up a single gene are directly examined; with linkage analysis, markers that are co-inherited with a specific gene that causes a genetic condition are analyzed; through biochemical testing, scientists examine the protein products of genes; and with cytogenetic testing, individual chromosomes are examined. Commercially available genetic tests can be accessed online at GeneTests, <http://www.genetests.org/>

Genetic counseling should be offered to couples with a personal or family history of a heritable genetic disorder. The nurse must be aware of, and be able to provide education regarding the potential for an increased risk for various diseases found among certain racial and ethnic populations (Table 7-5). Testing for many common genetic diseases is now available. For diseases in which the responsible gene has not been identified, the risk can sometimes be estimated by comparing fetal DNA with that of affected and non-affected family members.

Ethnocultural Considerations— Maintaining and communicating a caring and accepting attitude

It is important for the nurse to be knowledgeable of various cultural practices and beliefs that may impact on the development of the fetus. Culture and experience influence every aspect of individuals' lives and how they care for themselves and their families. For example, women from some ethnic groups choose to visit health healers and lay midwives throughout pregnancy.

The nurse should maintain an unbiased and accepting attitude when working with patients from populations with varying

Table 7-5 Racial and Ethnic Groups with Increased Risk for Diseases Caused by Recessive Genes

Racial/Ethnic Group	Disease
African, Mediterranean, Caribbean, Latin American, or Middle Eastern descent	Hemoglobin gene mutations are more common in persons from these areas. African Americans have an increased incidence of sickle cell anemia. Southeast Asians have a greater likelihood of carrying hemoglobin E, an abnormal hemoglobin.
Mediterranean or Asian origin	These individuals have a higher risk of the hereditary anemia thalassemia.
Jewish ancestry	Individuals with Jewish ancestry have an increased risk for diseases associated with inborn errors of metabolism caused by different enzyme deficiencies (e.g., Tay-Sachs, Canavan, and Gaucher).
Caucasian or northern European descent	The most common disorder found among this population is cystic fibrosis.

beliefs and practices. Awareness and understanding of personal practices and beliefs constitutes the first step toward ensuring an unbiased disposition when providing patient care. Recognizing that cultural values and experiences shape an individual's likelihood to continue or discontinue familial beliefs and practices helps the nurse to develop a more accepting attitude and deliver appropriate care in a culturally sensitive manner.

Hereditary and Genetics

According to the CDC, the leading cause of infant death in the United States in 2002 was related to problems associated with congenital malformations, deformations, and chromosomal abnormalities. These conditions accounted for 20% of all infant deaths (CDC, 2004b). Birth defects, or **congenital anomalies**, are structural abnormalities present at birth. Congenital anomalies may result from four different pathological processes: malformation, disruption, deformation, and dysplasia. **Malformation** is the alteration in embryonic development caused by genetic transmission, chromosomal anomalies, environmental factors, and multifactorial/unknown causes. This defect results from an intrinsic abnormal development that is present from the beginning of development, such as one that arises from a chromosomal abnormality. A disruption is caused by an external force that alters previously normal tissue and interferes with normal development. Maternal exposure to teratogens, such as drugs, viruses or environmental hazards, may also cause a disruption. Disruptions are not inherited although an individual may be predisposed to the development of a disruption. **Deformations** are physical alterations in form, shape, or position that are caused

by extrinsic mechanical factors (e.g., clubfoot that results from intrauterine fetal restraint or fetal compression defects that result from decreased amniotic fluid [oligohydramnios]). **Dysplasia** (an abnormal development of tissue) is caused by an abnormal organization of cells that results in abnormal tissue formation. (See Chapter 11 for further discussion.)

Damage that may alter embryological development can occur to the chromosomes of one or both parents prior to conception. During the pre-embryonic period (up to 14 days after conception), while the zygote is protected by the zona pellucida, exposure to teratogens most likely causes either no harmful effects or produces severe damage that results in loss of the pregnancy.

“What to say” — Prenatal identification of a fetal anomaly

Prenatal testing may identify a fetus with a congenital anomaly. When this occurs, families are generally faced with a flood of emotions and difficult decisions. The nurse plays an important role in providing support and education regarding options available to these couples. A nonjudgmental and caring attitude is vital at this difficult and vulnerable time.

Therapeutic communication is enhanced when the nurse uses statements such as:

“It’s normal to have fear, grief, or even be angry.”

“It’s normal to have concerns about your ability to have a normal baby.”

“I am here to answer your questions and listen to your concerns. If I don’t know the answers I will either find and share them or arrange for a colleague to meet with you.

The nurse should avoid using statements such as:

“You can always have other children.”

“I know how you feel.”

“At least you don’t know the baby yet.”

Optimizing Outcomes— Including the father of the baby

Health care providers frequently focus primarily on the pregnant woman. It is important that nurses remember to include fathers and care for the couple when providing patient education and support.

Maternal Age and Chromosomes

Advanced maternal age (age 35 and above at the time of birth) is associated with an increased risk of chromosomal abnormalities (1% risk beginning at age 35 and increasing each year, up to an 8% risk at age 46), with trisomy 21 (**Down syndrome**) consisting of half of these. The risk of giving birth to a child with Down syndrome increases with age: the incidence is approximately 1 in 1350 for a 25-year old woman; 1 in 400 for a 35-year-old woman; and 1 in 30 for a 45-year-old woman. However, children

with Down syndrome may be born to mothers of any age: approximately 80% of children with Down syndrome are born to mothers younger than 35 years (National Down Syndrome Society, 2006).

A **trisomy** occurs when there are three particular chromosomes instead of the normal number of two. Figure 7-14 illustrates the extra chromosome that occurs with Down syndrome. The three most common trisomies found in live newborns are trisomy 18 (Edward syndrome), trisomy 21 (Down syndrome), and trisomy 13 (Patau syndrome).

Trisomy 13 and trisomy 18 are rare; each occurs only about once in every 5000 live births. Trisomy 21 is the most common trisomy and occurs in approximately every 650 live births (Scanlon & Sanders, 2007). The prognosis for both trisomy 13 and 18 is very poor; approximately 70% of infants with these chromosomal disorders die within the first 3 months of life from complications associated with respiratory and cardiac abnormalities. Neonatal effects from these three most common trisomies include central nervous system abnormalities, mental retardation, and hypotonia at birth. Although children with Down syndrome are mentally retarded, there is a wide range of mental ability among this group.

Deletion and translocation describe other chromosomal abnormalities. Women younger than 35 years of age who have previously given birth to a child with a chromosomal abnormality have a 1% increased risk of having another affected child. A **deletion** is a loss of a portion of DNA from a chromosome (Fig. 7-15). This alteration can be caused by an unknown event, mutation, or exposure to irradiation, or it may occur during cell division. When a gene necessary for cell function is absent, disease may result. A **translocation** occurs when all or a segment of one chromosome breaks off and attaches to the same or to a different chromosome (Fig. 7-16). Parents who have a chromosomal translocation or who have had a child with structural malformations are at increased risk for having another affected child.

Figure 7-15 Deletion. (Courtesy of National Human Genome Research Institute.)

Figure 7-16 Translocation. (Courtesy of National Human Genome Research Institute.)

Multifetal Pregnancy

Monozygotic (identical) twins develop from one fertilized oocyte (zygote) that divides into equal halves during an early cleavage phase (series of mitotic cell divisions) of development (Fig. 7-17). This type of twinning occurs in approximately 1 of 250 live births (Benirschke, 2004). Monozygotic twins are genetically identical, always the same gender, and very similar in physical appearance. The number of amnions and chorions depends on the timing of division (cleavage) of the zygote. If the division occurs during the two to eight cell stages, there will be two amnions, two chorions, and two placentas. For most monozygotic twins, the division occurs at the end of the first week after fertilization and results from the division of the singular embryoblast into two embryoblasts. When the division occurs during this time, each fetus has its own amnion, but resides within a single chorion and receives oxygen and nutrients from the same placenta. Depending on the timing of cleavage, the following multifetal combinations occur:

- Division that occurs during the first 72 hours after fertilization: two embryos, two amnions, and two chorions develop with two distinct placentas, or a single fused placenta.
- Division that occurs between the fourth and eighth day: two embryos, each in a separate amnion sac covered by a single chorion.
- Division that occurs approximately 8 days after fertilization after the chorion and amnion have differentiated: two embryos in a common amniotic sac.
- Division that occurs after the embryonic disk has formed: cleavage is incomplete and conjoined twins result.

Conjoined twins occur when the embryonic disc does not divide completely, or when adjacent embryonic discs fuse. Conjoined twinning occurs in approximately 1 in 50,000 to 100,000 births. Twins may be connected to one another by the skin only or by cutaneous and other tissues. In many cases, surgical separation is possible but, depending on the anatomical region of attachment and the sharing of vital organs, may not be feasible.

Figure 7-17 Multiple gestations. **A**, Monozygotic twins with one placenta, one chorion and two amnions. **B**, Dizygotic twins with two placentas, two chorions and two amnions

Dizygotic (fraternal) twins develop from two zygotes and may be the same or different genders. Dizygotic twins are no more genetically similar than other siblings born to the same parents. There are separate amnions and chorions although the chorions and placentas may be fused. The incidence of dizygotic twinning is approximately 1 in 500 Asians, 1 in 125 Caucasians, and as high as 1 in 20 in some African populations. Triplets may result from the division of a single zygote into three zygotes (one original fertilized egg), or from the division of one zygote (identical twins are formed) plus another zygote (a total of two original fertilized eggs), or from three different zygotes (a total of three original fertilized eggs).

Now Can You— Discuss maternal age-related chromosomal problems and the origins of twinning?

1. Differentiate among the terms “malformation,” “disruption,” “deformation,” and “dysplasia”?
2. Define “trisomy” and identify two of the most common trisomies?
3. Explain how twinning occurs?

The Nurse’s Role in Minimizing Threats to the Developing Embryo and Fetus

Nurses provide holistic care to the family unit. The nurse must assess for environmental and lifestyle risks that may harm the fetus or mother. Ongoing evaluations should include assessment of the patient’s knowledge, lifestyle patterns, environmental conditions, and physical and psychosocial well-being. Reduction of maternal–fetal risks and helping to ensure the birth of a healthy newborn to a healthy mother remains the essential goal throughout pregnancy.

Ideally, counseling about strategies to promote optimal maternal and fetal health should begin before pregnancy occurs. Preconception counseling allows for the early identification of maternal risk factors and often provides an opportunity for intervention before pregnancy. Poor maternal health and illness can have a number of adverse effects on the developing fetus. In years past, women with chronic illnesses such as diabetes and hypertension were unable to conceive or were advised not to become pregnant. The advent of insulin and antihypertensive medications has allowed these women to not only contemplate pregnancy but to successfully carry a pregnancy to maturity with healthy outcomes for both the mother and her baby.

Nursing Insight— Karyotyping as a component of preconception counseling

Karyotyping of the parents as well as their child with a genetic disorder may be appropriate during the preconception period. A **karyotype** is a photomicrograph of the chromosomes of a single cell; the chromosomes are then arranged in numerical order (Venes, 2009) (Fig. 7-18). Cells, obtained from a sample of peripheral venous blood or a scraping of the buccal membrane tissue, are stained and photographed following a period of growth in the laboratory. *Fluorescence in situ hybridization* (FISH) is a rapid technique that allows for immediate karyotyping without a period of cell growth.

Through preventive strategies, preconception counseling can significantly decrease the incidence of birth defects and problems associated with preterm birth along with other disorders linked to maternal illness and nutritional deficiencies. Counseling should include discussion of possible fetal risks from exposure to teratogens. Factors that could potentially harm the developing fetus are identified and the woman is advised of her risks. When possible, strategies to reduce or prevent risk to the fetus are

Figure 7-18 Karyotype of human chromosomes of male and female.

discussed with the woman and her family. If exposure has occurred, every effort should be made to identify the timing of the contact and the amount of exposure. This information is essential, since the calculation of risk varies according to the particular teratogen, and the timing and dose of the exposure. (See Chapter 10 for further discussion.)

Optimizing Outcomes— Formulating nursing diagnoses for women and couples seeking genetic screening and assessment

Nursing diagnoses that may be applicable for genetic screening and assessment include:

- Health-seeking behaviors related to potential for genetic transmission of disease
- Deficient knowledge related to inheritance pattern of the family’s inherited disorder
- Fear related to outcome of genetic screening tests
- Decisional conflict related to testing for an untreatable genetic disorder

After the infant’s birth, diseases that may increase the risk for infection, cause liver damage, mental retardation, or death can often be identified through newborn screening tests. Newborn screening, which was initiated in the 1960s, was the first population-based screening program to test for genetic conditions. Through screening, diagnosis and treatment for many diseases and disorders can take place before permanent damage occurs. One of the *Healthy People 2010* goals is to ensure that all newborns are screened at birth as mandated by their state-sponsored screening programs, that follow-up diagnostic testing for positive findings is performed in the appropriate time period, and that infants with diagnosed

disorders are enrolled in appropriate service interventions in a timely manner. Additional information about the *Healthy People 2010* national initiative is available at <http://www.healthypeople.gov/Publications>.

summary points

- ◆ The Human Genome Project that ended in 2003 provided important insights into our understanding of the genetic complexity of humans.
- ◆ A genotype is an individual's gene composition; a phenotype refers to the observable expression of a person's genotype; a genome is a complete copy of the genes present.
- ◆ The developing embryo/fetus lives in a unique environment where all essential elements needed for normal growth and development is provided.
- ◆ The gestational period, which lasts an average of 40 weeks from the time of fertilization, occurs in three stages: the pre-embryonic stage; the embryonic stage; and the fetal stage.
- ◆ During the embryonic stage the heart begins to beat and the body's circulation is established.
- ◆ Structural refinement and perfection of function of all systems occur during the fetal stage.
- ◆ Teratogens, substances that cause harm to the developing fetus, may be in the form of chemicals, viruses, environmental agents, physical factors, and drugs.
- ◆ By educating pregnant women about fetal developmental events and avoidance of potential hazards, nurses can help to ensure a healthy outcome for the mother and her infant.

review questions

Multiple Choice

1. The nurse working in reproductive health is aware that the goal of the Human Genome project was to:
 - A. Identify exact human DNA sequences and genes.
 - B. Identify human DNA and RNA sequences.
 - C. Measure exact human DNA sequences for chromosomal diseases.
 - D. Measure exact human DNA sequence maps for disease prevention.
2. At the obstetrician's office, a couple receives information about assisted reproductive technologies. The nurse explains that the in vitro fertilization procedure involves the following:
 - A. Approximately 35 to 60 hours after fertilization in the laboratory, an embryo is injected into the woman's cervix.
 - B. An embryo is injected into the fallopian tubes at 50 hours after fertilization in the laboratory.
 - C. Many sperm cells and ova are injected into the fallopian tubes to achieve fertilization inside the tubes, where it normally occurs.
 - D. Many sperm cells and ova are injected into the cervix to achieve fertilization inside the woman.

3. When describing fetal growth and development, the perinatal nurse correctly identifies the gestational week that the heart begins to beat as the:
 - A. Second
 - B. Third
 - C. Fourth
 - D. Sixth
4. The perinatal nurse provides information about fetal growth and development to parents in a prenatal class. The nurse explains that fetal urine production begins at:
 - A. 6 to 8 weeks
 - B. 9 to 12 weeks
 - C. 12 to 16 weeks
 - D. 15 to 18 weeks
5. During preconception counseling, the clinic nurse explains that the time period when the fetus is most vulnerable to the effects of teratogens is from:
 - A. 5 to 10 weeks
 - B. 2 to 8 weeks
 - C. 4 to 12 weeks
 - D. 6 to 15 weeks

True or False

6. The perinatal nurse describes the process of inception for identical twins as monozygotic or coming from one fertilized oocyte.
7. When describing fetal circulation to the student nurse, the clinic nurse explains that most of the fetus's blood bypasses the lungs by shunting through the ductus arteriosus.

Fill-in-the-Blank

8. The clinic nurse is aware that the primary sources of amniotic fluid in pregnancy are fetal _____ and _____ secretions.
9. The perinatal nurse explains to the student nurse that the growing embryo is called a _____ beginning at _____ weeks of gestational age.
10. The perinatal nurse defines a _____ as any substance that adversely affects the growth and development of the fetus.

CONCEPT MAP

Nurse's Role: Minimizing Threats:

- Preconception counseling
- Assessment → environmental risks, patient's knowledge, physical/psychosocial well-being
- Newborn screening → disease, genetic conditions

Ethnocultural Considerations:

- Caring/acceptance results from knowledge about cultural practices/beliefs

Nursing Insight:

- Stage of development guides care/needs in premature infants

Optimizing Outcomes:

- Prenatal screening for maternal drug use
- Use of folic acid to prevent neural tube defects

What To Say:

- Nonjudgmental and caring approach when congenital anomalies are identified

Across Care Settings:

- Any prenatal care setting; Education/active involvement → increases understanding and self-care

Now Can You:

- Discuss the characteristics of embryonic/fetal growth
- Identify the unique aspects of fetal circulation
- Identify the pattern of human development by periods
- Discuss substances that may adversely affect development

The Prenatal Journey

Physiological and Psychosocial Changes During Pregnancy

chapter 8

Everything in nature bespeaks the mother. The sun is the mother of the earth and gives it its nourishment of heat; it never leaves the universe at night until it has put the earth to sleep to the song of the sea and the hymn of the birds and brooks. And this earth is the mother of trees and flowers. It produces them, nurses them, and weans them. The trees and flowers become kind mothers of their great fruits and seeds. And the mother, the prototype of all existence, is the eternal spirit, full of beauty and love.

—Kahlil Gibran

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Describe the physiological changes that occur during pregnancy and their etiologies.
- ◆ Identify nursing measures to relieve the discomforts caused by the physiological changes.
- ◆ Describe the psychosocial changes that occur during pregnancy and the factors that influence these changes.
- ◆ Identify nursing interventions to help families adapt to the psychosocial changes.

moving toward evidence-based practice Parental Efficacy

de Montigny, F., & Lacharité, C. (2005). Perceived parental efficacy: Concept analysis. *Journal of Advanced Nursing*, 49(4), 387–396.

The purpose of this study was to (1) distinguish perceived parental efficacy from parental confidence and parental competence; (2) clarify perceived parental efficacy by identifying its attributes, antecedents, and consequences; (3) explore changes that have occurred in the concept over time; and (4) explore areas of agreement and disagreement across the nursing and psychology disciplines. A concept analysis of literature from psychology and nursing covering a 20-year period from 1980 to 2000 was completed to include the topics of parental self-efficacy, competence, and confidence. One hundred and thirteen articles were obtained. Of these, 30 were selected to represent each discipline based on the extent to which the concepts were represented in the discussion. Data analysis was carried out in a thematic manner similar to the content analysis suggested by Rodgers and Knafl (2000).

The researchers defined parental efficacy as “beliefs one holds in one’s capabilities to organize and execute the courses of actions required to produce given attainments” as identified in Bandura’s Social Cognitive Theory. The following theory concepts were selected to serve as the framework for the concept analysis: personal beliefs, capabilities and power, ability to organize and

execute actions that produce results, and situation-specific tasks related to parenting a child.

Based on interpretation of Bandura’s theory, concept definitions included:

- Parents beliefs/judgment: Refers to judgments held by the parent and strength of that judgment
- Capabilities: Refers to what “one can do under a different set of conditions with whatever skills one possesses”
- Actions that are organized and executed to produce a set of tasks: Means “being able to integrate sub skills into appropriate courses of actions and to execute them well under difficult circumstances”
- Situation-specific tasks related to parenting a child: Refers to situation-specific tasks that are related to parenting, be they instrumental tasks such as feeding, or affective tasks, such as comforting” (de Montigny & Lacharité, 2005, p. 390).

The attribute “perceived parental efficacy” included positive enactive mastery experiences, vicarious experiences, verbal persuasion, and an appropriate physiological and affective state.

(continued)

moving toward evidence-based practice (continued)

“Enactive mastery experiences” provide information regarding an individual’s capabilities and limitations and contribute to one’s overall belief system. Mastery, which occurs as a result of successful parenting experiences, can include childcare experiences before becoming a parent. “Vicarious experiences” provide a reference point for comparison with others who have attained competencies. These experiences are transmitted through observation and role modeling. “Verbal persuasion” is important as a form of reinforcement of one’s beliefs and the capacity of significant others in the relationship to believe in that parent’s perception. “Physiological and affective states” refers to fluctuations, such as those caused by stress, which can lead to vulnerability and a decrease in feelings of being efficacious.

It was concluded that parental efficacy could be described as “beliefs or judgments a parent has about their capabilities to organize and execute a set of tasks related to parenting a child” (Rodgers & Knafl, 2000).

1. What research limitations can be identified from the above synopsis of this study?
What additional research may be indicated?
 2. How is this information useful to clinical nursing practice?
- See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

From the time just before conception, and then for the following 10 lunar months, the woman’s body undergoes many complex alterations that prepare her to nurture a new life. The physical, psychological, and emotional changes that accompany pregnancy are all focused on the growth, development, and future envelopment of the baby into a new family. The beginning of a new life is a time of awe and amazement shaped by a myriad of events that bring about unique changes for the woman and her family.

This chapter explores the physiological and psychosocial changes that occur during pregnancy and their effects on the woman, the fetus, and her family.

Physiological Preparation for Pregnancy

HORMONAL INFLUENCES

Many hormones are responsible for the changes that take place during and beyond pregnancy. Each serves a specific function in the nurturing process for the embryo, fetus, and neonate. The pituitary gland secretes hormones that influence ovarian follicular development, prompt ovulation, and stimulate the uterine lining to prepare for pregnancy and maintain it until the placenta becomes fully functional. Other pituitary hormones alter metabolism, stimulate lactation, produce pigmentation changes in the skin, stimulate uterine muscle contractions, prompt milk ejection from the breasts, allow for vasoconstriction to maintain blood pressure, and regulate water balance.

After conception, ovulation ceases. The corpus luteum produces progesterone and, to a lesser degree, estrogen. Progesterone is the hormone primarily responsible for maintaining the pregnancy. Once implantation occurs, the trophoblast secretes human chorionic gonadotrophin (hCG) to prompt the corpus luteum to continue progesterone production until this function is taken over by the placenta. The ovarian hormones work in synchrony to maintain the endometrium, provide nutrition for the developing morula and blastocyst, aid in implantation,

decrease the contractility of the uterus to prevent spontaneous abortion, initiate development of the ductal system in the breasts, and prompt remodeling of maternal joint collagen.

The placenta provides hormones essential to the survival of the pregnancy and fetus. Placental hormones do the following:

- Prevent the normal involution of the ovarian corpus luteum
- Stimulate production of testosterone in the male fetus
- Protect the pregnancy from the maternal immune response
- Ensure that added glucose, protein, and minerals are available for the fetus
- Prompt proliferation of the uterus and breast glandular tissue
- Promote relaxation of the woman’s smooth muscle
- Create a loosening of the pelvis and other major joints

Each of these hormones plays a vital role in the maintenance of the pregnancy, and all body systems are affected by the profound changes that prepare the woman to nurture the growing fetus and neonate.

A & P review The Major Pregnancy Hormones and Their Effects on the Reproductive System

Estrogen and progesterone are the major hormones produced by the placenta during pregnancy. The effect of estrogen is one of “growth”; the effect of progesterone is one of “maintenance.”

Estrogen prompts hyperplasia and hypertrophy (growth of cells in number and size) during pregnancy. Because of the effects of estrogen, breast tissue enlarges and becomes functional and the uterus expands, a process that allows for stretching of the muscles to accommodate the growing fetus. Estrogen also enhances uterine contractility to prepare the muscles for labor.

Progesterone enables the pregnancy to thrive by its relaxation effect on the smooth muscle. Progesterone causes vasodilation and an increased blood flow to all body tissues, it slows the gastrointestinal tract to ensure

absorption of essential nutrients for fetal development, and it relaxes the uterine muscle to prevent the onset of labor until term. Progesterone has been called the “pro-pregnancy hormone.”

REPRODUCTIVE SYSTEM

The reproductive system undergoes the greatest changes in size and function and every organ within this system is affected by or focused on the needs of the growing fetus.

Uterus

The uterus provides a home for the growing fetus for its 10-lunar-month stay in the woman. Its pattern of growth is very predictable for the first 20 weeks of the pregnancy. Depending on fetal size, uterine growth over the next 20 weeks varies. The shape of the uterus changes dramatically. Very early in pregnancy the uterus is shaped like a “lightbulb” or inverted pear. By the end of the first trimester the uterus has developed into a soft, enlarged globular structure that has risen out of the pelvis and into the abdominal cavity (Fig. 8-1). Under the influence of estrogen and progesterone, the myometrial cells and muscle fibers undergo hyperplasia and hypertrophy, processes that allow the uterus to enlarge and stretch as the fetus grows. By term, the uterine wall thins to 0.6 inch (1.5 cm) or less and its weight will have increased from 1.8 oz. to 2.2 lb. (70 g to 1100 g).

Estrogen causes the uterine muscles to contract. Braxton-Hicks contractions are irregular and painless and may begin as early as the 16th week of gestation. As the pregnancy advances and the fetal size increases, the contractions become increasingly more frequent and intense and are easily felt by the woman. Until late in the second trimester the contractions serve to prepare the uterine muscles for the synchronized activity necessary for effective labor. As long

Figure 8-1 Pattern of uterine growth during pregnancy.

as the contractions are irregular in frequency and last for less than 60 seconds, the patient may be reassured of their normalcy. However, if a pattern of contraction regularity is noted or if the contractions are associated with bleeding, nausea, vomiting, or intense pain, the patient should be instructed to promptly report to her health care provider for evaluation.

Blood flow is increased from the effects of progesterone on the smooth muscle of the vasculature to provide adequate circulation for endometrial growth and placental function. The enhanced uterine circulation is important for ensuring adequate fetal nutrition and the removal of waste products.

After implantation, the endometrium lining the uterus is termed the **decidua**. The decidua consists of three layers:

Decidua vera is the external layer and it has no contact with the fetus.

Decidua basalis is the uterine lining beneath the site of implantation.

Decidua capsularis is the endometrial tissue that covers the embryo (Fig. 8-2).

Cervix

One of the earliest signs of pregnancy is the discoloration, or bluish purple hue, that appears on the cervix, vagina, and vulva. This color change is known as **Chadwick’s sign** (Fig. 8-3). High levels of circulating estrogen cause stimulation of the cervical glandular tissue, which increases in cell number and becomes hyperactive. Increased blood flow and engorgement produces the bluish discoloration.

Stimulation from the hormones estrogen and progesterone produces cervical softening (**Goodell sign**). This physiological change is related to several events, including a decrease in the collagen fibers of the connective tissue, increased vascularity and edema, and slight tissue hypertrophy and hyperplasia. Before pregnancy, the cervix is firm and its texture resembles that of the tip of the nose. After conception, the cervix softens and its texture begins to resemble that of an ear lobe.

Estrogen and progesterone cause a proliferation of the mucus-producing cervical glands. Early in pregnancy, the endocervical tissue begins to take on a honeycomb appearance. Cervical mucus fills the endocervical canal and forms a mucus plug (**operculum**), which helps to keep harmful

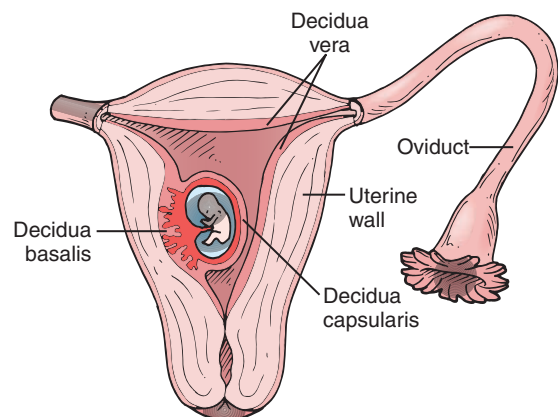

Figure 8-2 The layers of the decidua.

Figure 8-3 Chadwick's sign.

agents out of the uterus. **Leukorrhea**, an increased whitish vaginal discharge, results from hyperplasia of the vaginal mucosa and increased mucus production from the endocervical glands. The discharge is often profuse and may be worrisome. As the due date approaches, cervical effacement and dilation cause a breakdown of the mucus plug, resulting in an increased vaginal discharge. The nurse should reassure the patient about the normalcy of leukorrhea during pregnancy and instruct her to call her health care provider if the discharge appears thicker; becomes bloody or yellowish/green; is accompanied by a foul odor; or if it causes itching, irritation, or pain in the vulvar or vaginal area.

Vagina and Vulva

Changes that occur in the vagina and vulva are similar to those that take place in the cervix. An increased blood flow (hyperemia) produces a bluish-purple hue (Chadwick's sign). Thickening of the vaginal mucosa develops and the rugae (vaginal folds) become more prominent. The rugae deepen from hyperplasia and hypertrophy of the epithelial and elastic tissues and this change allows for adequate stretching of the vaginal vault during childbirth. As the pregnancy progresses, the area becomes edematous from poor venous return due to the weight of the gravid uterus. For some women, the increased pelvic congestion can lead to a heightened sexual interest and increased orgasmic experience (McKinney, James, Murray, & Ashwill, 2005). Leukorrhea results from increased cervical mucus along with elevated glycogen levels in the vaginal cells, which produces rapid sloughing of tissue. The increased glycogen levels also create a vaginal environment more susceptible to the growth of *Candida albicans*. Thus, during pregnancy the woman is more susceptible to the development of monilial vaginitis (yeast infections). The pH of the vaginal fluids becomes more acidic, and decreases from 6.0 to 3.5. This change results from the action of *Lactobacillus acidophilus* on the increased glycogen levels in the vaginal epithelium (Cunningham et al., 2005). The increased acidity helps to control the growth of most pathogens in the vaginal canal.

The nurse should discuss the importance of vulvar hygiene with the patient. Gentle external cleansing with plain soap and water is adequate. Douching, or internal

cleansing of the vagina, should be avoided because this practice can alter the vaginal pH and allow pathogens to grow as well as disrupt the cervical mucus plug.

Ovaries

After ovulation, the pituitary hormone luteinizing hormone (LH) stimulates the corpus luteum (functional cyst that remains on the ovary) to produce progesterone for 6 to 7 weeks. Once the placenta is developed and functional, it begins to take over the task of progesterone production. At that time, the corpus luteum ceases to function and is gradually absorbed by the ovary. The corpus luteal cyst enlarges while functioning and may reach the size of a golf ball before it begins to recede. In some cases the cyst may rupture, causing the woman some pelvic discomfort associated with bleeding into the pelvic cavity. The pain should dissipate as the cyst and blood are absorbed. If the pain is persistent or if vaginal bleeding occurs, the nurse should advise the woman to seek medical care. Ovulation ceases during pregnancy due to the high circulating levels of estrogen and progesterone, which inhibit the pituitary release of follicle-stimulating hormone (FSH) and LH.

Breasts

Estrogen and progesterone produce a number of changes in the mammary glands. Breast enlargement, fullness, tingling, and increased sensitivity occur during the early weeks of gestation. The superficial veins become more prominent from the vascular relaxation effects of progesterone. Often the venous congestion is more noticeable in primigravidas. Melanotropin, a hormone secreted by the pituitary gland, causes the nipples to become tender and more pronounced with darkening of the areola. The **Montgomery tubercles** (sebaceous glands) on and around the areola enlarge and provide lubrication for the nipple tissue. **Striae gravidarum** (stretch marks) may develop as the breast tissue stretches (Fig. 8-4).

During the second trimester, pre-colostrum, a clear thin fluid, is found in the acini cells, the smallest parts of the milk glands. Pre-colostrum becomes **colostrum**, a creamy whitish-yellow liquid that may leak from the nipples as early as the 16th week of gestation. This pre-milk substance contains antibodies, essential proteins, and fat to nourish the baby and prepare his intestines for digestion and elimination. Colostrum is converted to mature milk during the first few days after birth.

During prenatal care, the nurse should discuss the need for changes in bra size, options for infant feeding, and, if the patient wishes to breast feed, strategies to help her prepare for successful breast feeding. The process of lactation should be reviewed and the woman should be given a list of lactation support resources. Soft cotton liners can be used to pad the bra if leaking of the nipples is troublesome.

Now Can You— Describe major changes that occur in the reproductive system during pregnancy?

1. Identify four physiological changes that occur in the uterus and possible symptoms that may accompany these changes?
2. Explain the hormonal basis for changes in the vagina and vulva and identify patient teaching needs concerning the changes?
3. Describe three breast changes and identify the hormones responsible for the changes?

Figure 8-4 Integumentary system changes include darkening of the areolae, appearance of the linea nigra, and striae gravidarum.

INTEGUMENTARY SYSTEM

Estrogen, progesterone, and alpha-melanocyte-stimulating hormones cause many changes in the appearance, structure, and function of the integumentary system. Though seldom serious, the outward changes in appearance may negatively affect the woman's self-concept and body image.

The skin undergoes a number of pigmentation changes related to the influence of estrogen. Moles (nevi), freckles, and recent scars may darken or appear to multiply in number. The nipples, areolae, axillae, vulvar area, and perineum also darken in color.

The linea alba, a light line that extends from the umbilicus to the mons pubis (and sometimes upward to the xiphoid process), darkens, becoming the **linea nigra** (see Fig. 8-4). The linea is more noticeable in the woman with a naturally darker complexion. Melasma gravidarum, also known as **chloasma**, forms the "mask of pregnancy" (Fig. 8-5). This dark, blotchy brownish pigmentation change occurs around the hairline, brow, nose and cheeks and often gives the appearance of "raccoon eyes." The heightened pigmentation fades after pregnancy but can recur after exposure to the sun. During pregnancy the skin becomes photosensitive and sunburn may occur in a shorter exposure time than usual for the individual. The nurse should teach the patient about the importance of regular sunscreen use and decreased sun exposure time.

Alterations in hair as well as nail growth and texture may occur. The nails may become stronger and grow faster. The number of hair follicles in the dormant phase may decrease, and this change stimulates new hair growth. Once the infant is born, this process is reversed and there is an increase in hair shedding for approximately 1 to 4 months. Although this change may be disconcerting, the nurse can reassure the patient that virtually all hair will be replaced within 6 to 12 months (Cunningham et al., 2005). During pregnancy, hair may react differently to dyes and chemicals.

Figure 8-5 Chloasma.

Increased adrenal steroid levels cause the connective tissue to lose strength and become more fragile. This change can cause striae gravidarum, or "stretch marks" on the breasts, buttocks, thighs, and abdomen (see Fig. 8-4). Striae appear as reddish, wavy, depressed streaks that will fade to a silvery white color after birth but they do not usually disappear completely.

Increased levels of estrogen during pregnancy may cause **angiomas** and **palmar erythema**. Angiomas, also called "vascular spiders," are tiny, bluish, end-arterioles that occur on the neck, thorax, face, and arms. They may appear as star shaped or branched structures that are slightly raised and do not blanch with pressure. More common in Caucasian women, angiomas appear most often during the second to fifth month of pregnancy and usually disappear after birth. Palmar erythema is a condition characterized by color changes over the palmar surfaces of the hands (Fig. 8-6). Approximately 60% of Caucasian women and 35% of African American women experience palmar erythema during pregnancy, which presents as a diffuse, reddish-pink mottling of the palms. Increased blood flow, along with high levels of circulating hormones, can produce other skin changes such as inflammatory pruritus and acne vulgaris, a condition seen predominately in the first trimester. Hyperactivity of the sweat and sebaceous glands may cause some women to experience excessive perspiration, night sweats, and skin changes that can range from extreme dryness to extreme oiliness.

The nurse should offer reassurance and provide anticipatory guidance as these changes occur. Recommendations to the patient include daily bathing, the liberal use of lotions or oils for dry skin, the regular use of deodorant, and limited sun exposure with the diligent use of sunscreen.

NEUROLOGICAL SYSTEM

The central nervous system appears to be affected by the hormonal changes of pregnancy although the specific alterations other than those involving the hypothalamic-pituitary axis are less well known. Many women complain of a decreased attention span, poor concentration, and memory lapses during and shortly after pregnancy. Cunningham and colleagues (2005) identified a pregnancy sleep pattern phenomenon characterized by reduced sleep efficiency, fewer hours of night sleep, frequent awakenings, and difficulty

Figure 8-6 Palmar erythema.

going to sleep. Nurses can advise patients that afternoon napping may help alleviate the fatigue associated with the sleep alterations. Providing anticipatory guidance related to expected alterations is key in facilitating the woman's acceptance of these changes.

Edema from vascular permeability can lead to a collection of fluid in the wrist that puts pressure on the median nerve lying beneath the carpal ligament. This alteration leads to **carpal tunnel syndrome**, a condition that usually develops during the third trimester. It is manifested by pain and paresthesia (a burning, tingling, or numb sensation) in the hand that radiates to the elbow. The pain occurs in one (usually the dominant) or both hands and is intensified with attempts to grasp objects. Elevation of the hands at night may help to reduce the edema. Occasionally, a woman may need to wear a "cock splint" to prevent the wrist from flexing, an action that puts additional pressure on the median nerve. Carpal tunnel syndrome usually subsides after the pregnancy (and the accompanying edema) has ended although some women may require surgical treatment if symptoms persist.

Syncope (a transient loss of consciousness and postural tone with spontaneous recovery) during pregnancy is frequently attributed to orthostatic hypotension and/or inferior vena cava compression by the gravid uterus (Cunningham et al., 2005). It may also occur as increased intra abdominal pressure from the growing uterus places pressure on the vagus nerve. Coughing, straining during bowel movements, and upward pressure from the growing fetus can trigger a vasovagal response that produces faintness or loss of consciousness. Lightheadedness, sweating, nausea, yawning, and feelings of warmth are warning signs that often precede syncope. Educating the patient about signs and symptoms often helps to alleviate the fears that frequently accompany the fainting episodes. If lightheadedness or other warning signs are experienced, the woman is instructed to immediately assume a sitting or lying position. A left side-lying position is preferred to avoid compression of the vena cava (which can lead to supine hypotension) from the gravid uterus.

Now Can You— Discuss changes in the integumentary and neurological systems?

1. Identify four changes that occur in the integumentary system and discuss patient teaching needs for these changes?
2. Define carpal tunnel syndrome and identify two interventions to help alleviate the associated symptoms?
3. Discuss the physiological origins of syncope during pregnancy and patient education concerning syncope?

CARDIOVASCULAR SYSTEM

Heart

As growth of the fetus exerts pressure on the diaphragm, the maternal heart is pushed upward and laterally to the left (Fig. 8-7). Cardiac hypertrophy results from the increased blood volume and cardiac output. Exaggerated first and third heart sounds and systolic murmurs are common findings during pregnancy. The murmurs are usually asymptomatic and require no treatment. If symptomatic, the woman may experience palpitations, chest pain, shortness of breath, or a decreased tolerance to activity. The nurse should advise the patient that if these symptoms occur, she should see her health care provider immediately for evaluation. Systolic murmurs usually resolve within the first 2 weeks postpartum after the plasma volume levels return to normal. They may recur in subsequent pregnancies.

Blood Volume

An increase in maternal blood volume begins during the first trimester and peaks at term. The increase approaches 40% to 45% and is due primarily to an increase in plasma and erythrocyte volume. Additional erythrocytes, needed because of the extra oxygen requirements of the maternal and placental tissue, ensure an adequate supply of oxygen to the fetus. The elevation in erythrocyte volume remains constant during pregnancy.

Most of the increased blood flow is directed to the uterus, and of this amount, 80% is channeled to the placenta. Blood flow to the maternal kidneys is increased by 30% to 50%, and this alteration enhances the excretion of maternal and fetal wastes. Dilation of the capillaries and increased blood flow to the skin assist the woman in eliminating the extra heat generated by fetal metabolism. The extra blood volume decreases during the first 2 weeks postpartum and a substantial amount of fluid loss in the first 3 postpartal days occurs through maternal diuresis.

Iron

Iron is necessary for the formation of hemoglobin, the oxygen-carrying component of the erythrocyte. The increased need for oxygen requires the pregnant woman to increase her iron intake. The fetal need for iron is greatest during the last 4 weeks of pregnancy, when the fetal iron stores are amassed.

During pregnancy, the woman's hematocrit values may appear low due to the increase in total plasma volume

Figure 8-7 Growth of the uterus displaces the maternal heart upward and laterally to the left.

(on average, 50%). Since the plasma volume is greater than the increase in erythrocytes (30%), the hematocrit (a measurement of the red blood cell concentration in the plasma) decreases by about 7%. This alteration is termed “physiological anemia of pregnancy” or “pseud anemia.” The hemodilution effect is most apparent at 32 to 34 weeks. The mean acceptable hemoglobin level in pregnancy is 11 to 12 g/dL of blood. Some women experience symptoms of fatigue related to this phenomenon although altered sleep patterns may also contribute to the fatigue. The nurse should teach the patient to hydrate adequately by drinking 6 to 8 glasses of water each day, and also to ensure that her diet is high in protein and iron. Although gastrointestinal absorption of iron is enhanced during pregnancy, most

women must add supplemental iron to meet the needs of the expanded erythrocytes and those of the growing fetus.

Leukocytes, Proteins, Platelets, Immunoglobulins

The number of leukocytes also increases and the average white blood cell count ranges from 5000 to 15,000 /mm³. During labor and postpartum these levels may climb as high as 25,000/mm³. Although the exact reason for this increase is unclear, it is known that leukocyte counts normally increase in response to stress and vigorous exercise (Cunningham et al., 2005). Normal laboratory values during pregnancy are presented in Table 8-1.

Plasma proteins also increase, although due to the hemodilution effect during pregnancy, there is a decrease

Table 8-1 Common Laboratory Values in Pregnancy

Laboratory Values	Usual Normal Female Value	Normal Value in Pregnancy
Serum Values		
Hemoglobin	11.7–15.5 g/dL (mean Hgb is 0.5–1.0 g lower in African Americans, Mexican and Asian Americans have a higher hemoglobin & hematocrit than Caucasians)	Decreased by 1.5–2 g/dL Lowest point occurs at 30–34 weeks
Hematocrit	38–44%	Decreased by 4–7%, lowest point at 30–34 weeks
Leukocytes	4.5–11.0 × 10 ³ /mm ³	Gradual increase of 3.5 × 10 ³ /mm ³
Platelets	150–400 × 10 ³ /mm ³	Slight decrease
Amylase	30–110 U/L	Increased by 50–100%
Chemistries		
Albumin	3.4–4.8 g/dL	Early decrease by 1 g/dL
Calcium (total)	8.2–10.2 mg/dL	Gradual decrease of 10%
Chloride	97–107 mEq/L	No significant change
Creatinine	0.5–1.1 mg/dL	Early decrease by 0.3 mg/dL
Fibrinogen	200–400 mg/dL	Progressive increase of 1–2 g/L
Glucose (fasting)	65–99 mg/dL	Gradual decrease of 10%
Potassium	3.5–5.0 mEq/L	Gradual decrease of 0.2–0.3 mEq/L
Protein (total)	6.0–8.0 g/dL	Early decrease of 1 g/dL then stable
Sodium	135–145 mEq/L	Early decrease of 2–4 mEq/L then stable
Urea nitrogen	8–20 mg/dL	Decrease in 1st trimester by 50%
Uric acid	2.3–6.6 mg/dL	First trimester decrease of 33%, rise at term
Urine Chemistries		
Creatinine	11–20 mg/kg per 24 hr	No significant change
Protein	10–140 mg per 24 hr	Up by 250–300 mg/day by the 20th week
Creatinine clearance	75–115 mL/min/1.73 m ²	Increased by 40–50% by the 16th week
Serum Hormones		
Cortisol	8–21 g/dL	Increased by 20 g/dL
Prolactin	3.3–26.7 ng/mL	Gradual increase, 5.3–215.3 ng/mL, peaks at term
Thyroxine (T ₄) total	5.5–11.0 mcg/dL	5.5–16.0 mcg/dL
Triiodothyronine (T ₃) total	70–204 ng/dL	Early sustained increase of up to 50% 116–247 ng/dL (last 4 months of gestation)

in protein concentrations, especially in the level of albumins. Decreased plasma albumin leads to a drop in osmotic pressure, which causes body fluids to move into the second space. This change produces edema.

Although the platelet cell count does not change significantly, fibrinogen volume has been shown to increase by as much as 50%. This alteration leads to an increase in the sedimentation rate. Blood factors VII, VIII, IX, and X are also increased, and this change causes hypercoagulability. The hypercoagulable state, coupled with venous stasis (poor blood return from the lower extremities), places the pregnant woman at an increased risk for venous thrombosis, embolism, and when complications are present, disseminated intravascular coagulation (DIC). (See Chapter 11 for further discussion.)

The production of maternal immunoglobulins (IgA, IgG, IgM, IgD, IgE) is unchanged in pregnancy. Immunoglobulins protect the body from a variety of bacterial, viral, and parasitic infections. Three major types of immunoglobulins (IgG, IgA, and IgM) are primarily involved in immunity. Circulating levels of maternal IgG are decreased during pregnancy because of transfer across the placenta. As the only immunoglobulin transported across the placenta, IgG is active against bacterial toxins (Hacker, Moore, & Gambone, 2004). Although transport of IgG begins around the 16th week of gestation, the fetus does not acquire a significant amount of IgG until the last 4 weeks of pregnancy. At birth, the neonate's primary immunoglobulins (IgG) have been acquired from the mother via a process termed "passive acquired immunity" (Cunningham et al., 2005). Due to its large molecular size, IgM is unable to cross the placenta. IgA, IgD and IgE also remain in the maternal circulation. IgA, which is believed to provide protection to various secreting surfaces such as those in the respiratory tract, gastrointestinal tract, and eyes, is passed to the neonate in breast milk (Smeltzer & Bare, 2004). Immunoglobulins and their major actions are summarized in Table 8-2.

During pregnancy, resistance to infection is decreased as a result of depressed leukocyte function. Due to this normal physiological alteration, maternal autoimmune diseases such as lupus erythematosus may improve during pregnancy. (See Chapter 11 for further discussion.) Because of the increased susceptibility to infection, patients should be instructed to avoid crowds and individuals with active infections. Frequent, consistent hand washing and good respiratory hygiene should also be stressed.

Cardiac Output

Cardiac output increases, and peaks around the 20th to 24th week of gestation at about 30% to 50% above pre-pregnancy levels. It remains increased for the duration of the pregnancy. With the increased vascular volume and cardiac output, vasodilation (related to progesterone-induced relaxation of the vascular smooth muscle) prevents an elevation in blood pressure. The woman's pulse rate frequently increases up to 10 to 15 beats per minute to facilitate effective circulation of the increased blood volume.

During the first trimester, blood pressure normally remains the same as pre-pregnancy levels but then gradually decreases up to around 20 weeks of gestation. After 20 weeks, the vascular volume expands and the blood pressure increases to reach pre-pregnancy levels by term. Because of the relaxed vascular resistance and stasis of blood in the lower extremities, there is an increased risk of varicose veins and hemorrhoids. The nurse should instruct the woman to elevate her lower extremities by lying on her left side with the feet higher than her heart for 15 to 20 minutes daily to improve venous return from the lower extremities. Daily walks enhance circulation and also improve intestinal peristalsis, important in facilitating regular bowel function. Patients should be advised to drink at least 8 to 10 glasses of water each day and include adequate roughage in their diet. These strategies help prevent constipation and straining with bowel movements, both of which increase the likelihood of hemorrhoids.

Table 8-2 Immunoglobulins and Their Major Actions

IgG (75% of Total Immunoglobulin)	Appears in serum and tissues (interstitial fluid) Assumes major role in blood borne and tissue infections Activates the complement system Enhances phagocytosis Crosses the placenta
IgA (15% of Total Immunoglobulin)	Appears in body fluids (blood, saliva, tears, breast milk , and pulmonary, gastrointestinal, prostatic and vaginal secretions) Protects against respiratory, gastrointestinal, and genitourinary infections Prevents absorption of antigens from food Is transferred to the neonate via breast milk
IgM (10% of Total Immunoglobulin)	Appears mostly in intravascular serum Appears as the first immunoglobulin produced in response to bacterial and viral infections Activates the complement system No placental transfer during pregnancy
IgD (0.2% of Total Immunoglobulin)	Appears in small amounts in serum Possibly influences B-lymphocyte differentiation, but its role is unclear
IgE (0.004% of Total Immunoglobulin)	Appears in serum Involved in allergic and some hypersensitivity reactions Combats parasitic infections

Supine Hypotension Syndrome

The pregnant woman may experience **supine hypotension syndrome**, or **vena caval syndrome** (faintness related to bradycardia) if she lies on her back. The pressure from the enlarged uterus exerted on the vena cava decreases the amount of venous return from the lower extremities and causes a marked decrease in blood pressure, with accompanying dizziness, diaphoresis, and pallor (Fig. 8-8). Placing the woman on her left side can relieve the symptoms. Orthostatic hypotension is another condition that occurs frequently during pregnancy and results from stagnation of blood in the lower extremities. If the woman stands for too long or arises too quickly, gravity causes the blood to flow to the lower extremities, decreasing blood flow to the brain. **Mean arterial pressure** (MAP) indicates the average driving force for the movement of blood in the arterial system throughout the cardiac cycle (Darovic, 2004). The MAP is the same in all parts of the cardiovascular system when the patient is supine except during pregnancy, when the gravid uterus places pressure on the vena cava, and produces an alteration in the blood pressure. The change in the MAP leads to decreased blood flow throughout the body, particularly in the heart, brain, and uterus.

All of the changes in the circulatory system return to normal by the second to third week postpartum as the woman's body returns to a non-pregnant state. Reassurance can be given to the patient and she should be encouraged to arise slowly from a lying or sitting position. While standing, she should keep her feet moving to encourage adequate venous return from the lower extremities and avoid lying flat on her back.

Now Can You—Discuss changes in the cardiovascular system?

1. Describe two changes in the heart and the physiological basis for these changes?
2. Discuss why there is a need for an increase in erythrocytes during pregnancy?
3. Explain what is meant by “passive acquired immunity”?
4. Differentiate between supine hypotension syndrome and orthostatic hypotension?

RESPIRATORY SYSTEM

During pregnancy, a number of changes occur to meet the woman's increased oxygen requirements. The tidal volume (amount of air breathed in each minute) increases 30% to 40%. This change is related to the elevated levels of estrogen and progesterone. Estrogen prompts hypertrophy and hyperplasia of the lung tissue. Progesterone decreases airway resistance by causing relaxation of the smooth muscle of the bronchi, bronchioles, and alveoli. These alterations produce an increase in oxygen consumption by approximately 15% to 20%, along with an increase in vital capacity (the maximum amount of air that can be moved in and out of the lungs with forced respiration).

The enlarging uterus creates an upward pressure that elevates the diaphragm and increases the subcostal angle. The chest circumference may increase by as much as 2.4 inches (6 cm). Although the “up and down” capacity of diaphragmatic movement is reduced (due to increasing pressure from the growing fetus), lateral movement of the chest and intercostal muscles accommodate for this loss of

Figure 8-8 Supine hypotension, or vena caval syndrome, may occur if the pregnant woman lies on her back. This causes compression of the vena cava.

movement and keep pulmonary functions stable. Many women verbalize an increased awareness of the need to breathe and may perceive this sensation as dyspnea (difficulty breathing). The nurse should offer reassurance and educate the woman about normal alterations and symptoms. Under normal circumstances, resting with the head elevated while taking slow, deep breaths causes an improvement in the symptoms. However, certain lung diseases including asthma and emphysema may be aggravated by the normal physiological changes as the oxygen demands of the pregnancy increase. If symptoms persist or worsen, the woman should contact her health care provider.

Eyes, Ears, Nose, and Throat

EYES Blurred vision, the most common visual complaint in pregnant women, is caused by corneal thickening associated with fluid retention and decreased intraocular pressure. These changes begin during the first trimester, persist throughout pregnancy, and regress by 6 to 8 weeks postpartum. As part of anticipatory guidance, the nurse teaches that since the changes are only temporary, a corrective lens prescription should not be changed until the pregnancy has been completed.

EARS No changes have been noted in auditory function during pregnancy.

NOSE An increase in mucus production results from the combined effects of progesterone (increased blood flow to the mucus membranes of the sinus and nasal passages) and estrogen (hypertrophy and hyperplasia of the mucosa). Nasal stuffiness and congestion (rhinitis of pregnancy) are common complaints. The nurse should educate the patient about these normal changes and offer reassurance. Increasing the oral fluid intake helps to keep the mucus thin and easier to mobilize.

Edema (an effect of estrogen) of the nasal mucosa, along with vascular congestion (an effect of progesterone) may cause epistaxis (nosebleeds). The woman should be advised to use caution when blowing her nose and to avoid probing the nasal cavities with a cotton swab. The use of nasal sprays designed to relieve congestion should be avoided due to their rebound effect that causes the congestion to worsen. Normal saline nasal sprays may be used sparingly to moisten the nasal passages.

THROAT Hyperemia (congestion) occurs from increased blood flow and relaxation of smooth muscle. Swallowing may be difficult if food is not chewed well.

GASTROINTESTINAL SYSTEM

The gastrointestinal system is probably the source of most of the woman's discomforts during pregnancy. Nausea and vomiting during the first trimester most likely are related to rising levels of human chorionic gonadotropin (hCG) and altered carbohydrate metabolism. Changes in taste and smell, due to alterations in the oral and nasal mucosa, can further aggravate the gastrointestinal discomfort. A nonspecific **gingivitis** (inflammation of the gums) occurs frequently due to the increased blood supply to the gums, along with estrogen-related tissue hypertrophy and edema. Although the gums may bleed from routine oral hygiene, the nurse should stress the importance of regular dental maintenance and its effect on good maternal nutrition.

On occasion, red, raised nodules (**epulis gravidarum**) appear at the gum line (Fig. 8-9). These growths bleed easily, and usually regress within 2 months after childbirth (Beckmann et al., 2006). If associated with excessive bleeding, local excision may be necessary. **Ptyalism**, excessive saliva production often with a bitter taste, may occur and can be unpleasant or embarrassing. Its cause is uncertain, although stimulation of the salivary glands from eating starch or decreased unconscious swallowing when nauseated may be contributing factors (Cunningham et al., 2005). Limited relief can be obtained with the use of chewing gum and lozenges. Patients can also be advised to eat small, frequent meals and avoid starchy foods such as potatoes, bread, and pasta.

The effect of progesterone on smooth muscle causes relaxation of the esophagus. The movement of food is slowed and the gastroesophageal, or cardiac sphincter (circular muscle located at the top of the stomach) weakens. This alteration prevents efficient closure when the stomach is emptying and allows the reflux of stomach contents into the esophagus, producing heartburn, or **pyrosis**. Pyrosis results from irritation to the esophageal lining by gastric secretions and acids. Eating small meals, avoiding lying down after meals for at least 1 hour, and limited use of antacids can alleviate some of these symptoms.

Nausea and vomiting of pregnancy, or "morning sickness," occurs because of high levels of hCG and relaxation of the stomach, esophagus, and gastroesophageal sphincters. Food remains in the stomach longer for enhanced digestion and moves more slowly through the small intestine to allow for complete absorption of nutrients. Since the large intestine is also sluggish from the effects of progesterone on the smooth muscle, more water is reabsorbed from the bowel and bloating and constipation can occur. Straining at defecation may cause or exacerbate hemorrhoids (vein varicosities in the lower rectum and anus).

Figure 8-9 Gingival hypertrophy; epulis.

Patients should be encouraged to drink at least 8 to 10 glasses of water each day, add fiber to their diets to produce bulk, and exercise to encourage peristalsis. They should be taught to avoid straining with bowel movements. Warm sitz baths may be helpful for hemorrhoid discomfort. (See Chapter 15 for further discussion.)

The liver, which breaks down maternal toxins, must deal with fetal waste products and toxins as well. The additional workload can lead to altered liver function tests, especially if accompanied by hepatic vessel vasoconstriction associated with preeclampsia. (See Chapter 11 for further discussion.)

The gall bladder, or storehouse for bile, is also composed of smooth muscle and becomes more relaxed, resulting in inefficient emptying. This alteration can lead to stasis of the bile (cholestasia) or inflammation and infection (cholecystitis). In addition, the progesterone-induced prolonged emptying time, combined with elevated blood cholesterol levels, may predispose the woman to gallstone formation (cholelithiasis). Pain in the epigastric region after ingestion of a high-fat meal constitutes the major symptom of these conditions. The pain is self-limiting and usually resolves within 2 hours. Cholelithiasis occurs more often in obese individuals with fair skin and in women older than 40 years of age.

Liver functions are only slightly altered during pregnancy. Stasis of bile in the liver (intrahepatic cholestasis) occasionally occurs late in pregnancy and can cause severe itching (**pruritis gravidarum**). This condition disappears soon after birth. Patients should be advised that avoiding high-fat meals can reduce the presence or frequency of these symptoms.

URINARY SYSTEM

Pregnancy leads to changes in the structure and function of the urinary system. These changes facilitate normal waste elimination for the woman and the increasing waste products of her fetus. During the first trimester, the bladder, a pelvic organ, is compressed by the weight of the growing uterus. The added pressure, along with progesterone-induced relaxation of the urethra and sphincter musculature, leads to urinary urgency, frequency, and nocturia. In the second trimester, when the uterus becomes an abdominal organ, bladder pressure is largely relieved, along with most of the frequency and urgency. By the third trimester, the fetal presenting part descends into the pelvis. At this time, increased pressure is again exerted upon the bladder and symptoms of frequency, urgency, and nocturia return (Fig. 8-10).

Ascension of bacteria into the bladder can cause asymptomatic bacteriuria (ASB) or urinary tract infections (UTIs). These infections occur more frequently in pregnancy due to relaxation of the smooth muscle of the bladder and urinary sphincter, changes that allow bacterial ascent into the bladder.

The ureters, composed of smooth muscle, are also affected by progesterone. Elongation and dilation, especially of the right ureter, occurs. Peristalsis that normally facilitates the movement of urine from the kidneys to the bladder is reduced. This change, coupled with pressure on the ureters from the enlarging uterus, causes an obstruction of urine flow. The stagnant urine becomes an excellent

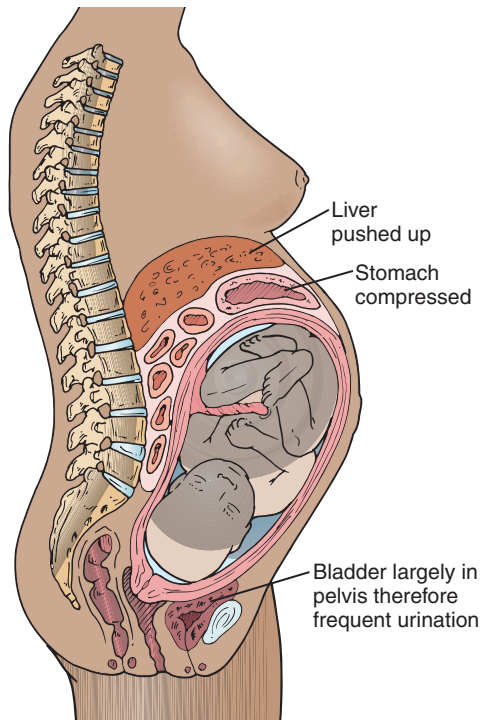

Figure 8-10 Compression of the bladder results from the growing uterus.

medium for the growth of microorganisms. Patients should be encouraged to drink at least 8 to 10 glasses of water each day and empty their bladders at least every 2 to 3 hours and immediately after intercourse. These measures help to prevent stasis of urine and the bacterial contamination that leads to infection.

The glomerular filtration rate (GFR) and renal plasma flow are increased due to hormonal changes, blood volume increases, the woman's posture, physical activity level, and nutritional intake. During the second trimester, the GFR increases up to 50% in most women. This alteration prompts an increase in renal tubular reabsorption. During pregnancy, there is a greatly increased load of glucose presented to the renal tubules. As a result, glucose excretion increases in virtually all pregnant women (Beckmann et al., 2006). Although it may be a normal finding, glucosuria should always be investigated to rule out gestational diabetes, as the quantitative urine glucose does not accurately reflect blood glucose levels. (See Chapter 11 for further discussion.)

Now Can You— Describe changes in the eyes, nose, and throat and respiratory, gastrointestinal, and urinary systems?

1. Describe one alteration that occurs in each of the following: eyes, nose, throat and suggest interventions for relief from the accompanying symptoms?
2. Identify changes during pregnancy that compensate for the reduced diaphragmatic movement that results from the enlarging uterus?
3. Differentiate among epulis gravidarum, ptyalism, and pyrosis and delineate patient teaching needs concerning these symptoms?
4. Explain the physiological basis for glucosuria during pregnancy?

ENDOCRINE SYSTEM

Thyroid Gland

The thyroid gland changes in size and activity during pregnancy. On palpation, the increase in size is appreciated. Enlargement is caused by increased circulation from the progesterone-induced effects on the vessel walls, and by estrogen-induced hyperplasia of the glandular tissue. In early pregnancy, elevated levels of thyroxine-binding globulins cause an increase in the total thyroxine (T_4) and total 3,5,3-triiodothyronine (T_3) (Beckmann et al., 2006). The active hormones free T_4 and free T_3 remain unchanged from normal non-pregnant levels. Levels of total T_4 continue to be elevated until several weeks postpartum. Increased T_4 -binding capacity is noted by an increase in the serum protein-bound iodine (PBI). These changes in thyroid regulation cause a progressive increase in the basal metabolic rate (BMR) of up to 25% by term. The BMR is the amount of oxygen consumed by the body over a unit of time (mL/min). Maternal effects of the increase in BMR include heat intolerance and an elevation in pulse rate and cardiac output. Within a few weeks following birth, thyroid function returns to normal levels (Hacker et al., 2004).

Parathyroid Glands

The parathyroid glands, which regulate calcium and phosphate metabolism, increase in size from estrogen-induced hyperplasia and hypertrophy. Maternal concentrations of parathyroid hormone increase as the fetus requires more calcium for skeletal growth during the second and third trimesters. Calcium intake is extremely important for the pregnant woman, whose daily intake should be at least 1200 to 1500 mg.

Pituitary Gland and Placenta

The anterior lobe of the pituitary gland, stimulated by the hypothalamus, increases in size and in weight. Pregnancy is possible because of the actions of FSH (stimulates growth of the graafian follicle) and LH, which prompts final maturation of the ovarian follicles and release of the mature ovum (Varney, 2004). If conception occurs, elevated levels of estrogen and progesterone (produced by the corpus luteum until about 14 weeks of gestation, when the placenta takes over this function) suppress production of FSH and LH. During pregnancy, ovarian follicle maturation may continue but ovulation does not occur.

Prolactin, also produced by the anterior pituitary gland, is responsible for initial lactation. Although this hormone increases 10-fold during pregnancy, the elevated levels of estrogen and progesterone inhibit lactation by interfering with prolactin-binding to the breast tissue. Prolactin may also play a role in fluid and electrolyte shifts across the fetal membranes (Hacker et al., 2004).

Oxytocin and vasopressin are produced in the posterior lobe of the pituitary. Oxytocin primarily causes uterine contractions but high levels of progesterone prevent contractions until close to term. Oxytocin also stimulates milk ejection from the breasts, or the **"let down" reflex**. Vasopressin causes vasoconstriction. Vasoconstriction leads to an increase in maternal blood pressure and exerts an antidiuretic effect that promotes maternal fluid retention to maintain circulating blood volume. The increased blood volume that occurs during pregnancy, along with

changes in plasma osmolarity (the fluid-pulling capacity of the plasma to retain fluids) controls the release of vasopressin.

Maternal metabolism is altered to support the pregnancy by thyrotropin and adrenotropin. These hormones, produced by the anterior pituitary gland, exert their effects on the thyroid and adrenal glands. Thyrotropin causes an increased basal metabolism and adrenotropin alters adrenal gland function to increase fluid retention by the kidneys.

Human placental lactogen (hPL), also known as human chorionic somatomammotropin (hCS), is produced by the placental syncytiotrophoblasts. It is an insulin antagonist and acts as a fetal growth hormone. Human placental lactogen increases the number of circulating fatty acids to meet maternal metabolic needs and decreases maternal glucose utilization, which increases glucose availability to the fetus (Hacker et al., 2004).

Adrenal Glands

The adrenal glands, located above the kidneys, change little during pregnancy. The adrenal cortex produces cortisol, a hormone that allows the body to respond to stressors. Cortisol is increased during pregnancy due to decreased renal secretion (an alteration prompted by high estrogen levels). Cortisol regulates protein and carbohydrate metabolism and is believed to promote fetal lung maturation and stimulate labor at term. Following birth, it may take up to 6 weeks for maternal cortisol levels to return to normal.

By the second trimester, the adrenal cortex secretes increased levels of aldosterone, a mineral corticoid that causes the renal reabsorption of sodium. This physiological alteration promotes the reclaiming of water and helps to enhance circulatory volume. The increase in aldosterone may be a protective response to the increased renal and excretory gland sodium excretion that occurs due to the effects of progesterone.

Pancreas

The pancreas secretes insulin produced by the beta cells of the islets of Langerhans. Pregnancy prompts an increase in the number and size of the beta cells. These changes are responsible for the alterations that occur in carbohydrate metabolism during pregnancy.

Prostaglandins

Prostaglandins are lipid substances found in high concentrations in the female reproductive tract and in the uterine decidua during pregnancy. Their exact function in pregnancy is unknown although they may maintain a reduced placental vascular resistance. A decrease in prostaglandin levels may contribute to hypertension and preeclampsia. At term, an increased release of prostaglandins from the cervix as it softens and dilates may contribute to the onset of labor.

MUSCULOSKELETAL SYSTEM

As the pregnancy progresses, the abdominal wall weakens and the rectus abdominis muscles separate (**diastasis recti**) to accommodate the growing uterus. As the weight of the uterus shifts upward and outward, a lumbar lordosis (anterior convexity of the lumbar spine) develops (Fig. 8-11). This alteration compensates for the changing center of gravity and allows centering to remain over the woman's legs.

Figure 8-11 Lumbar lordosis.

Low back pain usually accompanies this physiological change. Separation of the rectus abdominis muscles along with an increase in intra-abdominal pressure from the growing uterus may exacerbate an abdominal wall hernia.

Relaxin, a hormone produced by the placenta, along with the action of progesterone, causes a relative laxity of the ligaments. The pubis symphysis separates at approximately 28 to 30 weeks gestation. These changes, coupled with the change in the maternal center of gravity, result in an unsteady gait and a greater tendency toward falls. The patient's gait takes on the appearance of a "pregnancy waddle" as the bones of the pelvis shift and move. The woman should be encouraged to maintain good posture and keep the abdominal muscles toned through exercise. Sitting in a firm chair and the use of a small pillow or blanket rolled and placed in the lumbar region (lumbar roll) for support can help decrease lower back pain.

Pregnant women frequently complain of sharp pain in the lower abdominal quadrants or in the groin area. Most often, the pain is related to stretching and hypertrophy of the round ligaments that support the uterus (round ligament pain). Because of dextrorotation of the gravid uterus as it rises out of the pelvis, the right maternal side is most commonly affected. Once a serious medical condition (e.g., appendicitis) has been ruled out, the nurse should offer reassurance and instruct the patient to sit in a chair or rest on her left side. The application of heat may also be helpful. A brief review of the anatomical changes that occur during pregnancy may alleviate the patient's fear of appendicitis. Since the appendix is pushed up and posterior by the gravid uterus, the typical location of pain (McBurney's Point) is not a reliable indicator for a ruptured appendix during pregnancy. The pain should gradually subside but if it persists or is accompanied by fever, a change in bowel habits, or decreased fetal movement, the patient should promptly contact her medical provider.

Mobilization of calcium stores occurs to provide for the fetal calcium needs necessary for skeletal growth. The total maternal serum calcium decreases, but the ionized calcium

level remains unchanged from the prepregnant state. The increase in circulating maternal parathyroid hormone stimulates an increased absorption of calcium from the intestines and decreases the renal loss of calcium to maintain adequate calcium levels.

Calcitonin, a hormone important in the metabolism of calcium and phosphorus, suppresses bone resorption by inhibiting the activity of osteoclasts. Osteoclasts are a cell type that “digests” bone matrix, causing a release of calcium and phosphorus into the blood. Calcitonin is produced primarily in the thyroid gland, but it is also synthesized in a many other tissues, including the lungs and intestinal tract (Bowen, 2006). The activity of calcitonin, coupled with adequate nutrition, protect the maternal skeleton from a loss of bone density despite an increase in the turnover of bone mass. Calcium intake is of major importance during pregnancy, and women should be encouraged to increase their dietary calcium through the consumption of dairy products, calcium fortified orange juice, and dark green leafy vegetables.

Calcium supplementation may be advised for patients who are vegetarian or lactose intolerant. Pregnant women often complain of cramping in the lower extremities and calves, especially at night. The cramps, sometimes called “Charley horses,” can be extremely painful and are caused by poor circulation to the extremities. They have also been associated with imbalances in calcium and phosphorus. Increasing or decreasing calcium intake may be helpful. For immediate relief of the cramping, the woman should be instructed to stand and lean forward to stretch the calf muscle or have someone gently push her toes back toward her shin and hold this position for several seconds. Daily walks can also help because ambulation improves circulation to the muscles.

NURSING ASSESSMENT AND HEALTH EDUCATION

Nursing assessment must begin with a comprehensive history and examination at the first prenatal visit. The history should include information about the current pregnancy; the obstetric and gynecological history; a cultural assessment; and a medical, nutritional, social, and family (including the father’s) medical history. A complete review of all of the physical systems should be conducted followed by a physical examination that includes appropriate nutritional assessments and diagnostic procedures. This information is essential to the formulation of appropriate nursing diagnoses (Box 8-1). Ongoing health education should focus on the current trimester and its physical changes. A trimester-by-trimester approach to teaching needs is presented in Table 8-3.

Now Can You— Discuss major changes in the endocrine and musculoskeletal systems during pregnancy?

1. Describe maternal symptoms associated with an increased basal metabolic rate (BMR)?
2. Identify where cortisol is produced and name two important actions of this hormone?
3. Discuss two physiological alterations that produce the “pregnancy waddle” and suggest two strategies for the relief of back pain?
4. Explain why adequate calcium intake is essential during pregnancy?

Box 8-1 Nursing Diagnoses Related to Physiological Adaptations to Pregnancy

- Deficient Knowledge related to normal physiological changes of pregnancy
- Constipation related to changes in gastrointestinal tract occurring in pregnancy
- Imbalanced Nutrition: More than Body Requirements related to excessive intake of calories
- Imbalanced Nutrition: Less than Body Requirements related to inadequate information about nutritional needs during pregnancy
- Activity Intolerance related to fatigue from the physiological changes of pregnancy

Psychosocial Adaptations During Pregnancy

For many women, pregnancy is a time of turmoil that affects the ability to deal with stress and cope with the changes that will take place over many months. These changes affect not only the woman but her partner and other family members as well. Pregnancy and childbearing constitute major developmental phases, and these events are often accompanied by ambivalence and conflicting emotions. The nurse must have a basic understanding of how the woman’s progression through the developmental phases and the accompanying emotions affect her and her family’s acceptance of the pregnancy and the unknown child. Nursing care for the woman and her family through each pregnancy milestone should be tailored with respect to personal and family values, cultural customs, and spiritual beliefs and health maintenance behaviors. Topics for health education related to the psychosocial adaptations to pregnancy are presented in Table 8-4.

DEVELOPMENTAL AND FAMILY CHANGES

According to Duvall’s (1977) stages of family development, the expectant family sets about the task of preparing for its new role as childcare providers. The home must be reorganized to accommodate the infant; family member duties and responsibilities must often be realigned; and patterns of money management need to be altered. The couples’ sexual relationship must adapt to the physical and emotional changes that accompany pregnancy. Family relationships with relatives are often reoriented as the couple gradually moves away from the former role of “child” and instead seek recognition as parents. Friendships and relationships with work associates also must adapt to the couple’s changing lifestyle.

For both the expectant woman and her partner, emotional responses are often unpredictable and labile and require patience, understanding, and good communication. The couple needs to expand their knowledge about pregnancy, birth, and parenting to enhance their understanding of these life-altering events. Additional information also helps to empower them to better prepare for the major changes that will soon take place in their lives. With each subsequent pregnancy, the couple must adjust to the transitions in their relationship with one another and with each child. Each birth brings a new member who

Table 8-3 Health Education Topics Related to the Physiological Adaptations of Pregnancy

Topics to Include	First Trimester	Second Trimester	Third Trimester
Physiological Changes of Pregnancy and Related Discomforts	Pain and tingling in breasts	Enlargement of the abdomen	Dyspnea
	Nausea and vomiting (morning sickness)	Skin pigmentation	Leg and feet cramps
	Urinary frequency	Striae gravidarum	Constipation
	Fatigue	Vascular spiders	Indigestion, heartburn, gastric reflux
	Mood swings	Constipation	Pedal edema
			Fatigue
		Leg cramps	Vaginal discharge
		Groin pain from round ligament stretching	Urinary frequency
	Leukorrhea	Braxton-Hicks contractions versus True labor	
Danger Signs to Report to Health Care Provider	Vaginal bleeding	Vaginal bleeding	Visual disturbances
	Abdominal cramping or pain	Burning or painful urination	Headache
	Severe or prolonged vomiting	Fever, increased pulse rate	Hand and facial edema
		Decreased or absent fetal movements	Fever
		Unrelenting nausea and vomiting	Vaginal bleeding
		Abdominal pain or cramping	Abdominal pain; uterine contractions
		Swelling of face or fingers, headaches, visual disturbances or epigastric pain	Premature rupture of the membranes
			Decreased or absent fetal movement
General Health Teaching	Schedule of return visits for routine prenatal care	Reinforcement and reiteration of previous teaching	Signs and symptoms of labor/preterm labor
	General hygiene	Comfort measures	When to call the health care provider, when to go to the birthing center or hospital
	Comfort measures	Anticipatory guidance	Comfort measures
	Anticipatory guidance	Choices of prenatal education classes	Anticipatory guidance
	Sexual activity and restrictions	Signs and symptoms of preterm labor	Reinforcement and reiteration of previous teaching
	Physical activities, exercise and rest		Encouragement to attend a labor and birth class
	Nutritional guidance		
	Avoidance of alcohol, fetal alcohol effects		
Effects of smoking, and smoking cessation strategies if indicated.

Table 8-4 Health Education Topics Related to the Psychosocial Adaptations to Pregnancy

Topics to Include	First Trimester	Second Trimester	Third Trimester
Developmental Tasks of Pregnancy	Mother: Acceptance of pregnancy into her self-system	Mother: Binding-in to the pregnancy, ensuring safe passage, and differentiating the fetus from herself	Mother: Separating herself from the pregnancy and the fetus, trying various caregiving strategies
	Father: Announcement and realization of the pregnancy	Father: Anticipation of adapting to the role of fatherhood	Father: Role adaptation, preparation for labor and birth
	Couple: Realignment of relationships and roles	Couple: Realignment of roles and division of tasks	Couple: Preparation of the nursery
Psychosocial Changes During Pregnancy	Ambivalence about pregnancy	Active dream and fantasy life	Dislikes being pregnant but loves the child
	Introversion	Concerns with body image	Anxious about childbirth, but sees labor and birth as deliverance
	Passivity and difficulty with decision making	Nesting behaviors	The couple experiments with various mothering or fathering roles
	Sexual and emotional changes	Sexual behavior adjustment	Woman is introspective
	Changing self-image	Expanding to a variety of methods of expressing affection and intimacy	
	Ethical dilemmas of prenatal testing		

Adapted from Mattson, S., & Smith, J.E. (2004). *Core curriculum for maternal-newborn nursing*. St. Louis: W.B. Saunders.

must be introduced and incorporated into the existing family structure. Sibling rivalry, or competitiveness among the children, is common and can often be diminished by parental actions that actively involve each child with the pregnancy and anticipated birth.

MATERNAL TASKS AND ROLE TRANSITION

Rubin (1975) described specific tasks that a woman must accomplish to integrate the maternal role into her personality. The “tasks of pregnancy” generally occur concurrently during the pregnancy and help the woman develop her self-concept as a mother. To be successful in accomplishing these tasks, the pregnant woman must incorporate the pregnancy into her total identity. That is, she must “accept the reality of the pregnancy” and integrate it into her self concept, “accept the child,” “reorder” her relationships, learn to “give of herself for the child,” and “seek safe passage through the pregnancy, labor and birth” (Mattson & Smith, 2004). A summary of the maternal tasks of pregnancy is presented in Table 8-5.

Acceptance of the Pregnancy

The mother-to-be needs to accept the pregnancy and incorporate it into her own reality and self-concept. This process is known as “binding in.” During the first trimester, the woman’s focus centers on her physical discomforts (i.e., fatigue, nausea) and needs rather than on the developing child. By the second trimester, she feels fetal movement (quickenings), has most likely seen the baby on ultrasound and heard his heartbeat, and begins to conceptualize the child as an individual within her. During the third trimester, as the due date approaches, the mother-to-be wants the child and just as strongly wants the pregnancy to be over. At this point, she is tired and needs a

considerable amount of emotional and physical support from her family and friends.

Acceptance of the Child

Acceptance of the child is critical to a successful adjustment to the pregnancy. Acceptance must come from the expectant woman as well as from others. During early pregnancy, announcements are made to one another and to family and friends. A positive response from those closest to the pregnant woman helps to foster her acceptance of the child. There is a great value attached to this unborn child and she wants and needs others in the family to accept the child as well. In the second trimester, the immediate family needs to exhibit behaviors consistent with relating to the child as a sibling, a son or a daughter. In the third trimester, the woman must develop an unconditional acceptance of the child or she and others may reject him for not meeting their expectations.

Reordering Relationships

To facilitate the necessary family transition, the pregnant woman must reorder her relationships to allow for the child to fit into the existing family structure and learn to give of herself to the unknown child. At this time, she becomes reflective and examines what things in her life may need to be given up or changed for the infant. If this is her first child, she may grieve the loss of her carefree life. As the pregnancy progresses, the woman begins to identify with the child and makes plans for their life together after the birth. During the last few weeks of the pregnancy, the woman must work through doubts of her ability to be a good mother. At this time, positive support from family and friends is essential in boosting her confidence and in assisting her in overcoming these feelings of self-doubt.

Table 8-5 Maternal Tasks of Pregnancy

General Principles	Pregnancy progressively becomes part of the woman's total identity.
	She feels unique because she can't share her sensory experience with others.
	Her focus turns inward and she is overly sensitive.
	She seeks the company of other women and pregnant women.
Acceptance of Pregnancy	Absence of a female support system during pregnancy is a singular index of a high-risk pregnancy.
	First trimester: She accepts the idea of pregnancy but not the child.
"Binding-in"	Second trimester: With sensation of fetal movement, or "quickening," she becomes aware of the child as a separate entity.
	Third trimester: She wants the child and is tired of being pregnant.
Acceptance of the Child	First trimester: Acceptance of the pregnancy by herself and others.
	Second trimester: The family needs to relate to the infant.
	Third trimester: The critical issue is the unconditional acceptance of the child; conditional acceptance may imply rejection by the mother or family members.
Reordering of Relationships, Giving of Self	First trimester: Examines what needs to be given up.
	Trade-offs for having the infant.
	May grieve the loss of a carefree life.
	Second trimester: Identifies with the child.
Safe Passage	Third trimester: Has decreased confidence in her ability to become a good mother to her child.
	First trimester: Focuses on herself, not on her infant.
	Second trimester: Develops a strong attachment and places great value on her infant.
	Third trimester: Has concern for herself and her infant as a unit, shares a symbiotic relationship. At the seventh month, she is in a state of high vulnerability.
	She views labor and birth as deliverance and as a hope, not as a threat.

Adapted from Mattson, S., & Smith, J.E. (2004). *Core curriculum for maternal-newborn nursing*. St. Louis: W.B. Saunders.

Seeking Safe Passage Through Pregnancy, Labor, and Birth

Seeking safe passage through the pregnancy, labor, and birth are maternal tasks that receive the most attention during the pregnancy. In the first trimester, the woman focuses on her own discomforts and places her needs before those of the fetus. Symptoms of fatigue, nausea, and breast tenderness can be overwhelming during this often difficult time. In the second and third trimesters, the woman develops an increasing sense of the value of her infant. She comes to conceptualize her fetus as a separate being (fetal distinction) and she accepts her changing body image. She becomes extremely vulnerable during her seventh month and increasingly worried about the impending labor and birth. As the due date approaches, the woman's fears about labor may diminish as she begins to view childbirth as an "end point." Participation in childbirth preparation classes can greatly assist the woman and her family in dealing with the anxiety and fears that often surround labor and birth.

Other developmental tasks take place during the passage of pregnancy as well. The woman needs to validate the pregnancy, and initial feelings of uncertainty or ambivalence are normal. When caring for expectant women, the nurse should never assume that the pregnancy was planned

or wanted. Instead, the nurse should facilitate discussion of uncertainties or concerns with the patient and her family to facilitate acceptance of the pregnancy. Many women fantasize and dream about their pregnancy and how it will change their lives. The woman must incorporate the fetus into her body image, a process termed "fetal embodiment." Accomplishing this task allows her to accept the changes in her body size and shape as the pregnancy progresses. The significant other plays an important role as the woman becomes increasingly dependent on that individual for helping to meet her daily needs.

As the pregnancy advances, the woman begins to conceptualize the fetus as a separate individual. She comes to view her changing body as a "vessel of new life" and often feels closer to her own mother at this time. This deeper relationship with her mother begins as one of dependency and progresses to one in which she identifies with her mother as a peer. If her mother is not available, she may reach out to another valued maternal figure for identification and support. As she reaches the end of the third trimester, the woman begins to give up her symbiotic relationship with the fetus. She harbors feelings of anxiety about the childbirth process and begins to gather supplies and prepare for the baby's entry into the home. This process is termed "nesting." At this point in pregnancy, the woman is often

impatient with the awkwardness related to her increasing size and has a strong desire to see the pregnancy end so that she can begin her next phase as a mother.

Now Can You— Discuss the “tasks of pregnancy”?

1. Describe why it is important for the pregnant woman to successfully accomplish the tasks of pregnancy?
2. Discuss the value of ongoing family support throughout pregnancy in fostering acceptance of the child?
3. Identify what is meant by “seeking safe passage”?
4. Explain why pregnant women often feel closer to their own mothers as the pregnancy progresses?

Developmental Tasks and the Pregnant Adolescent

For the pregnant adolescent, ongoing age-related developmental tasks can create conflict when coupled with the developmental tasks of pregnancy. Tasks associated with adolescence focus on growth and maturity. They include developing a personal value system, choosing a vocation or career, developing personal body image and sexuality, achieving a stable identity, and attaining independence from parents. Conflicts may arise when these tasks are overshadowed by the developmental tasks of pregnancy. While seeking safe passage, the adolescent may not seek prenatal care unless pressured by authority figures or peers to do so. By nature, adolescents are not future oriented. Hence, the pregnant adolescent may not be able to readily accept the reality of the unborn child. Because the adolescent's sense of identity is still incomplete, bodily changes often feel awkward. Because the family may not react positively to the pregnancy, acceptance of the pregnancy by self and others may be hindered. Many times, the adolescent's parents come to assume the role of parent. Although this may be helpful at times, this situation limits the young mother's involvement with the newborn and her ability to fully give of herself.

PATERNAL ADAPTATION TO PREGNANCY

Pregnancy is psychologically stressful for men. Expectant fathers often experience a variety of reactions to the pregnancy. Some enjoy the role of nurturer and marvel in the changes that occur in the woman. Others feel alienated and begin to stray from the relationship. Many men view pregnancy as positive proof of their masculinity and take steps to assume a dominant or more supportive role in the relationship. Others find no meaning or personal value in the pregnancy and consequently fail to develop any sense of responsibility toward the mother or the child. There are several styles of paternal involvement during pregnancy, including “observer,” where the father is passive and detached; “expressive,” where the expectant father attempts to experience the pregnancy as much as possible, and “instrumental,” where the father is the caretaker (Callister, Matsumura, & Vehvilainen-Julkunen, 2003).

Couvade, in the traditional sense, is the observance of certain rituals and taboos by the male to signify his transition to fatherhood. This action affirms the man's psychosocial and biophysical relationship to his partner and the child. In recent times, couvade has come to describe the unintentional development of pregnancy-related symptoms such as weight gain, nausea, back pain, difficulty sleeping,

and depression by the pregnant woman's partner. Men who experience the couvade syndrome often assume a more involved paternal role during the childbearing year.

The father of the baby also experiences specific tasks of pregnancy that correspond with the trimesters. During the first trimester, the father is in an “announcement phase.” Similar to the woman's experience, the father may be ambivalent at this time. He must first accept the pregnancy as “real” in order to begin to incorporate the future child into his life and assume the expectant father role. In the second trimester, or “moratorium phase”, the man's “binding in” usually takes longer to achieve than the woman's, and this is related to his “remoteness” to the fetus. At this time, involvement in prenatal visits, listening to the baby's heartbeat, and visualization of the fetus during ultrasound can make the fetus seem more real to the father. He begins to accept the woman's changing body and the reality of the fetus as a child when he can feel fetal movement.

Optimizing Outcomes— Promoting prenatal paternal attachment

The nurse can be instrumental in promoting early paternal attachment. Encouraging the father to actively “engage” with the fetus through reflective journaling is one way to enhance prenatal bonding. One father later shared his recorded insights:

My earliest memories with Trina started the day she was born. No, they started before that. They started in the womb. I would come home and I would say, “Hello,” and she would flick and flutter in the womb. She would start kicking. If I put my hand on my wife's tummy when she was carrying Trina, she would move over to where my hand was. If I put it on the other side, she would move to that side. I used to sing to her. It's always been that way and has just continued pretty much that way. I remember one night laying with my head on my wife's stomach and singing a lullaby or something, I can't remember exactly which song. She was very active but she settled down, and then I put my hand on her stomach and she moved my hand.

Excerpt from Callister, L.C., Matsumura, G., & Vehvilainen-Julkunen, K. (2003). He's having a baby. The paternal childbirth experience. *Marriage & Families*. Retrieved from <http://marriageandfamilies.byu.edu/issues/2003/January/baby.aspx>

The couple's sexual relationship often changes as some men deal with fears of harming the fetus. The expectant father may also feel a rivalry with a male health care provider. Involvement of the father during examinations and tests with thorough explanations of the need for them can minimize the father's feelings of being left out. His partner's intense introspective nature may be confusing at times and he may feel pushed away. The man also fantasizes about being a father, although his fantasies are often centered on an older child rather than on an infant.

In the third trimester, the expectant father enters a “focusing phase.” During this time he negotiates what his role in labor and birth will be; prepares for the reality of parenthood; alters his self-concept to reflect that of a

more mature, or fatherly figure; becomes involved in setting up the nursery; and copes with his fears of the mutilation or death of his partner or child during birth. Fears and concerns are often lessened somewhat by participation in prenatal and parenting classes. The nurse should be aware of cues (i.e., lack of participation in prenatal care, behaviors that signal lack of interest in the woman, the fetus, or the pregnancy) that may indicate paternal detachment from the mother and the pregnancy. Referral for counseling, childbirth preparation classes, or other community resources may be appropriate. Pastoral care or local fathering support groups, if available, may also assist the father with his need for involvement. Problems such as a troubled relationship with his own father, a dysfunctional couple relationship, and sociocultural factors may be barriers that prevent the man from assuming a paternal role (Callister et al., 2003). Not uncommonly, the behavior associated with a “dead beat dad” stems from feelings of being pushed away or left out by the expectant woman and her other support systems.

ADAPTATION OF SIBLINGS AND GRANDPARENTS

The psychosocial reactions of other family members to the pregnancy and childbirth must also be explored, as these individuals often have a significant influence on the woman's passage through the developmental tasks of pregnancy. The reactions of siblings correlate closely to their age and level of involvement with the pregnancy. Children may express excitement, anticipation, anger, or despair. The toddler, characteristically involved in his own little world, may initially exhibit a reaction of indifference. However, the parents must be advised about the strong likelihood of a regression in age-appropriate behavior. For example, the child may want to nurse, drink from a bottle, or wear a diaper like the baby. The school-age child usually appears more interested but grasping the full reality of a baby in the family may not be realistic, since the process of concrete thinking is not fully developed until around age 10. Engaging the child in family discussions about the anticipated birth, encouraging the child to feel fetal movements, and listening to the fetal heart beat, sharing age-appropriate educational materials, and allowing him to attend sibling preparation classes are strategies that may help the child to feel that he is sharing in the pregnancy experience.

When a child reaches early adolescence, changing sexuality associated with this developmental phase may create a barrier between him and his mother. This sort of barrier makes it difficult for the adolescent to view his parent as a pregnant woman and may give rise to feelings of resentment toward the new child about to join the family. Parents need to be aware of ways to cope with potential negative behaviors and recognize that adolescents often appear to have knowledge and understanding about pregnancy and birth but their information may be incorrect and incomplete. The nurse can suggest that the child attend prenatal visits to listen to the baby's heartbeat and, if possible, view the fetus during ultrasound examinations. Parents should be assisted in developing other strategies to include the adolescent in the changes that are taking place during pregnancy and that will occur following the birth. Older children may benefit from attending prenatal classes or touring the birthing facility.

Grandparents are very often excited and eagerly await the birth of a grandchild, although this is not always the case. The grandparents' age at the time of the birth can exert a positive or a negative effect on their reactions. For example, if they will become first-time grandparents during their 30s or 40s, they may be ambivalent or feel they are not yet ready to assume the grandparent role. Conversely, those who are already grandparents may be excited with the prospect of another grandchild. Other factors (e.g., if the pregnancy was unplanned, if the mother is very young or unwed) may prompt feelings of anger and disappointment. Along with the woman's partner, the grandparents usually harbor concerns about the health and well-being of the expectant woman and her fetus. They also may be unsure about extent to which they should become involved in the childrearing process.

MATERNAL ADAPTATION DURING ABSENCE OF A SIGNIFICANT OTHER

If the woman has no involved significant other, she will need the presence of a strong support person to help her adapt to the pregnancy and the demands of parenting. The future she has planned for the child, such as the decision to place the child for adoption, can heavily influence her psychological needs. During prenatal visits, the nurse should ensure that the woman is given the opportunity to discuss her future plans for the child. After assessing the woman's needs, the nurse can make referrals to appropriate community resources that may include prenatal classes, psychological counseling, pastoral care or social services.

Now Can You— Discuss pregnancy-related role transitions for the adolescent, father, siblings and grandparents?

1. Describe why the adolescent may have difficulty achieving the developmental tasks of pregnancy?
2. Explain what is meant by the couvade syndrome?
3. Discuss the “focusing phase” that occurs during the third trimester and identify two behaviors that may indicate a lack of paternal attachment?
4. Contrast behaviors of toddlers, school-age, and adolescent children in response to the pregnancy?
5. Identify two factors that may influence the grandparents' ability to make role transitions in response to the pregnancy?

CULTURAL INFLUENCES AND PSYCHOSOCIAL ADAPTATIONS

Universally, some type of ritual or ceremony is attached to important life events. In pregnancy and childbirth, this ritual may involve special care of the mother and baby, events planned to welcome the new member of the family, or rigid requirements that must be met by the family and health care providers. There are a multitude of cultural messages that may influence the woman's adaptation to pregnancy, birth, and the newborn. The nurse should explore these cultural influences with the patient and her family. By acknowledging and documenting specific beliefs and needs, the nurse can help guide the woman and her family through the prenatal and intrapartum care system more effectively. Through open discussion, erroneous or conflicting beliefs

can be addressed and a plan can be developed to ensure a satisfactory, positive experience for the childbearing year.

HAZARDS OF HIGH-TECH MANAGEMENT ON MATERNAL ADAPTATION

The technology-focused society of today can lead to an increase in the level of anxiety and number of stressors experienced by the pregnant woman and her family. Moral and ethical dilemmas may arise from positive diagnostic tests. The pregnant woman's emotional and interpersonal needs may be overlooked by those caring for her as added importance is placed on the technology that surrounds the care. Full enjoyment of the pregnancy may not be possible, as the woman instead comes to focus on each test and its results. In this situation, the pregnancy becomes a "tentative pregnancy." A conflict of interest develops between the technology and the woman's trust of her own instincts and inner feelings. These conflicts can further undermine the woman's self-confidence. Collectively, these stressors interfere with the woman's ability to move through the tasks of maternal role development and delay her preparation for parenting.

SOCIETAL AND CULTURAL INFLUENCES ON FAMILY ADAPTATION

Cultural influences often affect how pregnancy is viewed and accepted by the woman and her family. Many cultures, such as the tribal Native Americans and most Latinos, consider pregnancy to be a normal and expected life event, not a state of illness. Some African nations impose rigid taboos concerning what a woman can eat, drink, wear, and do during her pregnancy. In some Middle Eastern cultures, pregnancy is viewed as "woman's work" and the father's involvement is minimal. In Korean and other southeastern Asian cultures, a harmonious balance such as yin/yang (masculine/feminine) or hot/cold must be closely observed. In the equilibrium model of health, achievement of balance allows for the normal growth of the baby and ensures the mother's recovery from the pregnancy. Some cultures place emphasis on certain behaviors designed to protect the pregnancy, such as avoidance of particular foods and harmful substances. Immigrants to America become acculturated to Western society. In so doing, they may give up their own health protective beliefs and behaviors and instead turn to the use of alcohol, drugs, and tobacco, or consume fast foods rather than a balanced diet. The nurse's role is to assess each patient's beliefs and develop a plan of care that is individualized and incorporates the woman's customs while providing comprehensive and safe care.

Ethnocultural Considerations— Myths, taboos, and "Old Wives' Tales"

In all cultures and subcultures there are myths, tales, and taboos associated with pregnancy. These have developed to explain the changes that occur during pregnancy or to link a cause to negative pregnancy outcomes. One myth concerns heartburn: if heartburn is experienced during pregnancy, the baby will be born with lots of hair. Another involves using the shape and height of the woman's belly or shape and fullness of her face as indicators to determine the baby's sex.

The Chinese and Malays believe that certain "cooling" foods—cucumber, cabbage, bananas, pineapples—and iced

drinks—coconut water and tea—are taboo during pregnancy because they contribute to poor blood circulation. For the Chinese, other taboo foods are those considered to be "acidic," such as pineapple, mango, lime, sour orange, tapai (fermented tapioca rice), and concentrated coconut milk. These foods are believed to possibly induce bleeding or miscarriage.

Many "Old Wives' Tales" surround pregnancy. One suggests that raising the hands up over the head can cause the baby to become entangled in its cord. Another warns the pregnant woman not to take baths because germs may enter the vagina and pass to the baby. Another encourages abundant water intake so that the baby won't get dirty.

FACTORS THAT INTERFERE WITH PSYCHOSOCIAL ADAPTATIONS DURING PREGNANCY

Grief and loss during the perinatal period can be triggered by spontaneous abortion; elective termination; plans to relinquish the child for adoption or surrogacy; and loss of the perfect child through prematurity, illness, deformity, or less preferred gender. Parental reactions can produce a separation from the infant and delay attachment, prompt feelings of personal inadequacy concerning the inability to produce a healthy infant, and alter healthy methods of relating to the infant.

The importance of prenatal education, labor and birth preparation, and parenting classes cannot be stressed enough by the nurse. Many women bypass the courses offered by their health care providers or hospitals in lieu of watching birth stories on television. These programs are a good adjunct but must be placed into context by information obtained at the prenatal visits and during attendance at prenatal and childbirth education classes taught by nurses and certified personnel.

NURSING ASSESSMENT OF PSYCHOSOCIAL CHANGES AND PRENATAL HEALTH EDUCATION

Nursing assessment of the psychosocial changes that occur during pregnancy must include a thorough history including the family background, past obstetrical events, and the status of the current pregnancy. Each prenatal visit provides an opportunity to ask the patient about her pregnancy experience since the last visit, address current concerns, and offer anticipatory guidance of what to expect from the present visit to the next appointment. Based on this information, the nurse formulates appropriate nursing diagnoses related to the maternal psychosocial adaptation to pregnancy (Box 8-2). Health education should be focused according to the current trimester and evaluated by the patient's or couple's ability to verbalize the content presented, their efforts to seek assistance and support with psychological concerns, and indicators of satisfactory coping with the psychological transitions that are occurring. Suggested topics for health teaching during each trimester are presented in Table 8-5. Pregnancy represents a time of great physical and emotional change. The woman and her family require ongoing support and education to ensure that they safely and successfully move through the stages of pregnancy and, in the end, are prepared to welcome the new baby into their lives.

Box 8-2 Nursing Diagnoses Related to Psychosocial Adaptations to Pregnancy

- Risk for Disturbed Body Image related to anatomical and physiological changes of pregnancy
- Ineffective Role Performance related to taking on new roles; changes in roles
- Risk for Situational Low Self-esteem related to pregnancy complications, changes in body image, roles
- Ineffective Sexuality Patterns related to changes in libido during pregnancy
- Interrupted Family Processes related to developmental stressors of pregnancy or loss
- Anxiety related to fear of the unknown
- Readiness for Enhanced Family Coping related to opportunity for growth/mastery
- Risk for Impaired Parenting related to lack of knowledge, skills, support
- Health-seeking behaviors: developmental tasks needed to prepare for parenthood
- Dysfunctional grieving related to stillbirth, ill or preterm newborn, loss of the ideal of the perfect child, loss of pregnancy, or loss of desired labor or birth

Adapted from Mattson, S., & Smith, J.E. (2004). *Core curriculum for maternal-newborn nursing*. St. Louis: W.B. Saunders.

Now Can You— Discuss the effects of high technology and other influences on psychosocial adaptation during pregnancy?

1. Explain how “high-tech” management can interfere with accomplishing the tasks associated with maternal role development?
2. Provide three examples of societal/cultural traditions that influence development of the maternal role?
3. Describe how assessment and education empower the pregnant woman and her family to successfully deal with the psychosocial changes that take place?

summary points

- ◆ Estrogen and progesterone are the major hormones produced by the placenta during pregnancy. Estrogen’s effect is one of “growth”; progesterone’s effect is one of “maintenance.”
- ◆ The reproductive system undergoes the greatest changes in size and function and every organ within this system is affected by or focused on the needs of the growing fetus.
- ◆ Every system in the body experiences dramatic changes in structure and function as a result of the hormonal changes of pregnancy.
- ◆ Pregnancy is a time of turmoil in the woman’s life that affects her ability to deal with stress and cope with the changes that will occur over many months. These changes affect not only the woman but also her partner and the other family members as well.
- ◆ Ethnocultural, familial, and spiritual beliefs exert a powerful influence on the woman’s and her family’s progress through the pregnancy and can enhance or interfere with routine prenatal care.

- ◆ The nurse’s responsibility in prenatal care is to ensure that the patient and her family understand the physiological and psychosocial changes that occur due to pregnancy and equip them with strategies to cope with these changes.

review questions

Multiple Choice

1. The perinatal nurse knows that the hormone most responsible for maintaining pregnancy is:
 - A. Estrogen
 - B. Progesterone
 - C. Relaxin
 - D. Human chorionic gonadotrophin
2. The perinatal nurse explains to the woman in the assessment area who is experiencing painless, irregular contractions at 28 weeks’ gestation that this is normal and is related to circulating levels of the hormone:
 - A. Estrogen
 - B. Progesterone
 - C. Relaxin
 - D. Prostaglandin
3. A speculum examination is performed during Kelly’s first prenatal visit. The clinic nurse notes a bluish-purple coloration of the cervix. This finding is probably a sign of pregnancy termed:
 - A. Goodell sign
 - B. Chadwick’s sign
 - C. Striae gravidarum
 - D. Linea nigra
4. During the prenatal class, the perinatal nurse explains to the expectant mothers and family members that one of the baby’s protections during pregnancy is the cervical mucus or:
 - A. Linea nigra
 - B. Rugae
 - C. Striae gravidarum
 - D. Operculum

Fill-in-the-Blank

5. The perinatal nurse explains to the student nurse that during pregnancy, the hormones estrogen and _____ influence the myometrial cells and muscle _____ of the uterus by the processes of _____ and _____.

Select All that Apply

6. The perinatal nurse talks with a pregnant woman at 20 weeks’ gestation who has monilial vaginitis. The best information the perinatal nurse can provide is:
 - A. Pregnancy is a time when women are at an increased risk for this type of infection.
 - B. Your vaginal area has increased secretions and discharge that are normal to pregnancy but burning and itching are signs and symptoms that should always be reported.
 - C. Gentle cleansing with plain soap and water is best during pregnancy.
 - D. Douching may be required to ensure cleanliness.

7. The perinatal nurse sees Jenny for a prenatal clinic visit. Jenny is now at 36 weeks' gestation. The nurse teaches Jenny that she should go to the hospital if she is aware of vaginal discharge that includes:
- Blood
 - A foul odor
 - Yellow-green particulate
 - Fleshy odor
8. During the prenatal class, the perinatal nurse describes breast changes that occur during pregnancy. Normal changes include:
- Leaking of colostrum
 - Decreased nipple lubrication
 - Darkening of the areola
 - Presence of striae or stretch marks
9. The clinic nurse provides health teaching to Rachel, a 28-year-old woman in her tenth gestational week. This is Rachel's first pregnancy. Rachel is planning a trip and has many questions concerning sun exposure. The nurse explains to Rachel that:
- During pregnancy, the skin is photosensitive.
 - She will need to use additional sunscreen.
 - She will need to decrease her exposure time to the sun.
 - The increased sun sensitivity will continue while she is breastfeeding.

True or False

10. The perinatal nurse is teaching the prenatal class attendees about the labor process. The ability of the vagina to accommodate the infant during childbirth is due to the hyperplasia of the vaginal rugae.

CONCEPT MAP

The Prenatal Assessment

chapter 9

We are weaving the future on the loom of today.
—Grace Dawson

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Outline a schedule for and describe the benefits of prenatal care.
- ◆ Summarize the components of the first prenatal visit in relation to history taking, physical assessment, and risk assessment.
- ◆ Discuss factors that influence participation in prenatal care.
- ◆ Discuss how nurses can empower women to become shared decision makers and active participants in planning their prenatal care.
- ◆ Recognize lifestyle choices that may be detrimental to maternal and fetal well-being.
- ◆ Differentiate presumptive, probable, and positive signs of pregnancy.
- ◆ Determine the estimated date of delivery together with the woman's gravidity and parity.
- ◆ Describe components of the focused obstetric examination.
- ◆ Discuss aspects of prenatal care for the adolescent and for women over age 35.

moving toward evidence-based practice Decline in Adolescent Pregnancy

Santelli, J.S., Lindberg, L.D., Finer, L.A., & Singh, S. (2007). Explaining recent declines in adolescent pregnancy in the United States: The contribution of abstinence and improved contraceptive use. *American Journal of Public Health, 97*(1), 150–156.

The purpose of this study was to explore the relationship among decreasing adolescent pregnancy rates, improved contraceptive use, and declining sexual activity. Data were analyzed from a national probability survey. The national survey is conducted every 7 years. For the purpose of this research, data from female respondents who were 15–19 years of age during the previous two survey years were used. Data were limited to include noninstitutionalized U.S. citizens 15–19 years of age, which included 1396 for the year of 1995 and 1150 for 2002. The analysis was based on two central measures: sexual activity and contraceptive use at the time of the most recent intercourse (within 3 months of the interview).

The researchers developed two indices: contraceptive risk index and overall pregnancy index. The “contraceptive risk index” was a summary of the overall effectiveness of contraceptive use among sexually active adolescents and included information concerning the nonuse of contraceptives. The “overall pregnancy index” was

a calculation that included the contraceptive risk index and the percentage of those who reported sexual activity.

Declines in sexual activity among the 18–19 years-of-age group were considered to be nonsignificant. The contraceptive risk index declined 46% among teens 15–17 years of age. The pregnancy risk index among the same group also declined by 38% overall. Seventy-seven percent of the decline in pregnancy risk was attributed to improved contraceptive use and 23% (of the decline) to a decrease in sexual activity. The researchers concluded that the decline in pregnancy rates was related to an improved use of contraceptives.

1. What may be considered as limitations to this study?
2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

The objective of this chapter is to enhance understanding of the complexities and challenges involved in providing individualized, competent prenatal nursing care. The information presented serves as a knowledge base and introduction to clinical skills while promoting critical thinking and empathetic understanding. Framed in the nursing role, various components of the prenatal assessment throughout pregnancy are explored.

Each prenatal visit offers an opportunity for the nurse to provide a comforting, supportive environment for the expectant woman and her family members. During these visits, educational needs can be identified and addressed, concerns can be discussed, reassurance can be provided, and problems or potential problems can be discovered. Promoting maternal physical, psychological, and spiritual health and facilitating maternal empowerment are key to promoting and enhancing fetal well-being and a positive pregnancy outcome.

A Time of Wonder and Growth...and Ambivalence

For most women, pregnancy is a special time of wonder and personal growth. However, when faced with a positive pregnancy test result, many women experience ambivalence or begin to question their desire to be pregnant. This reaction is a normal response that occurs irrespective of how determined and committed the couple is to the goal of beginning or expanding a family. Part of the ambivalence relates to the sudden realization that life as it has been known is going to change dramatically and this change will be a life-long endeavor. The woman especially can anticipate role changes in relation to her career and relationships and a need to prepare for the role of being a mother to an infant who will be dependent upon her for survival. Recognizing ambivalence and its normalcy in relation to pregnancy during the first trimester and providing support and reassurance are essential in helping the woman positively embrace and celebrate her journey into motherhood.

Concerns over Self-Preservation

Pregnancy also raises issues of maternal self-preservation. Despite tremendous improvements in perinatal care, women still die in childbirth and it is not unrealistic for a woman to fear for her own safety. The World Health Report “Make Every Woman and Every Child Count” (World Health Organization [WHO], 2005b) focuses on making pregnancy safer and asserts that reaching this goal centers on providing excellent antenatal care and constructing societies that support pregnant women. Antenatal care must be consistently accessible and responsive while incorporating patient-centered interventions, thereby removing barriers that prevent access to care. Perhaps one of the most significant roles that nurses can play in helping to achieve this important goal lies in promoting optimal prenatal care for all women.

Women who receive prenatal care experience a fivefold decrease in pregnancy-related maternal deaths and have better pregnancy outcomes than those who do not receive prenatal care (Harper, Byington, & Espeland, 2003). Prenatal care should offer the patient evidence-based medical and nursing care together with an educational program specifically designed to meet that patient’s needs. This approach to care enables informed and shared decision making (Kirkham, Harris, & Grzybowski, 2005).

Health care should begin during the preconception period and continue throughout the pregnancy and puerperium. Firmly grounded in an understanding of the physical, emotional, and psychological changes characteristic of the childbearing period, prenatal care should be focused on the early identification of deviations from the normal. Ideally, screening procedures are conducted where warranted, health maintenance and promotion are emphasized, and psychological support to facilitate optimal maternal and fetal outcomes is provided in a culturally sensitive setting. An integral aspect of all prenatal nursing care involves actively listening to the woman, providing individualized education, and respecting her choices. The woman has the right to expect continuity of care, clear explanations, consistent information, and the opportunity to discuss any aspect of her care at any time (Haire, 2000) (Fig. 9-1). A number of nursing diagnoses are applicable during the prenatal period. These are often related to maternal health-seeking behaviors (i.e., “health-seeking behaviors related to guidelines for activity and nutrition during pregnancy”) and family support and coping (Box 9-1).

Nursing Insight— Goals that guide nursing care of the prenatal patient

When providing care for the prenatal patient, essential nursing goals are:

- To recognize deviations from normal
- To provide individualized, evidence-based care
- To provide culturally appropriate prenatal education designed to meet the patient’s learning style and needs
- To empower women to become actively involved in their pregnancy by being informed recipients and shared decision makers

Figure 9-1 Actively listening to the patient and providing individualized education is an essential component of prenatal care.

Prenatal care usually begins in the first trimester of pregnancy, when the patient is seen every 4 weeks until she reaches 28 to 32 weeks' gestation. At that time, the appointments are changed to visits every 2 weeks and then occur weekly from 36 weeks of gestation until birth. Although this schedule has to some extent become the "standard of care," it has not been possible to substantiate the necessity for such frequent visits. Interestingly, the number of total prenatal visits varies tremendously from as few as 3 to 4 visits for low-risk women in some European countries to 14 or more visits for women with uncomplicated pregnancies in the United States (Partridge & Holman, 2005).

A recent meta-analysis revealed that a reduction in the total number of prenatal visits did not negatively affect maternal or infant outcomes, but did negatively affect the women's level of satisfaction with the care received (Villar, Carroli, Khan-Neelofur, Piaggio, & Gulmezoglu, 2004). Based on these findings, a more patient-centered approach to care for low-risk women may entail fewer visits with a medical provider and more frequent visits with a nursing team who can provide continuity of care, psychological support, and individualized strategies to meet the patient's educational needs.

Now Can You— Discuss aspects of prenatal care?

1. Discuss why ambivalence is frequently experienced during the first trimester?
2. Name three goals of prenatal care?
3. Describe the common prenatal visit schedule for a low-risk pregnancy?

Navigating the Health Care System

A woman's initial contact with the health care system may occur when she first seeks prenatal care. Attempts to navigate the system while becoming familiar with health

insurance or Medicaid coverage can result in an overwhelming, frightening experience. Many women have no financial resources for maternity care or for health care of any kind. Despite recent changes in legislation, approximately 45 million Americans remain without any source of health care insurance (Centers for Disease Control and Prevention [CDC], 2007). For uninsured women, pregnancy can create a major financial stress since health care for a single pregnancy may well exceed \$20,000.00, depending on the type of birth and the development of complications.

CAREing for the Patient

Throughout the childbearing experience, the nurse's primary role is to "CARE" for the patient. The "CARE" principle centers on communicating, advocating, respecting and enabling/empowering the individual (Box 9-2). Some patients find both the health care system and the health care staff to be intimidating and nonreceptive when they attempt to voice concerns, doubts, or desires. There is a lack of effective communication between the patient and the nurse. When this occurs, many women adopt what is perceived as the "typical patient role"—one where the patient simply does as requested without question. Unfortunately, nurses sometimes have a tendency to facilitate and reinforce this behavior.

The nurse's role encompasses that of being an advocate for the patient. An advocate verbalizes the patient's wishes if the patient is unable to do so herself and ensures that the patient's questions are answered in an understandable and comprehensive way. It is also the advocate's responsibility to help the patient to become an informed recipient

Box 9-1 Possible Nursing Diagnoses for the Prenatal Patient

- Knowledge Deficit related to normal physiological changes of pregnancy
- Altered Nutrition Risk: less than body requirement
- Risk for Fatigue
- Risk for Disturbance in Body Image
- Risk for Altered Role Performance
- Altered sexual patterns
- Family coping
- Change in comfort level related to advancing pregnancy
- Change in sleep pattern disturbance
- Altered urinary elimination due to enlarging uterus or engagement of fetal part
- Anxiety
- Family coping
- Adolescent
- Family processes, altered

Adapted from Doenges (2005).

Box 9-2 CARE Principles

Communication

The exchange of information between individuals, for example, by means of speaking, writing, or using a common system of signs or behavior

A spoken or written message

The communicating of information

A sense of mutual understanding and sympathy

Advocate

One who argues for a cause; a supporter or defender

One who pleads in another's behalf; an intercessor: Advocates for abused children and spouses

Respect

To feel or show admiration and deference toward somebody or something

To pay due attention to and refrain from violating something

To show consideration or thoughtfulness in relation to somebody or something

Enable

To provide somebody with the resources, authority, or opportunity to do something

To make something possible or feasible

Source: Encarta® World English Dictionary © 1999 Microsoft Corporation. All rights reserved. Developed for Microsoft by Bloomsbury Publishing Plc. (review <http://www.npaf.org/> - National Patient Advocate Foundation).

of care. Respecting the patient involves valuing her as an individual, listening attentively, and addressing all of her concerns.

Optimizing Outcomes— Being an advocate for the patient

The nurse is the ideal person to be an advocate for the pregnant patient. An advocate is a person who supports and represents the rights and interests of another individual in order to ensure the individual's full legal rights and access to services.

The nurse has the knowledge base to educate the patient and inform her of safe options or alternatives to meet her particular needs. The nurse also has the skills to communicate effectively with the patient, her family members, and her care provider. Thus, the nurse facilitates shared decision making and helps to promote patient satisfaction with the health care services received.

An informed recipient of care is an individual who has been made aware of available health care options and the possible consequences or outcomes of the choices made. Thus, the informed pregnant woman is able to discuss the advantages and disadvantages of various screening tools, diagnostic tests, and treatment options and she is empowered to make an informed choice that is right for her and her family. For the nurse, an important aspect of the advocate role involves remaining nonjudgmental and able to listen and respond accurately and objectively.

As health care professionals, nurses need to empower women by caring, actively listening, and recognizing their inner wisdom, strength, and abilities. In so doing, nurses gain insights to help them meet their patient's needs in relation to education; health promotion; and physical, psychological, emotional, and spiritual support. The pregnant woman has a journey ahead of her that should lead to greater self-understanding, enhanced feelings of self-worth, and the knowledge that she has the internal power to succeed.

Diminishing Stress and Improving Pregnancy Outcomes

Pregnancy is a developmental crisis that necessitates role adaptation and a restructuring of the tasks involved in daily living. It is a life-changing event that requires adjustments to the many physical and emotional changes that will take place. By nature, change is associated with stress. Eustress is defined as a normal, healthy level of stress. Most individuals are equipped with the resources needed to readily deal with eustress. However, when perceived stress exceeds the individual's resources, strategies, and abilities to effectively deal with it, the person moves into a state of distress.

Nursing Insight— Diminishing maternal stress

Women release oxytocin as a response to stress and when they engage in “tend and befriend” activities with friends. Oxytocin appears to buffer the stress response and produces a calming

effect. This physiological response to engagement in friendship behaviors helps women to dissipate stress (Taylor et al., 2002).

From a nursing perspective, there are a number of ways in which this information can be used. One strategy is to incorporate continuity of care, so that as the patient sees the same nursing staff throughout pregnancy, a professional relationship develops. This bond helps the patient to develop a sense of being cared for, appreciated and known as an individual by her care providers. Ultimately, this simple action can help to reduce maternal stress.

Maternal stress during pregnancy can be associated with difficulty accessing care. Transportation problems, appointment schedules that conflict with work commitments, and personal or family member illness may prevent the woman from keeping her prenatal appointments. Communication difficulties, perceptions of staff disinterest, and a lack of understanding about the importance of frequent prenatal visits are all potential sources of stress that may diminish the patient's ability to comply with the plan of care. By using an individualized approach with a focus on communication, personalized care, and education, nurses may help to reduce the patient's stress and increase her adherence to the care plan.

Pregnancy is a time of entering the unknown. The pregnant woman faces unpredictability and quite possibly the loss of control. Since the course of the pregnancy may differ from the anticipated experience, women need to be able to adapt to unexpected situations and meet unforeseen challenges as the pregnancy advances. The new stressors associated with pregnancy can become a deterrent to seeking or continuing prenatal care. Therefore, nurses must be cognizant of the fact that women, irrespective of culture, may face different stressors and often require a variety of resources and interventions to help them deal effectively with stress and improve their utilization of prenatal care.

Racial disparities exist in the provision and utilization of prenatal care. The effects of these discrepancies on pregnancy outcomes have been recognized for more than 90 years. One of the goals of the *Healthy People 2010* national initiative is to address these racial disparities and to increase the uptake of prenatal care in the first trimester of pregnancy for all women to 90% (Healy et al., 2006). By using the “CARE” principles, the nurse can provide individualized support to all patients irrespective of race or culture.

As an advocate, nurses can provide information about stress management for their patients. Social support is an important and positive factor in the reduction of stress (Fig. 9-2). If the pregnant woman has a good social support system, she is much more likely to have a venue to discuss issues of concern and gain morale support. It is important to note that a support system may be lacking for women who are trying to conceal a pregnancy or for women who are trying to keep the news of their pregnancy from relatives or friends until results from genetic tests are known. These individuals may need additional support from their nurses and other health care providers as they are placed in a powerless situation while awaiting results and face a pregnancy that may be in jeopardy.

Figure 9-2 Social support helps to reduce maternal stress.

Choosing a Pregnancy Care Provider

One of the first maternal tasks of pregnancy as described by Rubin (1984) is “Ensuring safe passage.” This stage encompasses the active lifestyle choices that the woman makes, and the behaviors that she adopts to promote her own and her fetus’s well-being. One of the early decisions the patient (and partner) makes concerns choosing a care provider. It is recommended that every patient arrange an appointment with a chosen care provider (obstetrician, family practice physician, certified nurse midwife) to discuss the management of pregnancy and childbirth as early as possible within the first trimester. The woman may seek childbearing care from an obstetrician, a family practice physician, or a certified nurse midwife (CNM) who is educated in the disciplines of nursing and midwifery and is certified by the American College of Nurse-Midwives (Box 9-3).

Approximately 90% of pregnant women choose an obstetrician as the primary care provider. Others use a CNM who can provide a more personalized, less routine approach to a normal, uncomplicated pregnancy and birth.

Healthy women who choose a CNM are as likely as those who choose an obstetrician to have an excellent outcome and they may also experience fewer medical interventions and a lower rate of cesarean births. Women who have complications related to the pregnancy or who are in a high-risk category should plan to meet with a perinatologist, an obstetrician with experience in managing high-risk pregnancies. The perinatologist works closely with the woman’s obstetrician to determine the best plan for managing the pregnancy, labor, and birth.

A woman’s journey through the pregnancy experience can have long-term effects on her self-perception and self-concept. Thus, it is especially important that the patient choose a care provider with whom she can openly relate and who shares the same philosophical views on the management of pregnancy. Continuity of prenatal care has been shown to be associated with increased maternal satisfaction and a need for fewer interventions during labor. The importance of developing a positive relationship with one’s care provider and receiving personal, individualized

Box 9-3 Definition of Certified Nurse-Midwife and Sphere of Practice

DEFINITION OF CERTIFIED NURSE-MIDWIFE AND SPHERE OF PRACTICE

A certified nurse-midwife (CNM) is an individual educated in the two disciplines of nursing and midwifery who possesses evidence of certification according to the requirements of the American College of Nurse-Midwives (ACNM).

MIDWIFERY PRACTICE

Midwifery practice, as conducted by certified nurse-midwives, is the independent management of women’s health care focusing particularly on common primary care issues; family planning and gynecological needs of women; pregnancy; childbirth; the post-period; and the care of the newborn. The certified nurse-midwife and certified midwife practice within a health care system that provides for consultation, collaborative management, or referral, as indicated by the health status of the client. Certified nurse-midwives practice in accord with the Standards for the Practice of Midwifery, as defined by the American College of Nurse-Midwives (ACNM), 2005.

care throughout the pregnancy is medically and psychologically advantageous (Hodnett, 2004).

During the initial interview with a care provider, it is helpful for the woman to discuss the provider’s work schedule and how births that take place when the provider is not on call are managed. This is also an ideal time for the care provider to introduce the pregnant woman’s Bill of Rights and to discuss the responsibilities the woman has to facilitate optimum health for herself and for her fetus (Appendix 9-1). Many pregnant women are not fully aware of their right of informed consent or of the obstetrician’s legal obligation to obtain their patient’s informed consent prior to treatment. The American College of Obstetricians and Gynecologists (ACOG) first publicly acknowledged the physician’s legal obligation to obtain the pregnant patient’s informed consent in its 1974 publication, *Standards for Obstetric-Gynecological Services*. The informed consent process is important in safeguarding the patient’s autonomy (Box 9-4).

American patients are becoming increasingly aware that well-intentioned health professionals do not always have scientific data to support common American obstetric practices, and that many of these practices are carried out primarily because they are part of medical and hospital tradition. More than 20 years ago, the distinguished obstetrician Dr. Roberto Caldeyro-Barcia articulated clearly his concerns with the medical management of low-risk pregnancy and delivery:

In the last 40 years, many artificial practices have been introduced that have changed childbirth from a physiological event to a very complicated medical procedure in which all kinds of drugs are used and procedures carried out, sometimes unnecessarily, and many of them potentially damaging for the baby and even for the mother (Haire, 2000).

A growing body of research makes it alarmingly clear that every aspect of traditional American hospital care during labor and birth must now be questioned as to its possible effect on the future well-being of both the obstetric patient and her unborn child. Care needs to be individualized to meet each patient’s particular needs, and

Box 9-4 Informed Consent and Communication

Informed consent is the willing and uncoerced acceptance of a medical intervention by a patient following the clinician's full disclosure of information that includes the nature of the intervention, the risks and benefits of the intervention, and the risks and benefits of any alternatives. The patient also has the right to informed refusal, that is, the right to refuse recommended medical treatment. Open, on-going communication about relevant information empowers the patient to exercise personal choice, and is central to the patient-clinician relationship.

Source: American College of Obstetricians and Gynecologists (ACOG). (2007). *Guidelines for Women's Health Care. A resource manual.* (3rd ed.). Washington, DC, ACOG.

procedures performed only when the advantage to the patient outweighs any possible disadvantage.

The provision of prenatal care offers the nurse a unique opportunity to make a difference not only in the patient's life but also in the lives of her family. To truly take advantage of this opportunity, the nurse needs an expansive array of tools including the ability to communicate effectively with patients irrespective of cultural background, educational level, health care beliefs, or age, to understand family and group dynamics; and to accept diversity without prejudice or bias. Family care during the prenatal period centers on education and health promotion.

A number of issues affect a woman's willingness to use health care services. These include personal beliefs about pregnancy, cultural expectations, previous relationships with health care providers and perceived benefits of prenatal care, together with the more practical issues of access to care, medical insurance and/or financial support. By using therapeutic communication, the nurse can gain insights into the patient's belief system and manage care appropriately. Maintaining a nonjudgmental attitude is essential, for example, if the woman is a late recipient of prenatal care. Creating an atmosphere where the patient feels accepted and valued for seeking care is a therapeutic, positive approach and one that will hopefully foster patient adherence.

Through discussion, the nurse can gain an understanding of the availability and acceptability of traditional health care services and whether they meet the patient's individual health care needs. Each culture embraces different customs and health practices that need to be respected, and wherever possible, accommodated. These requirements may relate to the gender of the health care provider, the patient's clothing requirements, diet, and/or food preparation. The prenatal interview provides an opportunity to develop a positive relationship with the patient and emphasize the benefits of prenatal care for her and her unborn child.

In both the local and national arenas, nurses can empower women and their families by advocating for prenatal care that is readily available and affordable for all, especially for low-income and vulnerable populations. The "Health Care Safety Net" is one mechanism for providing health services for the needy. Despite the availability of these types of programs, there are still women who receive inadequate or no prenatal care. In 2005, close to four percent of women in the United States received inadequate prenatal care (National Center for Health Statistics [NCHS], 2007).

**Across Care Settings: The health care safety net**

The health care safety net consists of a wide variety of providers who deliver care to low-income and other vulnerable populations, including the uninsured and those covered by Medicaid. Many of these providers have either a legal mandate or an explicit policy to provide services regardless of a patient's ability to pay.

Major safety net providers include public hospitals and community health centers as well as teaching and community hospitals, private physicians, and others who deliver a substantial amount of care to the targeted populations.

The health care safety net—the Nation's system of providing health care to low-income and other vulnerable populations—was recently described as "intact but endangered" (Agency for Healthcare Research and Quality 2003). Safety net monitoring initiative. Retrieved from <http://www.ahrq.gov/data/safetynet/netfact.htm>

**Now Can You— Discuss health promotion strategies for pregnancy?**

1. Identify and describe each component of the "CARE" principle?
2. Discuss how stress adversely affects pregnancy and identify nursing interventions to help decrease patient stress?
3. Describe four important elements of a teaching plan for family health promotion during pregnancy?

The First Prenatal Visit**THE COMPREHENSIVE HEALTH HISTORY**

Before initiating the interview, it is helpful for the nurse to review the paperwork to become familiar with the information to be gathered and to ensure an understanding of the relevance and appropriateness of the questions to be asked. The initial interview time with the patient should be used to build a positive, nonthreatening relationship and to gain her confidence. Strategies that are useful include active listening, validating responses when needed, maintaining eye-to-eye contact, and the use of humor as appropriate to relax the patient. Honesty is essential for effective communication. When uncertain of the answer to a question, the nurse should make a note to find the answer and report back to the patient at the end of the interview.

The first prenatal visit is an extremely important one that should take place as early in pregnancy as possible. Therapeutic communication skills are of paramount importance when obtaining the prenatal history. The information requested can often be of a very personal nature and it may be difficult for patients to disclose certain aspects of their past histories. Therefore, care must be taken to manage the environment to promote privacy and provide the patient with psychological and physical comfort.

It is important to avoid medical or technical jargon that may interfere with the patient's understanding, may intimidate her, or cause her to feel embarrassed due to a lack of

Family Teaching Guidelines...

"DEEPER CARE" for Promoting Family Health During Pregnancy

D	DIET	This is an ideal time to review the family diet and the way that foods are prepared. Encourage consumption of whole grains, dark green, yellow and orange vegetables, dry beans and peas; a variety of fresh or dried/canned fruit; increased low-fat and fat-free foods, milk and calcium-rich foods; poultry, low-fat meats, fish that are lowest in mercury (whitefish, haddock, pollock, sole, trout), nuts, and seeds.
E	EXERCISE	Aerobic exercise maintains physical fitness and promotes self-esteem and body image. It is a family activity that benefits all family members.
E	EDUCATION	Many childbirth education options are available to meet the needs of women and their families.
P	PLAY	Play is essential to health, happiness, and creativity. Fun family (couple) activities refresh, promote optimism, and provide an opportunity to "recharge and reconnect."
E	EXPECTATIONS	Pregnancy is a time of great expectations. Families need to know what changes are likely to occur and to be able to recognize normal from abnormal so they can recognize when to seek medical assistance.
R	RELAXATION	Relaxation benefits all family members by boosting immunity, lowering blood pressure, reducing stress, and increasing energy levels. Activities may include meditation, yoga, and visualization/positive thinking.
C	COMMUNICATION	Effective communication is essential to promote family cohesiveness. Communication includes both verbal and nonverbal language such as body posture, gestures, facial expressions, and tone of voice. Within the family, communication needs to be open and truthful and received in a nonjudgmental and accepting manner, ultimately affirming and supporting one other.
A	ATTITUDE	Positive thinking is under each individual's control but can be modeled. A positive attitude to life is associated with released stress, improved coping abilities, improved immunity, and a greater sense of well-being.
R	RESPECT	Healthy relationships require mutual respect, honesty, and trust. Compromise, negotiation, and shared responsibility are intrinsic to a positive relationship, as is equal distribution of power and control.
E	EMERGENCIES	Family members need to know the following danger signs of pregnancy and how to seek medical help: <ul style="list-style-type: none"> ◆ Reduction in fetal movements ◆ Signs of preterm labor such as low, dull backache, pelvic pressure feelings, uterine contractions, or menstrual cramps ◆ Vaginal fluid loss or vaginal bleeding ◆ Maternal fever over 100.5°F (38.1°C) ◆ Persistent headache associated with blurred vision or flashing lights in front of the eyes ◆ Continuous vomiting with weight loss, dehydration, weakness, dizziness, or fainting ◆ Couple has an "inner feeling that something is just not right." It is always better to confirm normality rather than deal with an avoidable emergency.

comprehension. Questions should be phrased in a way to encourage the patient to discuss and share information rather than asking closed-ended questions that require only a "yes" or "no" response. The value the patient places on the care she receives and her interactions with personnel will determine whether she returns for subsequent prenatal care. Therefore, the prenatal team's objective is to

provide a user-friendly service that is efficient, effective, caring, and patient centered. One major goal for this first visit is to explain the purpose of prenatal care and to establish specific goals. Care goals are determined through shared decision making with the patient and focus on promoting maternal and fetal health through assessment, education, screening, diagnosis, and treatment.

Biographical Data

Collection of the patient's biographical data, medical history, psychosocial history, and a medical examination are essential components of the first visit. To facilitate the collection of data, a number of prenatal forms such as the Prenatal Plus Program—Initial Assessment Form are available. This is a particularly in-depth and user-friendly tool produced by the Colorado Department of Public Health and Environment. This risk assessment form allows for the collection of information relating to the patient's pregnancy history, medical history, nutritional and exercise patterns, financial income, her vocational and educational goals, living arrangements, psychosocial history (includes depression and past suicidal tendencies), and lifestyle choices. It also provides an opportunity for the patient to request educational information on a variety of topics.

Completing the prenatal history form with the patient enables the nurse to provide personalized education that focuses on risk factors pertinent to that individual. For example, it may be appropriate to discuss the maternal and fetal effects of environmental substances to which the woman is exposed at home and in the work place. Common offenders include exposure to cigarette smoke (either directly or passively), alcohol consumption, recreational drugs, poor or inadequate diet, pollutants, viruses, and occupational hazards. It is estimated that approximately 10% of fetal malformations are related to exposure to environmental hazards (Silbergeld & Patrick, 2005).

The history should also include information concerning complementary and alternative therapies. An increasing number of individuals routinely use herbal or homeopathic remedies. Some of these substances, such as red raspberry tea, are safe and may be beneficial; others such as blue cohosh may be harmful if taken during pregnancy. Thus, it is essential to explore all nonprescription medications and supplements used.

Complementary Care: Red raspberry and blue cohosh

For centuries, the leaves of the red raspberry plant (*Rubus idaeus*) have been used as a medicinal herb for menstrual problems, pregnancy, childbirth, and breastfeeding. Safe to use during pregnancy, raspberry leaf is believed to aid fertility, ease the symptoms of morning sickness, and assist with the birth of the baby and the placenta (Natural Standard, 2008).

Blue cohosh (*Caulophyllum thalictroides*) belongs to the Barberry family. It also has a long history of use as a medicinal herb. It was known as “papoose root” and used by the American Indians to induce labor or abortion. Blue cohosh should be avoided during pregnancy—it has been linked with cardiovascular emergencies in the woman and anoxia in the fetus (Dugoua, Perri, Seely, Mills, & Koren, 2008).

The biographical information usually includes contact information for the patient such as address and phone number(s), along with the patient's occupation and educational level, marital/relationship status, insurance data, and contact person information. Some forms also contain a section for recording special requests such as spiritual or cultural considerations. To ensure currency, it is important to reconfirm contact information at least every 2 months

throughout the pregnancy. Maintaining a reliable and timely means for contacting the patient (i.e., to discuss screening or test results) is essential.

The woman's age and date of birth allow for easy recognition of potential risk factors (e.g., maternal age is one of the most commonly used indicators for initiating genetic testing). Teenage girls, who fall at the opposite end of the age spectrum, often need additional support and education throughout the prenatal period.

Social History

Together with the biographical details, additional information is obtained relating to the patient's educational level and occupation. These data help to establish the patient's socio-economic group and may provide some indication of family income, standard of housing and nutrition. Information regarding the patient's marital status is also obtained.

Nursing Insight— Homelessness and prenatal care

Homelessness presents a significant barrier to receiving prenatal care. Homeless women may have fears related to acceptance, judgment, costs, and the philosophies and/or expectations of health care providers (Bloom et al., 2004). Nurses, especially those working in the community, need to advocate for homeless women and their children and explore avenues for bringing prenatal and child care in a nonthreatening environment to those in need.

History of Intimate Partner Violence

Intimate partner violence (IPV), formerly known as domestic violence, is the most common form of violence experienced by women worldwide; approximately one out of every six women has been a victim of domestic violence (World Health Organization [WHO], 2005a). In the United States, the reported incidence of physical abuse during pregnancy ranges from 4% to 30% (El Kady, Gilbert, Xing, & Smith, 2005). Up to 45% of victims of intimate partner abuse before pregnancy continue to be abused during the pregnancy (McFarlane, Campbell, Sharps, & Watson, 2002).

Shockingly, IPV may occur for the first time during pregnancy or the nurse may identify evidence during the

where research and practice meet: Marital Status and Perinatal Outcomes

A recent study of 720,586 births in Canada demonstrated that birth outcomes were improved when the mother was legally married as opposed to being in a common-law union. Women not involved in a close relationship with the father of the child experienced the worse perinatal outcomes in relation to preterm births, low birth weight, small for gestational age infants, and neonatal mortality rates (Luo, Wilkins, & Kramer, 2004). It is important to remember that this research is applicable to the group studied and may not be transferable to different social groups. Marital status alone cannot be used to place an individual into an “at risk” group but when combined with other factors, it may be a useful indicator of a pregnancy that warrants close surveillance.

physical examination that is suspicious of ongoing physical abuse. It is estimated that every day at least three women in the United States die as a result of intimate partner violence (Bureau of Justice Statistics, 2003). **Femicide** is presently the leading cause of pregnancy-associated death in the United States (Stevens, 2005). Femicide refers to the death of a woman resulting from an act of violence against that woman (Bull, 2003).

IPV is a difficult subject to discuss and the nurse may fear insulting or psychologically hurting the patient more. A nonthreatening approach is to ask patients directly whether they feel safe going home and whether they have been hurt physically, emotionally, or sexually by a past or present partner. If the partner has accompanied the woman to the prenatal visit, these questions are postponed until the nurse is alone with the patient, for obvious reasons.

An alternative method is to use a standardized form that has valid and reliable questions concerning IPV. The form could be incorporated into the intake assessment data obtained from all patients. Women who have been sexually abused as children are at greater risk of IPV in adult relationships. Sequelae of abuse include depression, anxiety, substance abuse and post-traumatic stress disorder (Coid et al., 2001). As a women's advocate, nurses have a duty to be observant, to actively listen and to use communication skills to gain clarification and understanding. The Centers for Disease Control and Prevention (CDC) have adopted the acronym "RADAR," a term originally developed by the Massachusetts Medical Society (Alpert, Freud, Park, Patel, & Sovak, 1992) to guide nurses as they interview patients about relationship violence:

- Routinely screen every patient
- Ask directly, kindly, and in a nonjudgmental manner
- Document your findings
- Assess the patient's safety
- Review options and provide referrals

Nursing Insight— Screening for intimate partner violence

Domestic violence during pregnancy is more common than preeclampsia or gestational diabetes (Parson, 2000). Each year, approximately 324,000 pregnant women are abused by their intimate partner and that number increases by a factor of 2 to 4 if the pregnancy was unplanned (Gazmarian et al., 2000). Intimate partner violence can occur for a first time during pregnancy. Screening should be available to all pregnant women irrespective of social class or educational background.

Nurses need to promote screening for intimate partner violence so that it becomes a routine part of prenatal care.

Women may use a number of defenses to emotionally deal with abuse. One method may involve the use of recreational drugs. Irrespective of a history of intimate partner abuse, it is estimated that approximately 3% of pregnant women use nonprescription drugs such as cocaine, amphetamines, heroin, marijuana, or ecstasy (March of Dimes, 2006). Illegal or recreational drug use can have a number of detrimental effects (e.g., spontaneous abortion, low birth weight, placental abruption, and preterm labor) on maternal and fetal health during pregnancy. Selected recreational

drugs and their effects on the pregnancy and the infant are presented in Table 9-1.

The nurse's role is to promote a healthy life style for both the woman and her developing fetus. Recreational drug use puts both patients at increased risk, not only from the direct effects of the drugs but also from the behaviors needed to procure and maintain the supply of drugs. Women using drugs are more likely to have poor nutritional status and they are more prone to infection due to a lack of skin integrity and increased exposure to infective agents such as those responsible for sexually transmitted infections. Sex may be used as a bargaining tool or as a means of income to support a drug habit.

Developing a therapeutic nonjudgmental relationship with a drug-addicted woman is essential in order to provide education, support, and guidance. The majority of expectant women wish to do the best they can for their babies, so pregnancy is an ideal time to direct the woman to drug counseling, support groups, and medical care with the goal of reducing and eventually stopping the habit. For a woman to be successful in overcoming drug addiction, she must be internally motivated. The course to success with this problem is not an easy one and the nurse can be instrumental in helping her to achieve this goal.

Psychological Assessment

Pregnancy is a time of change, and usually change of any nature is linked with additional stress. How an individual deals with stress depends on learned behaviors, coping mechanisms, and support systems. Pregnancy is a major life change or developmental phase for all women. Each woman's approach to her pregnancy encompasses cultural values and family traditions and beliefs. One's status in relation to marriage or partnership, financial security, career, or educational achievements are influential factors that shape the overall childbearing experience. Past obstetric experiences including pregnancy outcomes, interactions with care providers, and level of physical health during and after pregnancy are instrumental in forming the woman's attitude toward this pregnancy. The loss of a previous pregnancy may adversely affect a woman's ability to bond with her present pregnancy. Understandably, she may be reluctant to invest in a pregnancy that she fears may not come to fruition. In other situations, acceptance of pregnancy may be delayed if it was unplanned or unwanted. Ambivalence is a normal initial reaction to pregnancy that usually diminishes as the woman accomplishes the developmental tasks of pregnancy.

Although the developmental tasks of pregnancy may be reviewed in a systematic way, it is important to remember that each woman is an individual who harbors a host of unique medical and psychological factors. For example, a woman with a history of a previous eating disorder may experience difficulty maintaining a healthy diet and achieving appropriate weight gain during pregnancy. Another woman may have struggled with anxiety and depression or alcohol or drug use or issues related to domestic violence prior to pregnancy. These are all factors that can have a significant impact on the prenatal course. Many tools such as "The Edinburgh Postnatal Depression Scale" are available to guide the nurse in conducting the prenatal and postpartal psychological assessment. (See Chapter 16 for further discussion.)

Table 9-1 Effects of Recreational Drug Use in Pregnancy

Name	Street Name	Route	Effect	Pregnancy	Newborn
Methamphetamines	Meth	Smoked	Stimulant	Spontaneous abortion	Withdrawal
	Crank	Snorted			Tremors
Dextroamphetamine	Speed	Swallowed		Prematurity	Poor muscle tone
	Ice	Injected			?↑SIDS
		Inhaled		Breastfeeding not recommended	http://otispregnancy.org/otis_fact_sheets.asp
Cocaine	Coke	Inhaled	Stimulant	Spontaneous abortion	Birth defects – abnormalities of brain, skull, face, eyes, heart, limbs, intestines, genitals and urinary tract.
		Smoked		Placental abruption	Neonatal withdrawal
				Preterm birth	Visual disturbances
				Breastfeeding not recommended	Delay in cognitive and/or learning ability http://otispregnancy.org/otis_fact_sheets.asp
Ecstasy (MDMA – compound may contain amphetamines and hallucinogens)	E, Adam, Roll, Bean, X and XTC· Clarity, Essence, Stacy, Lover's Speed, Eve	Pill form usually swallowed.	Stimulant	Spontaneous abortion	Congenital abnormalities – cleft palate
		Crushed and Snorted	Mood enhancer	Placental abruption Preterm birth	Low birth weight (www.ravesafe.org/otherinfo/pregnancy.ht)
		Injected per rectum (Known as 'shafting')			Rats exposed to ecstasy showed memory and learning deficiencies (http://www.acde.org/common/ecstasy.htm)
		Smoked			
Marijuana	Pot	Ingested	Stimulant	Intrauterine growth restriction	Possible link to increased incidence of childhood cancers
Cannabis	Weed	Smoked	Psychedelic	Preterm birth	Withdrawal symptoms
	Grass	Snorted	Depressant		Decrease in verbal ability and memory, plus lower impulse control
	Mary Jane	Injected			http://www.marchofdimes.com/professionals/14332_1169.asp
Heroin	Boy, brown, china white, dragon, gear, H, horse, junk, skag, smack	Swallowed	Sedative	Spontaneous abortion	Neonatal withdrawal syndrome
				Intrauterine growth restriction	http://www.patient.co.uk/showdoc/27000496/
				Preterm labor/birth Stillbirth	

THE OBSTETRIC HISTORY

Previous Pregnancies

One of the first steps in the prenatal interview process is to obtain an accurate and detailed obstetric history that provides the interviewer with essential information so that questions can be formulated and asked in a manner that respects and acknowledges the patient's past experiences with pregnancy. The history should cover the current pregnancy as well as all previous pregnancies and their outcomes, since complications experienced in a prior pregnancy often reoccur in subsequent pregnancies.

A history of preterm labor and delivery, defined as a birth that occurs before the 37th completed week of pregnancy, provides one example of the importance of the obstetric history in identifying potential problems during the current pregnancy. Preterm labor is the leading cause of perinatal mortality and morbidity in the United States, where the incidence is 11%, although this figure is much lower (5%) in some European countries including France and Finland. Once a woman has experienced a preterm birth, her risk of preterm labor in subsequent pregnancies is increased by 20% to 40%. Although the etiology for this condition remains largely unknown, there are a number of predisposing factors. Education, resources, and early interventions are important strategies since earlier diagnosis means earlier treatment and better outcomes. (See Chapter 11 for further discussion.)

A previous history of preeclampsia increases the woman's likelihood of a recurrence during subsequent pregnancies. (See Chapter 11 for further discussion.) Interestingly, if a woman did not experience preeclampsia with previous pregnancies but has a new partner for her current pregnancy, her risk of developing preeclampsia is similar to that of a woman who is pregnant for a first time. Although preeclampsia is a systemic disorder that occurs only during pregnancy, it is generally recognized via two classic symptoms: elevated blood pressure and proteinuria. The complication of preeclampsia places both the patient and her fetus at additional risk both during pregnancy and in the postpartum period.

A history of pregnancy-related diabetes or gestational diabetes (GDM) (carbohydrate intolerance that occurs during pregnancy) is also significant. GDM is estimated to affect up to 7% of pregnancies, and approximately one half of women who have had a previous pregnancy affected by GDM will develop this condition again in a subsequent pregnancy (American Diabetes Association, 2003). Since GDM is associated with a number of fetal and maternal complications, early screening is essential. (See Chapter 11 for further discussion.)

Patients who indicate a pattern of repeated spontaneous miscarriages most likely would benefit from genetic counseling, preferably during the preconception period. A family pedigree is often useful in determining the need for further screening and specific testing. Prenatal genetic screening questionnaires have been developed to guide counseling and intervention approaches. The Human Genome Project, completed in April 2003, provided information useful in facilitating the early diagnosis of genetic disorders and the timely initiation of medical care. For example, in April 2003, the gene for Hutchinson-Gilford Progeria Syndrome (HGPS) was identified. This finding prompted the development of a

genetic test for the early diagnosis of the syndrome (National Human Genome Research Institute, 2003). Because of the rapid advances in the field of genetics, nurses must have a working knowledge of genetics terminology and recent findings so that they can initiate referrals when appropriate. The "Core Competencies in Genetics Essential for All Health Care Professionals" is a useful document with which all perinatal nurses should be familiar (Appendix 9-2).

Nursing Insight—Preconception genetics counseling

Birth defects affect about one in every 33 babies born in the United States each year. They are the leading cause of infant deaths and account for more than 20% of all infant deaths.

Although it is never possible to guarantee a family a "perfect" baby, nurses can help recognize patients who may benefit from preconception or prenatal counseling and genetic testing. Keeping abreast of advances in prenatal genetic diagnosis or knowing where to seek pertinent information is a valuable asset in providing patient centered-care (CDC, 2007).

The loss of a previous pregnancy or the death of an infant brings a staggering cascade of emotions to a subsequent pregnancy. Fear of another fetal loss or infant death undoubtedly increases the couple's anxiety and stress. Although no couple is ever guaranteed a baby that is 100% perfect, the couple who has dealt with the death of a child or loss of a pregnancy faces the prospect of awaiting prenatal diagnostic test results with increased trepidation. Support and continuity of care are essential along with providing advice and listening to the woman's (couple's) concerns. As is true with any pregnant patient, emphasis on healthy lifestyles is of paramount importance. If the previous loss was a result of sudden infant death syndrome (SIDS), the nurse should provide the patient with information about strategies to reduce the incidence of SIDS, such as breast feeding if at all possible, avoiding cigarette smoke and positioning the baby on the back to sleep. Support groups may also help couples facing a new pregnancy after the loss of a previous one. (See Chapter 14 for further discussion.)

During the initial prenatal visit it is especially important to educate the woman about the developing embryo/fetus during the first few weeks of pregnancy. This is a time when the woman needs to be particularly conscious of potential **teratogens**. A teratogen is a substance that adversely affects fetal development. The vulnerability of the developing embryo/fetus during the early weeks of gestation underscores the importance of a healthy body and a healthy lifestyle.

Now Can You—Discuss various components of the prenatal assessment?

1. Describe biographical information to be elicited from the prenatal patient?
2. Explain how to ask the patient about intimate partner violence?
3. Discuss why the psychological assessment is an important component of the prenatal assessment?
4. Explain the importance of past pregnancies in the obstetric history?

Current Pregnancy

When obtaining the medical history, the nurse should begin with the events of the current pregnancy. For the woman, the current pregnancy is the issue of most importance to her at this time and what has brought her to the office for prenatal care. Information is gathered to assist with confirmation of the pregnancy and to determine the expected date of birth (EDB). It is usually possible to determine from the patient's responses whether this was a planned or unexpected pregnancy. "Unexpected" does not necessarily mean "unwanted." Instead, this term refers to the fact that the pregnancy occurred when the couple was not actively trying to conceive. Often, pregnancy comes as a complete surprise when the menstrual period is missed or other signs of pregnancy appear. The diagnosis of pregnancy is based on the patient's reported symptoms and the presence of objective signs elicited by the health care provider. The signs and symptoms are traditionally divided into three classifications: presumptive (experienced by the patient), probable (observed by the examiner), and positive (attributable only to the presence of the fetus).

PRESUMPTIVE SIGNS OF PREGNANCY. The subjective signs of pregnancy are the symptoms that the patient experiences and reports. Because these symptoms may be caused by other conditions, they are the least indicative of pregnancy. In combination with other pregnancy symptoms, the following presumptive signs may serve as diagnostic clues:

- **Amenorrhea** (the absence of menses) is one of the earliest symptoms and is especially significant in a woman whose menstrual cycle is ordinarily regular. Amenorrhea may also be caused by chronic illness; infection; or endocrine, metabolic, or psychological factors.
- Nausea and vomiting ("morning sickness") may actually occur at any time and women who experience this symptom tend to have a decreased incidence of spontaneous abortion and perinatal mortality. Nausea and vomiting may also be caused by infection or gastrointestinal or emotional disorders.
- Frequent urination (urinary frequency) is caused by pressure exerted on the bladder by the enlarging uterus. Urinary frequency may also be caused by infection, cystocele, pelvic tumors, or urethral diverticuli.
- Breast tenderness results from hormonal changes during pregnancy. This symptom may also be associated with premenstrual syndrome, mastitis, and **pseudocyesis** (false pregnancy).
- Perception of fetal movement (quickening) occurs during the second trimester. The sensation of fetal movement may also result from flatus, peristalsis, and abdominal muscle contractions.
- Skin changes include stretch marks (striae gravidarum) and increased pigmentation. These changes may also result from weight gain and oral contraceptive pills.
- Fatigue may also be associated with illness, stress, or lifestyle changes.

PROBABLE SIGNS OF PREGNANCY. The probable signs of pregnancy are objective indicators that are observed by the examiner. These signs result from physical changes in the reproductive system. However, because they may be

caused by other conditions, a positive diagnosis of pregnancy cannot be based on these findings alone.

- Abdominal enlargement may also be caused by uterine or abdominal tumors.
- **Piskacek sign** (uterine asymmetry with a soft prominence on the implantation side) may also be associated with uterine tumors.
- **Hegar sign** (softening of the lower uterine segment) may also be caused by pelvic congestion.
- **Goodell sign** (softening of the tip of the cervix) may also be caused by infection, hormonal imbalance or pelvic congestion.
- **Chadwick sign** (violet-bluish color of the vaginal mucosa and cervix) may also be caused by pelvic congestion, infection, or a hormonal imbalance.
- **Braxton-Hicks sign** (intermittent uterine contractions) may also be associated with uterine leiomyomas (fibroids) or other tumors.
- Positive pregnancy test may occur from certain medications, premature menopause, choriocarcinoma (malignant tumors that produce human chorionic gonadotropin), or the presence of blood in the urine.
- **Ballottement** (passive movement of the unengaged fetus) may be due to uterine tumors or cervical polyps instead of the presence of a fetus.

POSITIVE SIGNS OF PREGNANCY. The positive indicators of pregnancy are attributable only to the presence of a fetus:

- Fetal heartbeat
- Visualization of the fetus
- Fetal movements palpated by the examiner

Establishing the Estimated Date of Birth

The antenatal period begins with the first day of the last normal menstrual period and ends when labor begins. This time frame is approximately 280 days in length or 40 weeks or 10 lunar months or 9 calendar months. Pregnancy is divided into three trimesters. Each trimester is approximately 14 weeks or 3 months in duration. A term pregnancy is defined as one that begins after the 37th completed week of pregnancy and ends before the 42nd week of pregnancy.

The **estimated date of birth** (EDB) or the **estimated date of delivery** (EDD) (formerly termed the "estimated date of confinement," or EDC) is based on the date of the last normal menstrual period with the assumption that the woman has a 28-day cycle. An important aspect of history taking involves collecting data that help to confirm the accuracy of the duration of the pregnancy. First, the date and a description of the last normal menstrual period are obtained to help determine if the LMP was a "normal" period rather than bleeding associated with implantation. The nurse should ask the patient if her last period was normal for her in relation to the amount and duration of blood loss. The length of the menstrual cycle and its predictability are also important factors. The EDB may be calculated using **Naegele's rule**. To use Naegele's rule, add 7 days, then subtract 3 months from the date of

Box 9-5 Naegele's Rule

Naegele's rule is used to calculate the Expected Date of Birth (EDB) – Expected Date of Delivery (EDD)

This calculation is based on the first day of the woman's last normal period.

7 days are added to the LMP and 3 months subtracted and where necessary a year added.

For example, if the woman's LMP was June 8, 2007

Add 7 days = June 15, 2007

Subtract 3 months = March 15, 2007

Add a year = March 15, 2008 EDB = March 15, 08

(An alternative way is to add 7 days and then add 9 months = year where needed)

Remember to ask the women about her last menstrual period (LMP).

Did her period start on the expected date?

Was blood loss normal (the same as her usual menstrual blood loss)?

Was her period different in any way?

What form of contraception had she been using and when was this method discontinued?

(Hormonal contraception may delay the return to a normal ovulation pattern.)

These questions will help you to determine an accurate date for the woman's last normal menstrual period.

Remember: Some women experience bleeding at the time of implantation, which normally occurs 7–9 days after fertilization. Care needs to be taken not to mistakenly use the date of implantation bleeding as the LMP.

the patient's last normal menstrual period (LMP) and add a year where necessary (Box 9-5). Since Naegele's rule is based on a 28-day menstrual cycle, menstrual cycle irregularity and variations in cycle length most likely invalidate the use of Naegele's rule as the sole method for estimating gestational age. A gestation wheel is a useful tool for readily determining the gestational age during pregnancy (Fig. 9-3).

Now Can You— Correctly calculate the EDB?

Calculate the estimated date of delivery/birth using Naegele's Rule?

Lynne is a 28-year-old woman who comes to the clinic with a history of amenorrhea and a positive home pregnancy test.

Her last menstrual period began on August 26, 2006. She bled for the usual amount of time and reports that the amount of blood loss was normal. Assuming that Lynne had a 28-day cycle, use Naegele's Rule to calculate her estimated date of birth.

Important to remember: The month of August has 31 days

August 26 + 7 days = September 2

(September) 9th month – 3 = 6th month (June)

EDD/EDC/EDB=June 2

Correct calculation of the EDB is dependent on a reliable date of the last menstrual period (LMP). Hormonal birth control methods such as combined oral contraceptive pills (OCP) and long-lasting progesterone injections can cause continued suppression of ovulation. Therefore, a discrepancy may exist between when the woman thought she ovulated and conceived and when these events actually occurred. Thus, the LMP may not be an accurate tool for estimating the due date.

Figure 9-3 A gestation wheel is a handy tool for determining the gestational age. The arrow labeled “first day of LMP” is placed on the date of the LMP. The date at the arrow labeled “expected delivery date” is then noted.

Occasionally, pregnancy occurs in women who are taking oral contraceptives, usually as the result of a “pill failure” from forgotten pills or due to poor absorption that may result from various causes such as vomiting, diarrhea, or antibiotic use. Thus, contraceptive pill use may have unwittingly been continued during the early weeks of gestation. The nurse can assure the patient that prenatal hormone exposure associated with normal contraceptive use has not been shown to have any detrimental effects on the developing fetus (Kandinov, 2005).

THE PREGNANCY CLASSIFICATION SYSTEM

Another important task associated with the initial prenatal interview is to determine the patient's gravidity and parity. **Gravid** is the state of being pregnant; a **gravida** is a pregnant woman. **Gravidity** relates to the number of times that a woman has been pregnant, irrespective of the outcome.

where research and practice meet: Depo-Provera Use Before Pregnancy

Bone mass can be adversely affected by the use of depot medroxyprogesterone acetate (Depo-Provera). The extent to which bone mass is lowered appears to be linked to the length of use (Banks, Berrington, & Casabonne, 2001). Calcium has two main physiological functions: promoting skeletal growth and maintaining bone mass. Unfortunately, humans only absorb approximately 10% of the dietary calcium consumed. There are three periods in human life when calcium uptake is increased: during infancy, adolescence (growth spurt) and in the latter half of pregnancy (Heaney, 2006). To counsel prenatal patients appropriately, nurses should understand the benefits associated with meeting the recommended intake of daily calcium, and be knowledgeable about factors that increase absorption. Pregnancy is a time when maternal calcium absorption is increased. To take advantage of this physiological alteration, pregnant women should be encouraged to eat a well-balanced diet with adequate amounts of calcium, protein, and vitamin D and routinely participate in weight-bearing exercises (Heaney, 2006).

The term **nulligravida** is used to describe a woman who has never experienced a pregnancy. A **primigravida** is a woman pregnant for the first time and a **secundigravida** is a woman pregnant for a second time. Although officially correct, this term is seldom used and instead the term **multigravida** is used in its place. A **multigravida** describes a woman who is pregnant for the third (or more times). **Parity** refers to the number of pregnancies carried to a point of viability (500 g at birth or 20 weeks of gestation), regardless of the outcome. For example, “para 1” indicates that one pregnancy reached the age of viability. A para 2 means that two pregnancies reached the age of viability. It is important to note that the term parity (or “para”) denotes the number of pregnancies, not the number of fetuses/babies, and does not reflect whether the fetuses/babies were born alive or stillborn. Some facilities use a digital system (i.e., GTPAL) for recording the number of pregnancies and their outcomes.

G Gravida

T Number of **T**erm pregnancies

P Number of **P**reterm deliveries

A Number of **A**bstortions, both spontaneous and induced

L Number of **L**iving children

PREGNANCY TESTING

A detectable level of human chorionic gonadotropin (hCG) must be present in the urine or blood for a pregnancy test to be positive. hCG is produced by the syncytiotrophoblastic cells found in the outer layer of the trophoblast and secreted into the maternal plasma and then excreted in the urine. Human chorionic gonadotropin levels peak between days 60 and 70 of pregnancy and then gradually decrease over approximately the next 40 days to reach a plateau that is maintained throughout the pregnancy. hCG can be detected in maternal blood as early as 1 day after implantation and in urine around day 26. The hCG molecule contains both an alpha-subunit and a beta-subunit. Because of the large number of commercial pregnancy tests available, women should be advised to use a home pregnancy test that is specific for the beta-subunit of hCG since this marker prevents cross reactions with other hormones. The alpha-subunit is very similar in molecular structure to luteinizing hormone (LH). Women with high LH levels (i.e., those experiencing perimenopause) who use a pregnancy test designed to detect the complete hCG molecule risk obtaining a false-positive result. If the over-the-counter pregnancy test used relies on urinary hCG, the patient should be advised to follow the manufacturer’s recommendations carefully to avoid an unreliable result. If a home pregnancy test is negative and the signs and symptoms of pregnancy persist, the test should be repeated in a week or the woman should see her health care provider.

A “chemical pregnancy” is a term used to describe a situation that occurs when a home pregnancy test has confirmed the presence of hCG, but a late and often heavy menstrual period follows. In these instances, conception probably occurred but for some reason the pregnancy was unable to continue and develop into a viable embryo. The frequency of this occurrence is difficult to estimate accurately but it is thought to affect approximately 30% to 50% of all pregnancies. Before the development of sophisticated methods for detecting an early pregnancy, most of these early and unfruitful fertilizations would have gone undiagnosed.

where research and practice meet: The Home Pregnancy Test

Despite advertising to the contrary, the majority of home pregnancy tests (HPTs) are not sensitive enough to detect pregnancy accurately at the time of the first missed period. In a study conducted in 2004, Cole and colleagues determined the levels of hCG from 25 women in New Mexico. The women were within a time period of 4 weeks and 4 weeks plus 3 days from the date of their last normal menstrual period. The investigators determined that to detect 95% of pregnancies at this gestation, a sensitivity of 12.5 mIU/mL hCG would be needed. Of the 18 types of HPTs tested, only one met this requirement (Cole, Khanlian, Sutton, Davies, & Rayburn, 2004).

Although this study had a small sample size, there are implications for nursing practice. Nurses should encourage women to recognize the limitations of early home pregnancy tests. Patients need to use the first urine sample of the day when hCG levels are most concentrated and they should also be encouraged to postpone testing until 1 week after the date of the expected (missed) period in order to obtain a more reliable result.

Optimizing Outcomes— Promoting a healthy beginning for the fetus

The first few weeks of gestation are of paramount importance to the developing fetus. During this time, the fetus is most susceptible to teratogenic substances such as alcohol, drugs, and environmental toxins. If a woman suspects that she may be pregnant despite a negative home pregnancy test, the nurse should advise her to avoid substances that could be potentially harmful to the developing fetus.

The diagnosis of a multiple gestation places the pregnancy into a “high risk” classification. An early diagnosis of a multiple gestation allows for the development of a care plan that includes more frequent visits for maternal-fetal surveillance. As with any pregnancy, early and ongoing prenatal care offers an opportunity for the timely recognition of complications (more often associated with multiple gestations) and the initiation of interventions to maintain the pregnancy as long as possible. The woman expecting a multiple birth also needs additional psychological support, practical advice, and education. She may experience more intense discomforts of pregnancy and need to deal with upsetting and extreme body changes. In addition, she also faces the financial challenges associated with a potentially complicated pregnancy, possible preterm birth, and the economic burden of providing for multiple newborns.

Now Can You— Discuss essential aspects of the current pregnancy?

1. Differentiate among the “presumptive,” “probable,” and “positive” signs of pregnancy?
2. Explain how to calculate the estimated date of birth using Naegele’s rule?
3. Describe the GTPAL pregnancy classification system?
4. Explain what women should be taught about home pregnancy testing?

THE MEDICAL HISTORY

To provide the patient with appropriate care to meet medical needs during pregnancy, it is essential that a detailed medical history be obtained. This information gives insights into the patient's past and present health status and use of preventative services. The nurse should obtain contact information for the primary care provider in order to facilitate continuity of care. Lack of a family physician may be related to financial difficulties, lack of medical insurance, or cultural/value differences. The nurse can explore these issues through sensitive and respectful questioning and when appropriate, refer the patient and her family to local agencies that provide services such as the WIC (Women, Infants, and Children) program for nutritional support (Box 9-6).

Some European countries offer “shared” care for low-risk patients to serve as a link between the patient's primary care provider and her obstetrician. The pregnant woman visits her family physician for the majority of her prenatal care but also sees an obstetrician for two to three visits. If any complications arise, the patient is transferred for the remainder of the pregnancy to the care of the obstetrician. Since any complications that occur during pregnancy are associated with maternal and family stress, referral to a “known” obstetrician hopefully helps to diminish some of the anxiety.

Dental Health

Together with the overall evaluation of medical well-being, it is essential to explore dental health. The initial interview is an ideal time to provide education about the benefits of preventative dental care and to dispel common myths such as “for every pregnancy, a tooth is lost.” It has been well established that the hormones of pregnancy predispose women to increased plaque and the development of gingivitis, or gum inflammation (Hey-Hadavi, 2002).

There is a link between periodontal disease in pregnancy, gingivitis, and preterm labor. It is believed that oral bacteria and their products travel via the bloodstream to the placental membranes, where an inflammatory response occurs. The inflammation may trigger the onset of preterm

labor (López, Da Silva, Ipinza, & Gutiérrez, 2005). Oral caries may also pose a greater threat during pregnancy. This is especially true during early pregnancy, when vomiting from “morning sickness” causes the mouth to harbor an acid environment that favors cariogenic activity. Other investigators suggest that women's dental health practices suffer after pregnancy due to a lack of time and result in an increase in dental caries (Hey-Hadavi, 2002). To promote dental health among pregnant women, some European countries such as England offer free dental care during pregnancy and for the first year following childbirth. Part of the nurse's role during the prenatal period is to promote dental hygiene to reduce the incidence of periodontal disease such as gingivitis (which is reversible). Pregnant women need to receive regular dental examinations and appropriate treatment as determined by their dental practitioner.

Optimizing Outcomes— Promoting dental health during pregnancy

- Encourage regular dental examinations.
- Promote twice daily brushing and flossing.
- Recommend the use of a fluoride toothpaste.
- Encourage a healthy diet.
- Encourage chewing gum containing Xylitol after meals.

Eye Health

An ophthalmic evaluation is also recommended early in pregnancy, most often during the first trimester or at any time visual changes occur. This is especially important for women with medical conditions such as essential hypertension, Graves' disease, or diabetes mellitus, and for women who wear contact lenses. During pregnancy, a number of normal physiological ophthalmic changes occur, including corneal thickening, increased curvature of the cornea, and a decrease in corneal sensitivity and intraocular pressure. These changes usually resolve spontaneously during the postpartum period. Medical conditions peculiar to pregnancy such as pregnancy-induced hypertension, eclampsia, and gestational diabetes can also have detrimental effects on eye health and vision (Somani & Ahmed, 2004).

Box 9-6 WIC at a Glance

The WIC target population includes those who are low-income and nutritionally at risk:

- Pregnant women, and up to 6 weeks postpartum or after pregnancy ends
- Breastfeeding women (up to infant's first birthday)
- Non-breastfeeding postpartum women (up to 6 months after the birth of an infant or after pregnancy ends)
- Infants (up to first birthday). WIC serves 45% of all infants born in the United States
- Children up to their fifth birthday

BENEFITS

- Supplemental nutritious foods
- Nutrition education and counseling at WIC clinics
- Screening and referrals to other health, welfare, and social services

where research and practice meet: Eye Examinations During Pregnancy

During an eye examination, it is a relatively common practice to dilate the pupils to facilitate ocular assessment. Although occasional use of parasympatholytics (i.e., atropine) and sympathomimetics (i.e., epinephrine) is thought to be safe, repeated use is contraindicated because of possible teratogenic effects. Mydriatics (medications that dilate the pupils) are also contraindicated for breastfeeding mothers because they have a hypertensive and anticholinergic effect on the infant (Somani & Ahmed, 2005). This information is important to nurses who counsel prenatal and postpartal patients. All prenatal and breastfeeding patients should be advised that certain components of the eye examination may carry risks during pregnancy and they should make certain their eye care professional is aware that they are pregnant (or breastfeeding).

Screening for hepatitis should be available to individuals with a history of sexually transmitted infections or a history of incarceration. Since blood contact constitutes another high-risk factor, patients who receive blood products or are undergoing hemodialysis should also be screened and vaccinated. Due to their potential contact with bodily fluids, health care workers are also at risk and need to be screened and vaccinated.

Other Preexisting Medical Conditions

Preexisting maternal medical conditions such as diabetes, epilepsy, and phenylketonuria need to be managed appropriately to limit the risk of adverse fetal effects. For example, prenatal exposure to hydantoin (phenytoin) [Dilantin, DPH] has been associated with cleft lip and palate due to its folic acid antagonistic properties (Hernandez-Diaz, Werler, Walker, & Mitchell, 2000). Preconception care is important. The earlier that appropriate management/treatment is implemented, the better the pregnancy outcome.

Environmental Hazards

The developing fetus is at risk from maternal exposure to environmental toxins. Air pollution is one of the most common concerns for maternal and newborn health (Dyjack, Soret, Chen, Hwang, Nazari, & Gaede, 2005). Concentrations of air pollutants are approximately three to five times less outdoors than indoors, where the majority (up to 90%) of time is spent. Adverse birth outcomes including congenital anomalies, intrauterine growth restriction, and preterm birth have been linked to in utero exposure to various air pollutants (Bobak, 2000; Liu, Krewski, Shi, Chen, & Burnett, 2003; Maisonet, Bush, Correa, & Jaakkola, 2001).

Nurses can help to improve the fetal environment by educating women about the dangers of direct and passive smoking during pregnancy. Smoking cessation programs designed for pregnant women are readily available through the American College of Obstetricians and Gynecologists (ACOG, 2005). Effects of tobacco use during pregnancy are well documented and predispose to premature rupture of the membranes, preterm labor, placental abruption, placenta previa, and infants who are small for gestational age (SGA). The detrimental effects on the fetus/neonate continue well into childhood and are associated with problems such as upper respiratory infections, childhood asthma, and wheezing (Gilliland, Li, & Peters, 2001; Jaakkola & Gissler, 2004). Since chemicals, heavy metals, and other environmental hazards that pose a threat to the embryo–fetus may be present in the home or workplace, this information should be elicited and recorded in the prenatal assessment. (See Chapters 7 and 10 for further discussion.)

Now Can You— Discuss how the prenatal patient's medical history guides care?

1. Explain why dental and eye care are important during pregnancy?
2. Identify three viruses known to adversely affect the developing fetus?
3. Name four essential guidelines that should be included in a teaching plan for pregnant women who test positive for hepatitis B?

THE GYNECOLOGICAL HISTORY

The nurse needs to obtain a concise gynecological (GYN) history primarily to determine if any event in the patient's past places the current pregnancy at risk or warrants further investigation. Women ages 35 and older and foreign-born women should be questioned about in utero exposure to **diethylstilbestrol** (DES). Diethylstilbestrol is a nonsteroidal, synthetic estrogen that is several times more potent than natural estrogens.

In the United States, diethylstilbestrol was widely prescribed during the late 1930s until the early 1970s as a preventative treatment to reduce the likelihood of spontaneous abortion (miscarriage) or preterm delivery (Smith, 1948). It is estimated that between 1 and 2 million pregnant women received this oral medication. Exposure to DES during intrauterine development produces both structural and functional gynecological abnormalities that are associated with numerous problems including infertility, increased incidence of ectopic pregnancies, preterm labor and birth, and vaginal adenocarcinoma (Smith, 1948; Cunningham et al., 2005). Unfortunately, DES is still being used during pregnancy in some countries (National Cancer Institute, 1999).

Screening and Diagnostic Tests During Pregnancy

Before prenatal testing it is essential to determine the gestational age accurately since a number of screening and diagnostic tests have different ranges of normality based upon the maturity of the pregnancy. Before a patient is asked to consent to any investigation, she should be counseled about the purpose of the test, its reliability, and the implications of a negative or positive result. The nurse also needs to explain the difference between a screening test and a diagnostic test.

Nursing Insight— Educating patients about screening and diagnostic tests

To facilitate patient understanding of care options, nurses should explain the differences between screening and diagnostic tests.

A screening test: Identifies patients at increased risk for developing a disorder or disease

Identifies patients who need diagnostic testing

A diagnostic test: Confirms the presence of a disorder or disease

At the first prenatal visit, venous blood samples are taken so that abnormal findings can be identified and promptly treated. Blood is drawn for a number of tests: the patient's blood group and rhesus (Rh) factor; antibody screen (Kell, Duffy, rubella, varicella, toxoplasmosis, and anti-Rh), RPR (rapid plasma reagent)/VDRL (Venereal Disease Research Laboratory) screen for syphilis, and if the woman has not received the hepatitis B vaccine, she is tested for hepatitis B surface antigen (HbsAG) and hepatitis B surface antibody (HbsAB). A complete blood count (CBC) with hemoglobin, hematocrit, and differential cell

count is obtained and assessed using laboratory values established for pregnancy. Testing for antibody to the human immunodeficiency virus (HIV) is recommended for all pregnant women (ACOG, 2004) and a sickle cell screen is recommended for women of African, Asian, or Middle Eastern descent. In the United States, sickle cell anemia is one of the most common genetic blood disorders and occurs most often in African American populations (NIH, 2006). (See Chapter 11 for further discussion.) During this visit, a Tine or purified protein derivative (PPD) tuberculin test may also be administered to assess for exposure to tuberculosis.

SEXUALLY TRANSMITTED INFECTIONS

Based on the patient's risk factors, screening for sexually transmitted diseases/infections (STDs/STIs) may need to be repeated during the pregnancy. The presence of an STI can predispose to a number of adverse pregnancy outcomes including ectopic pregnancy, spontaneous abortion, preterm labor, and increased neonatal morbidity. Taking a sexual history is an important component of the prenatal nursing assessment. Self-awareness and the use of effective communication techniques foster open, honest discussion of sensitive issues in a non-threatening environment (Box 9-8).

The sexual history should include signs or symptoms (i.e., vaginal/rectal discharge, dyspareunia, ulcers, rashes, or anogenital itching) that may be indicative of infection. Information concerning recent sexual partners is also important so that when indicated, prior contacts can be notified and offered treatment. High-risk behaviors such as intravenous drug use, acquisition of tattoos, exposure to blood or blood products or sex with an individual from a high-risk category (e.g., a sex industry worker) should also be noted (Sexually Transmitted Diseases Services, 2005).

Human Immunodeficiency Virus

Infection with human immunodeficiency virus (HIV) leads to a progressive disease that results in acquired immunodeficiency syndrome (AIDS). (See Chapter 11 for further discussion.) Perinatal transmission may occur transplacentally, at birth from exposure to maternal blood and vaginal secretions and via breast milk. The incidence

of perinatal transmission (HIV-positive mother to her fetus) ranges from 25% to 35%. Maternal treatment with zidovudine (AZT, Retrovir) reduces the risk of perinatal transmission and the risk of infant death. Elective cesarean birth has been shown to significantly reduce the risk of transmission from the mother to the infant (Brocklehurst & Volmink, 2002).

In 2004, the American College of Obstetricians and Gynecologists (ACOG) published a recommendation that all pregnant women be tested for HIV as part of the routine battery of prenatal tests, although patients may choose to opt out of this testing. Screening for HIV is done via an enzyme-linked immunosorbent assay (ELISA) on a blood sample. If the result from this test is positive, the finding is confirmed via a Western blot test.

Nurses need to be patient advocates and ensure that patients receive individualized and informed care. One aspect of the nurse's role in this situation is to make certain that each patient receives comprehensive pre- and post-counseling in relation to HIV testing. Clearly, it is medically advantageous for the pregnant patient to be diagnosed and treated (for HIV) during pregnancy to promote maternal well-being and to reduce the incidence of perinatal HIV transmission (Nielsen, 2006).

Syphilis

A syphilis infection during pregnancy can cause significant damage to the fetus after the 16th to 18th week of intrauterine life, when the cytotrophoblastic layer of the placental villi has atrophied and is no longer protective. Caused by the spirochete *Treponema pallidum*, syphilis is readily treated with penicillin or erythromycin. If the condition is treated before the 18th week, the fetus is rarely affected. Left untreated, transplacental transmission to the fetus is likely to occur (congenital syphilis) and may result in deafness, cognitive difficulties, osteochondritis, or fetal death.

Chlamydia trachomatis, Neisseria gonorrhoeae

Other routine screening tests including chlamydia and gonorrhea are obtained during the pelvic examination. Secretions from the cervix, vagina, and anus may be used to obtain samples for culture media. *Chlamydia trachomatis* is a bacterial infection that is prevalent in sexually active populations, especially those in the under 25-age group. Most patients with this infection are asymptomatic and consequently do not seek treatment. Complications of chlamydial infections include salpingitis, pelvic inflammatory disease, infertility, ectopic pregnancy, premature rupture of the membranes, and preterm birth. Transmission to the neonate may occur during birth and results in ophthalmia neonatorum and chlamydial neonatal pneumonia. During pregnancy, chlamydia is treated with oral anti-infectives or penicillin-based agents. (See Chapter 11 for further discussion). It is recommended that pregnant women be retested 3 weeks after treatment, although the validity of this practice has not yet been established (CDC et al., 2006a).

Gonorrhea is caused by the gram-negative intracellular diplococcal bacteria *Neisseria gonorrhoeae*. It is readily treated with antibiotics. When left untreated, ascending maternal infection may occur after rupture of the membranes. Transmission to the fetus can occur during vaginal delivery and may result in disseminated infection

Box 9-8 Tips for Taking A Sexual History

SELF-AWARENESS

Know your own comfort level and your ease at discussing sexual issues with patients.

Acknowledge areas of discomfort.

EFFECTIVE COMMUNICATION

If you are embarrassed, this will be apparent though body language, eye-to-eye contact, tone of voice, type of questioning chosen, for example, closed-ended questions as opposed to exploratory questions.

Use terminology: words/terms that the patient understands.

Environment: ensure privacy and confidentiality.

Never make assumptions or be judgmental in your response or attitude

Source: Royal Adelaide Hospital Clinic, Sexually Transmitted Diseases Services. STD interview checklist (2005). Retrieved from http://www.stdservices.on.net/management/checklists/cl_interview.htm.

and ophthalmia neonatorum. (See Chapter 11 for further discussion.) Concomitant treatment for gonorrhea and *Chlamydia* is recommended because coinfection is common (CDC et al., 2006a).

Herpes Simplex Virus

Herpes simplex virus type 1 (HSV-1), transmitted non-sexually, is most commonly associated with fever blisters. Herpes simplex virus II (HSV-2) is usually transmitted sexually and is associated with genital lesions, although depending on sexual practices, both types are not exclusively associated with the respective sites. HSV-2 occurs more frequently in women (23%) than in men (11%), which most likely results from the greater likelihood of male-to-female transmission. Although HSV infection is not a reportable disease, it is estimated that 50 million Americans are infected with genital herpes (CDC, 2006a; Winer & Richwald, 2007).

The initial HSV genital infection generally produces flu-like symptoms including malaise, muscle aches, and headache accompanied by dysuria and the appearance of multiple painful blister-like lesions. The symptoms may persist for several weeks. A prodromal period characterized by marked skin sensitivity and nerve pain in the affected area may precede the outbreak of lesions (Gardner, 2006).

HSV-2 infection during pregnancy can have adverse effects on both the mother and her fetus. Primary infection during the first trimester is associated with congenital infection and an increased risk of pregnancy loss. In the neonate, herpes simplex virus infection is associated with a 60% mortality rate, and of those who survive, approximately 50% suffer serious neurological damage (Gardner, 2006). There is no cure for genital herpes. Care management centers on providing symptomatic relief. Although several antiviral agents are available, the safety of these medications during pregnancy and lactation has not been established (CDC, 2006a). (See Chapters 4, 11, and 19 for further discussion.)

CERVICAL CANCER

Cervical screening is usually a component of the first prenatal examination. Screening and treatment of cervical dysplasia (cancerous cellular changes) significantly reduces the chances that carcinoma will develop. This fact lends credence to the recommendation that screening via Papanicolaou testing be performed on all young adults. Furthermore, 50% of all women diagnosed with cervical cancer are diagnosed during the ages of young adulthood. (See Chapter 4 for further discussion.)

The Prenatal Physical Examination

PREPARING THE PATIENT

The patient should be given adequate private time to prepare for the examination and encouraged to void if needed (a urine specimen may also need to be collected). Before conducting the physical examination, it is essential to properly prepare the environment. The room should be warm, with a cover for the patient and a gown for her to wear. Ensure privacy for the patient, such as a “Do not disturb—exam in progress” sign affixed to the closed door.

Before the examination begins, the patient should receive an explanation of what the examination will involve and what she is expected to do. Obtain her consent to be examined. During a physical examination, the patient is usually scantily clothed and must remain on her back in a vulnerable position for the majority of the time. Gaining permission from the patient before proceeding gives her control, as she “allows” the examiner to continue. This action is especially important for women with a history of abuse, particularly, sexual abuse. Actively engaging the patient through dialogue during the examination process provides an excellent opportunity for teaching. Also, ongoing interaction while describing the findings and their relevance empowers the patient and dispels the oft-experienced feeling that something is being “done” to her. Before beginning the physical examination, the nurse should have collected all of the equipment that may be needed, along with any teaching literature that the patient should receive. It does not inspire confidence or relieve the patient’s anxiety if the nurse is constantly leaving the room to retrieve forgotten items.

Optimizing Outcomes— Demonstrating professionalism during the physical examination

To convey respect and minimize the transmission of infection, the nurse should:

- Ensure that the fingernails are short and all jewelry items that may cause skin trauma have been removed.
- Wash hands thoroughly in the patient’s presence. This simple act demonstrates respect and an understanding of and appreciation for the risk of cross-infection.
- Develop the habit of always washing the hands when entering and leaving a patient’s room.

The physical examination should proceed in the same order each time (preferably head to toe) to reduce the likelihood of unintentionally omitting any component. The examination should be organized in a manner that reduces the movements the patient must make. Also, it is less threatening to the patient when less invasive procedures are performed first. Throughout the examination, it is essential for the nurse to use good communication skills and to advocate for and treat the patient with respect. These actions empower patients to participate actively in all health care decisions. The time before, during, and after the examination provides the nurse with an excellent opportunity to develop a good rapport while enhancing the patient’s comfort level. Proper management of the clinical environment plays an important role in facilitating the patient’s feelings of safety, privacy, and security.

PERFORMING THE GENERAL ASSESSMENT

The general assessment begins by simply observing the woman. Information that can be obtained includes her overall health/nutritional status; posture; ease of movement and gait; appearance (includes clothing and cleanliness); affect and speech pattern; eye contact; and general orientation to place, person, and time. As the pregnancy advances, changes in maternal gait become apparent due to increasing lordosis (curvature of the spine) in response to the increasing weight and size of the gravid uterus that changes the woman’s center of gravity.

The nurse then obtains anthropometric measurements. When obtaining the weight it is valuable to ask the patient what her normal prepregnant weight was and to document this information (Fig. 9-4). The prepregnant weight gives an indication of how the patient is adapting to pregnancy. A dramatic, unintended weight loss can be indicative of severe nausea and vomiting (hyperemesis gravidarum). The height and weight are also recorded and used to calculate the patient's body mass index (BMI) and to determine nutritional needs. The BMI can be used to calculate whether the maternal weight is appropriate for height. (See BMI discussion in Chapter 10.) Women who are underweight before pregnancy and have a low weight gain during the pregnancy are at a greater risk for preterm labor.

Obtaining Information and Promoting Good Nutrition

An important nursing goal is to promote appropriate weight gain during pregnancy through healthy nutrition. It may be helpful to use a 24-hour diet recall form to help provide pertinent information about the patient's nutritional intake and food preparation/cooking preferences. On average, during the second and third trimesters a woman's caloric need increases by 300 per day. A well-balanced diet that contains the necessary vitamins and nutrients is essential. It is important to educate women that prenatal vitamins are an option to ensure that their daily needs are being met, but megadoses of vitamins can be harmful. A woman's need for folic acid doubles during pregnancy and ideally supplementation with 400 mcg/day should be initiated prior to conception and continued at least through the first 3 months of pregnancy, to help reduce the incidence of open neural tube defects (NTDs) (CDC, 2005). (See Chapters 7 and 10 for further discussion.)

In the mid-1970s, nutritionist Agnes Higgins developed "The Higgins Method of Nutritional Rehabilitation During Pregnancy." This program focused on the individual woman's nutritional needs based on age, prepregnant

Figure 9-4 The weight is recorded and tracked throughout the pregnancy.

weight, activity level, pregnancy weight gain, and risk factors. The Higgins Method, still relevant today, is grounded in the philosophy that each woman has specific dietary needs, and by meeting those needs, one can promote optimal growth and development of the fetus (Higgins, 1976). (See Chapter 10 for further information about dietary needs in pregnancy.)

Optimizing Outcomes—Vitamin C and premature rupture of the membranes

Low levels of vitamin C may predispose women to premature rupture of membranes. As the cellular availability of vitamin C decreases, the rate of degradation of cervical collagen increases (Vadillo et al., 1995; Woods et al., 2001, cited in Modena, Kaihura, & Fieni, 2004). With decreased collagen, the cervix ripens more easily, prompting effacement and dilatation.

Recording Vital Signs

The vital signs are taken and documented. Blood pressure is a particularly important measurement and should be recorded under standardized conditions (making note of the arm used and the patient's position) and with the appropriate size blood pressure cuff. Since the initial prenatal visit may be the patient's first adult interaction with a health care professional, physiological indicators of anxiety (e.g., tachycardia, elevated blood pressure) may be present. In these situations, the nurse should record the first set of vital signs and then repeat the recordings later when the patient has had time to become familiar with her surroundings and is more relaxed.

Ethnocultural Considerations—Hypertension and pregnancy

Nurses should be aware that hypertension is more prevalent in African American and Mexican American cultures, probably due to hereditary factors (Nabel, 2003). It is the most common medical condition affecting pregnancy and may worsen as the pregnancy progresses.

Obtaining the Urine Specimen

Before the physical examination, the nurse should ensure that the patient has had an opportunity to void and, if needed, a mid-stream urine sample is obtained (Procedure 9-1). A clean sample of urine should be cultured for asymptomatic bacteriuria during this first prenatal visit. As the name suggests, this type of urinary tract infection (UTI) does not cause symptoms but is present in more than 10% of pregnant women. Left untreated, a UTI may lead to a number of complications including preterm labor and pyelonephritis.

PERFORMING THE GENERAL PHYSICAL EXAMINATION

The general physical examination is then conducted with sensitivity to lifestyle choices, behaviors, and cultural beliefs. Together with physical data, the nurse should also gather

Procedure 9-1 Obtaining A Mid-Stream Urine Sample

Preparation

1. Complete the information requested on the container label. Include the patient's full name, and the date and time of collection of the specimen. If a requisition is needed, note the date and time on the requisition.
2. Explain the procedure to the woman to ensure she understands why a urine sample is requested, the purpose of any tests to be performed, and directions on how to obtain a mid-stream urine sample.

Equipment

- Approved empty sterile container for collection
- Towelette for cleaning in between the labia
- Tissue

Procedural Steps

Instruct the patient to do the following:

1. Wash and dry your hands thoroughly or use an alcohol-based hand-rub

RATIONALE: To reduce the risk of specimen contamination. Alcohol-based hand-rubs are fast acting, reduce the number of microorganisms on the skin and may cause less skin irritation or dryness.

2. Remove the container cap and set it on a clean, even surface with the inner surface pointing up. Do not touch the inner surface of the lid or the container.

RATIONALE: To reduce the risk of specimen contamination.

3. Sit on the toilet seat and separate the labia (vaginal lips) using your nondominant hand. Clean the urogenital area from the front to back with the towelette provided. Wipe for only one stroke and then discard the towelette.

RATIONALE: To reduce the risk of specimen contamination and to reduce the number of microorganisms on the skin. Cleansing from front to back prevents bringing rectal contamination forward.

Patient cleansing labia.

4. Holding the labia apart, begin to pass urine. Allow the beginning urine to go directly into the toilet.

RATIONALE: The initial stream of urine washes urethral microorganisms and other debris away from the urethral meatus. The midstream collection ensures that a sterile specimen is obtained.

5. Continue to urinate and hold the container under the urine stream. Avoid touching the inside of the container. Remove the container when it is approximately half full.

Patient urinating into specimen cup.

6. Carefully replace the cap and secure tightly.

RATIONALE: Placing the cap on the container prevents inadvertent spilling and possible contamination of the urine specimen.

7. Wash your hands again after the specimen collection.

Clinical Alert Pregnant women are at an increased risk for developing urinary tract infections, especially if they are diabetic or have gestational diabetes. Urinary tract infections may also predispose to the onset of preterm labor

Teach Patient

Teach the patient to recognize common signs of a urinary tract infection:

- Dysuria—pain (burning sensation) on urination
- Urinary frequency associated with small amounts of urine
- Hematuria—blood or red blood cells in the urine

Documentation

11/10/10 1100 Patient educated re midstream urine collection. Patient verbalized understanding. Sample obtained, labeled with name, date, time and type of specimen. Sent to lab at 1120 per Dr. Garner's order.

-M. D'Arcy-Evans, RN, CNM

information relating to the patient's usual state of health, her use of health promotion and maintenance strategies, and details of any present concerns or symptoms. The physical examination is a basic review of systems that includes ears, nose, mouth, and throat; cardio-respiratory; musculoskeletal; and neurological function with an in-depth evaluation of the maternal physical adaptation to the pregnancy.

 **Now Can You—** Discuss aspects of the initial prenatal health assessment?

1. Identify five screening tests routinely performed on the patient's serum during the initial prenatal examination?
2. Briefly discuss why screening for human immunodeficiency virus and *Chlamydia trachomatis* is recommended during pregnancy?
3. Identify four major components of the prenatal physical assessment?

THE FOCUSED OBSTETRIC EXAMINATION

Head, Neck, and Lungs

With the patient in a sitting position, the physical examination proceeds in a head to toe fashion beginning with a general evaluation of the skin and hair. Many women notice that their hair is healthier and more luxurious during pregnancy. Hair loss, common during the postpartum period, can be indicative of a vitamin or mineral deficiency. Increased levels of estrogen are responsible for a number of objective and subjective changes such as hypertrophy of the gingival tissue, nasal stuffiness, and an increased tendency for nosebleeds.

The thyroid gland is palpated while the patient remains in a sitting position. Enlargement is common during pregnancy due to increased vascularity and hyperplasia of the glandular tissue. The size and position of the thyroid are documented along with the presence of nodules or swelling (Koscica & Berstein, 2003). Anterior and posterior lung sounds are auscultated and the cardiac rhythm and rate are evaluated for adventitious sounds. During pregnancy, approximately 90% of women exhibit systolic heart murmurs due to an increase in blood volume. The systolic murmur may be clearer when the woman holds her breath. Heart sounds should be evaluated with the woman in both a sitting and lying position. Beginning late in the second trimester, the gravid uterus causes an upward and lateral displacement of the heart and the point of maximal impulse. Also, as pregnancy advances, the patient's breathing becomes thoracic in nature (rather than abdominal) due to the enlarged uterus.

The Skin

Assessment the skin may reveal pregnancy-associated changes such as chloasma (the mask of pregnancy) and hyperpigmentation of the areolae, vulva, abdomen, and linea (linea nigra). The skin is evaluated for color consistent with the woman's ethnic background, and for the presence of lesions or indicators of drug abuse (i.e., skin scratches, bruising or track marks, nasal discharge or irritated mucosa, constricted or dilated pupils).

The Breasts

The patient is assisted to a recumbent position for the breast examination. Depending on the gestational age, it may be advisable to place a wedge under one of her hips to prevent compression of the vena cava from the gravid uterus (supine hypotension syndrome). Inspection of the breasts usually reveals pregnancy-related changes including nodularity, striae, and enlargement and hyperpigmentation of the nipples and Montgomery tubercles. Areas of indentation or skin puckering are not normal findings. Colostrum, a precursor to breast milk, may be expressed from the nipples as early as the first trimester of pregnancy. The lymph nodes should not be palpable.

 **Optimizing Outcomes—** Promoting breast comfort during pregnancy

As a component of health teaching during pregnancy, the nurse should encourage patients to wear a firm, supporting bra. For some, professional fitting/measuring may be beneficial to promote both support and comfort. As the breasts increase in weight, bras with wider straps may be more comfortable. Some women choose to wear a "sleeping" bra during the night for added comfort.

The Abdomen

The obstetric abdominal examination focuses on recognizing signs and changes associated with pregnancy. It is not intended to replace a comprehensive abdominal examination. The patient should be appropriately draped to maintain her privacy, comfort, and body temperature. The abdominal shape is assessed and inspected for the presence of scars (previous surgery should be documented), linea nigra, striae gravidum, or signs of injury (i.e., bruising). As the pregnancy advances, visual inspection of the abdominal shape may reveal the fetal position, especially if transverse. Also, it may be possible to observe and palpate fetal movements. Patients generally become aware of fetal movements around the 16th to 20th week of pregnancy. A primigravida is usually able to identify fetal movements around 18 to 20 weeks; a multigravida may notice fetal movements as early as 16 weeks. This difference in awareness of fetal activity is most likely due to past experience in recognizing the movements along with a decrease in maternal abdominal muscle tone.

Uterine Size and Fetal Position

Abdominal palpation is used to evaluate the uterine size, to determine fetal position, and later in pregnancy, to determine whether the presenting part has engaged in the maternal pelvis. (See Chapter 12 for further discussion.) **Fundal height** is an indication of uterine size; periodic measurements of the fundal height should correlate strongly with fetal growth (Fig. 9-5). The relationship of the fundus (top part) of the uterus to specific maternal abdominal landmarks is used throughout pregnancy as a gauge to assess fetal growth. The fundal height measurement correlates to the weeks of gestation from approximately 22 to 34 weeks of gestation (Table 9-2). At 12 weeks of gestation, the fundus should be at the level of the

Table 9-2 Approximate Fundal Height in Relation to Weeks of Pregnancy

Weeks of Gestation	Approximate Expected Fundal Height
12	Level of the symphysis pubis
16	Halfway between the symphysis pubis and the umbilicus
20	One to two finger-breadths below the umbilicus
24	One to two finger-breaths above the umbilicus
28–30	One-third of the way between the umbilicus and the xyphoid process
32	Two-thirds of the way between the umbilicus and the xyphoid process
36	At the xyphoid process
38	One to two finger-breadths below the xyphoid process
40	Three to four finger-breadths below the xyphoid process

symphysis pubis; at 20 weeks, the fundus should be at the umbilicus. The fundal height can be measured by using a tape measure or finger-breadths in combination with known maternal landmarks. For example, two finger-breadths above the umbilicus would be equivalent to approximately 24 weeks of gestation. Although convenient, using finger-breadths as a measuring tool is subject to variations in finger size among different examiners. This method of fundal height measurement is appropriate only if the same examiner consistently assesses uterine size.

Most often, the fundal height is measured with a tape measure. This method is usually initiated at around 22 weeks of gestation. The end of the measuring tape with the zero mark is held on the superior border of the symphysis pubis. Using the abdominal midline as guide, the tape is stretched over the contour of the abdomen to the top of the fundus (McDonald's method; see Fig. 9-5). The measurement (in centimeters) is recorded and equals the weeks of gestation. For example, at 28 weeks of gestation, the fundal height should be approximately 11 inches (28 cm; Fig. 9-6).

LEOPOLD MANEUVERS The next step in abdominal palpation involves the use of **Leopold maneuvers**, a four-part clinical assessment method, to determine the lie, presentation, and position of the fetus. The first maneuver determines which fetal body part (e.g., head or buttocks) occupies the uterine fundus. The examiner faces the patient's head and places the hands on the abdomen, using the palmar surface (not the fingertips) of the hands to gently palpate the fundal region of the uterus. The buttocks feel soft, broad, and poorly defined. It moves with the trunk. The head feels firm and round and moves independently of the trunk (Fig. 9-7).

The second maneuver determines the location of the fetal back or spine. Facing the maternal abdomen, the

**Figure 9-5** Obtaining the fundal height measurement.**Figure 9-6** Fundal measurement should approximately equal the number of weeks of gestation.

palmar surface of one hand is placed on one side of the patient's abdomen to provide support. The palmar surface of the opposite hand is used to palpate the fetal spine, which feels like a firm, continuous, smooth, convex structure. An irregular shape or fetal kicks indicate that the back is on the opposite side (Fig. 9-8).

The third maneuver ("Pawlik maneuver") compares the fetal part in the fundal region with the part in the lower uterine segment, primarily to confirm that the fetus is in a cephalic (head) presentation. The hands are placed just above the symphysis and the examiner notes whether the palpated part feels like the fetal head or the buttocks (breech; Fig. 9-9).

For the fourth maneuver, the examiner uses the fingertips of both hands. One hand is placed on each side of the woman's lower abdomen with the palmar surfaces down. The hands are moved gently down the sides of the uterus toward the symphysis pubis as the fingertips palpate the presenting part to determine whether it is moveable (ballotable). If the presenting part is moveable, **engagement** (when the largest diameter of the presenting part reaches or passes through the maternal pelvic inlet) has *not* occurred. If the presenting part is fixed, engagement has occurred. With the first pregnancy, engagement occurs around 37 weeks gestation; with subsequent pregnancies, engagement may not occur until labor has begun (Figs. 9-10 and 9-11).

Figure 9-10 Fourth Leopold maneuver.

Figure 9-11 Assessing fetal presentation/position.

Fetal Heart Auscultation

The information obtained during fetal palpation includes fetal presentation, lie, position, and engagement status (Table 9-3). (See Chapter 12 for further discussion.) Determining the fetal presentation facilitates fetal heart auscultation. The fetal heart rate (FHR) is heard most clearly directly over the fetal upper back (the maternal right or left lower abdominal quadrants) in a vertex presentation. The intensity of the fetal heart tones (FHT) varies according to the fetal position (Fig. 9-12). With a breech presentation, the fetal heart tones may be best heard in the patient's right or left upper abdominal quadrants. If fetal heart tones are auscultated most clearly in that location, the patient's care provider should be advised, as further assessment may be indicated to confirm the fetal presentation. This is especially important when the patient is in labor. However, before approximately 32 weeks of pregnancy, it is not uncommon for the fetus to be in a breech presentation. In most instances, by 36 to 37 weeks of gestation, the majority of fetuses will have spontaneously converted to a vertex (head down) presentation.

The normal heart rate for a fetus is approximately 120 to 160 beats per minute (bpm). If a slower heart rate is detected, the maternal pulse should first be evaluated to

determine if the two heart rates are synchronous. If they are synchronous, the maternal pulse has inadvertently been auscultated through the abdomen and an attempt should be made to locate the fetal pulse. If the two pulses differ, the nurse should position the patient on her left side and seek assistance. Oxygen may be administered by mask and the patient should be instructed to take slow deep breaths. The nurse should continue to monitor the fetal heart rate and provide explanations and reassurance to the patient.

The fetal heart can be auscultated using a number of different devices. The least intrusive method involves the use of a Pinard stethoscope or a fetoscope (Fig. 9-13). Both of these devices are used without any additional equipment. However, they do require the examiner's ability to be able to palpate the woman's abdomen accurately to determine the fetal position and locate the fetal shoulder to ascertain the correct location for placement of the stethoscope. This method of fetal heart auscultation is ideal if the patient has expressed a desire to avoid an ultrasound (Doppler) stethoscope. Following the invention of the Doppler ultrasound stethoscope, use of the fetoscope and Pinard stethoscopes in clinical practice has decreased. The Doppler ultrasound stethoscope is a hand-held device that uses ultrasound to

Table 9-3 Defining Terms in Relation to Maternal Abdominal Palpations

Lie of the Fetus	Where is the fetal spine in relation to the maternal spine? The maternal spine is always longitudinal. If the fetal spine is parallel to the maternal spine, the fetus is in a "longitudinal lie." If the fetal spine lies horizontally across the maternal spine, the fetus is in a "transverse lie." If the fetal spine lies obliquely across the maternal spine, the fetus is in an "oblique lie." "Lie" describes the relationship of the fetus to the long axis of the mother. Normal lie is longitudinal (the fetal long axis, or spine, is in line with the maternal long axis).
Presentation	Refers to the fetal part that would be delivered first in a vaginal birth. Normally, the fetal head is the part of the fetus that is presenting.
Position	The head is the most common presentation. When the fetus is in a well-flexed position (the fetal knees and chin against its body), the occiput area is determined to be the presenting part since this is the lowest part of the fetal head. To determine position, it is necessary to assess where the fetal occiput is, in relation to the maternal pelvis. If the fetal occiput faces toward the front near the symphysis pubis, the fetus is in an anterior position. If the occiput is on the maternal right side, the fetus is in a right occipito-anterior position (ROA). If on the maternal left side, the fetus is in a left occipito-anterior position (LOA). If the fetal occiput is toward the side of the maternal pelvis, the fetus is in a lateral (or transverse) position. If the occiput is on the maternal right, the fetus is in a right occipito-lateral position (ROL). If on the maternal left, it is a left occipito-lateral (LOL) position. If the fetal occiput is toward the maternal spine, the fetus is in a posterior position. If the occiput is on the maternal right, the fetus is in a right occipito-posterior position (ROP). If on the maternal left, it is a left occipito-posterior (LOP) position.
Engagement	When palpating the presenting part, is it moveable? If the presenting part is fixed (i.e., you are unable to move it) when palpating the maternal abdomen, the presenting part is said to be engaged.

locate fetal heart sounds (Fig. 9-14). Use of the Doppler stethoscope to auscultate fetal heart tones is simple and requires no special skills since placement of the instrument in the general vicinity of the fetal heart will most likely produce audible heart tones. Although this approach may provide an easy, quick assessment, the nurse who uses this method may not be performing a detailed patient examination and may miss vital information. With the Doppler stethoscope, FHTs may be auscultated by 10 to 12 weeks or by 17 to 19 weeks with the fetal stethoscope.

Figure 9-12 Fetal heart tone intensity varies according to the fetal position. RSA = right sacrum anterior; LSA = left sacrum anterior; ROP = right occipito-posterior; LOP = left occipito-posterior; RMA = right mentum anterior; LMA = left mentum anterior; ROA = right occipito-anterior; LOA = left occipito-anterior.

Figure 9-13 Auscultating the fetal heart tones with a fetoscope.

Figure 9-14 Auscultating the fetal heart tones with a Doppler ultrasound stethoscope.

Some sophisticated Doppler models provide a print-out similar to those of the more conventional fetal heart rate monitors. Beginning in the later weeks of the second trimester, standard electronic fetal monitors may be used to record the fetal heart rate in conjunction with uterine activity. Electronic fetal monitoring during the prenatal period is generally limited to pregnancies designated as being high risk due to maternal or fetal factors. In these situations, a **non-stress test** (NST) may be ordered to provide an evaluation of the fetal heart rate in response to fetal movement and/or uterine activity. A reactive test (the desirable result), is one in which the heart rate accelerates by at least 15 beats per minute for at least 15 seconds, with at least three “acceleration episodes” in a 20-minute period of monitoring. It is important to remember that a reactive non-stress test is only an indicator of the fetus’s present condition rather than a test that can be used to predict future fetal well-being. (See Chapter 11 for further discussion.)

Nurses must be cautious not to place too much reliance on technology. Instead, nurses should use clinical skills coupled with evidence-based theory to transition from novice to expert practitioner. To attain this level of expertise, it is essential to maintain hands-on patient care. Experienced clinical nurses attain a sixth sense, or “specialty intuition,” that enables them to quickly recognize deviations from normal and provide expert care in a timely manner. With regard to electronic fetal monitoring and other high-tech modalities, the nurse must be careful not to rely on imperfect tools and instead use sound clinical judgment and decision-making.

 **Now Can You—** Discuss various methods of clinical fetal assessment?

1. Describe how to perform a fundal height measurement?
2. Identify how to perform each component of Leopold maneuvers and explain what the findings indicate?
3. Compare and contrast the technique of fetal heart auscultation using a fetoscope and a Doppler ultrasound stethoscope?

The Vagina and Pelvis

A vaginal examination is usually performed at the initial prenatal visit following assessment of the maternal abdomen. Most women find this part of the examination to be intrusive and may fear being exposed, hurt, or embarrassed. An essential component of the nurse’s role is to explain to the patient what to expect and to help her to verbalize any fears. The patient’s permission to conduct a vaginal assessment must always be obtained before proceeding. Demonstrating awareness of the patient’s feelings can be conveyed by simple strategies: remaining gentle and respectful; showing equipment that will be used with a demonstration of how it works; and ensuring privacy with appropriate drapes. Eye-to-eye contact maintains a connection between the nurse and the patient and allows the nurse to be aware of nonverbal communication. Some women feel less anxious if they are actively involved in the examination. For example, if desired, a mirror can be placed so that

the patient can view her cervix or be shown changes such as Chadwick’s sign.

There are essentially four components to the examination, which begins with an assessment of the external genitalia (Fig. 9-15). Information can be obtained regarding secondary sexual characteristics by observing the pattern of hair growth. This is also an ideal time to check for the presence of **pediculosis**, or pubic lice. Signs of vaginal infection may be indicated by redness, edema, or an offensive vaginal discharge. The presence of lesions, condylomata (human papillomavirus), vesicles (herpes), ulceration (syphilitic chancre), or inflammation need to be recognized and investigated. Bruising or tenderness may be present as a result of trauma or abuse. Observation of the perineal body may show evidence of a previous episiotomy or perineal tear. Women who have been subjected to female circumcision show varying degrees of genital mutilation. Women from cultures that support this practice may prefer to have a female care provider.

The second part of the examination includes visual inspection of the vaginal mucosa and cervix along with the collection of specimens such as the Papanicolaou test (Pap smear), cultures for gonorrhea or *Chlamydia* and, if indicated, wet smear slides to determine the cause of vaginal discharge. The examiner selects an appropriate size speculum. Specula may be constructed of metal or plastic and are generally available in two types: the Graves’ speculum, useful for examining multiparous women, and the more narrow, flat Pedersen speculum, commonly used for children, women who have never been sexually active, nulliparous women and some postmenopausal women. The speculum is inserted into the vagina at an oblique angle, then rotated to a horizontal angle and gently advanced downward against the posterior vaginal wall. Once in position, the speculum blades are opened to allow visualization of the cervix (Fig. 9-16).

Figure 9-15 A, The vaginal examination begins with a visual inspection of the external genitalia. B, The thumb and index finger are used to separate the labia minora.

The cervix and vaginal mucosa are inspected for color and for the presence of inflammation, lesions, ulcerations, or erosion. The cervix is usually about 1 inch (2.5 cm) in length and the external cervical os is round in women who have never given birth (nulliparous) and appears “slit” shaped in the multigravida (Fig. 9-17).

The remaining part of the assessment includes clinical pelvimetry and the bimanual examination. Bimanual examination is an evaluation of uterine shape, position, and size (Fig. 9-18). The uterus is normally anteverted (tipped forward). As it enlarges during pregnancy, the uterus becomes more midline and globular in shape. The size of the pregnant uterus should be equal to the estimated weeks of gestation. If the uterus is larger than anticipated, this finding may be associated with a number of factors including miscalculation of the date of conception, multiple pregnancy, hydatidiform mole, uterine fibroid tumors or, later in pregnancy, a condition known as **hydramnios** (an increase in the volume of amniotic fluid). A uterus smaller than expected may indicate miscalculation of dates or a missed abortion. (See Chapter 11 for further discussion.) The manual examination provides an ideal time to evaluate vaginal and perineal muscle tone and to determine the presence of a cystocele (bladder prolapse), urethrocele (urethral prolapse), or rectocele (rectal prolapse). Women should be reminded to practice Kegel exercises to help maintain perineal muscle tone.

The rectovaginal examination is performed after completion of the bimanual examination. The examiner removes his or her hand from the vagina and dons a clean pair of gloves. A water-based lubricant is applied to the fingertips of the dominant hand. The index finger is

reinserted into the vagina; the middle finger is inserted into the rectum. The rectal finger is advanced forward as the abdomen is depressed with the nondominant hand. Palpation of the tissue between the examining fingers allows for assessment of the strength and irregularity of the posterior vaginal wall. The fingers are withdrawn and any stool present on the glove may be tested for occult blood.

The final component of the physical examination involves the clinical evaluation of the pelvis, also known as clinical pelvimetry. The goal of this assessment is to recognize any abnormality in shape or size that may be associated with a difficult or traumatic vaginal birth. The four basic pelvic types include the gynecoid, found in more than 40% of women, the android (male), the anthropoid (most common in nonwhite races), and the platypelloid, which is the most rare type and is found in fewer than 3% of women. The internal pelvic measurements provide the diameters of the inlet and outlet through which the fetus must pass during birth. The measurements most commonly made include the diagonal conjugate, the true conjugate (conjugate vera), and the ischial tuberosity diameter. Clinical pelvimetry is performed by the physician, nurse midwife, or advanced practice nurse; it is generally not repeated in women who have previously given birth to an infant weighing 7 pounds or more (3.18 kg) unless there is a history of pelvic trauma in the intervening period between pregnancies.

The **diagonal conjugate** is the distance between the anterior surface of the sacral prominence and the anterior surface of the inferior margin of the symphysis pubis. This measurement, performed with the patient in a

lithotomy position, indicates the anteroposterior diameter of the pelvic inlet—the most narrow diameter and the one most likely to create a problem with misfit of the fetal head. If the diagonal conjugate is greater than 12.5 cm, the pelvic inlet is considered to be adequate for childbirth (Fig. 9-19).

The **true conjugate** (conjugate vera) is the measurement between the anterior surface of the sacral prominence and the posterior surface of the inferior margin of the symphysis pubis. This measurement is estimated from the dimension made of the diagonal conjugate. It cannot be measured directly. The true conjugate is the actual diameter of the pelvic inlet through which the fetal head will pass. On average, the diameter of the true conjugate ranges from 4.1 to 4.3 inches (10.5 to 11 cm).

The **ischial tuberosity** diameter (also known as the intertuberosity or biischial diameter) is a measurement of the distance between the ischial tuberosities (e.g., the transverse diameter of the outlet). Often assessed with a pelvimeter (a special device for measuring the pelvis), the diameter can also be measured with a ruler or with the examiner's clenched fist or handspan (the exact measurements of the fist and hand must be known). A diameter of 11 cm is considered adequate for passage of the widest diameter of the fetal head through the pelvic outlet. Using palpation, the examiner assesses the coccyx for mobility. A mobile nonprominent coccyx allows for some flexibility of the pelvic outlet during birth.

Subsequent Prenatal Examinations

The plan of care for the first prenatal visit should be amended to meet each individual woman's needs, based on medical, social, cultural, and individual factors. Subsequent prenatal visits are usually not as in depth, but should be designed to recognize any deviations from normal so that appropriate investigations can be ordered and care managed accordingly. Normally, patients are seen at a frequency of every 4 weeks until 28 to 32 weeks of pregnancy, then every 2 weeks until 36 weeks, and then weekly until childbirth. At each visit, standard of care includes an evaluation of the maternal weight gain, blood pressure, urine (for glucose and protein), uterine growth, fetal heart tones, fetal movements, and presentation (Box 9-9). The patient is also assessed for the presence of edema. Each prenatal appointment provides an ideal opportunity for education related to the patient's particular stage of pregnancy and what to expect before the next visit. A review of the warning signs of pregnancy is also essential and the nurse should confirm that the woman is able to verbalize when and how to seek professional assistance.

Evaluation of fetal well-being includes documentation of the patient's perception of fetal movements. Depending on the circumstances, fetal evaluation may also include electronic heart rate monitoring, ultrasonography to monitor growth patterns and/or placental aging and a biophysical profile. In addition, the patient may be offered various

Figure 9-19 A, The diagonal conjugate and the true conjugate (conjugate vera). B, Use of a pelvimeter to measure the ischial tuberosity diameter.

screening tests during pregnancy to detect fetal genetic or structural abnormalities. (See Chapters 10 and 11 for further discussion.)

Now Can You— Discuss the vaginal examination, clinical pelvimetry, and assessments routinely made during each prenatal visit?

1. Compare and contrast the purpose of the vaginal speculum examination and the bimanual examination?
2. Explain the purpose of clinical pelvimetry and identify three measurements that are commonly included in this assessment?
3. Name seven maternal–fetal assessments routinely performed during each prenatal visit?

Assessing Special Populations

THE ADOLESCENT

Sexual Behavior and Pregnancy

Teenage pregnancy is not a new phenomenon. The transitional period of adolescence, which spans the years from 11 to 19, marks the biological and psychological passage

from childhood into adulthood. Pregnancy during adolescence has far-reaching implications for society as well as for the young woman and her family.

In the American culture, the expectation is that women marry, ideally after having completed an acceptable level of education, before the couple plans the birth of their first child. Teenage pregnancy meets none of these expectations and as such is not condoned by American society in general. Despite this stigma, adolescent pregnancies continue to occur, are often fathered by teenage males or, in some cases, by men significantly older (Bunting & McAuley, 2004).

Not all teen pregnancies are accidents. For some adolescents, pregnancy provides a means of escape from an unpleasant situation, a method for achieving a goal, or someone to love. Relationships with the unequal power dynamics often present between an older male and a teenage female can predispose to coercion in sexual activity. Pregnancy may also result from sexual assault, incest, and dating violence that involves sexual intercourse (Silverman, Raj, & Clements, 2004).

Problems that develop in the wake of teen pregnancy are not limited to the duration of the pregnancy. Instead, they appear to be much longer lasting. For example, although many teenagers who become pregnant manage to complete high school, only a small percentage continue their education to earn a college degree. Without advanced education, their earning capacity and career opportunities are somewhat limited and this factor may become a life-long limitation.

In addition to the many developmental, social, educational, and life-long consequences for both the young mother and her child, the teenage patient is also at additional risk for a host of obstetric complications including anemia, preeclampsia, and preterm birth. Preterm birth and low-birth-weight infants are major causes of neonatal morbidity and mortality. Survival of a compromised infant may necessitate a lifetime of care and considerable economic resources.

The rate of adolescent pregnancy in the United States is almost double that of other developed countries. Clearly, teen pregnancy is a complex, multifaceted issue that must be addressed at the local, state, and national levels. One goal of the *Healthy People 2010* national health initiative directly addresses the number of pregnancies that occur in the adolescent population. It calls for a reduction in pregnancy rates among adolescent females to no more than 43/1000 adolescents from a baseline of 68/1000.

The Nurse's Role

Nurses can help the nation to achieve this goal by heightening public awareness of the complex personal and societal repercussions of adolescent pregnancy. Nurses can also empower women and their families with factual information and strategies to reduce unwanted pregnancies among this young population. In the community setting, nurses can advocate for responsible sexual behavior by providing educational programs for youth in schools, churches, clubs, and after school activities. In the clinical setting, nurses can listen to, counsel, and educate young patients to help prepare them for responsible sexual decision making. Nurses can also empower mothers and fathers of young adults with methods for facilitating open, honest family discussions about sexuality and sexual behavior.

Box 9-9 Essential Components of Subsequent Prenatal Visits

Review the Woman's Overall Health Status.

- Signs/symptoms of pregnancy
- Discomforts of pregnancy
- Changes in medications/over-the-counter/herbal/homeopathic
- Psychological assessment (emotional or psychological distress) including factors such as affect, sleep patterns, and diet

MATERNAL WELL-BEING

- Record vital signs
 - Ensure blood pressure is recorded using an appropriately sized cuff and under the same conditions each visit (i.e., maternal position).
- Record maternal weight
 - Weight gain is usually 1 pound per week during the second and third trimesters.
 - Excessive weight gain may be indicative of fluid retention and requires investigation.
 - Weight loss may be due to maternal disease or inadequate dietary intake: nursing assessment needed.
- Evaluate for edema: dependent edema especially in hot weather and at the end of the day is a normal finding.
- Where indicated, assess reflexes and check for clonus.
 - Any signs of preterm labor such as uterine contractions, or backache
 - Ensure patient knows indicators of preterm labor and know how to seek medical advice.
- Assess for any signs of domestic/intimate partner abuse

EVALUATE FETAL WELL-BEING

Listen to fetal heart tones, usually can be heard from approximately 12 to 14 weeks gestation with a Doppler stethoscope: normal rate is 120 to 160 bpm

- Discuss pattern and frequency of fetal movements
 - Encourage patient to monitor and record fetal movements daily.
 - Educate patient on the importance of fetal movements as an indicator of general fetal well-being.
 - Ensure the patient knows to immediately report a decrease in fetal movements.
- Evaluate uterine growth
 - Measure fundal height.
 - Document findings and evaluate pattern of growth.
 - Weeks of gestation are equivalent to measurement in centimeters: MacDonald Method (measure from the top of the symphysis pubis to fundus, from approximately 24 to 34 weeks' gestation) - for example, at 30 weeks' gestation the fundal height should be 11.8 inches (30 cm).
 - Measurement less than expected could indicate intrauterine growth restriction, oligohydramnios or incorrect dates.
 - Measurement greater than expected could indicate multiple pregnancy, macrosomic infant, hydramnios or incorrect dates.

PATIENT TEACHING

- Provide education related to stage of pregnancy (i.e., what physical changes to expect or danger signs that need to be reported such as vaginal bleeding or fluid loss, abdominal pain or visual disturbances).
- Encourage attendance in prenatal education classes.
- Encourage tour of facility where patient intends to give birth.
- Later in pregnancy, focus of education needs to include preparation for care of the newborn (i.e., car seats, male circumcision, immunizations) so that parents can make informed decisions.

Screening and laboratory testing may include:

Ultrasound	Some health care providers offer routine ultrasound examinations in the first trimester of pregnancy to confirm dates and ensure single pregnancy; may be repeated later in pregnancy
Prenatal screening	MSAFP – screening for open neural tube defects and Down syndrome is done around 16 weeks – if indicated, follow-up may include amniocentesis
Screening for gestational diabetes	Offered around 24-28 weeks gestation Patient drinks solution containing 50 g of glucose and then has blood drawn 1 hour later – results should be below 140 mg/dL.
Rh screening	Rh negative woman: Check for Rh antibodies and if negative, 300 mcg of Rh ₀ immune globulin (RhoGAM) is prescribed at 28 to 32 weeks of gestation.
Hemoglobin/hematocrit	Usually repeated mid-pregnancy and then as indicated.
Group B <i>Streptococcus</i> screening	Normally offered at 37 weeks of gestation to determine whether antibiotic coverage is needed during labor.

Confirm the patient's contact information (address/telephone numbers) and ensure she has a scheduled return appointment. Always provide time for the patient to ask questions, confirm her understanding and that she has no other concerns that need to be addressed.

Strategies that use a holistic family approach such as promoting open communication between parents/guardians and teenagers, together with teaching self-respect, setting boundaries, and providing appropriate supervision are essential components of any successful approach to reduce teenage pregnancy (Table 9-4).

“What to say” — *Dialoging with teens about sex*

When talking with teens about sex, it is important to use language with which they can relate. For example, the nurse may say:

“You would not give your \$100 mobile phone to just anyone, so do not give your body to just anyone” (Harris, 2005, p. 15).

Some groups advocate mandatory sex education for all adolescents; others support programs that only teach sexual abstinence. There is little scientific evidence to determine which approach is most effective. Because individuals’ responses and actions are shaped by personality, cultural norms, and observed social patterns and behaviors, any one doctrine is rarely applicable to every group.

Impact on Society

APPROACHES TO ADDRESSING THE PROBLEM OF ADOLESCENT PREGNANCY. Over the years, a variety of local and national efforts have attempted to dissuade adolescents from engaging in early sexual activity. Strategies have ranged from public awareness campaigns to public chastisement, conviction as a sex offender, and institutionalization for unacceptable moral behavior. The various approaches have met with some success, but usually on a short-term basis.

Table 9-4 A Holistic Family Approach to Preventing Teenage Pregnancies

Parental Influences	Strategies
<ul style="list-style-type: none"> Parents have the strongest influence on teenage behavior. 	<ul style="list-style-type: none"> Promote open communication. Foster safe and nonjudgmental environment to facilitate discussion of issues relating to vaginal and oral sex, relationships, self-esteem, self-worth and how to say “no” to unwanted sexual contact.
<ul style="list-style-type: none"> Parents/adults need to model behaviors that are respectful, honest, nonaggressive, and healthy. 	<ul style="list-style-type: none"> Ways to interact and communicate are learned through observation. Observing a relationship between adults where each is given equal power and respect can help to initiate a sense of self-worth irrespective of gender.
<ul style="list-style-type: none"> Promoting family values, caring behaviors and closeness. 	<ul style="list-style-type: none"> Shared family activities, eating meals together, taking time to be with one another to enjoy a shared interest.
<ul style="list-style-type: none"> Build a trusting, loving relationship 	<ul style="list-style-type: none"> Take time to know teenagers’ friends and their families. Become involved, provide adequate supervision of activities. Promote group activities rather than early dating.
<ul style="list-style-type: none"> Providing accurate information to include both abstinence and contraception 	<ul style="list-style-type: none"> Parents may need help to increase their own comfort level and knowledge before being able to confidently help their child. Need to develop active listening skills, and ensure it is a two-way conversation, not a mini lecture. Dispel myths. Don’t promote double standards. – Teenage sex is not to be encouraged irrespective of gender. Make expectations clearly known. Use situations as they arise. For example, watching television together may provide an opportunity to discuss some relationship or sexual issue based on a program being viewed.
<ul style="list-style-type: none"> Understanding developmental stages related to teenagers, such as egocentric thinking and their sense of invincibility 	<ul style="list-style-type: none"> Use scenarios within the family setting to demonstrate formal reasoning – the ability to recognize alternatives and the consequences of their choices, both short and long term. Help the adolescent to see the “whole” picture and not just focus on their immediate needs (egocentric thinking). Teenagers are generally unable to recognize and appreciate behavioral risk; they are more likely to ignore or fail to understand the logical laws of probability “It won’t happen to me” – is the opinion much more likely to be believed.
<ul style="list-style-type: none"> Future plans 	<ul style="list-style-type: none"> Discuss plans for the future – set goals. Let it be known that education is essential to a bright future.

Source: The National Campaign to Prevent Teen and Unplanned Pregnancy (2004). Parent power: What parents need to know and do to help prevent teen pregnancy.

Current discussions center on the issue of whether providing sex education to children promotes early sexual activity. Rosengard and colleagues (2005) reported that although a majority of sexually active teenage boys did not intend to cause a pregnancy, they acknowledged that it was a possibility. Providing teenagers with sex education is an approach that endeavors to take the “secrecy” out of sex and instead provide basic, accurate information. It is believed that this strategy will empower adolescents with the knowledge needed to make informed decisions or, in the least, with the confidence necessary to seek guidance. When teenagers perceive sex to be a taboo subject, they are left to rely on friends, acquaintances, or peers who may not have a sound knowledge base to share. This paradigm supports the argument that knowledge reduces the need for experimentation and discovery. Experimentation without facts can lead to accidental pregnancy and sexually transmitted infections.

Teaching sexual abstinence before marriage can be effective in some cultures or populations, especially if the approach focuses on both genders. Discrepancy may exist between what is acceptable behavior or action for a teenage female and a teenage male. Interpretation of the phrase “sexual abstinence” may vary from no sexual contact of any description to simply maintaining virginity. In 1996, the U.S. Congress provided financial support of \$87.5 million per year to states that provided abstinence-only education, irrespective of the lack of substantive data demonstrating the effectiveness of this approach.

Along with a tendency to behave impulsively, adolescents lack the ability to make informed, complex decisions or to accurately compare alternatives. Neurobiological factors may be responsible for this deficit. The brain’s prefrontal cortex is responsible for all “executive functions.” Maturity of this area is not fully attained until an individual has reached age 20 or older. Nurses need to incorporate this information into the design of health education classes that will enable teenagers to understand better the process of making an informed decision. Ensuring that the adolescent has a realistic perception of related risks and the potential short-term and long-term outcomes is an essential component of any educational effort.

Cultural Influences on Adolescent Pregnancy

Adolescent pregnancy exists within every culture although the prevalence varies and it is not always viewed negatively. Within the sub-Saharan African region, girls often as young as 12 or 14 years of age are still sold to prospective husbands in exchange for a negotiated amount of money or in exchange for animals. In this culture, arranging a good marriage for a young teenage girl can often be a solution to family poverty.

In the United States, black and Hispanic adolescents represent the groups most likely to engage in early sexual activity, and not surprisingly, these groups have the highest rates of teenage pregnancy, although the discrepancy among different cultures is decreasing. In 2000, the rate of pregnancy among black teenagers 15 to 19 years of age was 15.3%, compared to the national average of 8.3% (Box 9-10). **Pregnancy rate** is defined as the total number of pregnancies, including those that end in spontaneous

Box 9-10 Sexual Activity and Pregnancy Rates Among Black Teenagers in the United States

- Have the highest pregnancy rate when compared with all major racial and ethnic groups
- Before the age of 20, approximately 57% will have experienced at least one pregnancy
- Have more sexual partners and are more sexually experienced
- As a group, black teens demonstrated one of the highest reductions (31.5%) in teen pregnancy during the decade 1990-2000. The overall teen pregnancy rate during this time fell by 28.5%. In comparison, Hispanic teenage pregnancies decreased by 15%. (The Alan Guttmacher Institute, 2004).
- In 2002 almost 96% of black women between the ages of 15 and 19 who gave birth were unmarried (Martin et al., 2003; National Campaign to Prevent Teenage Pregnancy, 2004).

abortion, elective abortion, or birth. In 2002, there were 425,000 births to girls 15 to 19 years of age, and of this group, approximately 25% were black (National Campaign to Prevent Teenage Pregnancy, 2004).

Along with cultural influences, many other factors, such as education, spiritual beliefs and group support, family structure, and income also impact the occurrence of adolescent pregnancy. As educational level increases, the age at which first intercourse occurs also increases while the risk of pregnancy decreases. Teenagers from middle-class, two-parent families are more likely to delay their first sexual experience. This tendency is also documented among adolescents who report an affiliation with a church, synagogue, or other religious institution. These individuals benefit from the group support associated with their church-related activities.

In 2005, two national organizations, the National Campaign to Prevent Teen Pregnancy and the National Coalition of Pastors’ Spouses, produced a document intended to heighten public awareness of the issues concerning pregnancy among black teenagers. The collaborative effort underscored the value of family and the faith community on adolescent sexual behavior. The premise of the report holds that a teenager’s religious and moral beliefs, personal experiences, and perception of family love and commitment are strongly reflected in sexual behaviors. Statistics concerning the long-term effects of teenage pregnancy were used to illustrate the magnitude of the problem:

- At age 27, 72% of African American girls who first gave birth at age 15 or younger were living in poverty, as were 59% of those who first gave birth at ages 16 or 17, compared to 45% of those who first gave birth at ages 20 to 21.
- Children of teen mothers are at great risk for a number of economic, social, and health problems. For example, compared to children with older mothers, children of adolescent parents are twice as likely to be abused and neglected; 22% more likely to become teen mothers themselves; and 50% are more likely to have children out-of-wedlock (The National Campaign to Prevent Teen Pregnancy, 2004, p. 2).

Identifying Adolescents at Greatest Risk for Unwanted Pregnancy

Adolescents who lack the support, security, and love of a family home are more likely to engage in high-risk behaviors including sex at an early age, multiple sexual partners, failure to use contraception, and unplanned pregnancy. Incarcerated juveniles constitute the most vulnerable group, especially when placed in an environment away from family support. These teenagers often have histories of physical neglect as well as severe physical, emotional, and sexual abuse. This group is more likely to experiment with high-risk behaviors, such as substance abuse, gang involvement, and violence. They may be more susceptible to peer pressure and are more likely to succumb to negative behaviors in an attempt to gain acceptance or peer status. Consequently, many begin sexual experimentation at a very early age and predictably experience unwanted teenage pregnancy (Carbone, 2001).

The Impact of Pregnancy on Meeting the Developmental Tasks of Adolescence

A pregnant teenager is required to be able to make informed decisions regarding continuing the pregnancy and, if the pregnancy comes to fruition, future plans for the child. This action hinges upon the premise that the adolescent has the necessary skills to appreciate the implications of these decisions as well as the potential life-long consequences associated with these decisions. Kaiser and Hays (2004) assert that pregnant adolescents face a dual task: meeting the developmental tasks of being a teenager, coupled with the developmental tasks associated with adapting to become a mother.

Nursing Insight—Pregnancy and the developmental tasks of adolescence

According to Erikson (1963), there are four developmental tasks of adolescence:

- To establish a sense of self-worth and a value system
- To establish lasting relationships
- To emancipate from parents
- To choose a vocation

Pregnancy during adolescence creates an especially vulnerable situation because the developmental tasks of pregnancy are superimposed on those of adolescence.

For a teenager to successfully adapt and fulfill the role of being a mother, she must achieve four major developmental tasks:

- Gain acceptance of pregnancy: This involves disclosing the presence of the pregnancy to her family, the father of the child, and her friends; facing family reactions; and hopefully gaining support.
- Set goals: Make realistic and attainable plans for the future. These goals will be different from her original ones and will focus on her role as a mother of a dependent child.
- View self as mother: This task addresses self-image and redefining self as a woman with a child rather than as a teenager with the freedom to explore being an adolescent and the opportunity to mature gradually.

- Grow up: Being a competent mother demands maturity with the ability to place someone else's needs before one's own. Developmentally, teenagers are typically at an egocentric stage of development. Being a mother is demanding and requires the sacrifice of being a care-free teenager (Kaiser, 2002).

Delayed Entry into Care

Denial, a common reaction to an unplanned and unwanted pregnancy, is often the reason why adolescents do not seek early prenatal care. In some situations, even close family members do not suspect or recognize the signs of advancing pregnancy. Unfortunately, denial and postponement of care may place the teenager and her fetus at a greater risk for medical problems. Complications such as iron-deficiency anemia, preterm labor, and preeclampsia may progress without detection and treatment. Without ongoing emotional support and education throughout pregnancy, the teenager enters labor psychologically unprepared and lacking a knowledge base to understand the natural events that surround birth. (See Chapter 11 for further discussion.)

Dulit (2000) describes three clinical types of adolescent pregnancy denial. During the first of these clinical types, the teenager realizes that pregnancy is a possibility but continues to hope that it will not come to fruition, and if it does, that it will disappear on its own accord. As the pregnancy advances, the adolescent recognizes the need to acknowledge the pregnancy and will usually seek assistance.

The second type of denial is a continuation of the first except that the teenager actively conceals the pregnancy and deliberately uses whatever skills necessary to intentionally deceive and hide the changes taking place in her body. The third type is considered true denial. In this situation, the teenager is absolutely unaware of any of the physical or psychological signs or symptoms of pregnancy and experiences an unconscious denial of impending motherhood. In this situation, the onset of labor is truly an unexpected event. A teenager who experiences this type of clinical denial is displaying psychopathology coupled with a significant ego pathology. The trauma of the birth may be sufficient to trigger a psychotic episode.

Infants born to this group of teenagers are at highest risk for being victims of neonaticide, as the mother fails to develop any form of attachment. Neonaticide is defined as the killing of a baby within the first 24 hours of birth. Active neonaticide is a deliberate action that occurs when the infant's death is the intended outcome of an act of violence. Passive (negligent) neonaticide results from an inability to provide the means for infant survival, for example, by maintaining an open airway, keeping the baby warm, or providing nutrition. Unfortunately, the victims are often the infants found abandoned in dumpsters or in public restrooms.

Be sure to—Advocate for newborns at risk

Nurses must actively advocate for newborns at risk. One way is by becoming knowledgeable about their practice state's Safe Haven laws and programs. This information may be accessed at: <http://www.adopting.org/adoptions/legalized-abandonment-state-safe-haven-laws-and-programs.html>

Nursing Care of the Pregnant Adolescent

For a teenager, pregnancy presents a number of issues: deciding whether to continue with the pregnancy; securing a means for gaining access to prenatal care; planning for infant/child care in a secure home environment; and arranging for economic resources to meet the needs of a dependent new family member. Social isolation may leave the expectant teen without peer support. When this occurs, the physical, emotional, and psychological transitions associated with pregnancy are more difficult for the teenager to accomplish successfully. Since the risk of pregnancy complications (e.g., iron-deficiency anemia, preeclampsia, intrauterine growth restriction, and cephalopelvic disproportion) are increased among this group, early and ongoing prenatal care is essential. A nursing approach that is designed to meet the special needs of the adolescent patient promotes adherence and an optimal pregnancy outcome.

ASSESSMENT. Assessment of the pregnant adolescent is similar to that of older women. The initial visit includes a personal health history and family history to determine whether medical problems such as diabetes or infectious diseases may threaten maternal or fetal health. Throughout the course of pregnancy, the young patient needs to be closely monitored for iron-deficiency anemia, STIs, and preeclampsia. She should also be assessed for high-risk behaviors such as tobacco, alcohol, and drug use and screened for sexual abuse. Therapeutic communication with the adolescent is enhanced when the interview is conducted in a warm, conversational style that conveys caring and acceptance.

It is important to assess the young patient's knowledge and level of understanding concerning personal care during pregnancy and care of the infant following birth. An educational plan individualized to meet the adolescent's specific needs can be developed during the initial visit and refined and altered as needed throughout the pregnancy. An approach that values the patient's support persons while recognizing the need to foster her personal sense of independence is essential. A plan of care that combines the collaborative efforts of various professionals including the physician, nurse, health educator, nutritionist, school counselor, and social worker is important in optimizing the outcomes for the young patient and her fetus. Reinforcing information, allowing ample time to discuss concerns, emphasizing the need to keep return appointments, and confirming that the patient can verbalize when and how to seek help are essential components of each visit.

Be sure to— Allow the pregnant adolescent to make health care decisions

Sometimes it is difficult for parents to allow an adolescent daughter to make health care decisions concerning her pregnancy. By law, a pregnant adolescent is an emancipated minor (a person capable of making health care decisions), so she may sign for her own care.

Framing the physical examination in a friendly, learning context helps to diminish the young patient's anxiety and fear and reinforces the information provided at each

visit. Use of the Doppler stethoscope allows the patient to hear the fetal heart tones. This action reinforces the presence of the fetus and helps the teenager to acknowledge the reality of her pregnancy. Emphasizing the progression in the fundal height measurement at each visit confirms that her fetus is growing and reinforces that she is successfully nourishing her developing child.

DIAGNOSIS AND PLANNING. Because of unawareness or denial of the pregnancy, adolescents often do not enter the prenatal care system until the second or third trimester. They may be frightened, confused, and unsure where to go for care. They are usually unaware of maternal needs, such as nutritional requirements, during pregnancy. Prenatal care is often received sporadically in the adolescent population.

Optimizing Outcomes— Formulating a nursing diagnosis for the pregnant adolescent patient

Due to a lack of information about pregnancy, "Risk for Ineffective Health Maintenance related to lack of knowledge of measures to promote health during pregnancy and family stress" is an appropriate nursing diagnosis for most pregnant adolescent patients.

Expected outcomes are based on the situation. For example, the patient will: keep scheduled prenatal appointments; follow recommended strategies for health promotion; attend childbirth and child care classes; and the family will: voice emotions and concerns and provide consistent support throughout the childbearing experience.

INTERVENTIONS: STRATEGIES TO PROMOTE A HEALTHY PREGNANCY.

Nursing interventions are structured to address the patient's identified needs. For example, the young patient may have difficulty accessing care due to her school schedule or transportation difficulties. The nurse helps to locate a prenatal clinic that schedules appointments in the late afternoon or evening and when needed, works with community resources to arrange for transportation to the clinic. Many facilities offer "teen clinics" that are geared to meet the special needs of young pregnant women. Some of these provide after-school transportation to the clinic, serve nutritious snacks, encourage patient participation in certain aspects of care (i.e., checking the urine with a dipstick; recording the weight), and provide education in small peer-oriented group settings that use repetition and reinforcement of information.

Optimizing Outcomes— with a CenteringPregnancy program

CenteringPregnancy is a group prenatal care program developed to improve pregnancy outcomes in the adolescent population. The CenteringPregnancy model incorporates a holistic approach that recognizes the adolescent's developmental need for socializing and peer support. Comprehensive prenatal care that includes risk assessment, education, and support is provided in a group-focused environment (Moeller, Vezeau, & Carr, 2007; Reid, 2007). Additional information may be found at: <http://www.centeringpregnancy.com/>

Referrals to other community resources such as WIC and home health nursing may be appropriate throughout pregnancy and during the puerperium.

Nursing Insight— *Adolescents and pregnancy outcomes with multiple gestations*

Adolescents are at an increased risk for poor birth outcomes, particularly when multifetal pregnancies are involved. Adverse outcomes include low birth weight and very low birth weight, preterm and very preterm births, small-for-gestational age infants, and fetal and neonatal death (Shumpert, Salihu, & Kirby, 2004).

PROMOTING OPTIMAL NOURISHMENT FOR THE PATIENT AND HER FETUS. Pregnancy during adolescence is associated with a higher risk for maternal and fetal complications. Adolescents who are still growing and those who have recently experienced menarche are at greatest risk for pregnancy complications. Growing adolescents continue to add fat to their own bodies during the third trimester, and as a result, tend to have smaller infants.

Pregnant adolescents need more calcium, magnesium, and phosphorus to help meet their own growth needs. Teens often skip meals and have a tendency to choose convenience or “fast foods” that are high in calories, fat, and sodium and low in vitamins, minerals, and fiber. Educating the young maternity patient about the importance of nutrition during pregnancy, seeking her input in making simple dietary changes, and offering nutritious snacks during prenatal visits are examples of nursing interventions that have been successful in many settings.

The Adolescent Expectant Father

Although most partners of adolescent mothers are within 2 to 3 years of their age, approximately 7% are 6 or more years older. Many become “absent” parents who rarely see or assume any responsibility in childcare. The majority of adolescent fathers admit that they are not ready for fatherhood. Confusion, depression, and guilt may predominate as the young expectant father struggles with the conflicting tasks of adolescence and impending fatherhood.

The adolescent father may accompany the young woman to the clinic for pregnancy confirmation or for prenatal care. Some attend childbirth preparation classes and participate in the childbirth experience; others shy away and avoid contact with the young expectant girl. Often, support during the pregnancy and in the early months after birth diminishes as other interests and responsibilities become more important. However, nurses must guard against stereotyping young expectant fathers as being irresponsible and disinterested; many genuinely care and wish to be involved. When desired by the pregnant adolescent, the father’s participation should be encouraged. It is a source of additional support for the young patient and allows the father an opportunity to work toward defining his role as a parent. Unfortunately, a large number of teenage expectant fathers come from low socioeconomic backgrounds and lack the resources, education, and job skills needed to be able to support their children.

Be sure to— **Recognize the adolescent father’s lack of legal rights**

If the adolescent father is not married to the pregnant teenager, he has no legal rights to participate in her decision making concerning the pregnancy, elective abortion, or plans for adoption.

Evaluation

Evaluation of the interventions is reflective of the expected outcomes. For example, did the patient keep her scheduled prenatal clinic appointments? Did she adhere to suggested health-promoting strategies? Did she attend the childbirth/child classes? Did her family remain supportive throughout the pregnancy?

Now Can You— **Discuss various aspects of adolescent pregnancy?**

1. Explain how pregnancy affects the developmental tasks of adolescence?
2. Develop a plan of care that is appropriate for a pregnant adolescent?
3. Identify strategies for involving the adolescent father in the pregnancy?

THE PREGNANT WOMAN OLDER THAN AGE 35

Maternal age is an important factor in the management of pregnancy. Today, more and more first pregnancies are occurring in women over the age of 35, who are no longer referred to as the “elderly primigravida.” As maternal age increases, there is a greater likelihood of pre-existing medical conditions such as diabetes and hypertension, which may be associated with maternal morbidity and poor fetal outcomes. Benign uterine leiomyomas (fibroids) occur with greater frequency in women over age 35 and may interfere with cervical dilation during labor and cause postpartum hemorrhage. Other obstetric complications including vaginal bleeding, preeclampsia, multiple gestation, gestational diabetes, preterm labor, dysfunctional labor, and cesarean birth are also increased in older primigravidas. The fetus is at greater risk for low birth weight, macrosomia, chromosomal abnormalities, and congenital malformations.

However, the risks are considerably reduced when the patient’s preconception and prenatal care is managed by a team of nurses, medical specialists, perinatologists (obstetricians with a specialty in high-risk obstetrics), nutritionists, and other health professionals. Optimal maternal-fetal outcomes result from early and ongoing care along with healthy lifestyle factors that are appropriate for women of any age: being physically, psychologically, and emotionally well; remaining physically active, having an ability to access and utilize health care services; having received an adequate education, and belonging to a socioeconomic advantaged section of society.

Preconception and prenatal care for women in the over-35-age group is focused on recognizing chronic medical conditions (e.g., hypertension, diabetes) and identifying detrimental lifestyle habits such as alcohol, drug, and tobacco use. As is true with any population of women, a

healthy lifestyle is an important first step toward achieving a good perinatal outcome. It is essential to listen actively to patients and their partners so that their concerns can be addressed, and, where appropriate, referrals can be made for counseling and screening or prenatal diagnostic procedures. Early prenatal care affords the opportunity for timely prenatal testing. Unfortunately, the older woman may mistake a scanty or missed period for signs of early menopause rather than pregnancy. When this occurs, entry for prenatal care is often delayed.

Optimizing Outcomes— Early prenatal care facilitates prenatal diagnosis for the expectant couple older than age 35

After age 35, there is an increased risk of conceiving a child with Down syndrome. Genetic testing is routinely offered to older expectant couples to permit the early diagnosis of chromosomal abnormalities.

Reactions to pregnancy in women 35 and older range from shock and disbelief to elation and joy. Many have reached the point in their lives where they have financial resources and economic stability, established careers, and the security of a stable interpersonal relationship. For women whose long-awaited pregnancy comes after months or years of attempts to conceive, pregnancy is a positive, exhilarating experience. Other women react with feelings of denial, uncertainty, and worry about how the pregnancy will affect their lives.

Nurses must be sensitive to each woman's situation and needs. Despite an abundance of other resources, peer support may be lacking. Often, the majority of the woman's contemporaries will have completed their childbearing many years earlier and are now the parents of almost-grown children. Effective nursing interventions include providing information and referral for genetics counseling and specialized diagnostic testing; structuring prenatal education to meet the unique needs of the older woman and her partner; and offering assistance in locating support groups, exercise, and childbirth preparation classes oriented toward the older woman. A timetable for screening for chromosomal abnormalities associated with advanced maternal age is presented in Table 9-5. Genetic abnormalities are also increased when the father is older than 40 years.

The physical examination should be conducted with a special focus on the identification of breast abnormalities and circulatory problems. After a careful breast examination, the patient should be encouraged to continue with monthly breast self-examination, as the incidence of breast cancer is increased in the older woman. Particular attention should be paid to inspection of the lower extremities because varicosities are also more common in older women. During the first trimester, the nurse should carefully assess for the presence of fetal heart sounds since the incidence of hydatidiform mole is increased in women over age 40. (See Chapter 11 for further discussion.)

Screening for Fetal Chromosomal Abnormalities

The American College of Obstetricians and Gynecologists (ACOG) now recommends that all pregnant women are offered a screening test for Down syndrome (ACOG, 2007).

Table 9-5 Timetable for Prenatal Diagnosis

Test	Significance
Maternal serum AFP screening	Sample of maternal blood obtained between 14 and 16 weeks of pregnancy. High levels may be indicative of an open neural tube defect, but may also result from incorrect dates, multiple pregnancy or fetal demise. Low levels of serum AFP are associated with Down syndrome. The incidence of Down syndrome increases with maternal age to approximately 1 in 100 at age 40 or older.
Triple test: alpha-fetoprotein (AFP), human chorionic gonadotropin (hCG), and unconjugated estriol.	Levels of hCG are increased and levels of unconjugated estriol are decreased when a trisomy 21 (Down syndrome) is present. A low level of hCG can indicate trisomy 18. The sensitivity of the AFP test in detecting trisomy 21 is increased by 40% to 50% when hCG levels are added.

The incidence of having a child affected by Down syndrome (trisomy 21) increases dramatically with maternal age (Table 9-6). Although a variety of screening and diagnostic tests are available to detect a fetus with Down syndrome, it is essential that before implementing any of these, the patient and her significant other or family support person are provided with appropriate information concerning the tests. This information is valuable in helping them to understand the reliability of the screening or diagnostic test and the implications of the results. The early diagnosis of an affected pregnancy gives the patient and her family the opportunity to determine whether termination of pregnancy is an option for her. Alternatively, early discovery of

Table 9-6 Risk of Down Syndrome Related to Maternal Age

Maternal Age at Term	Risk of Down Syndrome
Younger than 25	1 : 1500
30	1 : 910
35	1 : 380
40	1 : 110
42	1 : 65
44	1 : 35
46	1 : 20
48	1 : 11
50	1 : 6

Source: Data from <http://www.wolfson.qmul.ac.uk/epm/screening/calcrisk.shtml#markers>

a fetal problem provides time for the parents to become informed and make preparations for rearing a child with Down syndrome. If the patient chooses an elective termination of pregnancy, the earlier the gestation, the lower the maternal morbidity associated with the procedure.

Throughout the screening and diagnosis process, the patient deserves an unbiased counselor who can provide continuity of care and up-to-date, accurate, and in-depth information. The counselor also needs to be able to facilitate open discussion whereby the patient can voice concerns related to issues such as spiritual beliefs; financial constraints; family dynamics; emotional feelings; and cultural, philosophical, and ethical values. Whatever decision the patient makes regarding the pregnancy, she needs a sound support system that will help her and her family deal with the issues that arise during pregnancy and provide the appropriate aftercare.

Down syndrome screening may be initiated in the first or second trimester of pregnancy. In the first trimester, three “markers” (the Triple Screen or Triple Test) are evaluated: Pregnancy Associated Plasma Protein-A (PAPP-A), free β -human chorionic gonadotropin (free β -hCG), and nuchal translucency (NT). NT is an ultrasound-directed measurement of the swelling directly beneath the skin at the back of the fetal neck. A positive result for Down syndrome is associated with a decreased PAPP-A (approximately one half of the normal level), an elevated level of free β -hCG, (approximately twice the normal level), and a high measurement of the NT thickness (Reddy & Mennuti, 2006). In the second trimester, four “markers” (termed a Quad Screen) are used: α -fetoprotein (AFP), unconjugated estriol (uE3), free beta-human chorionic gonadotropin (free β -hCG), and inhibin A (inhibin). Inhibin is a hormone produced by the ovarian granulosa cells that suppresses the release of follicle-stimulating hormone (FSH). It is classified into subtypes inhibin-A and inhibin-B. Levels of inhibin-A are elevated in the presence of Down syndrome.

A diagnostic test such as an amniocentesis is usually offered if the calculated risk for Down syndrome is 1 in 150 or greater. If an open neural tube defect is suspected based on an elevated (2.5 times higher than the average for the number of gestational weeks) AFP, a diagnostic ultrasound examination can be obtained. All patients who have experienced prior pregnancies associated with fetal chromosomal abnormalities should be offered diagnostic testing such as chorionic villus sampling or amniocentesis (Barts and The London Queen Mary’s School of Medicine and Dentistry, 2006). (See Chapter 11 for further discussion.) The most recent data now indicate that chorionic villus sampling carries no greater risk to pregnancy duration than amniocentesis (Caughey, Hopkins, & Norton, 2006).

Nursing Insight— Maternal age and Down syndrome screening results

An older woman is more likely to have a screen-positive result than a younger woman because she starts with a higher age-specific risk of Down syndrome. Approximately 70% of pregnancies affected by Down syndrome is detected in women aged 25 or younger, while 99% of pregnancies affected by Down syndrome is detected in women older than the age of 45 (Wald & Rudnicka, 2004).

where research and practice meet: A Variety of Cultural, Medical, and Lifestyle Factors May Affect Prenatal Screening Tests

Prenatal screening tests results are affected by a number of factors.

- AFP levels tend to be about 20% higher and free β -hCG levels about 10% higher in Afro-Caribbean women than in Caucasian women.
- Free β -hCG levels tend to be about 10% higher and uE3 (estriol) levels about 10% lower in women who have become pregnant as a result of in vitro fertilization (IVF), as compared with non-IVF pregnancies.
- Free β -hCG levels tend to be about 20% lower and inhibin levels are about 60% higher in women who smoke, as compared with women who do not smoke.
- Second-trimester serum marker levels are increased in twin pregnancies.
- Women with insulin-dependent diabetes mellitus usually have lower levels of AFP (decreased by 18%), inhibin (decreased by 12%), and uE3 (decreased by 6%) than women without insulin-dependent diabetes.
- Vaginal bleeding that occurs immediately before a second trimester blood sample is obtained can affect the screening result since bleeding may increase the maternal serum AFP level. When bleeding has occurred, it may be advisable to delay the screening test until a week after the bleeding has stopped.
- If an amniocentesis has been attempted in the pregnancy before obtaining a second-trimester blood sample, the result cannot be correctly interpreted due to the possibility of a feto-maternal transfusion, which can increase the maternal serum AFP level.
- Nurses should use this information to appropriately counsel patients who will be undergoing prenatal screening tests.

Data from <http://www.wolfson.qmul.ac.uk/epm/screening>

Now Can You— Discuss aspects of care for the pregnant woman older than age 35?

1. Explain why women older than age 35 may experience more pregnancy complications than younger women?
2. Identify two components of the physical examination that merit special attention?
3. Identify three tests that are useful in the prenatal diagnosis of Down syndrome?

summary points

- ◆ Education and involvement in prenatal care empowers patients and their families to make informed decisions.
- ◆ The first prenatal visit includes a health history, physical examination, and laboratory testing. Establishing good rapport through effective communication is essential in creating an environment where the patient is more likely to return.
- ◆ Prenatal follow-up visits are shorter than the initial assessment, but they are important in monitoring maternal-fetal health and in providing anticipatory guidance for the patient and her family.

- ◆ Early and ongoing prenatal care is key to an optimal maternal–fetal outcome. Families should be involved in activities for health promotion and educated about strategies for self-care during the childbearing year.
- ◆ The diagnosis of pregnancy is based on three types of signs: presumptive, probable, and positive. Presumptive and probable signs may be caused by conditions other than pregnancy; positive signs can have no other cause.
- ◆ The teenage pregnant patient is at risk for a number of obstetric complications including anemia, preeclampsia, and preterm birth.
- ◆ Factors including education, culture, spiritual beliefs, and family support and income impact the occurrence of adolescent pregnancy.
- ◆ Preconception and prenatal care for the woman over 35 focuses on the recognition and management of chronic medical problems and strategies to promote a healthy lifestyle.

review questions

Multiple Choice

1. The clinic nurse informs the low-risk pregnant woman at 20 weeks' gestation that she should schedule her next routine prenatal appointment for:
 - A. 1 week
 - B. 2 weeks
 - C. 3 weeks
 - D. 4 weeks
2. Laura, a 38-year-old woman, calls the clinic to ask about a pregnancy test as she has missed her last period by 2 weeks. The clinic nurse recommends that Laura use a home pregnancy test:
 - A. That is specific to the beta subunit of hCG
 - B. That is specific to the alpha subunit of hCG
 - C. In 1 week
 - D. At the end of 2 weeks
3. The clinic nurse knows that a probable sign of pregnancy is:
 - A. Piskacek sign
 - B. Nausea and vomiting
 - C. Fetal heartbeat
 - D. Frequency of urination
4. The clinic nurse obtains information from Emma, a 22-year-old primigravida. Her last menstrual period was December 25th and it lasted 3 days (normal duration for Emma). The calculated Expected Date of Birth (EDB) would be:
 - A. October 1
 - B. September 1
 - C. October 2
 - D. September 30

True or False

5. The perinatal nurse recognizes that the diagnosis of pregnancy may cause a woman to be afraid for her own safety.

6. The clinic nurse routinely includes information on genetic testing and diseases as a component of prenatal care to ensure informed choice for women and their families.

Fill-in-the-Blank

7. The clinic nurse encourages and schedules prenatal visits with patients because health care provided during pregnancy _____ mortality and _____ morbidity.
8. The clinic nurse uses the RADAR acronym as a tool for abuse screening. The "D" refers to _____ your _____.
9. The clinic nurse is aware that obtaining a woman's obstetric history is important to her care. A history of a _____ birth increases the woman's chances by 20% to 40% of a reoccurrence in a subsequent pregnancy.
10. The clinic nurse teaches pregnant women in their first trimester that frequency of urination is due to _____ on the bladder exerted by the _____.

CONCEPT MAP

The Prenatal Assessment

- Pregnancy:**
- Wonder/growth
 - Ambivalence
 - Self-preservation concerns

For best outcomes

- Prenatal Care:**
- Begins in first trimester
 - Visits: once every 4 wks for 28–32 wks → q2wks
 - Focus: early identification of deviations from the norm
 - Facilitate health promotion/health maintenance via screenings
 - Psychosocial support

FIRST VISIT

- Comprehensive Health History:**
- Biographical data/social history
 - History of intimate partner violence
 - Psychological assessment
 - OB history/past pregnancy
 - Gynecological history
- Current Pregnancy:**
- Presumptive, probable and positive symptoms
 - Establish estimated date of birth
 - Determine gravidity and parity
 - Complete pregnancy testing
 - Identify multiple gestation
- Medical History:**
- Identifies present health status
 - Dental and eye health
 - Status of maternal immunizations
 - Educate re: environmental hazards

- Where Research And Practice Meet:**
- Legal marriage improves birth outcomes
 - Increase calcium/weight bearing exercise when Depo-Provera used pre-pregnancy
 - Limitations exist in home pregnancy tests
 - Repeated use of eye exam meds can be teratogenic
 - Female infants at increased risk for hepatitis C

- Ethnocultural Considerations:**
- HTN more prevalent in African American and Hispanic women

- What To Say:**
- Use language a teen can relate to during discussions about sex

- Across Care Settings:**
- Health care safety net for vulnerable populations

- Family Teaching Guidelines:**
- DEEPERCARE acronym

- Nursing Insight:**
- Continuity of care decreases maternal stress
 - Homelessness is a barrier to prenatal care
 - Domestic violence is more common than preeclampsia or gestational diabetes in pregnancy
 - Identify couples who would benefit from genetic testing
 - Educate re: difference between screening and diagnostic testing
 - Adolescents have greater health risks with multiple gestation
 - Developmental tasks of pregnancy superimposed on those of adolescence

- Complementary Care:**
- Do not use blue cohosh

Assist Patient With

- Nursing Role: CARE ing:**
- Communicating
 - Advocating
 - Respecting
 - Enabling/empowering

- Choosing a care provider
- Management of pregnancy/childbirth
 - Individualized care

- Eustress:**
- Role adaptation
 - Restructuring of tasks
- Distress:**
- Accessing care
 - Unknown/loss of control
 - Lack of social support

- Navigating the health care system
- Coping with financial concerns

- Prenatal Physical Exam:**
- Explain; obtain consent
 - Ensure privacy
 - Actively engage patient
 - Same order each visit
- Includes:
- General assessment → i.e., observation, weight, VS
 - Focused OB exam → Skin; breasts; abdomen, uterine size, fetal position, fetal heart auscultation, vagina, pelvis

- Pregnant Adolescents:**
- Long term social and developmental consequences
- Nursing:
- Heighten public awareness; ID those teens at greatest risk
 - Advocate for responsible sexual behavior
 - Empower families with information: provide age-appropriate health education classes
 - Be aware of denial of pregnancy → neonaticide
 - Assess in a caring/accepting manner; frame exam in a learning context
 - Assist with access to prenatal care
 - Promote optimal nutrition

- Screening and Diagnostic Tests:**
- Blood tests: blood type, Rh, antibody screens, RPR, VDRL, hepatitis, CBC, HIV, sickle cell anemia, PPD
 - STI screening: HIV, syphilis chlamydia, gonorrhea
 - Cervical cancer

- Woman Older than 35:**
- Increased risk of preexisting medical conditions/obstetric complications
- Nursing:
- Be aware of varying responses to pregnancy
 - Structure prenatal education to meet unique needs
 - Special assessment for breast/circulatory abnormalities
 - Education re: screening tests for chromosomal abnormalities

- Be Sure To:**
- ✓ Advocate for newborns at risk
 - Allow adolescents to make health care decisions
 - Recognize adolescent dad's rights

- Now Can You:**
- Discuss goals of prenatal care
 - Discuss health promotion strategies for pregnancy
 - Discuss components of prenatal assessment and various methods of clinical fetal assessment
 - Discuss aspects of care for the pregnant adolescent and woman older than 35

chapter 10

Promoting a Healthy Pregnancy

Little Seth, Precious One
What a miracle to be
A new life formed
Created from our deep love
And blessed by everyone above.

Our love combined as one
Creating a miracle of joy
Filling our hearts completely
Producing a baby boy.

Even though we have never seen your face
Or even heard your first cry
A special bond has been formed
Well deep from inside.

A bond that will never be broken
For as long as life shall be
Love will last forever
Far beyond than anyone can see.

As each day passes on
Your beginning edging nearer
We shield you from harm and
Pray for your well being
Until we may protect you in our arms.

You are our miracle soon to behold
For life is a beauty sometimes unseen
Ten tiny fingers, ten tiny toes
Perfection only to be seen.

You are so tiny, so small
So fragile, so sweet
A life not yet known
And yet loved so complete.

With all our love,
Mommy and Daddy
—Tamera and Daniel Ayriss

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Discuss holistic approaches for empowering women in planning for a healthy pregnancy.
- ◆ Describe factors that must be integrated to achieve optimal nutrition and weight gain during pregnancy.
- ◆ Assist a pregnant patient in formulating a daily food intake plan.
- ◆ Develop an exercise plan for women in the first, second, and third trimesters of pregnancy.
- ◆ Identify the signs of pregnancy and methods to manage the common associated discomforts.
- ◆ Recognize signs of impending complications of pregnancy and discuss interventions to decrease morbidity and mortality.
- ◆ Discuss the various methods of childbirth education.
- ◆ Assist a pregnant patient in developing a birth plan.

moving toward evidence-based practice Vitamin D Status During Pregnancy

Javaid, M.K., Crozier, S.R., Harvey, N.C., Dennison, E.M., Arden, N.K., Godfrey, K.M., & Cooper, C. (2006). Maternal vitamin D status during pregnancy and childhood bone mass at age 9 years: A longitudinal study. *The Lancet*, 367, 36–43.

The purpose of this longitudinal study was to investigate the effect of maternal vitamin D levels during pregnancy on childhood skeletal growth. The sample was composed of 198 Caucasian women who had participated in a previous study related to maternal nutrition and fetal growth. Other criteria for inclusion in the study were:

- Age greater than 16 years
- Initiated prenatal care before 17 weeks of gestation
- Delivered a singleton fetus at term

During the first and third trimesters the women completed a lifestyle questionnaire that included information concerning pre-pregnancy weight, smoking habits, and the use of dietary supplements during pregnancy. Assessments of maternal body build, nutritional status, and serum vitamin D levels were conducted. Beginning in the 7th month of gestation, personal exposure to ultraviolet B radiation was estimated from the number of hours of sunshine recorded by a local meteorological station.

After birth, each neonate's weight, crown–heel length, crown–rump length, and mid-upper-arm circumference were measured. Serum calcium levels were obtained from cord blood to provide a baseline indicator for vitamin D status, since vitamin D is essential for the metabolism of calcium.

Approximately 9 years later, the study participants and their children who continued to reside in the community were interviewed. At that time, nutritional status, physical activity patterns, and socioeconomic status were assessed for each mother and child. Each child's height, weight, whole body and lumbar-spine bone mineral content, bone area, and bone density were also obtained.

Findings from the study included the following:

Of the women participants:

- Average age was 27 years.
- 53% were primiparous.
- 31% smoked at the time of the last menstrual period; 20% continued to smoke during pregnancy.

- Vitamin D levels during late pregnancy were insufficient in 31% and deficient in 18%.
- All shared the same social class and general body build.

Of the offspring:

- Birth size and gestational length were similar.
- Birth weight, length, and abdominal and head circumference were unrelated to the maternal vitamin D level measured late in the pregnancy.
- Anthropometric characteristics at age 9 years were similar; the boys were slightly taller, heavier, and had a lower fat mass than the girls did.
- Those whose mothers had lower serum concentrations of vitamin D during late pregnancy had a reduced whole body bone mineral content and bone area at age 9 years.
- Neither height nor lean body mass were associated with the mother's vitamin D status during pregnancy.

Based on the findings, the researchers reached the following conclusions:

- Reduced maternal serum concentrations of vitamin D during late pregnancy were associated with decreased whole body and lumbar spine bone mineral content in the children at age 9 years.
- Bone mass in children and maternal vitamin D concentration were related to maternal use of vitamin D supplements and ultraviolet B radiation during late pregnancy.
- Insufficient vitamin D during pregnancy is associated with reduced bone-mineral accumulation during childhood.
- Vitamin D supplements taken during pregnancy may reduce the risk for osteoporosis-related fractures in the offspring.

1. What might be considered as limitations to this study?

2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

This chapter focuses on health promotion of childbearing women during preconception and throughout pregnancy. Counseling is an essential component of preconception care and provides information and education to women and families, which enables them to plan for their pregnancy and to develop a healthy body and a healthy mind surrounding the pregnancy.

Another important facet of health promotion during pregnancy is adequate nutrition and weight gain. Women need to have an understanding of essential elements required for a healthy pregnancy and of how to incorporate them into their daily diets. Along with diet and nutrition,

exercise, work, and rest must be balanced in order to achieve an optimal pregnancy outcome. Health care providers must provide guidelines for safe and beneficial exercise, which include teaching pregnant women about the effects of exercise and work.

This chapter also discusses the effects of medications during pregnancy and provides information concerning safe versus unsafe medications. Included in this section is information about over the counter medications, herbal therapies, and prescription medications. Certain medications are considered to be safe for use during pregnancy and these are incorporated into the discussion about the common discomforts of pregnancy.

Nurses and other health care providers can teach patients about common pregnancy discomforts to help alleviate anxiety and fear. Prenatal education also promotes empowerment that encourages women to manage pregnancy in a healthy manner. Pregnant women must also be knowledgeable about signs and symptoms of danger, including interventions that can be incorporated at home along with an understanding of when to seek professional care.

The course of a normal pregnancy, along with information concerning prenatal visits, is discussed in this chapter. Included in this section is a schedule for prenatal visits, information to be covered by the nurse at each visit, and laboratory tests that are completed with each visit. The nursing diagnosis: “*health seeking behaviors related to interest in maintaining optimal health during pregnancy*” is usually appropriate for women who regularly engage in prenatal care. Examples of other nursing diagnoses that address health promotion of the pregnant woman and her fetus are presented in Box 10-1.

Lastly, this chapter presents information about childbirth education, including a comparison of methods and strategies for finding information about various prenatal and childbirth education classes. As an integral part of promoting a healthy pregnancy and incorporating a holistic approach to care, women should be encouraged to develop a birth plan, which includes their preferences for care during the labor and birth of their child.

Planning for Pregnancy

Healthy People 2010 targets women of childbearing age with the goal of improving “the health and well-being of women, infants, children, and families” (U.S. Department of Health and Human Services [USDHHS], 2000, p. 16-3). To meet this goal, specific objectives are identified, focusing on the number of women receiving prenatal care, attendance at prepared childbirth education classes, delivery of low-birth-weight and very-low-birth-weight infants, preterm delivery, and maternal weight gain. One of the most important ways to facilitate meeting these objectives is for nurses and health care providers to promote healthy pregnancies in women

Box 10-1 Possible Nursing Diagnoses Related to Health Promotion of the Pregnant Woman and Her Fetus

- Anxiety related to minor symptoms of pregnancy
- Disturbed Body Image related to change of appearance with pregnancy
- Fatigue related to metabolic changes of pregnancy
- Risk for Deficient Fluid Volume related to nausea and vomiting of pregnancy
- Constipation related to reduced peristalsis during pregnancy
- Deficient Knowledge related to inadequate information regarding nutritional needs during pregnancy
- Health-seeking Behaviors related to a lack of information about childbirth and newborn care
- Ineffective Coping related to lack of support people
- Risk for Fetal Injury related to maternal substance abuse

through preconception counseling, individualized prenatal care, and identification and treatment of medical concerns and problems throughout the pregnancy.

Pregnancy care is a continuum that begins in adolescence. Once a female reaches menarche and is capable of reproduction, she should be cognizant of the fact that she could become pregnant and strive to achieve the best level of health that is possible. This timeframe, which represents the earliest stage of the pregnancy continuum, is called **preconception**. The pregnancy continuum spans across the childbearing years and encompasses the prenatal period, birth, postpartum, and parenthood. **Periconception** is a term that generally refers to the time immediately before conception through the period of organogenesis, while **interconception** is the time period between the end of one pregnancy and the beginning of the next pregnancy. It is considered to be an optimal time to address problems that occurred with the previous pregnancy to minimize the likelihood of a repeated poor pregnancy outcome (Moos, 2006).

PRECONCEPTION COUNSELING: A TOOL TO HELP PROMOTE A POSITIVE PREGNANCY OUTCOME

It is during preconception that a woman builds the foundation for a healthy pregnancy long before she may ever think of becoming pregnant. When a woman accesses her care provider during this time, it is known as preconception care. Ideally, health promotion for the pregnant woman should begin during the preconception period. Working with her health care provider during this time provides opportunities for empowering the woman for planning and carrying out a healthy pregnancy and birth.

The purpose of preconception care is to identify conditions, whether physical, psychological, or social, that could adversely affect a future pregnancy. By identifying these conditions early, interventions can be initiated to reduce or prevent potential complications that may be associated with them. Although certain conditions cannot be ameliorated, it may be possible to manage or treat them so that they have the smallest impact possible on future pregnancies. Each time a woman of childbearing age presents to her care provider for an annual gynecological exam, preconception counseling should be included, regardless of whether or not the woman is planning a pregnancy now or at any time in the foreseeable future.

Optimizing Outcomes— Endorsing preconception care

The past decade has shown a growing trend among clinicians in women’s health to expand the definition of prenatal care to include preconception counseling. National organizations such as the March of Dimes and the Centers for Disease Control and Prevention (CDC) endorse preconception counseling as an important component of care for women contemplating pregnancy or at risk of unintended pregnancy (Phillips, 2007). Nurses play a major role in endorsing preconception care for all women of childbearing age.

THE HEALTHY BODY

Preparing for pregnancy before becoming pregnant is the ideal, as it empowers women to become educated about the workings of their bodies and the benefits gained from pregnancy planning. During the preconception visit, the provider reinforces the importance of early and ongoing prenatal care and counsels the woman about establishing realistic expectations for pregnancy and its outcomes (American College of Obstetricians and Gynecologists [ACOG], 2005) (Fig. 10-1).

Menstrual and Medical History

When pregnancy is desired, the nurse can be instrumental in empowering the woman to take charge of her conception care by embracing a healthy lifestyle to ensure the best possible outcome. During the preconception visit, a review of the menstrual history guides the nurse in identifying specific needs so that an individualized conception plan can be developed. Determining the frequency and length of menstrual periods is essential information for teaching about the fertile period and how to enhance the likelihood of conception. The patient should be educated about the value of keeping an accurate menstrual calendar. She can be instructed to mark the first and every successive day of her

Figure 10-1 Health promotion for pregnancy begins during the preconception visit.

menstrual periods on the calendar (Fig. 10-2). This information will help her to determine the length of each cycle and when to time sexual intercourse in succeeding months to increase the likelihood of conception. When pregnancy does occur, one of the first questions she will be asked is, “What was the first day of your last normal menstrual period (LNMP)?” If she has recorded this information, she can easily refer to her calendar for the accurate date.

There are times when charting a menstrual calendar also provides clues to menstrual and, perhaps, fertility problems. Some women have irregular cycles that are too close together or too far apart. This information, documented in a calendar, may signal the need for referral to a reproductive specialist.

A review of the family history is another important component of the preconception visit. Through the information gained, the woman’s and her partner’s extended families can be assessed for potential illnesses or diseases that tend to run in families. For this reason, it is desirable for the patient’s partner to be present at the preconception visit so that he can accurately provide information about his family.

Complementary Care: Ayurveda to enhance the preconception period

Ayurveda is a term derived from the words *ayur*, or life, and *veda*, or science. Developed hundreds of years ago in ancient India, Ayurveda is a system of natural and medical healing that includes diet, herbs, massage, exercise, music therapy, meditation, yoga, and aromatherapy. Practitioners of this modality believe that Ayurveda is beneficial during the preconception period in promoting optimal maternal and fetal health. According to Ayurveda, a healthy lifestyle is achieved by maintaining a mutually satisfying, harmonious emotional relationship while avoiding stress, tobacco, alcohol and drugs, meat, and dairy products (consume a vegetarian diet).

Now Can You— Discuss preconception care?

1. Differentiate among preconception, periconception, and interconception?
2. Identify the purpose of preconception care?
3. Describe how to create a menstrual calendar?

INSTRUCTIONS: Shade in the appropriate box for every date of menstrual bleeding

Figure 10-2 The menstrual calendar provides an accurate record for recording menstrual periods.

The Physical Examination

Using the patient history as a guide to help identify problems or special needs, the health care provider performs a complete physical examination. Along with the general physical assessment, a complete pelvic examination is also performed to evaluate the organs and bony structures of the pelvis. Abnormalities in this region can be crucial during pregnancy and childbirth. A Papanicolaou test (Pap smear), cultures for sexually transmitted infections (STIs), and cultures for other infections are often obtained during this exam as well. (See Chapter 9 for further discussion.)

Laboratory Evaluation

Every pregnant woman who presents for prenatal care is tested for various potential problems during the first visit and periodically throughout the antepartal period. The complete blood count (CBC) serves as the primary test for anemia via analysis of the hemoglobin and hematocrit. If the woman is anemic, the indices can aid in identifying the type of anemia (e.g., iron-deficiency, etc.). The patient can also be screened for infection by the white blood cell (WBC) count. If the WBCs are elevated, more information can be ascertained via the differential analysis. Platelets, essential components of the clotting mechanism, are also evaluated in a CBC.

Blood is also drawn for the identification of the woman's blood type, Rh status, and the presence of irregular antibodies. The blood type and Rh status are important in determining if the woman is at risk for developing isoimmunization during her pregnancy. This problem can occur if the woman's blood is Rh(D) negative and the fetus she is carrying is Rh(D) positive. Screening identifies the presence of antibodies that have been produced in response to exposure to fetal blood or other irregular antibodies that could potentially cause problems. (See Chapter 11 for further discussion.)

Exposure to Childhood Illnesses

Some of the routine maternal laboratory tests screen for childhood diseases that are known to cause congenital anomalies or other pregnancy complications if contracted during early pregnancy. Rubella, or German measles, was once a common childhood disease. Today, most women of childbearing age received rubella immunization during childhood. When contracted during the first trimester, rubella causes a number of fetal deformities. Therefore, all pregnant women are screened for rubella. A positive rubella screening test is indicative of immunity, and the woman cannot contract the disease. If the screening test is negative, the patient is advised to stay away from children who could possibly have the disease, and she is immunized for rubella after the infant is born.

Varicella (chickenpox) is another common childhood disease that may cause problems in the developing embryo and fetus. At present, an immunization for chickenpox is available and given to most children. If a woman presents for a preconception visit and her history reveals no prior chickenpox infection, she should be immunized before attempting pregnancy. Pregnant women should be questioned about childhood chickenpox, and a varicella titer may be obtained to confirm immunity. If nonimmune, the patient should be advised to avoid children who could potentially expose her to the chickenpox virus.

Finally, all adults should receive a tetanus booster immunization at least every 10 years. A booster can be given to the woman during the preconception period if she has not been immunized within the previous 10 years.

Exposure to Sexually Transmitted Infections

Sexually transmitted infections (STIs) may cause maternal and fetal complications during pregnancy. Routine screening for STIs aids in early detection and treatment. The Venereal Disease Research Laboratory (VDRL) test is a screening titer for syphilis that measures antibodies produced in mid-disease, but can produce a false positive result in women who are pregnant or who have rheumatoid arthritis or systemic lupus erythematosus. For these patients, a rapid plasma reagin (RPR) screening test may be used to confirm the presence of antibodies. In the event of a positive result, further testing is needed to confirm the findings and to determine whether the infection is in an active or latent phase.

In addition to screening for syphilis, all women should be screened for human immunodeficiency virus (HIV) during pregnancy (ACOG, 2004). If positive, therapy can be initiated to decrease the likelihood of transplacental viral transmission to the fetus. An important nursing role includes educating all women about HIV and the methods for decreasing the risk of infection.

Gonorrhea and chlamydia are cervical infections that can ascend through the cervix and increase the risk of premature rupture of the membranes and preterm labor. A cervical sample obtained during a speculum examination can be tested to determine if either of the pathogens is present.

Hepatitis B virus is a blood-borne infection that is acquired primarily by sexual contact or through exposure to infected blood. The Hepatitis B Surface Antigen (HBsAg) is used to screen for this infection. If the screening test is positive, further testing is indicated.

Now Can You— Identify essential laboratory tests during preconception planning?

1. Discuss components of the CBC?
2. Explain the importance of identifying the woman's blood type and Rh status?
3. Identify routine screening tests performed for childhood diseases?
4. Describe the processes for sexually transmitted infection screening?

Genetic Testing

During the patient's first interview and visit, the nurse should ask questions that relate to the patient's and family's genetic history. Depending on the information gained, further blood work and testing may be indicated. For example, a positive family history of sickle cell disease or trait should be followed up with a maternal hemoglobin electrophoresis. If the patient tests positive, her partner should also be tested.

All women should be offered screening with maternal serum markers. Several different tests are available, such as the Triple Marker screen and the Quadruple Marker screen. Each tests for the presence of alpha-fetoprotein (AFP), estradiol, human chorionic gonadotropin (hCG),

and other markers. These tests screen for potential neural tube defects, Down syndrome, and trisomy 18. If the screen is positive, the woman should be referred to a genetics specialist for counseling, and further testing, such as chorionic villus sampling (CVS) or amniocentesis, should be performed (ACOG, 2007).

While it is not possible to inquire about every inheritable disease or disorder, those most frequently encountered are addressed in Table 10-1.

Optimizing Outcomes—Prenatal genetic testing

Prenatal nursing care is enhanced with the implementation of interventions for early diagnosis and treatment for the prevention of complications related to birth defects.

Best outcome: Provide prenatal interventions, including folic acid supplementation for all women of reproductive age, conduct rubella screening and immunization, teach women to avoid alcohol consumption during pre-conception and pregnancy, offer screening and detection of prenatal genetic disorders and early treatment of disorders when possible, and offer termination of pregnancy for severe defects.

Exposures Related to Lifestyle Choices

Several factors related to lifestyle choices can have detrimental effects on the developing fetus, including use of tobacco, alcohol, caffeine, artificial sweeteners, marijuana, and cocaine.

TOBACCO. Smoking during pregnancy causes a plethora of problems for the woman and the developing fetus. Carbon monoxide in the cigarette smoke binds more readily than oxygen to hemoglobin, thereby decreasing the oxygen-carrying capacity of the red blood cells. This alteration decreases the amount of oxygen traveling to the placenta, thereby decreasing the amount of oxygen available to the fetus for growth and development of tissues and organs.

The nicotine in the cigarette smoke also poses a significant risk to the developing fetus. Depending on the amount and the frequency of smoking, nicotine can act as either a stimulant or a relaxant. Nicotine causes the release of epinephrine, stimulating the “fight or flight” response that results in tachycardia, hypertension, and tachypnea. This response occurs in both the woman and her fetus. The stimulation of the sympathetic nervous system also prompts the release of cortisol from the adrenal glands, increasing blood glucose levels, and altering the body’s immune response. Vasoconstriction results from stimulation of the sympathetic nervous system, causing decreased blood flow through the arteries and decreased oxygen transport to the placenta and the developing fetus.

Smoking is associated with spontaneous abortion, low birth weight, intrauterine growth restriction, preterm labor and birth, placenta previa, placental abruption, and premature rupture of the membranes. Infants born to mothers who smoke are more likely to be small for gestational age. Each of these complications predisposes the fetus to complications related to growth and physical and cognitive development. In fact, babies born to mothers

who smoked during pregnancy are three times more likely to die from sudden infant death syndrome (SIDS) than babies born to women who do not smoke (U.S. Department of Health & Human Services [USDHHS], 2004).

Women who smoke should be encouraged to participate in a smoking cessation program. These programs are 50% to 70% effective in assisting and empowering women who smoke to be successful in quitting (March of Dimes, 2006). Smoking cessation during pregnancy reduces perinatal complications, even if the woman does not quit until the second or third trimester. (See Chapter 7 for further discussion.)

ALCOHOL. Alcohol consumption during pregnancy can cause physical and mental abnormalities in the developing fetus. Each year, more than 40,000 babies are born with complications resulting from alcohol use during pregnancy (March of Dimes, 2006). The current recommendation is that no alcohol consumption during pregnancy is safe, as no safe level has been determined.

Alcohol passes quickly through the placenta and reaches the fetal bloodstream much more rapidly than it does in adults. Fetal body system functions are immature and unable to metabolize alcohol, resulting in elevated alcohol levels and damage to developing organs and tissues. The resulting problems are manifested in the facial features associated with fetal alcohol syndrome (FAS): a low nasal bridge, short nose, flat midface, and short palpebral fissures. FAS is one of the most common causes of mental retardation. Body organs affected include the heart and the brain. Children born with lesser damage are diagnosed with fetal alcohol effects (FAEs), fetal alcohol spectrum disorder (FASD), or alcohol-related birth defects (ARBDS). (See Chapter 19 for further discussion.)

Heavy maternal drinking can result in spontaneous abortion or a low-birth-weight infant. In fact, heavy drinkers are two to four times more likely to have a spontaneous abortion than are nondrinkers (Centers for Disease Control & Prevention [CDC], 2002). While drinking alcohol should be discouraged for the duration of the pregnancy, many women do not know they are pregnant during the first few weeks. During this time, occasional alcohol consumption is not believed to harm the fetus. (See Chapter 7 for further discussion.)

Now Can You—Discuss complications related to alcohol consumption during pregnancy?

1. Identify facial anomalies associated with FAS?
2. Identify fetal body organs affected by alcohol exposure?
3. Describe pregnancy complications related to alcohol consumption?

CAFFEINE. Caffeine acts as a central nervous system (CNS) stimulant, causing tachycardia and hypertension. Since caffeine readily passes through the placenta to the fetus, the effects of caffeine affect fetal heart rate and movement. High caffeine intake during pregnancy has been associated with preterm labor and birth as well as intrauterine growth restriction. However, no clear causation exists.

The primary sources of caffeine for most pregnant women include coffee, tea, and sodas. Other lesser known sources include chocolate, over-the-counter medications that contain

Table 10-1 Genetics Screening During Pregnancy

Disorder	Population Affected	Pathology	Pregnancy and Newborn Complications
Sickle cell disease	African Americans	<ul style="list-style-type: none"> Autosomal recessive hemolytic disease 	Spontaneous abortion
	Persons of Mediterranean descent	<ul style="list-style-type: none"> Involves an abnormal substitution of an amino acid in the structure of hemoglobin 	<ul style="list-style-type: none"> Preterm labor
		<ul style="list-style-type: none"> Red blood cells assume abnormal, sickle shape in response to triggers, including hypoxia, infection, dehydration 	<ul style="list-style-type: none"> Intrauterine growth restriction

Tay–Sachs disease	Ashkenazi Jews	<ul style="list-style-type: none"> Lipid storage disease that results from a deficiency in hexosaminidase 	<ul style="list-style-type: none"> Infants appear normal at birth, until about 3–6 months of age
	Jewish people from eastern or central Europe	<ul style="list-style-type: none"> Both parents must carry and pass on the trait to the child 	<ul style="list-style-type: none"> Neurological system begins to deteriorate
	French Canadians		<ul style="list-style-type: none"> Death occurs between the ages of 2 and 4 years
	Cajuns		
Thalassemia	Greeks	<ul style="list-style-type: none"> Disorder of hemoglobin synthesis 	<ul style="list-style-type: none"> Children appear normal at birth
	Italians	<ul style="list-style-type: none"> Thalassemia minor: person is heterozygous for the trait; experiences fewer symptoms 	<ul style="list-style-type: none"> During first two years, become pale, lethargic, and develop jaundice
	Southeast Asians	<ul style="list-style-type: none"> Thalassemia major: person is homozygous for the trait; experiences more severe symptoms 	<ul style="list-style-type: none"> Results in enlarged liver, spleen, and heart
	Filipinos		<ul style="list-style-type: none"> Death results from heart failure and infection
Hemophilia	Males affected	<ul style="list-style-type: none"> Mutation in the gene for coagulation factor VIII 	<ul style="list-style-type: none"> Males can have excessive bleeding when circumcised
	Females are carriers	<ul style="list-style-type: none"> Causes a defect in blood clotting Leads to frequent bleeding episodes and hemorrhage 	<ul style="list-style-type: none"> Increased incidence of intracranial hemorrhage Easy bruising and bleeding with injuries
Glucose-6-phosphate dehydrogenase (G6PD) deficiency	African Americans Seen mostly in males	<ul style="list-style-type: none"> Causes drug-induced destruction of red blood cells when taking certain medications (e.g., sulfonamides) 	<ul style="list-style-type: none"> Increased incidence of pathological jaundice or hyperbilirubinemia due to destruction of red blood cells
Cystic fibrosis	Caucasians	<ul style="list-style-type: none"> Autosomal recessive genetic disorder 	<ul style="list-style-type: none"> Results in chronic obstructive lung disease from thick mucous secretions in the lungs
		<ul style="list-style-type: none"> Causes exocrine gland dysfunction 	<ul style="list-style-type: none"> Frequent lung infections occur Causes a deficiency in pancreatic enzymes that prevents normal digestion

Data from: Cunningham et al., (2005); Kilpatrick & Laros (2004); & Lashley (2005).

caffeine as an ingredient, and dietary supplements. Women should be counseled that coffee and tea labeled “caffeine-free” still contain small amounts of caffeine.

Moderate intake of caffeine during pregnancy has not been found to cause perinatal problems. Women who are

pregnant should limit their intake of caffeine to less than 300 mg/day, which is the equivalent of two (caffeinated) beverages per day (National Toxicology Program Center for the Evaluation of Risks to Human Reproduction, 2005). (See Chapter 7 for further discussion.)

ARTIFICIAL SWEETENERS. Aspartame (NutraSweet®, Equal®), acesulfame potassium (Sunett®), and sucralose (Splenda®) have not been shown to have any negative effects associated with the developing fetus. However, because aspartame consists of two naturally occurring amino acids, women who have phenylketonuria (PKU) should not use this product. Saccharin, another artificial sweetener, is considered to be unsafe for use during pregnancy and should be avoided altogether.

MARIJUANA. No studies have documented fetal teratogenic effects associated with marijuana. Women who use marijuana, however, may engage in other high-risk behaviors (e.g., alcohol use) and the combination of effects may be associated with poor fetal outcomes. (See Chapters 7 and 9 for further discussion.)

COCAINE. It is difficult to determine the effects of cocaine use in pregnancy due to the high potential that the woman may be using other drugs and engaging in additional high-risk behaviors. Fetal exposure to cocaine is associated with an increased risk for congenital anomalies that most frequently occur in the cardiac and central nervous systems. The pregnant woman who uses cocaine is at risk for pregnancy complications that include stillbirth, abruptio placentae, preterm labor, preterm birth, and giving birth to an infant who is small for gestational age (SGA) (Stuart & Laraia, 2005). (See Chapters 7, 9, and 11 for further discussion.)

Now Can You— Discuss substances to be avoided during pregnancy?

1. Name one harmful effect of caffeine during pregnancy?
2. Identify women who should be counseled to avoid the artificial sweetener aspartame?
3. Name three maternal/fetal complications that can result from cocaine use during pregnancy?

THE HEALTHY MIND

Maternal attachment to the fetus is an important area to assess and can be useful in identifying families at risk for maladaptive behaviors (Youngkin & Davis, 2004). The nurse should assess for indicators such as unintended pregnancy, intimate partner violence, difficulties in the partner relationship, sexually transmitted infections, limited financial resources, substance use, adolescence, poor social support systems, low educational level, and the presence of mental conditions that might interfere with the patient's ability to bond with and care for the infant (ACOG, 2006). It is important to remember that, depending on what is going on in her life at the time of the pregnancy, any woman has the potential for maladaptive behaviors.

Readiness for Motherhood

Motherhood is not necessarily instinctive for the pregnant woman. Each woman must work through the “process” of becoming a mother. Much of the woman's reservoir of beliefs about motherhood relate back to how she was parented as a child (Attrill, 2002). The pregnant woman must be able to see herself as a mother. To do so, she relies on her life experiences of how she was nurtured as a child and the types of relationships that she has developed over

the years with other women (Lederman, 1996). The relationship with her own mother plays a significant role in how she views motherhood. If the woman's mother is available, accepting the pregnancy and respect for her daughter's autonomy play an integral role in assisting the woman to become a successful mother. Absence of some of these components may impede the pregnant woman's ability to develop into the motherhood role.

One way that a pregnant woman can demonstrate a positive attitude toward her pregnancy is by educating herself about maternal changes during pregnancy, fetal growth and development, and motherhood (Fig. 10-3). Many helpful books, brochures, online resources, and community programs on pregnancy and parenting are available for mothers-to-be.

Psychological Changes During Pregnancy

Hormone levels during pregnancy often play havoc with the pregnant woman's psyche. Progesterone exerts a depressant effect. Physical changes, changes in body image and fears related to becoming a mother, the impending labor and birth, and the increased responsibilities that accompany pregnancy and parenthood often produce anxiety or heightened depression during pregnancy (Youngkin & Davis, 2004). Providers must be aware of this potential and remain cognizant for signs and symptoms of mental illness in the pregnant woman. Referral to a mental health professional may be necessary.

The Healthy Relationship

The incidence of intimate partner violence (IPV) during pregnancy is high and, statistically, as many as 20% of pregnant women experience violence in the home (ACOG, 2006). Every woman should be screened for IPV during the initial visit and then as necessary (e.g., if bruises or other injuries are present) throughout the pregnancy. (See further discussion in Chapter 9.)

Maternal stress also has a negative effect on the developing fetus. Women who are anxious or stressed during their pregnancy are more likely to deliver preterm or to give birth to smaller babies. The nurse should assess all pregnant women for stressors and coping skills during pregnancy. (See Chapter 9 for further discussion.)

Figure 10-3 Learning about maternal changes, fetal growth and development and motherhood fosters a positive attitude toward the pregnancy.

Complementary Care: Promoting stress management during pregnancy

There are several complementary therapies that can safely be used during pregnancy, often recommended by nurse midwives and obstetricians:

- Massage therapy: Increases blood flow to maternal and fetal tissues; increases relaxation
- Chiropractic care: Treats lower back pain and headaches related to increased hormone levels
- Acupuncture and acupressure: Treat many physical ailments during pregnancy without the introduction of medications
- Relaxation exercises, meditation, and breathing techniques: Increase blood flow to maternal and fetal tissues; increase relaxation
- Light therapy: Enhances mood and treats depression
- Reflexology: Stimulates nerve pathways to increase blood flow and energy flow to corresponding areas of the body
- Aromatherapy: Increases relaxation

Readiness for Fatherhood

In preparation for parenthood, the male partner moves through a series of developmental tasks. During the first trimester, the father begins to deal with the reality of the pregnancy. At this time, he may worry about financial strain and his ability to be a good father. Feelings of confusion and guilt often surface with the recognition that he is not as excited about the pregnancy as is his partner. Couvade syndrome, the experience of maternal signs and symptoms, may develop. (See Chapter 8 for further discussion.)

In the second trimester, the pregnancy becomes more real for the father. The pregnancy begins to “show,” and he is able to identify fetal movement through the maternal abdomen. Since there is an increased paternal willingness to learn about fetal growth and development during this time, the second trimester is the best time to provide prenatal education for the expectant couple.

During the third trimester, both parents are preparing for their new roles. Many of the father’s early concerns regarding financial demands, personal parenting skills, and partner safety during birth return during this time. Conflicting feelings may emerge between excitement over the prospect of a new baby and the major lifestyle changes that will accompany the presence of a new family member. Most couples attend prenatal classes in preparation for the birth experience during the third trimester. The father may fear for the safety of his partner. How well the couple progresses through the developmental tasks of pregnancy has a major influence on their level of adaptation once the baby is born.

Now Can You— Discuss common paternal reactions and educational needs during pregnancy?

1. Name two overriding concerns sometimes harbored by fathers during the first trimester?
2. Explain why pregnancy becomes more “real” for fathers during the second trimester?
3. Identify the trimester when education is likely to be most beneficial for the expectant couple?

Nutrition and Weight Gain

Nutrition and weight management play an essential role in the development of a healthy pregnancy. Not only does the patient need to have an understanding of the essential nutritional elements, but she must also be able to assess and modify her diet for the developing fetus and her own nutritional maintenance. To facilitate this process, it is the nurse’s responsibility to provide education and counseling concerning dietary intake, weight management, and potentially harmful nutritional practices (Fig. 10-4).

Optimizing Outcomes— Resources for optimal nutritional counseling

The document “Dietary Guidelines for Americans 2005” is an evidence-based resource guide for professionals and consumers that offers strategies for promoting health and reducing the risk for chronic diseases through diet and physical activity. Dietary guidelines, food composition, the food guide pyramid, dietary supplements, and resource lists are included in the guide (USDHHS & U.S. Department of Agriculture [USDA], 2005).

The nurse should obtain a nutritional history on all pregnant patients and patients of childbearing age. Information that is gained in a general nutritional assessment includes questions regarding eating patterns; changes in appetite, chewing, swallowing, and taste; presence of vomiting, diarrhea, or constipation; food allergies and intolerances; and self-care behaviors. In addition to these questions, the nurse needs to gain specific information related to the pregnancy, including:

- Foods that are preferred during pregnancy, which may provide information about cultural and environmental dietary factors
- Special diets, which will assist the nurse in planning for education or interventions for risk factors associated with dietary practices
- Cravings or aversions to specific foods

Figure 10-4 Nutritional counseling is an important component of prenatal care.

IMPORTANT NUTRITIONAL ELEMENTS

Many elements combine to facilitate a healthy pregnancy. Often pregnant women are told to eat as much as they want since “they are eating for two.” However, this is not necessarily accurate advice. Practitioners must evaluate the amount as well as the nutritional value of the food consumed. Calories are an important consideration when planning the patient’s daily food intake. Other essential nutritional elements are protein, water, iron, folic acid, and calcium. Maternal dietary practices that may exert a negative influence on the pregnancy must also be addressed.

Calories

A calorie, or unit of heat, signifies the energy expenditure of food. A kilocalorie (kcal) is equivalent to 1000 calories. It is the basic unit of measurement that more accurately defines the amount of energy needed to metabolize food and provide an energy source from this food (Venes, 2009). The body’s energy needs are met by carbohydrate, fat, and protein in the diet.

The Recommended Daily Allowance (RDA) for caloric intake for nonpregnant women ranges from 1200 to 2400 kcal/day, depending on activity level. Women who are sedentary and who exercise less than 30 minutes per day should have a daily intake of 1200 kcal/day. Women who exercise vigorously for at least 30 minutes per day, 5 to 7 days per week, and engage in cardiovascular and strength training activities, should consume 2000 to 2400 kcal/day.

During pregnancy, the RDA for caloric intake increases only slightly, and requires only a 300 kcal/day increase from pre-pregnant needs. Growth during the first and second trimesters occurs primarily in the maternal tissues; during the third trimester, growth occurs mostly in the fetal tissues. An increase in maternal caloric intake is most important during the second and third trimesters. In the first trimester, the average maternal weight gain is 1 to 2.5 kg and thereafter the recommended weight gain for a woman of normal weight is approximately 0.4 kg per week. For overweight women, the recommended weekly weight gain during the second and third trimesters is 0.3 kg; for underweight women, it is 0.5 kg.

Pregnant women should be counseled about healthy ways to incorporate the additional 300 kcal needed in their daily diets. For example, adding an additional serving from each of the major food groups (skim milk, yogurt or cheese; fruits; vegetables; bread, cereal, rice or pasta) meets this need. It is essential for health care providers to stress to patients that the additional kilocalories should not be met through an increased intake of “empty calories” such as soda, candy, or simple carbohydrates.

Protein

Protein is necessary for tissue growth and repair. For pregnant women, protein is important for growth of maternal tissues, including the uterus and the breasts, and for development of fetal tissues and organs. Only a modest increase in protein is required; increasing intake of milk and dairy products by one or two servings per day meets the daily requirement for protein.

Protein is typically found in animal sources, specifically in meat, poultry, and fish. However, other protein sources are also available. Dairy products are a great

source of protein, and include eggs, milk, cheese, and yogurt. For women who do not prefer dairy sources of protein, or who may be lactose intolerant, soy milk and soy cheese are available as protein-rich substitutes. In addition, beans and legumes provide a rich source of protein as well as fiber to the diet and can be substituted for protein servings in many meals. Peanut butter is another source rich in protein, but potentially high in fat. Beans and legumes are combined protein sources that provide carbohydrates with protein to supply the essential amino acids that may be missing when insufficient protein from animal sources is consumed.

A word of caution should be provided by health care providers to pregnant women with regard to microbial foodborne illness (USDHHS, 2005). Raw, or unpasteurized, milk, as well as partially cooked eggs and foods containing raw or partially cooked eggs should be avoided. Deli meats, luncheon meats, and frankfurters should be heated before consumption. In addition, raw shellfish and fish high in mercury, including shark, swordfish, tilefish, and king mackerel should be avoided. Fresh or frozen tuna, red snapper, and orange roughy contain moderate amounts of mercury and women who are pregnant or planning to become pregnant should limit their intake of these products to 12 ounces per week.

Water

Water is necessary for all body tissues and all body system functions. It is essential for the maintenance of life, and must be consumed in sufficient quantity to sustain homeostasis. All persons should consume six to eight (8-oz.) glasses of fluid daily; however, pregnant women should have an intake of eight to ten (8-oz.) glasses of fluid per day. The increased amount needed during pregnancy is necessary to meet the changing physiology of the maternal cardiovascular system and to maintain adequate blood flow to the fetus.

During pregnancy, blood volume increases about 1500 mL, which represents a 40% to 50% increase from the pre-pregnancy blood volume. The increase in maternal blood volume occurs for three primary reasons: to meet the needs of the hypertrophied vascular system of the enlarged uterus, to adequately hydrate maternal and fetal tissues, and to provide a fluid reserve for blood loss during childbirth. In addition, adequate blood flow to the fetus is necessary for oxygenation of body tissues and maintenance of a normal acid–base balance.

Water intake can be in the form of many different types of fluids, including fruit juice and vegetable juice. However, at least four to six glasses of the fluid consumed each day should be water. Patients should be cautioned to consume certain beverages, such as diet sodas (high in sodium and contain artificial sweeteners) and caffeinated drinks (promote diuresis) in moderation. Alcohol should be avoided entirely throughout the pregnancy, as no safe amount has been determined.

Minerals and Vitamins

Women who eat a balanced diet that includes recommended servings and serving sizes may meet the recommended nutritional needs during pregnancy without vitamin supplementation. However, the need for an increased intake of specific nutrients must be taken into consideration as the pregnant woman plans her diet. Specifically, the daily intake

of calcium, iron, and folic acid must be adequate to meet the maternal–fetal needs for adequate growth and development.

CALCIUM AND VITAMIN D. The RDA for calcium is 1000 mg/day in pregnant and pre-pregnant women. Calcium requirements are increased in pregnant adolescents, who need an intake of 1300 mg/day. Without supplementation, most women fail to consume adequate amounts of dietary calcium. Calcium is essential for maintaining bone and tooth mineralization and calcification. During pregnancy, calcium must be available to the fetus for the growth and development of the skeleton and teeth.

Dairy products, especially milk and milk products, constitute the best nutritional sources of calcium. Three daily servings of dairy products are recommended for women; one to two additional daily servings of milk are recommended during pregnancy (USDHHS, 2005). Other rich sources of calcium include legumes, dark green leafy vegetables, dried fruits, and nuts.

Optimizing Outcomes— Teaching patients to avoid bone meal supplements

Bone meal, sometimes used as a calcium source, should be avoided during pregnancy. This supplement is frequently contaminated with lead, a toxin that readily crosses the placenta and can result in high levels in the fetus.

Vitamin D is important in the absorption and metabolism of calcium. Milk and ready-to-eat cereals constitute the major food sources of vitamin D, which is also produced in the skin by the action of sunlight. Women who do not include milk in their diets should be taught about other vitamin D sources such as cereals, egg yolks, liver, and seafood. Also, since the use of sunscreens with a recommended SPF rating of 15 reduces the skin vitamin D production by up to 99% (Scanlon, 2001), all women should be taught about the need for vitamin D-fortified foods or supplements.

Ethnocultural Considerations— Vitamin D deficiency

African Americans and other women with dark skin are at the greatest risk for vitamin D deficiency. Women who habitually cover most of their skin with clothing and those who live in northern latitudes with limited exposure to sunlight are also more likely to be deficient in vitamin D.

IRON AND VITAMIN C. As blood volume increases during pregnancy, the number of circulating red blood cells also increases. Maternal iron intake must be increased to maintain the oxygen-carrying capacity of the blood and to provide an adequate number of red blood cells. Fetal iron needs are increased during the last trimester. At this time, iron is stored in the immature liver for use during the first 4 months of life while the liver matures and liver enzymes are being produced. The newborn uses the stored iron to compensate for insufficient amounts of iron in the breast milk and in non-iron-fortified infant formula.

The iron RDA for pre-pregnant women is 18 mg/day, and for pregnant women, this amount increases to 30 mg/day, starting by 12 weeks of gestation (Institute of Medicine,

1992). Iron can be found in a variety of food sources. Many individuals may not be aware that adequate amounts of iron are found in fortified ready-to-eat cereals, white beans, lentils, spinach, kidney beans, lima beans, soybeans, shrimp, and prune juice. Red meats, including beef, duck, and lamb, contain moderate amounts of iron as well. Some of the best food sources for iron include oysters, organ meats (liver, giblets), and fortified instant cooked cereals. Interestingly, canned, drained clams provide the highest amount of iron per serving, with 23.8 mg of iron in each 3-ounce serving.

While most other necessary nutrients can be met through a balanced diet, it is almost impossible to meet the maternal daily requirements for iron without a dietary supplement. Consideration must be given, however, to the gastrointestinal side effects of supplemental iron, which include constipation, black tarry stools, nausea, and abdominal cramping. These side effects may exacerbate other pregnancy-related gastrointestinal discomforts. Daily iron supplementation is often initiated at around 12 weeks of gestation in order to avoid compounding the nausea commonly prevalent during the first trimester. Adequate water intake helps to decrease constipation, and patients may take the iron at bedtime if abdominal discomfort is experienced when taking iron between meals.

Nursing Insight— When teaching about iron supplements

Nurses can teach patients about substances known to decrease the absorption of iron. Women should be taught to avoid consuming bran, tea, coffee, milk, oxalates (found in Swiss chard and spinach), and egg yolk at the same time as they take the iron supplement. Also, iron is best absorbed when taken between meals with a beverage other than tea, coffee, or milk.

medication: Ferrous Sulfate

Ferrous sulfate (**fer-us sul-fate**)

Pregnancy Category B

Indications: Prevention/treatment of iron-deficiency anemia

Actions: An essential mineral found in hemoglobin, myoglobin, and many enzymes. Prevents iron deficiency.

Therapeutic Effects: Prevents/treats iron deficiency

Pharmacokinetics

ABSORPTION: Therapeutically administered PO iron may be 60% absorbed; absorption is an active and passive transport process.

CONTRAINDICATIONS AND PRECAUTIONS: Use cautiously in peptic ulcer, ulcerative colitis; indiscriminate chronic use may lead to iron overload.

Adverse Reactions and Side Effects: Constipation, dark stools, diarrhea, epigastric pain, gastrointestinal bleeding

Route and Dosage (mg elemental iron): 100–200 mg/day (2–3 mg/kg per day) in three divided doses

Nursing Implications:

1. Assess nutritional status and dietary history to determine possible cause of anemia and need for patient teaching.
2. Assess bowel function for constipation or diarrhea; notify care provider and use appropriate nursing measures if these symptoms occur.

Data from Deglin, J.H., & Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

Vitamin C (ascorbic acid), important in tissue formation, also enhances the absorption of iron. Women who take iron supplements should consume foods or beverages that contain vitamin C. Food sources rich in vitamin C include red and green sweet peppers, oranges, kiwi fruit, grapefruit, strawberries, Brussels sprouts, cantaloupe, broccoli, sweet potatoes, tomato juice, cauliflower, pineapple, and kale. Most pregnant women are able to meet the recommended daily allowance (80 to 85 mg) by including at least one daily serving of citrus fruit or juice or vitamin C-rich food source, although women who smoke need more.

Inadequate iron intake can lead to anemia, a decrease in the oxygen-carrying capacity of the blood. Physiological anemia, common during pregnancy, occurs when the plasma volume increases more than the red blood cell mass, producing a modest decrease in the hemoglobin concentration and hematocrit. True anemia, or iron-deficiency anemia, occurs when the hemoglobin level drops below 10 g/dL. The blood's decreased oxygen-carrying capacity causes a reduction in oxygen transport to the developing fetus. Decreased fetal oxygen transport has been associated with intrauterine growth restriction (IUGR) and preterm birth.

Ethnocultural Considerations—Anemia during pregnancy

In the United States, maternal anemia occurs most commonly among adolescents, African American women, and women of lower socioeconomic status (Siega-Riz & Savitz, 2001; Swensen, Harnack, & Ross, 2001).

In recent years, there has been some controversy surrounding the value of iron supplementation during pregnancy (Haram, Nilsen, & Schall, 2001; Mahomed, 2002; Scholl & Reilly, 2000). Although iron supplementation enhances maternal hematological values, its role in improving pregnancy outcomes is unclear. However, maternal iron supplementation is believed to improve fetal iron stores and reduce the risk of anemia in the infant during the first year of life (Haram et al., 2001). Furthermore, women who have iron-deficiency anemia during the early months of pregnancy are at an increased risk for preterm birth (Scholl, 2005).

FOLIC ACID Vitamin B₉, or folic acid (folate), is a water-soluble vitamin that is closely related to iron. Working with vitamin B₁₂, folic acid helps to regulate red blood cell development and facilitates the oxygen-carrying capacity of the blood. Folic acid is essential in the production of DNA and RNA, and helps to maintain normal brain function and to stabilize mental and emotional health. Folic acid also works with vitamins B₆ and B₁₂ to control blood levels of homocysteine, an amino acid that, in elevated amounts, has been linked to heart disease, depression, and Alzheimer's disease.

Increased estrogen production during pregnancy alters the absorption and metabolism of folic acid, producing an increased maternal susceptibility for folic acid deficiency. Folic acid deficiency is primarily responsible for the development of neural tube defects, including spina bifida, cleft lip and palate, and anencephaly. The neural tube is the embryonic structure that divides during embryo-fetal development to form the CNS, including the spinal cord

and the brain. (See Chapter 7 for further discussion.) The folic acid RDA for nonpregnant women is 400 mcg/day. During pregnancy, a minimum of 800 mcg/day of folic acid is recommended, and this amount is usually provided through supplementation. Childbearing aged women who have previously given birth to an infant with a neural tube defect or those who have a positive family history of neural tube defects are encouraged to consume 1 to 4 mg of folic acid each day (ACOG, 2003a; Veterans Health Administration, 2002).

The neural tube develops during the first 4 weeks after conception. During these early developmental weeks, the majority of women do not yet know that they have conceived. Because of the strong connection between folic acid deficiency and the subsequent development of neural tube defects, all women of childbearing age should take a folic acid supplement of at least 400 mcg/day. Research has indicated that an adequate intake of folic acid during the periconceptional period can reduce the incidence of neural tube defects by up to 50% (Krishnaswamy & Madhavan Nair, 2001; Lewis, Van Dyke, Stumbo, & Berg, 1998). Findings from studies also show an association between folic acid deficiency, elevated homocysteine, and the development of Down syndrome and childhood leukemia (Thompson, Gerald, Willoughby, & Armstrong, 2001).

Foods that are rich in folic acid include dark leafy greens, asparagus, Brussels sprouts, soybeans, liver, root vegetables, beans, and orange juice. Since 1998, all enriched grain products produced in the United States contain folic acid (Lewis et al., 1998), and this nutritional supplementation has decreased the incidence of neural tube defects by 19%. Current recommendations include consuming folic acid with vitamin C to enhance the absorption of iron and folic acid.

Now Can You—Discuss aspects of good nutrition during pregnancy?

1. Identify two protein sources for women who wish to avoid dairy products?
2. Identify three calcium sources for women who wish to avoid dairy products?
3. Explain why adequate intake of vitamin C and folic acid are important during pregnancy?

WEIGHT GAIN DURING PREGNANCY

Weight gain is expected during pregnancy and results from a combination of maternal physiological changes and fetal growth. During early pregnancy, maternal weight gain is related to an increased blood volume, necessary to supply the enlarging uterus and support fetal growth and development. Dilation of the renal pelvis and ureters from increased blood flow adds volume to the bladder and results in an increased production of urine. Essential nutrients provided through the maternal blood supply enable fetal growth and development. As the pregnancy progresses, enlargement of the placenta and fetal body add to the woman's increase in weight. By term, maternal extracellular fluid, blood, uterine tissue, and breast tissue comprise 35% of the gestational weight gain; the maternal reserves comprise 27%; fetal tissue comprises 27%; and placental fluid comprises 11% of the total maternal weight gain (King, 2006).

Factors Affecting Weight Gain

In addition to maternal–fetal physiological factors, social influences are also important predictors of gestational weight gain (Stotland, 2006). Social factors related to an insufficient maternal weight gain may include an inability to purchase food, inadequate dairy intake, unplanned pregnancy, intimate partner violence, anorexia nervosa, shortened time period between pregnancies, and lack of prenatal care. Factors that may influence an excessive maternal weight gain during pregnancy include inadequate or inconsistent physical activity, a high carbohydrate or fat intake, excessive consumption of sweets, and lack of prenatal care.

An adverse outcome may result when the woman gains too much or too little weight during her pregnancy. Health care providers need to assess the patient's weight during the first prenatal visit and monitor the weight gain closely throughout the pregnancy. The amount of weight that is gained during the gestational period results from a combination of influences, including biological and social factors. Biological factors include genetic alleles that affect phenotypes responsible for regulating energy and fat metabolism. These, in turn, affect maternal weight and fat gain during pregnancy. High levels of insulin and leptin (a protein hormone that regulates energy metabolism and appetite) during the first trimester are also associated with higher maternal weight and fat gain during pregnancy (Stotland, 2006).

Women who gain too much weight during pregnancy are at an increased risk for gestational diabetes. This complication places the infant at risk for macrosomia (large body size), congenital anomalies, birth trauma, perinatal asphyxia, respiratory distress syndrome, hypoglycemia, hypocalcemia, cardiomyopathy, hyperbilirubinemia, and polycythemia. Gestational diabetes also increases the risk for maternal **preclampsia**. Preeclampsia is a condition associated with a decreased blood supply to the maternal organs and to the developing fetus and may result in preterm birth, premature rupture of membranes, maternal organ damage, thrombocytopenia, intrauterine growth restriction, and an altered acid–base balance in the fetus (Mayo Foundation for Medical Education and Research, 2005). (See Chapter 11 for further discussion.)

Management of Weight During Pregnancy

Classification of weight is often based on **body mass index (BMI)**, which is a method of evaluating the appropriateness of weight for height. The BMI is calculated using the formula:

$$\text{BMI} = \frac{\text{Weight}}{\text{Height}^2}$$

where the weight is recorded in kilograms and the height is in meters. For example, the calculated BMI for a woman who weighed 52 kg before pregnancy and is 1.58 m tall is:

$$\text{BMI} = \frac{52}{1.58^2} = 20.8$$

Persons with a BMI less than 18.5 are underweight; those with a BMI between 25 and 29.9 are overweight. Persons with a BMI between 30 and 34.9 are classified at Level 1 obesity; those with a BMI between 35 and 39.9 are classified at Level 2 obesity. Extreme obesity, or Level 3 obesity, includes persons with a BMI of 40 or above (Cogswell & Dietz, 2006). Given the increase in obesity in the United

States, one of the *Healthy People 2010* goals (USDHHS, 2000) is to increase the number of women who attain a recommended weight gain during their pregnancies, in consultation with their health care provider (Table 10-2).

There are also recommendations for specific populations of pregnant women. Pregnant adolescents and women of color should attempt to gain weight at the upper end of the appropriate range for their pre-pregnant BMI. Women of short stature (less than 62 inches [1.6 m] in height) should attempt to gain weight at the lower end of the appropriate range for the pre-pregnant BMI. Women pregnant with twins or triplets should gain a total of 35 to 45 lbs. (16 to 20.5 kg), primarily during the second and third trimesters.

Ideally, weight management begins before the pregnancy. At the preconception visit, women should be screened for height and weight, with the BMI calculated as a beginning point for determining an appropriate weight gain during pregnancy (Institute for Clinical Systems Improvement, 2005). The BMI and weight are then monitored at each prenatal visit. Throughout the pregnancy, counseling, educational interventions, and prophylaxis are provided (Table 10-3). Since excess weight gain during early pregnancy is associated with an increased incidence of gestational diabetes, new recommendations indicate that complications can be decreased if screening for gestational diabetes takes place during the first trimester (Riley, 2006).

PLANNING DAILY FOOD INTAKE

While planning daily food intake is based on individual preferences, consideration must be given to ensure that adequate nutrients are provided without an excessive increase in caloric intake. New guidelines indicate strategies for daily food consumption (USDHHS, 2005). The primary recommendations include the following:

- Including a variety of nutrient-dense foods and fluids while limiting saturated and trans fats, cholesterol, excessive sugar, salt, and alcohol
- Developing a balanced daily eating pattern, using the USDA Food Guide or the DASH Eating Plan (see below).

Specific recommendations for women of childbearing age and women who are pregnant incorporate the following strategies:

- Eating iron-rich foods or iron-fortified foods
- Including vitamin C to enhance the absorption of iron
- Including folic acid through consumption of fortified foods or supplemental folic acid

Table 10-2 Recommended Total Weight Gain During Pregnancy for a Single Birth

Pre-Pregnancy BMI	Recommended Total Weight Gain
Underweight (<19.8)	28–40 lbs.
Normal weight (19.8–26)	25–35 lbs.
Overweight (>26–29)	15–20 lbs.
Obese (>29)	15+ lbs.

From the National Heart, Lung and Blood Institute (2006). Body mass index. Retrieved from www.nhlbi.nih.gov/guidelines/bmi_tbl.htm.

The USDA Food Guide visualized by the new Food Pyramid is based on individual factors, including age, gender, and activity level. No longer does “one size fit all.” The new Food Pyramid is based on the guiding principles of overall health, up-to-date research, total diet, usefulness, realism, flexibility, practicality, and evolution. Using the name “MyPyramid” the Guide focuses the patient on developing an individual approach to daily dietary planning (see Fig. 4-1). The pyramid is color-coded to provide a visual view of the types and amounts of food that should be eaten. The bands are wide on the bottom and narrow on the top, indicating what nutrient-dense foods need to be consumed. The colors indicate the following:

- Orange: Grain group—make one half of the grain selections whole grains
- Green: Vegetable group—vary vegetables, and include green, red, and yellow vegetables
- Red: Fruit group—focus on fruits of various types
- Blue: Milk group—consume calcium-rich foods
- Purple: Meat and bean group—consume lean protein
- Yellow: Oils—not considered a food group, but essential as a source of essential fatty acids and vitamin E

The DASH (Dietary Approaches to Stop Hypertension) Eating Plan resulted from a study designed to investigate whether the typical American diet affected blood pressure (USDHHS, 2006). The diet plan includes the daily consumption of whole grain products, fish, poultry, and nuts. There is also a focus on reducing lean red meat, sweets, and added sugar found in foods and beverages. The DASH Eating Plan encourages an increased intake of potassium, magnesium, calcium, protein, and fiber. Table 10-4 compares the daily servings and serving sizes between the USDA Food Guide and the DASH Eating Plan.

 **Now Can You— Plan a Daily Menu for a Woman Who Is Pregnant?**

1. Identify proteins that meet pregnancy needs?
2. Suggest foods to increase daily intake of potassium, magnesium, calcium, protein, and fiber?
3. Describe foods that should be avoided by women who are pregnant?

case study Excessive Weight Gain During Pregnancy

Tamara, a 24-year-old primigravida at 26 weeks’ gestation, has presented for a routine second-trimester prenatal visit. During the interview with the nurse, Tamara voices no complaints. Her vital signs and laboratory data are assessed and all are within normal limits. However, her weight today is 155 lbs. (70.5 kg), which represents a 30-lb. (13.6 kg) weight gain from her pre-pregnancy weight. Tamara has no preexisting health conditions. She is married and lives in a mobile home. She works part time at a local fast food restaurant and readily admits that she enjoys eating the food served there.

Critical Thinking Questions

1. What are the major health concerns regarding Tamara at this time?
 2. What patient education should the nurse provide for Tamara?
 3. What additional care should be provided for Tamara?
- ◆ See Suggested Answers to Case Studies in the text on the Electronic Study Guide or DavisPlus.

FACTORS AFFECTING NUTRITION DURING PREGNANCY

Several additional factors affect nutrition during pregnancy, and may lead to potentially adverse effects. These factors include eating disorders and certain cultural variations.

Eating Disorders

PICA. **Pica**, the consumption of non-nutritive substances or food, is a common eating disorder that can affect pregnancy. Substances that are most often ingested include clay, dirt, cornstarch, and ice (Fig. 10-5). Some individuals engage in poly-pica, the practice of consuming more than one of the non-nutritive substances. Pica occurs with greater frequency in developmentally disabled persons. There is also a cultural link that is considered nonpathological and is seen more commonly in African Americans and persons of mid-Eastern lineage (Mills, 2007).

Causes of pica are believed to include nutritional deficiencies, cultural and familial factors, stress, low socioeconomic status, and biochemical disorders. Specific nutritional deficiencies associated with pica include deficiencies in iron, calcium zinc, thiamine, niacin, vitamin C, and vitamin D. The consumption of clay and starch is most commonly seen in southern, rural, African American communities, and it is believed that this practice, especially the practice of eating starch, was first initiated to alleviate the discomfort of nausea in early pregnancy.

Treatment of pica focuses on the diagnosis and treatment of underlying nutritional deficiencies. The practice usually subsides after the birth of the baby.

Ethnocultural Considerations— Consuming non-nutritive substances

Health care providers need to have an understanding of the cultural and religious factors associated with pica. In some cultures, non-nutritive food substances are thought to bring health or have positive spiritual effects for those who consume them. Some cultures believe that the consumption of specific non-nutritive substances plays a role in enhancing fertility or promoting luck within the family. The health care provider's knowledge and understanding about pica can provide opportunities for assessing complications in patients, providing education to reduce the behavior when harmful, or discussing alternatives for meeting the patient's needs.

ANOREXIA NERVOSA AND BULIMIA NERVOSA. Anorexia nervosa and bulimia nervosa are conditions characterized by a distorted body image. Both involve an intense fear of becoming obese and can have a major impact on the person's physical and psychological well-being. Patients with **anorexia nervosa** lose weight either by excessive dieting or by purging themselves of calories they have ingested. Patients with **bulimia nervosa** engage in recurrent episodes of binge eating, self-induced vomiting and diarrhea, excessive exercise, strict dieting, or fasting and display an exaggerated concern about body shape and weight (Venes, 2009).

Both of these eating disorders pose potentially harmful effects on the woman and the developing fetus, as nutrients are either not consumed or are quickly eliminated

Table 10-4 Comparison of USDA Food Guide and DASH Eating Plan

Food Groups and Subgroups	USDA Food Guide Amount	DASH Eating Plan Amount
Fruit Group	2 cups (4 servings)	2–2.5 cups (4–5 servings)
Vegetable Group	2.5 cups (5 servings)	2–2.5 cups (4–5 servings)
Dark green vegetables	3 cups/week	
Orange vegetables	2 cups/week	
Legumes	3 cups/week	
Starchy vegetables	3 cups/week	
Other vegetables	6.5 cups/week	
Grain Group	6 ounce-equivalents	7–8 ounce-equivalents (7–8 servings)
Whole grains	3 ounce-equivalents	
Other grains	3 ounce-equivalents	
Meat and Beans Group	5.5 ounce-equivalents	6 ounces or less of meat, poultry, fish 4–5 servings/week of nuts, seeds, and dry beans
Milk Group	3 cups	2–3 cups
Oils	27 grams (6 tsp)	8–12 grams (2–3 tsp)

Source: U.S. Department of Agriculture. Dietary Guidelines for Americans 2005: Sample USDA Food Guide and the DASH Eating Plan at the 2,000-Calorie Level.

Figure 10-5 Common sources of pica.

from the body. The health care practitioner needs to address the nutritional history of patients with these disorders and work closely with them and other appropriate resources to achieve a healthy pregnancy. Prenatal care should center on a team approach that includes nutritional counseling, psychological counseling, stress management and active participation in support groups for individuals with eating disorders.

Cultural Factors

Health care providers need to identify and address special cultural considerations in pregnant women from various ethnic backgrounds. The practitioner must possess an understanding of different dietary habits as well as knowledge of preparation and cooking methods and the basic ingredients commonly used in cooking.

For many cultures and religions, food items have a symbolic or special meaning, especially during pregnancy. Persons from different backgrounds need to be encouraged to continue their practices as long as there is adequate nutrition for the patient and her fetus. Food cravings during pregnancy are considered normal by most cultures although the specific foods craved are culturally influenced. In most cultures, women crave nutritionally acceptable foods. As the woman and her family become more integrated into the dominant culture, cultural influences on food usually lessen.

Vegetarian Diets

Most vegetarian diets include vegetables, fruits, legumes, nuts, seeds, and grains. However, there are many variations. For example, semivegetarian diets include fish, poultry, eggs, and dairy products but no beef or pork, and ovo-lacto-vegetarians consume plant and dairy products. Pregnant women who adhere to these diets may consume inadequate amounts of iron and zinc. Since strict vegetarians (vegans) consume only plant products, their diets are deficient in vitamin B₁₂, found only in foods of animal origin. Pregnant women who are strict vegetarians should be counseled to regularly consume vitamin B₁₂-fortified foods such as soy milk or to take a vitamin B₁₂ supplement. Other essential elements that may be deficient in women on this diet include iron, calcium, zinc, vitamin B₆,

calories, and protein. Nutritional counseling, along with ongoing assessment of maternal weight gain and laboratory testing for evidence of anemia, are important strategies in ensuring optimal maternal–fetal well-being.

Nursing Insight— Teaching about vitamin B₁₂ deficiency

When counseling patients who are vegetarians, nurses should educate them about vitamin B₁₂ deficiency. Vitamin B₁₂ deficiency is associated with maternal problems that include megaloblastic anemia, glossitis and neurological deficits. Infants born to mothers with vitamin B₁₂ deficiency are also more likely to have megaloblastic anemia and to exhibit neurodevelopmental delays.

Exercise, Work, and Rest During Pregnancy

The demands of daily life can create significant stressors during pregnancy as well as opportunities for incorporating facets of health promotion into a woman's life. Balancing these demands requires an understanding of the physical and emotional changes that occur during pregnancy and developing strategies to relieve the stress that may result from these changes. Activity and exercise benefit both the mother and her fetus, but consideration must be given to the current level of activity and precautions that are required as a result of the pregnancy. Work demands often create additional stress during a woman's pregnancy, requiring decisions of employment versus unemployment and maternity leave. For women not employed outside of the home, responsibilities of caring for the home and family must also be balanced. Rest becomes an important component of managing a healthy pregnancy, and patients need to understand how fatigue will impact their daily life and how to manage this fatigue throughout the pregnancy.

EXERCISE AND TRAVEL

Exercise can provide women who are pregnant with many benefits, whether they are just beginning to exercise to facilitate a healthy pregnancy or whether they are already active in an exercise program. The exercises practiced during pregnancy should focus on strengthening muscles without rigorous aerobic activity that may cause complications. Muscle strengthening will benefit the woman as she copes with the physical changes of pregnancy, including weight gain and postural changes, and will decrease the chances of ligament and joint injury. Pregnant women gain many additional benefits from exercise such as an increased energy level, improved posture, relief from back pain, enhanced circulation, increased endurance, decreased muscle tension, increased feelings of well-being, and strengthened muscles to prepare for labor and birth (Fig. 10-6).

When traveling for long distances, the pregnant woman should plan periods of activity combined with rest. While sitting, the woman can engage in slow, deep breathing,

Figure 10-6 Exercise during pregnancy has many benefits and enhances the woman's sense of well-being.

make circling motions with her feet and practice alternately contracting and relaxing different muscle groups. Automobile restraints that consist of a combination lap belt and shoulder harness should always be used. The shoulder harness is placed above the gravid uterus and below the woman's neck to avoid irritation. The woman should assume an upright position and ensure the headrest is properly aligned to avoid a whiplash injury (Fig. 10-7). Airline travel generally does not pose any maternal–fetal risks. The metal detectors used at security checkpoints are not harmful to the fetus. Since the airline cabin humidity is typically maintained at a low level, the nurse should advise the pregnant woman to drink plenty of water to remain hydrated throughout the flight. Also, taking brief walks around the cabin during each hour of travel helps to minimize the risk of superficial and deep vein thrombophlebitis (ACOG, 2001).

Now Can You— Define pica and describe the benefits of exercise during pregnancy?

1. Define the term pica and provide two examples of pica?
2. Name two benefits of muscle strengthening exercises during pregnancy?
3. Name four benefits of any physical exercise during pregnancy?

Safety Guidelines for Exercise

Although exercise provides significant benefits during pregnancy, women should adhere to some basic safety guidelines when formulating their exercise program. The most important consideration involves monitoring the breathing rate and ensuring that the ability to walk and talk comfortably is maintained during physical activity. Exercise must be stopped when the woman becomes tired, and she must be taught to never exercise to the point of exhaustion. Exercises that can cause any degree of trauma to the abdomen or those that include rigorous bouncing, arching of the back, or bending beyond a 45-degree angle should be avoided. Adequate fluid intake must be maintained before, during, and after exercise in order to prevent dehydration. Activities that require balance and

Figure 10-7 Proper use of the seatbelt and headrest during pregnancy.

coordination should also be avoided, especially during later pregnancy when the center of gravity shifts and the joints and ligaments soften and relax (ACOG, 2002).

Limiting strenuous aerobic exercise and engaging in low-impact aerobics, swimming, and cycling are strategies to ensure protection against increased metabolism and overheating. Increased maternal body temperature can cause reduced oxygen saturation and is associated with the development of fetal neural tube defects during early pregnancy. Decreased oxygen saturation in the maternal circulation directly affects fetal blood flow and oxygenation, and can result in delayed or improper growth and development. Also, as the pregnant woman's body temperature increases, the fetal body temperature increases as well. The fetus is unable to reduce body temperature through perspiration or other means and instead must rely on the mother's body for temperature regulation. Other adverse effects that may result from maternal overheating during exercise include spontaneous abortion, preterm labor, and fetal distress.

Basic Prenatal Exercises

Women who are pregnant can safely engage in several basic prenatal exercises designed to strengthen muscles and increase flexibility. These exercises can be accomplished in as little as 10 minutes each day (Box 10-2).

WORK

Many women who work outside of the home discover rather early in the pregnancy that they must make decisions regarding the continuation of employment, the safety of the workplace, the demands of the work environment, and plans for maternity leave. The majority of employed women continue to work as long as they remain healthy and free of any pregnancy-related complications. Some factors that women need to consider, in consultation

Box 10-2 Basic Prenatal Exercises

Basic prenatal exercises to help generate energy, diminish discomfort, and improve balance and stamina:

- **Arm and upper back stretch:** Raise your arms above your head, keeping the elbows straight, palms facing one another and hold for twenty seconds. Lower your arms to your sides. Bring the backs of your hands together behind your back and stretch.
- **Pelvic tilt:** Lie on your back with your knees slightly bent. Inhale through your nose while tightening your stomach muscles and buttocks. Flatten your back against the floor and tilt your pelvis slightly upward. Slowly exhale through your mouth while counting to five. Relax.
- **Sit-ups:** Lie on your back with your knees slightly bent. Inhale through your nose. While breathing out slowly through pursed lips, raise your head with your hands placed behind your head. Tuck your chin toward your chest and slightly lift your shoulders off the floor.
- **Kegels:** Before beginning this exercise for the first time, isolate the pubococcygeal (PC) muscle, which is the muscle used to start and stop the flow of urine. Practice stopping the flow of urine a few times; do not continue to do this as this may lead to a urinary tract infection. If you have difficulty isolating the muscle in this fashion, insert a clean finger into the vaginal opening and squeeze. This is the muscle that will tighten as the exercise is done properly. Kegel exercises will help to support the growing baby by strengthening the pelvic floor, assist during the birth process, decrease urinary problems during postpartum, and help to prevent hemorrhoids.
 - Squeeze the PC muscle for five seconds, then relax for five seconds. Repeat for a total of ten repetitions each day.
 - Squeeze and release the PC muscle as rapidly as possible for a total of ten times.
 - Increase this exercise up to 100 repetitions each day.
- **Squatting:** Move to a squatting position, with the knees located directly over the toes. Keeping your heels flat on the floor, stretch the back of the thighs. Hold for 20 to 30 seconds. Increase time to 60 to 90 seconds. Remember to keep your head and arms relaxed during this exercise.
- **Calf stretch:** Lean against a wall or flat surface with your hands against the surface. Move one leg behind you, keeping your heel flat on the floor. Lean into the wall to stretch the calf muscles. Hold for 20 to 30 seconds. Repeat with the other leg. This exercise will help to reduce leg cramps experienced during pregnancy.

with the health care provider, include general health and well-being, the overall progression of the pregnancy, present age, prior pregnancy complications, the type of work performed, the number of hours worked, and the environmental and safety risk factors associated with the work.

Evaluation of Work and Its Impact on the Pregnancy

The pregnant woman may be advised to reduce the number of hours worked if the job requires heavy lifting, prolonged standing, extensive walking, or physical exertion. When the nature of the work is physically demanding, safety concerns may require that she stop working altogether. The potential for maternal exposure to toxic substances such as chemotherapeutic agents, lead, and ionizing radiation (found in laboratories and health care facilities) or heavy machinery and other hazardous equipment should prompt reassignment to a different work

area. If reassignment is not possible, the woman may need to stop working until the pregnancy has been completed. Women who are currently experiencing pregnancy complications and those who have a history of pregnancy complications or other preexisting health disorders may be required to reduce their hours or stop working as well. Examples of problems and pregnancy complications that may necessitate a change in work hours include diabetes, kidney disease, heart disease, back problems, hypertension, and a history of spontaneous abortion or preterm labor.

Planning for Maternity Leave

Maternity leave provides the woman with time off from work during the pregnancy and after the birth of the child. While some companies may allow up to 6 weeks of paid time off, other companies may require that their pregnant employees use a combination of short-term disability, vacation time, sick time, and unpaid leave time. Health care providers can help women plan how much time they may need or wish to be away from work, and can provide them with options that may be available to them. All women who are employed outside of the home should be encouraged to meet with their employers to discuss the options that are provided by the workplace and to determine a satisfactory plan for their leave.

The Family and Medical Leave Act of 1993 (U.S. Department of Labor, 1995) guarantees most women, as well as men, 12 weeks of unpaid family leave following the birth or adoption of a child. By law, the employer is required to allow the family member to return to his or her job or a similar job with the same salary and benefits, without a reduction in seniority. Family members qualify for this benefit if they work for the federal, state, or local government or if the company has 50 or more employees working within 75 miles of the workplace. In addition, the family member must have worked for the employer at least 12 months or for at least 1250 hours in the previous year.

REST

Fatigue and tiredness are common symptoms associated with pregnancy. As the pregnancy progresses from one trimester to the next, the woman's level of fatigue changes along with the need for rest. An understanding of the expected alterations in maternal anatomy and physiology empowers the woman to anticipate and make changes in her daily routine to accommodate the necessary rest. Nurses should provide education about the anticipated need for additional rest and suggest strategies for managing fatigue and for promoting rest and relaxation.

Contributors to Fatigue During the First Trimester

During the first trimester, the woman's body begins to undergo changes that will support the developing fetus. One of the major changes is an increase in the production of progesterone, a hormone that causes increased fatigue and feelings of tiredness, especially during the day. The maternal blood volume also begins to increase

and frequently results in physiological anemia. Women with decreased iron stores may develop “true” (iron-deficiency) anemia. As the fetus grows, oxygen requirements increase and cause an increased workload on the woman’s body systems. These changes, along with the emotional stress often associated with adjustment to the news of the pregnancy, combine to produce fatigue. Strategies for coping with pregnancy-related fatigue should routinely be discussed with patients early in the pregnancy.

Contributors to Fatigue During the Second Trimester

During the second trimester the rapid physiological changes that occurred in the first trimester come into balance with the body’s workload demands. Pregnant women experience increased energy and endurance during this time and are able to focus more on planning for the upcoming birth. Some women, however, may continue to experience fatigue that persists into the second trimester. Potential causes of the fatigue include depression, external stressors, and anemia. Other underlying medical causes may also be a factor and should be investigated by the woman’s health care provider.

Contributors to Fatigue During the Third Trimester

The pregnant woman’s level of fatigue increases as the fetus continues to grow and develop. The maternal weight-bearing load associated with the fetus is compounded by a corresponding increase in extracellular fluid and blood volume, maternal reserves, placental mass, and amniotic fluid. The enlarging fetus causes the maternal diaphragm to be upwardly displaced, decreasing lung expansion. Increased bladder pressure from the gravid uterus causes increased voiding, especially at night, when the woman is trying to sleep. Each of these factors plays a role in the overwhelming fatigue common during the third trimester.

Through education, the health care provider can empower the expectant mother throughout the pregnancy to better manage her rest demands and cope with fatigue. Planning and making healthy choices concerning rest enables the woman to feel more relaxed and energetic and better able to cope with and manage this common discomfort of pregnancy.

Now Can You— Discuss work and fatigue during pregnancy?

1. Identify three situations in which women may need to stop working during pregnancy?
2. Name two reasons why fatigue is especially pronounced during the first and third trimesters?
3. Identify three strategies to help women cope with fatigue during pregnancy?

Medications

Medication use during pregnancy must be handled very carefully and the needs of the patient and her fetus should always be considered on an individual basis. Nurses need to be aware that their patients may be taking over-the-counter (OTC) medications and herbal preparations

and often do not readily report this information during the prenatal interview. Thus, the nurse should ask specific questions regarding prescription and OTC medications and the use of any herbal therapies.

SAFE VERSUS TERATOGENIC MEDICATIONS

A **teratogen** is anything that adversely affects the normal cellular development in the embryo or fetus (Venes, 2009). Although some medications are safe, others are known teratogens or the safety of their use during pregnancy has not been demonstrated. The fetus is most vulnerable to the effects of teratogens from the third week of gestation through the third month. However, the risk for fetal developmental anomalies continues to exist throughout the pregnancy. The third trimester is the most vulnerable time for cognitive impairment from a teratogenic insult.

Over-the-counter Medications

Nonprescription medications such as acetaminophen (Tylenol) and guaifenesin (Robitussin) are often taken for minor problems such as headaches, coughs, and colds. It is commonly assumed that a medication that requires no prescription must be safe to take. However, all medications, whether available by prescription or over the counter, have side effects, and many have adverse effects. The nurse needs to counsel women who are planning to become pregnant and those who are already pregnant not to take any medications (prescription or nonprescription) without first consulting with the primary health care provider. The provider will make a determination regarding the safety and necessity of the medication. Additional information (including a physical assessment) may need to be obtained and an alternate medication or therapy may be advised. When possible, all nonprescription drugs should be avoided during preconception and throughout pregnancy.

Herbal and Homeopathic Preparations

One of the most important facts about herbal and homeopathic preparations is that the U.S. Food and Drug Administration (FDA) has not approved these drugs and does not regulate or control them. Further, there are major drawbacks to the use of these substances. There is no regulation that controls product development, the dosages are not consistent between brands, and additives used in their composition may differ in type and amount. Also, since herbal and homeopathic products have not been subjected to rigorous research to determine their efficacy, effectiveness, side effects, therapeutic dosages, and adverse effects, there is no guarantee that the claims made about them are true. Although herbal and homeopathic treatments are considered to be “natural” because they have been developed from plants and other natural sources, many of these products are dangerous and toxic, and may cause effects that have not yet been discovered.

Several herbal products are recognized to be dangerous; others are known to have specific teratogenic effects. These substances need to be completely avoided during the periods of preconception and pregnancy. Nurses should warn patients about the use of these products,

Family Teaching Guidelines... Common Herbs to Avoid During Preconception and Pregnancy

During preconception counseling and pregnancy, nurses should educate couples to avoid the following common herbs:

- ◆ Uterine stimulants that may cause preterm labor
 - Barberry
 - Black cohosh
 - Feverfew
 - Goldenseal
 - Mugwort
 - Pennyroyal leaf
 - Yarrow root
- ◆ Blood thinners and anticoagulants that may cause miscarriage
 - Dong quai
- ◆ Laxatives that may overstimulate digestion and metabolism and cause fluid and electrolyte imbalance
 - Blessed thistle
 - Cascara sagrada
 - Drug aloe
 - Senna
- ◆ Cardiovascular stimulants that may elevate blood pressure or cause abnormal heart rhythms
 - Ephedra
 - Licorice root
- ◆ Others that may damage the fetus during development
 - Gotu kola
 - Juniper berries

provide written information that can be taken home, and reinforce the teaching at each visit.

Prescription Medications

Certain prescription medications may be necessary during preconception and pregnancy. Women who suffer from life-threatening illnesses, such as seizure disorders, heart disease, respiratory disorders, or infections need to continue or initiate treatment in order to maintain their own health and safety. The health care practitioner must be aware of all prescription medications currently being taken in order to evaluate the safety of their continued use. In some instances, dosages can be adjusted or the medications can be replaced with safer medications.

Prenatal vitamins are usually given during preconception or at the beginning of a pregnancy. Prenatal vitamins provide the recommended daily allowance (RDA) for most vitamins and minerals as well as the additional calcium, iron, and folic acid needed during pregnancy.

Certain prescription medications must be avoided completely. Isotretinoin (Accutane), prescribed primarily for the treatment of acne, is associated with spontaneous abortions and congenital anomalies when taken early in pregnancy. Some antimicrobials cause altered fetal growth and development and should be avoided during the later months of gestation. Sulfonamides, for example, are associated with delayed fetal skeletal development while prenatal exposure to tetracycline causes staining of the child's teeth.

Nursing Insight— Teaching childbearing aged women about Accutane

Isotretinoin (Accutane) is an extremely successful medication in the treatment of acne, and research demonstrates a successful remission (of acne) after only one treatment. However, there are significant adverse and teratogenic effects associated with the use of this medication. Isotretinoin is labeled as a pregnancy category X medication. Use during pregnancy may result in spontaneous abortion or stillbirth and there is a 50% chance of fetal anomalies that include physical deformities of the face, ears, heart, and brain and abnormal formation of internal organs (Goodheart, 2006). Women of childbearing age who are considering taking isotretinoin should use a reliable method of contraception for 1 month before treatment, during the entire course of treatment, and for 1 month after the cessation of treatment. Women who are considering pregnancy should not take isotretinoin (Encyclopedia of Genetic Disorders, 2008).

FDA CLASSIFICATION SYSTEM FOR MEDICATIONS USED DURING PREGNANCY

To determine the safety of medication use during pregnancy, the FDA devised a classification system according to known fetal risk, based on research findings. The following list summarizes the categories and associated fetal risk (see Chapter 7):

- Category A: No associated fetal risk; safe to take during pregnancy
- Category B: No associated fetal risk in animals; fetal risk in humans not identified
- Category C: Evidence of adverse effects in animal fetuses; fetal risk in humans not identified
- Category D: Evidence of adverse effects and fetal risk in humans; benefits and risks must be considered before prescribing
- Category X: Evidence of fetal risk and congenital anomalies in humans; risks outweigh the benefits; not prescribed during pregnancy

There are no absolutes when using any prescription or nonprescription drug during pregnancy. Each situation is different and requires individualized decision making that must be a mutual endeavor between the patient and her care provider. Cultural considerations, benefits, risks, and goals of all therapies must be assessed before any decisions are reached. Nurses play an essential role in gathering information for assessment and evaluation and in providing patient education and counseling.

 **Now Can You—** Discuss the use of herbal preparations and prescription medications in pregnancy?

1. Identify two major concerns related to the use of herbal and homeopathic preparations?
2. Name four herbs that should be avoided during pregnancy?
3. Identify two types of prescription medications that should not be used during pregnancy?
4. Discuss what is meant by a Category B medication?

Common Discomforts During Pregnancy

Common discomforts experienced during pregnancy are caused by the major hormonal and anatomical changes that take place in the woman's body. (See Chapters 8 and 9 for further discussion.) As the pregnancy progresses, most patients report at least some of the common discomforts, which are presented in Table 10-5. Anticipatory guidance includes educating women about the normal physiological changes that occur during pregnancy, symptoms that frequently accompany the changes, and strategies for dealing with the discomfort.

NAUSEA

Nausea is often one of the first symptoms of pregnancy experienced. Although commonly known as “morning sickness,” nausea can occur at any time of the day or night. While the exact cause of nausea is unknown, it most probably is related to the increased levels of the pregnancy hormones. Nausea is primarily noted during the first trimester of the pregnancy and usually resolves by 13 to 14 weeks, although it may persist throughout the pregnancy. Nausea during the early weeks of pregnancy is believed to be a reassuring indicator of embryo/fetal development with adequate hormonal support (Youngkin & Davis, 2004). Complaints of nausea should never be dismissed without further assessment to rule out pregnancy-related complications such as hyperemesis gravidarum, multiple gestation, gestational trophoblastic disease, or maternal gastrointestinal or eating disorders. (See Chapter 11 for further discussion.)

Nurses can suggest strategies to help offset the nausea, such as the avoidance of “trigger foods” (foods that cause nausea from sight or smell) and tight clothing that constricts the abdomen. The use of relaxation techniques (e.g., slow, deep breathing, mental imagery) can also help to decrease nausea. Other techniques that are often helpful include consuming plain, dry crackers or sucking on peppermint candy before arising; adhering to small, frequent meals; and remaining in an upright position after eating.

Medication is usually not necessary for the nausea of early pregnancy, although some women have found that taking vitamin B₆ or ginger tablets helps to lessen nausea. These oral supplements can be purchased over-the-counter and should be taken with meals. Acupressure bracelets, often used for the prevention of motion sickness, can also be purchased without a prescription and may be beneficial in reducing nausea during early pregnancy (Varney, Kriebs, & Geger, 2004; Youngkin & Davis, 2004;).

Table 10-5 Common Discomforts During Each Trimester of Pregnancy

Trimester	Common Discomforts
First	Nausea
	Vomiting
	Fatigue
	Urinary frequency
	Nocturia
Second	Dyspepsia
	Gum hyperplasia and bleeding
	Dependent edema
	Leg varicosities
	Hyperventilation and shortness of breath
	Numbness and tingling of fingers
	Supine hypotensive syndrome
	Fatigue
Third	Urinary frequency
	Dyspepsia
	Flatulence
	Gum hyperplasia and bleeding
	Leg cramps
	Dependent edema
	Leg varicosities
	Dyspareunia
	Nocturia
	Round ligament pain
All Trimesters	Supine hypotensive syndrome
	Ptyalism
	Nasal congestion
	Back pain
	Leukorrhoea
	Constipation
	Insomnia

VOMITING

Vomiting in early pregnancy often accompanies the nausea, although it is important to ascertain that the amount vomited is not excessive. During the assessment, nurses should question patients about vomiting frequency and amount, and their ability to consume and retain foods and liquids. It is important to assess for weight loss, dehydration, urine ketones, blood alkalosis, and hypokalemia, which are clinical findings that may be indicative of a more serious complication known as hyperemesis gravidarum (Youngkin & Davis, 2004). **Hyperemesis**

gravidarum is a pregnancy-related condition characterized by persistent, continuous, severe nausea and vomiting, often accompanied by dry retching (Venes, 2009). (See Chapter 11 for further discussion.)

PTYALISM

Ptyalism, or excessive salivation, can be quite distressing for the pregnant woman, who must frequently wipe her mouth or spit into a cup. Although the cause of ptyalism is unknown, it is most likely related to increased hormone levels. Ptyalism can also be a symptom of hyperemesis gravidarum and, when extreme, may be associated with maternal dehydration. While little can be done to reduce the amount of saliva, it is important to rule out dental abnormalities, upper gastrointestinal problems, and pica. Nurses can counsel patients to consume small, frequent meals; avoid starchy foods; drink plenty of water in small sips; suck on hard candies; and brush their teeth frequently (Youngkin & Davis, 2004).

FATIGUE

Fatigue occurs primarily during the first and third trimesters of pregnancy. In the first trimester, the fatigue is most likely related to physiological and hormonal changes. Psychological concerns may also lead to insomnia. During the third trimester, fatigue is usually related to physical discomforts and an increasing inability to sleep. Nurses can counsel patients to take naps during the day when possible, establish a bedtime “ritual” that includes going to bed at approximately the same time each night, increase daytime exercise, and practice relaxation techniques. If these strategies are not effective or the patient exhibits signs of psychosocial stress or depression, she should be referred for additional evaluation (Youngkin & Davis, 2004).

NASAL CONGESTION

Nasal congestion, a common maternal complaint, is known as rhinitis of pregnancy. Increased levels of estrogen and progesterone cause swelling of the nasal mucus membranes and produce symptoms of excess mucus and congestion. It is important to rule out colds and allergies. The nurse can suggest relief measures such as increasing fluids; taking a hot, steamy shower; using a vaporizer or humidifier; and the occasional administration of nasal saline drops. Decongestants should be avoided during the first trimester.

UPPER AND LOWER BACKACHE

Back pain during pregnancy results from the change in the center of gravity as the uterus enlarges. It is also related to high levels of progesterone, which cause a relaxation and softening of the connecting cartilage and joints. Low backache can be exacerbated by activities that require prolonged standing, walking, bending, or lifting. It is important to rule out other causes of backache, such as kidney stones, pyelonephritis, pancreatitis, ulcers, muscle sprain or strain, and preterm labor. For some women, a referral for physical therapy may be indicated (Varney et al., 2004).

Optimizing Outcomes— Relief of backache during pregnancy

Best outcome: Nurses educate all patients about strategies that may prevent or relieve backache. Women can be taught to wear supportive, low-heeled shoes; use proper body mechanics; perform back strengthening and pelvic rock exercises; take frequent rest periods; sleep on a firm, supportive mattress; and wear a well-fitting, supportive bra. Body massage and warm tub baths may also be helpful.

LEUKORRHEA

High levels of estrogen stimulate vascularity and hypertrophy of the cervical glands, causing an increase in vaginal discharge. The discharge is usually yellow to white in color, thin, and more acidic than normal. It is important to rule out vaginal and sexually transmitted infections, and rupture of membranes. The nurse can counsel the patient to wear cotton underwear, avoid tight-fitting clothing, and follow strict hygiene to prevent infection. If a panty liner or sanitary pad is worn to absorb moisture, it should be changed frequently to prevent dampness and odor.

URINARY FREQUENCY

In early pregnancy, urinary frequency is caused by pressure exerted by the enlarging uterus on the bladder. During the second trimester, bladder pressure lessens once the uterus becomes an abdominal organ. In the third trimester, a number of physiological events cause urinary frequency. The fetal presenting part once again exerts pressure on the bladder. Progesterone relaxes the muscles of the urethra and may lead to incontinence, while an increase in the glomerular filtration rate causes increased urine production. It is important to rule out urinary tract infection, rupture of the membranes, kidney stones, gestational diabetes, and stress urinary incontinence. The nurse can suggest relief measures, including intake of adequate hydration, Kegel exercises, use of panty liners, frequent voiding, and decreasing fluid intake two to three hours before bedtime.

DYSPEPSIA

Dyspepsia, or heartburn, results from reflux of acidic gastric contents into the lower esophagus. Dyspepsia is caused by the progesterone-induced relaxation of the cardiac sphincter and delayed gastric emptying. Due to these changes, stomach contents remain in the stomach for a longer period of time and can reflux into the esophagus. As the pregnancy advances, the enlarging uterus pushes up on the stomach and compresses it, causing a reduced capacity. Making changes in the diet and eating patterns may be helping reduce heartburn although it is unlikely to disappear until after the baby is born.

Nursing Insight— Relief measures for dyspepsia

Nurses can suggest a number of relief measures for dyspepsia, a common complaint during pregnancy. Patients can be taught to consume small, frequent meals to avoid overloading the stomach, maintain good posture, remain upright after

meals and avoid greasy and fatty foods, very cold foods and consuming beverages with meals. Drinking cultured or sweet milk and using over-the-counter antacids may also be helpful (Varney et al., 2004).

FLATULENCE

Flatulence (excessive gas in the stomach and intestines) is caused by decreased gastric motility that results from elevated levels of progesterone during pregnancy. Pressure of the enlarging uterus on the abdominal contents also contributes to the formation of gas. When excessive or particularly disturbing, other causes, such as irritable bowel syndrome or lactose intolerance should be ruled out. Patients can be counseled to avoid gas-forming foods, constipation, gum chewing, consuming large meals, and swallowing air.

CONSTIPATION

Elevated levels of progesterone relax the smooth muscles, causing decreased contractility of the lower gastrointestinal tract and slowed movement of the stool. As the uterus enlarges, the large intestines become compressed, further slowing movement of stool through the intestines. Supplemental iron may also be a contributor to the development of constipation. All patients should be taught about the importance of regular physical exercise and bowel habits, consuming a high-fiber diet with increased liquids, and to avoid straining at defecation and the use of mineral oil and bulk-forming laxatives.

DENTAL PROBLEMS

Elevations in pregnancy hormones cause the gums to become edematous and friable, which can lead to bleeding during brushing. Open lesions and other dental problems, such as caries, can open a direct pathway for pathogens to enter the bloodstream. Meticulous dental care during pregnancy is important to prevent infections and other dental complications. The dentist should be informed of the pregnancy so that an abdominal shield can be used if x-ray films are needed. If treatment is indicated, most local anesthetics can be used safely during pregnancy.

LEG CRAMPS

The actual cause of leg cramps is unknown, although decreased levels of calcium and phosphorus have been implicated. As the uterus enlarges, pressure is exerted on the major blood vessels, causing impaired circulation to the lower extremities. It is important to rule out thrombosed blood vessels, muscular strain, and other injuries to the lower extremities. The patient should be advised to engage in regular exercise and maintain good body mechanics; elevate the legs above the heart several times throughout the day; dorsiflex the foot; and consume a diet that includes adequate amounts of calcium and phosphorus (Varney et al., 2004; Youngkin & Davis, 2004).

DEPENDENT EDEMA

Edema in the lower extremities is caused by relaxation of the blood vessels (an effect of increased progesterone) and the increased pressure placed on the pelvic veins by the

enlarging uterus. Tight, restrictive clothing that inhibits venous return from the lower extremities increases the edema. Once pathological conditions, such as gestational hypertension, renal disease, liver disease, cardiac disease, vascular disorders, trauma, and infection have been ruled out, the nurse can suggest relief measures. These include avoiding constrictive clothing, elevating the legs periodically throughout the day, and assuming a side-lying position when resting.

VARICOSITIES

A positive family history, coupled with the normal physiological changes of pregnancy, predisposes the patient to the development of varicose veins. Physiological changes of pregnancy include vascular relaxation from the effects of progesterone and impaired venous circulation from pressure exerted by the enlarged uterus. Constrictive clothing also increases the risk for varicose veins. Nursing care for patients with varicosities includes regular assessment of lower extremity peripheral pulses and education. Patients should be taught to avoid crossing their legs and the use of constrictive clothing such as knee-high stockings. They should also be encouraged to elevate their legs above the level of the heart at least twice a day. For some women, a maternity girdle may provide relief (Varney et al., 2004; Youngkin & Davis, 2004).

DYSPAREUNIA

Dyspareunia, or painful intercourse, may result from pelvic congestion and impaired circulation caused by the enlarging uterus. Also, as the pregnancy advances, finding a position of comfort for intercourse may become increasingly difficult due to the enlarging abdomen. Concerns that intercourse will harm the fetus may also interfere with sexual enjoyment and increase the likelihood of dyspareunia. Unless a medical condition contraindicates intercourse, the patient and her partner should be reassured that intercourse is safe during pregnancy. Education about sexual intimacy should include suggestions for comfortable positions for intercourse and alternative methods for mutual sexual satisfaction (Varney et al., 2004).

“What to say” — When asked about sexual activity during pregnancy

Couples have many questions regarding sexual activity during pregnancy. These questions relate to the safety of sexual intercourse, potential complications, when to stop having intercourse, and sexual positions that facilitate comfort. It is important for the health care provider to address sexual activity early in the pregnancy in an honest, open manner and to encourage the couple to communicate with each other. The nurse can address the couple's concerns with the following statements:

“It is perfectly safe to continue sexual activity throughout your pregnancy unless your doctor or nurse midwife identifies risk factors that may preclude your activity (e.g., a risk for preterm labor). With no risk factors, sexual activity is safe for you and your baby as long as you continue to practice safe sex behaviors as you would if you were not pregnant. As you gain pregnancy weight, some sexual positions may be less comfortable; for comfort,

you can try woman on top and side-lying positions. A sexual activity to avoid during pregnancy includes oral sex during which water or air is placed in the vagina.”

NOCTURIA

Nocturia, or excessive nighttime urination, is more common during the first and third trimesters. When the woman assumes a recumbent position, the gravid uterus no longer compresses the pelvic vessels, and blood flow to the kidneys is enhanced. This factor, combined with an increased glomerular filtration rate, increases the need to urinate. Although there is no remedy for nocturia, the nurse can teach the patient about the cause of nocturia and advise her that limiting fluids in the few hours before bedtime may be helpful.

INSOMNIA

Insomnia may have a variety of causes, including physical discomfort, nocturia, caffeine, or stress. The nurse can suggest strategies to enhance relaxation and comfort before bedtime. For example, the woman may incorporate sleep-inducing night time rituals such as taking a warm bath, enjoying a warm drink such as milk, engaging in a restful activity like reading, practicing meditation and other forms of relaxation, and arranging the bed covers and pillows in an inviting way that promotes rest.

ROUND LIGAMENT PAIN

The round ligaments support the uterus as it enlarges during pregnancy. These structures attach to the fundus on each side, pass through the inguinal canal, and insert into the upper portion of the labia majora. As the uterus enlarges, the round ligaments stretch and produce a painful sensation in the lower quadrants. Once pathological conditions such as preterm labor, rupture of an ovarian cyst, ectopic pregnancy, appendicitis, gallbladder disease, and peptic ulcer disease have been ruled out, the nurse can educate the patient about the cause of the pain and make suggestions for relief measures. Taking a warm bath, applying heat, supporting the uterus with a pillow when resting, and using a pregnancy girdle may help to diminish the discomfort (Varney et al., 2004; Youngkin & Davis, 2004).

HYPERVENTILATION AND SHORTNESS OF BREATH

Increased metabolic activity during pregnancy increases the amount of carbon dioxide in the maternal respiratory system. Hyperventilation decreases the amount of carbon dioxide and may trigger a feeling of “air hunger.” Patients may also experience shortness of breath related to uterine enlargement and the upward pressure exerted on the diaphragm. Once pathological conditions such as upper respiratory infection, asthma, cardiac problems, and anemia have been ruled out, the nurse should explain the cause of hyperventilation to the patient and suggest that she consciously attempt to regulate her breathing. Other measures that may be helpful include breathing into a paper bag to decrease the symptoms of hyperventilation, maintaining good posture, and stretching the arms above the head (Varney et al., 2004; Youngkin & Davis, 2004).

NUMBNESS AND TINGLING IN THE FINGERS

Numbness and tingling in the fingers may be associated with hyperventilation or from nerve compression in the median and ulnar nerves in the arm. Maintaining good posture, elevating the hands on a pillow while sleeping, or wearing a wrist brace when sleeping may provide symptomatic relief.

SUPINE HYPOTENSIVE SYNDROME

Supine hypotension is caused by pressure of the enlarging uterus on the inferior vena cava while the woman is in a supine position. Vena caval compression impedes venous blood flow, reduces the amount of blood in the heart, and decreases cardiac output, causing dizziness and syncope. Pathological causes of supine hypotension include cardiac or respiratory disorders, anemia, hypoglycemia, dehydration, anxiety, and stress. Once these conditions have been ruled out, the nurse should educate the patient about the causes of supine hypotension and advise the woman to rest on her side and slowly move from a lying to a sitting to a standing position to minimize changes in blood pressure.

Now Can You— Discuss Common Discomforts of Pregnancy?

1. Name four strategies to alleviate nausea during early pregnancy?
2. Identify four pathological causes of backache during pregnancy?
3. Explain how you would counsel couples regarding sexual intercourse during pregnancy?

Recognizing Signs and Symptoms of Danger

Complications can occur at any time during the pregnancy. Nurses need to educate the pregnant woman and her family about danger signs and symptoms, teach them about interventions that can be initiated at home, and provide specific instructions about when to notify the health care provider.

FIRST TRIMESTER

Nausea and Vomiting

During the first trimester, nausea and vomiting are common discomforts. However, when vomiting becomes severe, weight loss and dehydration can occur and place both the woman and her fetus at risk. Severe, persistent vomiting is indicative of hyperemesis gravidarum. Causes of hyperemesis gravidarum include multiple gestation; thyroid disorder; and **hydatidiform mole**, which is the growth of abnormal tissue that results from conception but does not give rise to a viable fetus. Nausea and vomiting are managed with oral fluids, small, frequent meals, and emotional support. Dehydration may require intravenous fluids and hospitalization. (See Chapter 11 for further discussion.)

Abdominal Pain and Vaginal Bleeding

Abdominal cramping and vaginal spotting or bleeding may indicate spontaneous abortion, or miscarriage.

Spontaneous abortion is the termination of pregnancy by natural causes before 20 weeks' gestation. The majority of spontaneous abortions are related to chromosomal defects. Approximately 10% to 20% of clinically recognized pregnancies end in spontaneous abortion (White & Bouvier, 2005). A woman may assume she is having a heavy period when she is actually experiencing a miscarriage. (See Chapter 11 for further discussion.) Treatment includes bedrest and emotional support. If bleeding and/or pain are excessive, the patient should contact her primary health care provider or report to the emergency department.

Infection

Generalized symptoms of infection include chills, fever, malaise, and anorexia. Burning on urination may indicate a urinary tract infection, which is treated with antibiotics. Patient education to prevent a urinary tract infection includes advising the woman to use white, unscented toilet paper; to avoid bubble baths or the addition of "additives" in the bath; to wear underwear with cotton crotches; to drink at least 8 to 12 glasses of liquid each day; and to urinate before going to bed and before and after sexual intercourse. Diarrhea may indicate a gastrointestinal infection, which may be treated with antibiotics if bacterial in origin.

SECOND TRIMESTER

Maternal Complications

Preeclampsia is one of the most common pregnancy complications during the second trimester. It is a pregnancy-specific systemic syndrome that is clinically defined as an increase in blood pressure (140/90) after 20 weeks' gestation accompanied by proteinuria (National High Blood Pressure Education Program Working Group, 2000; Peters & Flack, 2004). Early signs and symptoms of preeclampsia include headache, vision changes, elevated blood pressure, and edema. Patients who experience any of these symptoms should promptly notify their health care provider. Bedrest is the first intervention implemented in an effort to reduce blood pressure and alleviate the myriad of other problems that can be associated with this disorder. (See Chapter 11 for further discussion.)

Premature rupture of the membranes, which is rupture of the membranes before the onset of labor, can also occur during the second trimester. Patients are taught to promptly seek advice from their health care provider if vaginal discharge is present. Although increased vaginal discharge is normal during pregnancy, the provider will determine if the vaginal discharge is normal, is associated with a vaginal infection, or results from the leakage of amniotic fluid. Women who have experienced premature rupture of membranes must be closely monitored for signs of infection. (See Chapter 11 for further discussion.)

The presence of uterine contractions during the second trimester may indicate preterm labor (PTL). **Preterm labor** is defined as regular uterine contractions and cervical dilation before the end of the 36th week of gestation (ACOG, 2003b). All pregnant women are taught the signs and symptoms of preterm labor and instructed to contact their health care provider if the symptoms appear. True

labor must be differentiated from Braxton-Hicks contractions (disorganized tightenings of the uterine muscles as they stretch to prepare for labor) so that appropriate interventions may be initiated. (See Chapters 11 and 12 for further discussion.)

Fetal Complications

During the second trimester the fetus is assessed for well-being. The fundal height measurement should correlate to the weeks of gestation from approximately 22 to 34 weeks of gestation. A decreased fundal height may indicate intrauterine growth restriction, while increased fundal height is suggestive of multiple gestation, fetal macrosomia, or hydramnios. The gestational age is also determined from a variety of sources that include the patient's menstrual history, contraceptive history, pregnancy test results, first documentation of fetal heart sounds, and ultrasonography. (See Chapters 9 and 11 for further discussion.)

A number of potential fetal problems may occur during the second trimester. These include hypoxia from maternal hypertension, irregular or absent heart rate, preterm birth, infection from premature rupture of membranes, and absence of fetal movements after quickening. If the woman experiences an absence of fetal movements, she is instructed to drink two full glasses of water, rest on her left side for 2 hours, and assess for fetal movements once again. If fewer than 10 fetal movements are noted after the liquid intake, the patient must be evaluated by her health care provider. (See Chapter 11 for further discussion.)

THIRD TRIMESTER

Maternal Complications

During the third trimester, the patient may develop the same problems that can occur during the second trimester, such as preeclampsia, premature rupture of the membranes, and preterm labor. Also, gestational diabetes may develop during this time. A Glucose Challenge Test (Glucola screening) is performed between 24 and 28 weeks of gestation and a positive test warrants further screening with a 3-hour oral glucose tolerance test (OGTT). A positive OGTT indicates the presence of gestational diabetes and patient care involves education and a team approach that usually includes the obstetrician, internist, endocrinologist, diabetes educator, neonatologist, dietitian, and nurse. (See Chapter 11 for further discussion.)

Hemorrhagic disorders may also develop during the third trimester. **Placenta previa** is an implantation of the placenta in the lower uterine segment, near or over the internal cervical os. The abnormal location of the placenta can cause painless, bright red vaginal bleeding as the lower uterine segment stretches and thins during the third trimester. Depending on the placental location, the patient may need to adhere to strict bedrest and a cesarean birth may be necessary. **Abruptio placentae**, or placental abruption, is the premature separation of a normally implanted placenta from the uterine wall. An abruption results in hemorrhage between the uterine wall and the placenta, causing abdominal pain and vaginal bleeding. Interventions may include hospitalization, bed rest, Trendelenburg position, intravenous fluids, and delivery. (See Chapter 11 for further discussion.)

Fetal Complications

Leopold maneuvers are used to determine the lie, presentation, and position of the fetus. (See Chapter 9 for further discussion.) To monitor fetal growth, the fundal height is measured and compared to the estimated date of delivery at each prenatal visit during the second and third trimesters. During the third trimester, non-stress tests may be performed to evaluate fetal well-being. (See Chapter 11 for further discussion.) Fetal complications during the third trimester are the same as for the second trimester although hypoxia related to poor placental perfusion may become more of a threat during this time.

Optimizing Outcomes— Fetal activity and well-being

Maternal involvement in activities to monitor fetal well-being is an important component of prenatal care. Beginning in the second trimester, the patient should consistently assess fetal movements. Reassuring findings include a count of at least four movements within 1 hour, during rest after meals.

Best outcome: Fetal well-being is maintained during the third trimester, labor, and birth. The neonate is full term and appropriate for gestational age. Normal physiological transitions in the neonate occur without difficulty.

Now Can You— Identify danger signs during pregnancy?

1. Discuss the significance of abdominal cramping and vaginal bleeding during the first trimester?
2. Identify two actions the pregnant woman should take if she experiences an absence of fetal movements?
3. Name two placental problems that can cause hemorrhage, especially during the third trimester?

Using a Pregnancy Map to Guide Prenatal Visits

A prenatal care map that includes a timetable for prenatal visits helps to ensure consistency of care, especially when many health care professionals are involved in the woman's care. The care map can be placed in the patient's chart during the initial visit and an abbreviated version that outlines the schedule for prenatal care visits may be given to the patient. Some facilities add a grid that provides additional space for entering scheduled appointment dates. An example of a prenatal care map is presented in Table 10-6. In other institutions, the care map consists of a comprehensive guide with check boxes and identifies counseling and education needs throughout pregnancy and during the postpartum period (Fig. 10-8).

Childbirth Education to Promote a Positive Childbearing Experience

Childbirth education provides a wealth of information to parents who are having a baby for the first time as well as to parents who have already experienced childbirth. The

difficulty often lies in finding the right class to meet the specific needs of the expectant parents. Traditionally, childbirth education focused on managing labor and birth. Contemporary classes focus on a wide variety of topics, with the primary goal centered on facilitating a positive childbearing experience, including pregnancy, childbirth, postpartum, and newborn care. Topics typically discussed in childbirth classes include anatomy and physiology related to pregnancy; comfort measures during each trimester of pregnancy; the labor and birth process; relaxation and pain management, including pharmacological and nonpharmacological measures; complications related to pregnancy, labor, and birth; vaginal and cesarean births; postpartum care; newborn care; and newborn feeding, including bottle feeding and breastfeeding (Fig. 10-9).

METHODS OF CHILDBIRTH PREPARATION

Expectant parents can choose from a variety of available childbirth education classes. Ideally, they will select one that is in harmony with their beliefs and values about the childbearing experience and be able to engage in the educational process without reservation and with complete commitment. While different, all childbirth preparation classes incorporate a holistic approach to childbearing, which encompasses the biological, psychological, and social factors related to the experience. For many expectant parents, the experience of childbearing is more than just a physical and biological one; the experience can have emotional, mental, and spiritual meaning. This holistic approach to having a child allows the parents to assimilate all aspects of the experience in order to be prepared physically and mentally for becoming a parent.

Many childbirth education programs in the community combine aspects from the traditional stand-alone methods of childbirth preparation. Combining philosophies and activities into the classes allows the couple to identify more strongly with features that fit their individual and collective needs. The most common childbirth methods include the Lamaze and the Bradley methods of natural childbirth.

Lamaze Method

The Lamaze childbirth experience was started in 1960 by the American Society for Psychoprophylaxis in Obstetrics (ASPO) as a way to bring families together in the labor and delivery process while focusing on the normality of birth. The concepts were founded on principles and techniques used by Dr. Fernand Lamaze, giving rise to the familiar labeling of the association as ASPO/Lamaze. It was not until the 1970s that the organization officially changed its name to Lamaze International, becoming known as such throughout the United States.

The heart of the Lamaze method is empowerment, recognizing the woman's innate ability to give birth, while finding strength and support from her family and the members of the health care team during the labor and birth process. The Lamaze Philosophy of Birth (Box 10-3) identifies the core ideals of the organization and provides the template for the classes. Historically, Lamaze has focused on breathing techniques during labor and birth. As the philosophy indicates, this method incorporates the ideology of empowerment into the entire experience, providing more than just instruction on breathing.

Table 10-6 Example of a Prenatal Care Map

Trimester	Schedule for Return Visits	Components of the Nursing Interview	Lab Tests to Be Obtained
First	Every 4 weeks	• Reason for seeking care	• CBC with differential
		• Presumptive signs	• Blood type and Rh
		• Review of systems	• Rubella titer
		• Medical history	• VDRL or RPR
		• Family history	• HIV
		• Gynecologic and obstetric history	• Hemoglobin electrophoresis (sickle cell, thalassemia)
		• Nutritional history	• Urinalysis
		• Social history	• Pap test
		• Drug use	• Vaginal smear
		• Assessment of abuse risk	
Second	Every 4 weeks	• Birth plan	
		• Summary of relative events since last visit	• Hematocrit
		• General emotional state	• Urinalysis
		• Complaints/problems/questions	• Urine culture
		• Vital signs	• AFP or Triple Marker
Third	Every 4 weeks through weeks 28–32	• Weight	
		• Presence of edema	
		• Primary concerns	• Hematocrit
	Every 2 weeks through week 36	• Attendance at childbirth education classes	• Urinalysis
		• Physical assessment	• Urine culture
		• Psychosocial responses	• Glucose tolerance test
		• Vital signs	• Repeat, if needed: VDRL or RPR, HIV, CBC, sickle cell prep, vaginal smears
Every week thereafter	• Weight		
	• Presence of edema		
	• Confirmation of gestational age		

As the Lamaze method has evolved over the years, many myths have continued to prevail regarding this method of childbirth preparation. The organization identified and addressed these myths (Lamaze International, 2005), and they include:

- *Lamaze is all about breathing:* In fact, Lamaze classes provide education on movement and position, massage, relaxation, and use of heat and cold in addition to the traditional focused-breathing techniques.

- *Lamaze promises painless childbirth:* Pain is a natural and normal part of childbirth. Instead of attempting to alleviate the pain, women are taught strategies for coping with the pain associated with labor and birth in positive ways. The strategies provide the woman with education to understand and respond to the pain signals and to facilitate the process of labor and birth.
- *Lamaze childbirth means you cannot have an epidural:* Education on epidural use is provided during Lamaze

This Guide is intended as a resource for clinicians involved in the design and implementation of prenatal care services. This information should not be interpreted as excluding other acceptable course of care based upon medical judgement and patient preferences. The Guide reflects the current opinion of IPN for a standard approach to prenatal care. The use of pre-printed standardized antenatal record is recommended to reduce errors of omission.

Note: It is strongly recommended that prenatal care begin in the first trimester.

This document reflects the consensus of the Indiana Perinatal Network (IPN) State Perinatal Advisory Board—a constituency of professional organizations (i.e. ACOG, AAP) and individuals (i.e. CNMs, MDs, consumers). It is intended to serve as recommendations—not as established standards or rigid rules. Health care providers must make the best decisions possible within the limitations of the particular situation.

Figure 10-8 cont'd Prenatal Care Guide.

Figure 10-9 Childbirth education classes help to prepare the expectant couple for many aspects of the childbearing year.

education in addition to education on natural pain relief. Lamaze educators stress that women need to make the decision that is personally best for them, with the knowledge that elimination of the pain makes it difficult to respond appropriately to contractions. In addition, after an epidural is placed, hospitals usually require that women remain in bed, have continuous fetal monitoring, and use medication to augment their contractions. The addition of these added procedures takes away from the philosophy that childbirth is a natural process.

- *Lamaze does not work:* When the woman has a complete understanding of the process of birth, the strategies for coping with the pain of the birth process, and the support of her family and members of the health care team, she is able to experience the birth of her baby as a normal and natural experience.
- *Lamaze is not for everyone:* The strategies used by Lamaze educators stress the natural process of childbearing. The philosophy of birth according to Lamaze International provides education and strategies for coping with labor and delivery that can be used by anyone who chooses this method.

Controlled breathing is the primary coping strategy used by proponents of the Lamaze method. Different breathing techniques and continued childbirth partner coaching facilitate each stage of labor. During the first stage of labor, breathing is used to relax the abdominal muscles and enlarge the abdominal cavity to enhance fetal descent. The woman inhales slowly, expanding her chest and abdominal cavity, and focuses on energy entering her body. As she exhales slowly, she focuses on tension leaving her body.

As the woman enters the second phase of the first stage of labor, known as transition, contractions become stronger and more frequent. Often it becomes difficult to concentrate on breathing. During this time, the woman's partner watches for signs of hyperventilation and helps her to focus on slow-paced breathing. During the second stage of labor, the active or pushing stage, the woman uses her breathing patterns to increase abdominal pressure in order to expel the fetus. She takes a breath, holds it for several seconds,

Box 10-3 Lamaze Philosophy of Birth

- Birth is normal, natural, and healthy.
- The experience of birth profoundly affects women and their families.
- Women's inner wisdom guides them through birth.
- Women's confidence and ability to give birth is either enhanced or diminished by the care provider and place of birth.
- Women have a right to give birth free from routine medical interventions.
- Birth can safely take place in birth centers and at home.
- Childbirth education empowers women to make informed choices in health care, to assume responsibility for their health, and to trust their inner wisdom.

Source: Lamaze International (2005). *About Lamaze International, Inc.* Retrieved from www.lamazechildbirth.com/fact_sheet.html

and exerts downward pressure on her stomach muscles. As she releases her breath, she continues to focus on releasing tension from her body. Once the fetal head reaches the pelvic outlet, the partner coaches the woman to continue with bearing down and pushing efforts until the baby is born. (See Chapters 12 and 13 for further discussion.)

The Bradley Method of Natural Childbirth

While the Lamaze method uses techniques that focus the woman on recognizing the signals of labor and using controlled breathing and muscle relaxation to facilitate the birth, the Bradley method uses techniques that focus the woman on inward relaxation, by means of breathing control, abdominal breathing, and general relaxation. The partner facilitates the implementation of these techniques, through coaching, giving rise to the term "husband-coached childbirth." To assist the partner in coaching the laboring woman to relax, there is an emphasis on darkness, solitude, and quiet in order to reduce stimulation and enhance the calm and comfort needed to conserve energy that will be required for birth and to decrease anxiety and tension in the woman (Bradley, 1965).

Dr. Robert Bradley developed this method of childbirth in the 1960s after a decision that radically changed the traditional delivery room. Bradley became the first obstetrician to allow fathers into the delivery room and to seek out methods to involve them in the labor and birth of their child in order to provide the woman with another individual who could provide her with support. After noting the dramatic effects of having the father present during the labor and birth, educational programs were developed to teach the fathers to be labor coaches and have an active role in the experience. It is through this active participation by the fathers that the woman is able to remain relaxed, assume positions that are most comfortable, and experience the childbirth as a more natural and spiritual event.

One of the primary differences in the Bradley method when compared to the Lamaze method is the breathing technique. The Bradley method teaches that women should breathe normally throughout the labor and birth process in order to maintain a state of relaxation and to oxygenate the baby adequately. The concern with the breathing techniques taught in the Lamaze method is that

they can lead to dizziness and hyperventilation, resulting in decreased oxygenation of the fetus.

Other Methods

While the Lamaze and Bradley methods remain the top childbirth education formats, with training to prepare educators to teach parents the strategies, other methods for childbirth exist. Prepared childbirth classes incorporate approaches from diverse methods to assist expectant couples in developing coping skills that will work best for them. Additional methods and techniques include the following:

- **Dick-Read:** The underlying philosophy in Dick-Read's approach to childbirth still focuses on the natural aspect of giving birth. After witnessing a birth in the 1920s, without the use of the traditional chloroform to render the laboring woman unconscious, he discovered that it was possible for women to experience pain-free birth. Through his study of physiology, he hypothesized that the pain associated with childbirth was caused by fear and tension, stimulating the sympathetic nervous system. This physiological event decreased blood flow to the uterus and created uterine muscle cell hypoxia. Through various relaxation techniques that consist of conscious and progressive relaxation of different muscle groups, the tension is reduced and blood flow to the uterus is restored. Although Dick-Read did not advocate the use of pharmacologic pain management during labor and delivery, he approved of its use when the woman was unable to relax or was experiencing complications (Dick-Read, 1987).
- **HypnoBirthing:** Classes using this method are based on Dick-Read's fear-tension-pain philosophy. Couples are taught, in four sessions, relaxation techniques to eliminate the pain associated with the fear and tension.
- **LeBoyer method:** Using this method, the baby is born in a dimly lit room that is conducive to relaxation and facilitates a tranquil entrance into the world. Immediately after birth, the newborn is placed in a warm water bath to enhance the transition from the intrauterine to the extrauterine environment. The infant is then moved to the mother's abdomen to initiate bonding. Through the gentle handling and the quiet, smooth transition, the newborn is able to open her eyes and breathe with minimal external stimulation.
- **Odent method:** This method arose from the LeBoyer method and includes moving the woman into a warm water bath for the birth. In addition to reducing labor pain, the warm water provides a comforting atmosphere to transition the newborn to extrauterine life. The underlying concept is that the infant can safely be born while submersed in water, without fear of drowning, since the fetus has lived in fluid for the duration of the pregnancy. Not all women are candidates for hydrotherapy. It is not an option for women who have rupture of the membranes or other complications that require continuous fetal monitoring.
- **Birthing From Within:** This method views childbirth as a rite of passage for parents and their infant. The underpinnings of this method focus on the psychological and spiritual aspects of birth, using art, writing, painting, and sculpting to encourage self-discovery. The focus is not on the birth process, but on the experience of birth.

FINDING INFORMATION ON CHILDBIRTH EDUCATION

There are many ways that expectant mothers and their partners can locate information on childbirth education. The best strategy is to begin with the health care provider, who can provide information about potential birth locations and childbirth education provided by the individual facilities. Internet sources can also assist couples in finding classes that are available to them locally. Expectant couples can engage in online childbirth education classes as well as home education through the purchase of comprehensive childbirth programs.

In determining the childbirth preparation class that will meet the individual needs of the parents, the following questions should be considered:

- Who sponsors the class?
- How many classes will we be expected to attend?
- How many couples are in the class?
- Can I bring more than one support person to the class?
- What types of teaching and learning strategies are used?
- What topics are covered in the course?
- Where will the classes be held?
- Is there a cost involved?
- Is the instructor certified? If so, with what organization is the instructor affiliated?

With the abundance of childbirth methods available and the different certifications that exist for childbirth educators, it is important for expectant parents to identify the approaches and methods that best meet their needs in order to make the childbirth experience as meaningful as possible to them. It is helpful not only to examine the questions listed above, but also to consider what the most important factors are with regard to personal values and beliefs. Using the list below, nurses can direct parents to the appropriate education program to meet their needs. The woman should identify which four of the following factors are most important in selecting a childbirth education class:

- Familiarize me with hospital routines
- Prepare me for a natural, nonmedicated birth
- Teach me breathing patterns and distraction techniques
- Give my partner the skills necessary to be an active and informed labor coach
- Teach us as parents to be childbirth consumers and to take responsibility for our child's birth
- Follow current medical policies
- Represent the most common type of childbirth education class in our area
- Teach relaxation and natural breathing
- Stress good nutrition and exercise
- Discuss medication options without making value judgments

CREATING A BIRTH PLAN

From the moment a woman discovers that she is pregnant, she begins to consider ideas for her birth experience. Although the birth is usually not imminent, previous knowledge and experience, along with information shared by friends and family, prompt her to seek out information on options that are available and choices that she can make to prepare for the birth. While the birth plan is not a concrete document from which to outline every step of the

labor and birth, it provides written information that identifies preferences for labor and birth, empowering the expectant couple with the control that is needed to reduce the anxiety associated with labor. Birth plans can be tailored to meet the needs of expectant couples that anticipate a hospital delivery, a birthing center delivery, a home delivery, a cesarean delivery, or a multiple delivery. Developing a birth plan in conjunction with the health care provider assures that the woman's individual situation is considered, especially important for high-risk pregnancies.

Birth Plan Choices

There are many issues to consider when developing a personal birth plan. One concerns the presence of additional people in the birthing room. The woman may wish to include her partner, friends, relatives, a **doula** (a woman who is experienced in childbirth and provides physical and emotional support to the mother during the prenatal period, during labor, during birth, and during the postpartum period) or birthing coach, and children. She may desire to personalize the experience by wearing her own clothes, listening to music, and taking pictures or videotaping the birth. Fluids and food preferences can be noted, along with the woman's desire for a saline or heparin lock or an intravenous line. While most hospitals utilize continuous fetal monitoring, the woman can identify her wish for intermittent monitoring or no monitoring at all, unless an emergency develops. Preferences for laboring and birthing positions can also be noted. Choices regarding strategies for pharmacological and nonpharmacological pain management are identified, with the understanding that the woman has the right to change her mind and alter her plan at any time.

The woman who anticipates a vaginal birth should identify her preference regarding an episiotomy and the use of medication to augment labor contractions. The partner's desired level of involvement in the birth should also be identified. The woman can decide if she would like to hold her baby immediately after birth and, if she plans to breastfeed, whether she wishes to do so at that time.

Women who anticipate a cesarean birth or who discover that they need a cesarean birth can usually maintain some degree of control over this procedure as well. They may be allowed to have their partner present during the surgery. The partner may be permitted to hold the newborn during the first moments of life if there are no immediate health concerns. The mother may also choose to initiate breastfeeding in the recovery room. Other preferences regarding infant feeding, rooming-in and circumcision should be noted in the birth plan.

Choosing a Health Care Provider

Selecting a health care provider for the preconception, pregnancy, and birth experience is an essential first step that empowers the woman and her partner to become actively involved in care during the childbearing year. Approximately 90% of pregnant women choose an obstetrician as the primary care provider. Others use a certified nurse-midwife (CNM), who is trained in both nursing and midwifery and can provide a more personalized, less routine approach to a normal, uncomplicated pregnancy and birth. It is especially important that the patient choose a care provider with whom she can openly relate and who shares the same philosophical views on the management of pregnancy. (See Chapter 9 for further discussion.)

Choosing a Birth Location

A hospital is the most common birth location. In this setting, health care providers and patients have access to technology and individuals trained to manage any complications that may arise. Obstetricians and certified nurse midwives attend and facilitate childbirth in the hospital setting. When choosing the facility that best meets their needs, the expectant couple should identify the type of setting provided by the hospital. For example, some institutions have separate labor, delivery, recovery, and postpartum rooms. This arrangement requires the family to be moved from one location to another during their hospital stay. The newest facility models place emphasis on family-centered care and offer large, comfortable rooms where the woman remains for the duration of the childbirth experience.

Free-standing birthing centers were first opened in 1974 to provide women with a more homelike atmosphere in which to give birth. Although these facilities are located near the hospital in the event of an emergency, they are recommended for women with low-risk pregnancies. A major benefit of the birthing centers is that they have fewer restrictions and generally allow the parents more freedom to make personal decisions regarding labor and birth.

Home births are returning as an option for women with low-risk pregnancies and no known labor complications. Although obstetricians will not deliver babies at home, many CNMs are willing to do so. Many expectant couples believe that giving birth at home enriches the childbirth experience and allows them to better integrate the birth as a normal and natural event in their lives. However, the parents must be open to transfer to a hospital if complications arise.

Now Can You— Discuss childbirth preparation, birth plans, and doulas?

1. Compare and contrast the Lamaze, Bradley and LeBoyer methods of childbirth preparation?
2. Discuss the purpose of a birth plan?
3. Describe the role of a doula?

summary points

- ◆ Preconception counseling empowers families to plan for pregnancy and develop healthy bodies and minds to optimize birth outcomes.
- ◆ Nurses and other health care providers must collaboratively provide families with prenatal education and incorporate interventions for a holistic approach to pregnancy.
- ◆ A balance of diet and nutrition, exercise, work, and rest enhances the development of a healthy pregnancy.
- ◆ To determine safety of use during pregnancy, all medications, including prescription, over-the-counter, and herbal preparations, must be carefully evaluated. It is essential that the nurse obtain a comprehensive medication history during each prenatal visit.
- ◆ Ongoing prenatal education regarding pregnancy danger signs and symptoms, and appropriate home interventions is key in reducing complications.

- ◆ Nurses can help to empower families by providing information about childbirth education programs and other community resources.
- ◆ A holistic approach to a healthy pregnancy and birth includes all members of the family and the health care team. Encouraging the family to develop a birth plan is an important step in helping to create a positive, satisfying birth experience.

review questions

Multiple Choice

1. The perinatal nurse knows that the most ideal time to address issues related to a poor outcome in a past pregnancy is:
 - A. Postpartum
 - B. Prenatally
 - C. Preconception
 - D. Interconception
2. The prenatal nurse provides nutritional counseling during pregnancy to ensure adequate weight gain. The nurse teaches that the additional daily calories required are the equivalent of:
 - A. One glass of skim milk
 - B. Two servings of yogurt
 - C. Two apples
 - D. Three ounces of cheese
3. The perinatal nurse knows that the blood volume in pregnancy increases, on average, by:
 - A. 20–30%
 - B. 30–40%
 - C. 40–50%
 - D. 50–60%

Select All that Apply

4. The perinatal nurse knows that the *Healthy People 2010* national initiative suggests the use of specific outcomes to measure goals that are critical to the health of women and families. These outcomes include:
 - A. The number of women receiving prenatal care
 - B. The number of very low birth weight infants
 - C. The level of maternal anxiety associated with prenatal care
 - D. The preterm birth rate
5. The clinic nurse encourages all pregnant women to eat foods rich in folic acid such as:
 - A. Cheese
 - B. Chicken
 - C. Brussel sprouts
 - D. Orange juice
6. The clinic nurse offers smoking cessation programs to all prenatal women who smoke because cigarette smoking during pregnancy increases the risk for:
 - A. Sudden infant death syndrome
 - B. Spontaneous abortion
 - C. Intrauterine growth restriction
 - D. Postdate pregnancy

True or False

7. As part of preventive health care, the clinic nurse encourages all adults to have a tetanus booster every 10 years.

Fill-in-the-Blank

8. The clinic nurse includes tracking of a woman's _____ history as part of her preconception visit. Determining the _____ and length of _____ periods will enhance the likelihood of conception.
9. The clinic nurse is providing education to a pregnant woman who has come for her first prenatal visit at 8 weeks gestation. The nurse explains that _____ is common during the next few weeks but will usually resolve between thirteen and _____ weeks and is usually caused by adequate hormonal support for the pregnancy.
10. The clinic nurse knows that _____ is a hormone that acts as a depressant in pregnancy.

CONCEPT MAP

Caring for the Woman Experiencing Complications During Pregnancy

Apprehension, uncertainty, waiting, expectation, fear of surprise, do a patient more harm than exertion.

—Florence Nightengale, 1860

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Discuss the importance of ongoing assessment of the pregnant patient for potential complications throughout her pregnancy.
- ◆ Describe the roles of the perinatologist, neonatologist, obstetric nurse, visiting nurse, chaplain, nutritionist, and social worker in caring for the family experiencing complications during a pregnancy.
- ◆ Discuss the importance of understanding and respecting the cultural differences the nurse may encounter when caring for a diverse population experiencing a high-risk pregnancy.
- ◆ Plan nursing assessments and interventions for the woman experiencing complications of pregnancy.
- ◆ Discuss the importance of complete and accurate documentation in caring for the patient experiencing an obstetric emergency.
- ◆ Identify complications of pregnancy that require fetal surveillance.
- ◆ Describe fetal surveillance tests that may be warranted to evaluate fetal well-being.
- ◆ Relate the effects of antenatal bedrest to the physical, psychological, and social adjustment of a high-risk pregnancy.

moving toward evidence-based practice Risk of Adverse Pregnancy Outcomes Related to Weight Changes

Villamor, E., & Cnattingius, S. (2006). Interpregnancy weight change and risk of adverse pregnancy outcomes: A population-based study. *The Lancet*, 368, 1164–1170.

The purpose of this study was to explore the relationship between overweight or obesity and adverse pregnancy outcomes. The association between the pre-pregnancy body-mass index (BMI) from the first to the second pregnancy and the risk of adverse outcomes during the second pregnancy were examined. The study sample consisted of data from 151,025 women who experienced first and second consecutive singleton births during the time interval from 1992 to 2001.

The participants' BMI was calculated during the first antenatal visit of each pregnancy. Interpregnancy changes in the BMI from the beginning of the first and second pregnancies were also calculated and the participants were placed in the following categories based on changes in BMI units:

- less than -1
- -1 to less than 1

- 1 to less than 2
- 2 to less than 3
- 3 or more units

The interpregnancy interval (months between birth of the first child and the estimated date of conception of the second child) included the following groups:

- 12–23 months
- 24–35 months
- 36 or more months

Based on the BMI at the beginning of the first pregnancy, participants were grouped using the following categories:

- Underweight (BMI <18.4)
- Healthy (BMI 18.5–24.9)

(continued)

moving toward evidence-based practice (continued)

- Overweight (BMI 25.0–29.9)
- Obese (BMI >30)

Demographic data included the number of years of formal education: 9 years or less; 10–11 years; 12 years; 13–14 years; and 15 years or more. Outcome measures included maternal complications (e.g., preeclampsia, gestational hypertension, gestational diabetes, and cesarean birth) and perinatal complications (e.g., stillbirth [fetal death at 28 weeks or later] and large for gestational age birth [more than 2 standard deviations above the mean for gestational age]) associated with the second pregnancy.

Data analysis revealed the following findings:

- On average, participants gained slightly more than one-half of a BMI unit during a mean pregnancy interval of 24 months.
- Weight gain declined between pregnancies with increasing maternal age and years of education.
- Weight gain (based on the BMI at the first pregnancy) and the incidence of complications increased with maternal tobacco use.
- There was an increased risk of adverse outcome associated with increased weight gain between pregnancies.

- The incidence of maternal/perinatal complications began to increase with a BMI of 1 to less than 2.
- The risk for preeclampsia and large for gestational age birth fell significantly in women who lost more than one BMI unit between pregnancies.
- After a gain of 3 or more BMI units between pregnancies, the risk for a stillbirth was 63%.
- An interpregnancy increase of 3 or more BMI units was associated with the following adverse pregnancy outcomes: preeclampsia, gestational hypertension, gestational diabetes, stillbirth, and large-for-gestational-age birth.
- Weight gain between pregnancies demonstrated a strong association between risk of a major maternal and/or perinatal complication and an increase in the interpregnancy BMI.

1. What might be considered as limitations to this study?
2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

Pregnancy is a normal physiological function of all living species. Couples (or, in more recent times, single individuals) who have chosen to become parents look forward to having a healthy, happy, and bright newborn enter their lives. They anticipate the arrival of a baby who they will be able to love and nurture over the years to grow into a happy, healthy and productive adult. However, pregnancies do not always progress smoothly and the pregnant woman and her family or significant other may experience a complication at some point during the childbearing year. Complications that arise during this time are often challenging and demand the perinatal nurse's skills, knowledge, and expertise combined with the nursing process to first identify the pregnant patient at risk and then formulate, implement, and evaluate an appropriate, holistic plan of care. Identification and activation of appropriate community resources is also an essential component of the care plan. Throughout the entire process, the nurse must remain cognizant of the unique individuality of the patient and her family and deliver care that is respectful of their diversity and culture.

Interviewing is a skill basic to nursing. A carefully conducted interview is a tool that enables nurses to collect data, recognize signs and symptoms of emerging problems, identify risks, and formulate nursing diagnoses and counseling strategies (Givens, Moore, & Freda, 2004). The signs and symptoms of the complications that may arise during pregnancy can be subtle. The nurse's need to elicit information from the patient through the interview and to process that information cannot be overemphasized. Anticipatory nursing care is invaluable in preventing a complication from becoming a major health crisis. Notifying the primary health care provider immediately of signs or symptoms of alterations from the expected clinical pro-

gression during pregnancy can facilitate early intervention and guide an appropriate management plan.

The complications described in this chapter can be extremely serious to both the patient and her fetus and result in severe morbidity or even death. It is essential that women feel comfortable and confident with the care they receive. Maternal health care often represents the first point of contact between immigrant women and the U.S. health care system. Since many do not speak and/or read English, the nurse must facilitate an interview in the woman's primary language. Use of the woman's native language greatly increases her level of comfort and acceptance and is paramount to establishing an accurate diagnosis and appropriate plan of care (Givens, Moore, & Freda, 2004). When indicated, every effort should be made to secure a female interpreter who is not a member of the family. In most cases, children are not suitable translators, as many assessment questions involve subjects that women may not wish to discuss with their children or with men. Friends and family members who serve as interpreters are not bound by a code of conduct and may breach confidentiality, editorialize, or omit information they find threatening or embarrassing. The woman's privacy may also be jeopardized (Givens, Moore, & Freda, 2004). By providing culturally competent nursing care to childbearing families, many potential complications can be identified in a timely manner to allow for effective treatment and improved outcomes.

Early Pregnancy Complications

PERINATAL LOSS

Perinatal loss can be divided into two major types: death of the fetus or newborn or birth of a less than a perfect child. The perinatal period encompasses the total embryonic,

fetal, and neonatal life span. Because there is a greater danger to life during this period than at any other time during the life cycle, adverse outcomes can be expected. Loss of a child, whether it is an embryo, fetus, or neonate, can be totally devastating not only to the woman but to the entire family as well. Supporting the family through a perinatal loss can be very challenging to the obstetric nurse who must be in touch with personal feelings in order to help understand the family's response to their loss. (See Chapter 14 for further discussion.)

“What to say” — *Communicating with the family who has experienced a perinatal loss*

The nurse approaches the family with compassion and sincerity. Expressions of caring are conveyed in the following statements:

“I understand this is a very difficult time for you and your family, but I want you to know that I am here and willing to listen if you want to talk. You let me know if and when you are ready.”

“It is normal for you to be sad and you will probably feel like this for some time. Losing a baby, no matter how far along in your pregnancy, is very difficult. I can recommend some support groups if you think you might be interested.” If the patient says she does not want the information at this time, continue with “Please do not hesitate to call us if you change your mind. We can always give you the information.”

“Does your baby have a name?” The nurse would then refer to the fetus by name. Do not use the term “fetus” with the patient. To her the deceased fetus was her baby.

ECTOPIC PREGNANCY

An ectopic pregnancy is one that implants outside of the uterine cavity. Implantation may occur in the fallopian tube (99%), on the ovary, the cervix, on the outside of the fallopian tube, the abdominal wall, or on the bowel (Fig. 11-1). Patients who present with vaginal bleeding, a missed period, and abdominal tenderness or pain should

always be evaluated for an ectopic pregnancy. Pain increases after rupture of the ectopic pregnancy and the woman may experience referred shoulder pain from diaphragmatic irritation caused by blood in the peritoneal cavity.

A number of factors place a woman at risk for experiencing an ectopic pregnancy. These include past and current medical and gynecological problems such as:

- History of sexually transmitted infections or pelvic inflammatory disease
- Prior ectopic pregnancy
- Previous tubal, pelvic, or abdominal surgery
- Endometriosis
- Current use of exogenous hormones (i.e., estrogen, progesterone)
- In vitro fertilization or other method of assisted reproduction
- In utero diethylstilbestrol (DES) exposure with abnormalities of the reproductive organs
- Use of an intrauterine device

Diagnosis

To prevent major morbidity or death, an ectopic pregnancy should be diagnosed before the onset of hypotension, bleeding, pain, and overt rupture. The patient's history (e.g., unilateral, bilateral or diffuse abdominal pain, missed period) and physical exam (a palpable mass is present on bimanual examination in approximately 50% of women) should alert the health care professional to the possible presence of an ectopic pregnancy. Active bleeding is associated with rupture; other symptoms of this complication may include hypotension, tachycardia, vertigo and shoulder pain. Diagnostic laboratory tests include a beta-human chorionic gonadotropin (β -hCG) that is low for gestational age (because an ectopic pregnancy has a poorly implanted placenta, the level of a β -hCG does not double every 48 hours as in normal implantation) and a white blood count (WBC) that can range from normal to 15,000/mm³. Transvaginal ultrasonography should be performed to confirm intrauterine or tubal pregnancy (Farquhar, 2005). Ultrasonographic identification of an intrauterine pregnancy rules out the presence of an ectopic pregnancy in most women (Murray, Baakdah, Bardell, & Tulandi, 2005).

Figure 11-1 Ectopic pregnancy.

Management

Salpingectomy (removal of the ruptured fallopian tube) by **laparotomy** (surgical procedure in which the abdomen is opened to visualize the abdominal organs) has long offered an almost 100% cure for the treatment of an ectopic pregnancy. However, current clinical emphasis is aimed not only on prevention of maternal death but also on the prompt restoration of health through a rapid recovery with preservation of fertility. To achieve this goal, **laparoscopic** (visualization of the reproductive organs using a laparoscope inserted into the pelvic cavity through a small incision in the abdomen), **salpingostomy** (incision into the fallopian tube to remove the pregnancy) and partial salpingectomy are replacing laparotomy as the treatment mode of choice. At present, laparotomy is performed only when a laparoscopic approach is too difficult, the surgeon is not trained in operative laparoscopy, or the patient is hemodynamically unstable.

Methotrexate, a chemotherapeutic drug and folic acid inhibitor that stops cell production and destroys remaining trophoblastic tissue, is used in the management of uncomplicated, non-life-threatening ectopic pregnancies. Patients are considered to be eligible for methotrexate therapy if the ectopic mass is unruptured and measures 1.6 inch (4 cm) or less on ultrasound examination. Patients with larger ectopic masses, embryonic cardiac activity, or clinical evidence of acute intra-abdominal bleeding (acute tender abdomen, hypotension, or falling hematocrit) are not eligible for this mode of treatment (Murray et al., 2005).

GESTATIONAL TROPHOBLASTIC DISEASE

Gestational trophoblastic disease (GTD) is a clinical diagnosis that includes the histologic diagnoses of hydatidiform mole (“molar pregnancy”), locally invasive mole, metastatic mole, and choriocarcinoma. It is a disease characterized by an abnormal placental development that results in the production of fluid-filled grapelike clusters (instead of normal placental tissue) and a vast proliferation of trophoblastic tissue (Fig. 11-2). It is associated with loss of the pregnancy and rarely, the development of cancer. GTD occurs in 1 in 1200 pregnancies (Berman, DiSaia, & Tewari, 2004).

Pathophysiology

The cause of molar pregnancy is unknown, but it is thought that complete moles result from the fertilization

Figure 11-2 A hydatidiform mole pregnancy is one in which the chorionic villi degenerate into a mass of fluid-filled grapelike clusters.

of an empty ovum (one whose nucleus is missing or nonfunctional) by a normal sperm. Since the ovum contains no maternal genetic material, all chromosomes in a molar pregnancy are paternally derived. The most common chromosomal pattern for complete moles is 46 XX. A complete mole is characterized by trophoblastic proliferation and the absence of fetal parts. Incomplete moles often appear with a coexistent fetus that has a triploid genotype (69 chromosomes) and multiple anomalies. Most fetuses associated with incomplete moles survive only several weeks in utero before being spontaneously aborted. Incomplete moles are almost always benign and have a much lower malignancy potential than complete moles. An invasive mole is similar to a complete mole but has invaded the myometrium layer of the uterus. Invasive moles rarely metastasize. Choriocarcinoma is invasive, malignant trophoblastic disease that is usually metastatic and can be fatal (Berman et al., 2004).

Risk Factors

The incidence of hydatidiform mole, whether complete or partial, increases with maternal age (especially in women 50 or older) and in those with a history of a previous molar pregnancy. The risk for a second molar pregnancy is 1% to 2% while the risk for a third molar pregnancy after two previous molar pregnancies is approximately 2.5 percent. Higher incidences have been found in geographical areas where the maternal diet is low in beta-carotene, animal fats, and folic acid and also in women with blood type A whose partners are of blood type O (Bess & Wood, 2006). There is also a higher incidence among women who have experienced prior miscarriages and in those who have undergone ovulation stimulation with clomiphene (Clomid).

Signs and Symptoms

More than 95% of patients experience vaginal bleeding which may be scant or profuse and ranges in color from dark brown to bright red. In early pregnancy, there is often a discrepancy between uterine size and dates. Uterine enlargement results from the rapidly proliferating trophoblastic tissue and the large accumulation of clotted blood. Anemia may result from the blood loss. Also, the patient may complain of excessive nausea and vomiting (hyperemesis gravidarum) and abdominal pain caused by uterine distention. Preeclampsia may occur, usually between 9 and 12 weeks of gestation but any symptoms of gestational hypertension before 24 weeks of gestation may be indicative of hydatidiform mole. Clinical and laboratory findings include an absence of fetal heart sounds, a markedly elevated quantitative serum hCG (may be >100,000 mIU/mL), and very low levels of maternal serum α -fetoprotein (MSAFP). Hyperthyroidism and trophoblastic pulmonary emboli are less common but serious complications of hydatidiform mole.

Diagnosis

The diagnosis of a molar pregnancy is made by an ultrasound examination. The placental tissue appears in a “snowstorm” pattern due to the profuse swelling of the chorionic villi. When a complete mole is present no fetus is identified in the uterus.

Management

Clinical management involves removal of the uterine contents with meticulous follow-up that includes serial β -hCG levels. A sensitive marker, hCG is secreted by the molar cells and the amount of this hormone measured in maternal serum is directly related to the number of viable molar cells. The hCG levels should be assessed every 1 to 2 weeks until hCG is undetectable on two consecutive determinations. Thereafter, hCG should be measured every 1 to 2 months for at least a year (Cunningham et al., 2005). Effective contraception is needed during this time to prevent pregnancy and the resulting confusion about the cause of changes in the hCG levels. In addition, pregnancy could mask an hCG rise associated with malignant GTD. The perinatal nurse should carefully counsel the patient about different methods of contraception and stress the importance of avoiding pregnancy for a year.

Collaboration in Caring— Dealing with a molar pregnancy

With any pregnancy loss, a challenging situation exists. However, the couple experiencing a molar pregnancy not only must realize that there will be no baby, but attempts at becoming pregnant must be delayed for at least a year. There is also the fear of malignant sequelae. The perinatal nurse's role is to support the couple, educate them regarding their contraceptive options, encourage them to voice their fears and concerns, and answer their questions appropriately. Involving community resources such as social services, support groups, and spiritual advisors can be of significant benefit.

Chemotherapy is initiated immediately if the hCG titer rises or plateaus during follow-up or if **metastases** (movement of cancer cells from the original site to another site) are detected at any time. Surgery may be indicated if chemotherapy is not successful or for patients who have completed their childbearing. Radiation therapy is usually reserved for treating brain and liver metastases (Cunningham et al., 2005).

Prognosis

Invasive moles are generally not metastatic and respond well to single-agent chemotherapy. Choriocarcinoma spreads to the lungs, vagina, pelvis, brain, liver, intestines, and kidneys. Since choriocarcinoma can occur weeks to years after any type of gestation, patients usually present with signs and symptoms of active metastases. The long-term prognosis depends on the degree of metastases and the patient's response to the chemotherapy.

SPONTANEOUS ABORTION

Not all conceptions result in a live-born infant. Of all clinically recognized pregnancies, 10% to 20% are lost, and approximately 22% of pregnancies detected on the basis of hCG assays are lost before the appearance of any clinical signs or symptoms (White & Bouvier, 2005). By definition, an early pregnancy loss occurs before 12 weeks of gestation; a late pregnancy loss is one that occurs between 12 and 20 weeks of gestation.

A **spontaneous abortion** (SAB) or miscarriage is a pregnancy that ends before 20 weeks gestation. The type of SAB that occurs is defined by whether any or all of the products of conception (POC) have been passed and whether or not the cervix is dilated.

Spontaneous abortions may be classified as the following:

- **Abortus:** Fetus lost before 20 weeks of gestation, less than 17.5 oz. (500 g), or less than 9.8 inches (25 cm) in size
- **Complete abortion:** Complete expulsion of all POC before 20 weeks of gestation
- **Incomplete abortion:** Partial expulsion of some but not all POC before 20 weeks of gestation
- **Inevitable abortion:** No expulsion of products, but bleeding and dilation of the cervix such that a pregnancy is unlikely
- **Threatened abortion:** Any intrauterine bleeding before 20 weeks of gestation, without dilation of the cervix or expulsion of any POC
- **Missed abortion:** Death of the embryo or fetus before 20 weeks of gestation with complete retention of the POC; these often proceed to a complete abortion within 1 to 3 weeks but occasionally they are retained much longer.

Etiology

It is estimated that 60% to 80% of all SABs in the first trimester are associated with chromosomal abnormalities (Griebel, Halvorsen, Goleman, & Day, 2005). Infections (e.g., bacteriuria and *Chlamydia trachomatis*), maternal anatomical defects, and immunological and endocrine factors have also been identified as causes of early pregnancy loss, although many have no obvious cause. Second-trimester spontaneous abortions (12 to 20 weeks) have been linked to chronic infection, recreational drug use, maternal uterine or cervical anatomical defects, maternal systemic disease, exposure to fetotoxic agents, and trauma (Cunningham et al., 2005).

Diagnosis

A woman who is experiencing a spontaneous abortion usually presents with bleeding and may also complain of cramping, abdominal pain, and decreased symptoms of pregnancy; cervical changes (dilation) may be present on vaginal examination. An ultrasound is performed for placental evaluation and to determine fetal viability. Laboratory tests include a quantitative level of β -hCG, which should show a lower value than when associated with a viable pregnancy (Fig. 11-3), hemoglobin and hematocrit, blood type and Rh status determination, and indirect Coombs' screen (Cunningham et al., 2005).

Management

Incomplete, inevitable, and missed abortions are usually managed via a dilatation and curettage (D & C: the cervix is dilated and a curette is inserted and used to scrape the uterine walls and remove the uterine contents). In the case of an incompetent cervix, an emergent **cerclage** (placement of ligature to close the cervix) may be performed. An unsensitized, Rh-negative woman should be given Rh₀(D) immune globulin (RhoGAM) to prevent

Figure 11-3 hCG levels.

antibody formation. (See discussion later in this chapter.)

Depending on the circumstances, the nurse can provide counseling or make an appropriate referral. Not all couples who suffer a pregnancy loss require formal assessment, but all couples should be offered a formal evaluation after several losses. The nurse should also allow the family to express as much grief as they are feeling at the moment and are willing to share, allow them to talk freely of what their hopes and expectations had been for this new life, and acknowledge that this is a very difficult time for them. The nurse may offer to enlist the assistance of social services, a chaplain, or rabbi or appropriate support groups if the couple so desires.

Optimizing Outcomes— Follow-up for women who experience habitual abortions

Patients who experience habitual (three or more) abortions may be offered these tests:

- A karyotype obtained from the products of conception and from both parents
- Examination of maternal anatomy, beginning with a hysterosalpingogram. If abnormal, hysteroscopy or laparoscopy
- Screening tests for maternal hypothyroidism, diabetes mellitus, antiphospholipid syndrome (APS; an acquired hypercoagulable state that involves venous and arteriole thrombosis) and systemic lupus erythematosus (SLE)
- Serum progesterone level during the luteal phase of the menstrual cycle
- Cultures of the cervix, vagina, and endometrium
- Endometrial biopsy during the luteal phase of the menstrual cycle (Cunningham et al., 2005)

INCOMPETENT CERVIX

Patients with cervical incompetence usually present with painless dilation and effacement of the cervix, often during the second trimester of pregnancy. They frequently give a history of repeated second trimester losses with no apparent etiology. Incompetent cervix is estimated to cause approximately 15% of all second trimester losses (Cunningham et al., 2005).

Nursing Insight— Identifying clues when taking the patient history

The importance of knowing your patient's history cannot be overemphasized. Remember to read the prenatal records and also question your patient about all previous pregnancies and their outcomes. Since we live in such a mobile society, prenatal records may not always be available. A woman who is visiting on vacation or who has recently moved into the community often has no prenatal records with her. Many communities regularly see pregnant women seeking refuge from a war-torn country who arrive at the hospital with no records or who have had no prenatal care. You may also need to work with a medical interpreter to obtain an accurate history that can provide insights into present problems.

Etiology

Reduced cervical competence can be acquired (i.e., after trauma or surgery) or congenital (i.e., resulting from uterine anomalies or a history of DES exposure). Some women provide a typical history of painless cervical dilation in the first and every subsequent pregnancy, while others have experienced a progressively earlier delivery with each pregnancy until a typical "incompetent" history occurs.

The diagnosis of incompetent cervix is made when examination reveals cervical dilation in the absence of strong, regular contractions. The diagnosis may also be made before pregnancy or during the first trimester if a typical history of painless cervical dilation and effacement can be documented. Ultrasound examination may be useful in demonstrating funneling and shortening of the cervical length or effacement of the internal cervical os (ACOG, 2003b; Rust, Atlas, Kimmel, Roberts, & Hess, 2005).

Management

Management may include the vaginal placement of a **cerclage** or pursestring suture that is put beneath the cervical mucosa either at the cervical–vaginal junction (a McDonald cerclage) or at the internal cervical os (a Shirodkar cerclage). The intent of the cerclage is to close the cervix. The cerclage is usually removed in the office or clinic at 37 weeks of gestation to facilitate vaginal birth. A new cerclage will need to be placed with subsequent pregnancies. The cerclage may also be left in place, necessitating a cesarean delivery. Sometimes a cerclage is placed via an abdominal incision. It may be placed electively before pregnancy or at 12 to 14 weeks of gestation or as an emergency procedure (Rust & Roberts, 2005). Emergency cerclage may prolong pregnancy and increase the chance of a viable pregnancy outcome (Cockwell & Smith, 2005).

Patients who have an abdominal cerclage must give birth via cesarean section. Before and after cerclage placement, prophylactic **tocolytics** (medications used in an attempt to stop labor) may be given to prevent uterine contractions. Bedrest is an important part of the expectant management and patients may also be placed on home uterine activity monitoring. Depending upon the gestational age and imminence of delivery, patients may receive betamethasone, a glucocorticoid shown to decrease the chance of respiratory distress syndrome (RDS) in premature infants.

 **Now Can You—** Discuss the care of the patient experiencing an early pregnancy loss?

1. Name three signs and symptoms associated with spontaneous abortion, ectopic pregnancy, and gestational trophoblastic disease?
2. Describe your plan of physical and emotional care for the patient who is suffering a pregnancy loss?
3. Identify other team members you would involve in your plan of care?

HYPEREMESIS GRAVIDARUM

Nausea and vomiting is a common condition of pregnancy that affects 70% to 85% of pregnant women and usually resolves by the 16th week of gestation. **Hyperemesis gravidarum** represents the extreme end of the nausea/vomiting spectrum in terms of severity. Criteria for the diagnosis of hyperemesis gravidarum include persistent vomiting unrelated to other causes, a measure of acute starvation (usually large ketonuria), and some discrete weight loss, most often 5% of the pre-pregnancy weight. Hyperemesis gravidarum is the most common indication for admission to the hospital during the first part of pregnancy and is second only to preterm labor as the most common reason for hospitalization during pregnancy (ACOG, 2004a; Hunter, Sullivan, Young, & Weber, 2007).

Etiology and Risk Factors

Although the exact etiology of nausea and vomiting of pregnancy is unknown, several theories have been proposed. Hyperemesis gravidarum may be related to the elevated levels of estrogen or hCG. Or, it may be associated with the transient elevation of thyroid hormone during pregnancy. Others have hypothesized a relationship between hyperemesis and the intrinsic hormones of the gastrointestinal tract (Cunningham et al., 2005). Psychological and metabolic causes have also been explored.

Risk factors include an increased placental mass associated with multiple gestation and molar pregnancy, a history of hyperemesis gravidarum in a previous pregnancy, and a history of motion sickness or migraine headaches. Daughters and sisters of women who experienced hyperemesis gravidarum and women who are pregnant with a female child are also considered to be at risk (ACOG, 2004a).

Maternal and Fetal Effects

In contrast to the early part of the 1900s, maternal mortality is rare today with very few cases reported. Serious complications of hyperemesis gravidarum for the woman and fetus arise in the group of women who cannot maintain their weight despite antiemetic therapy. In addition to increased hospital admissions, some women experience psychosocial morbidity of such significance that they feel compelled to terminate the pregnancy. Depression, **somatization** (the conversion of mental experiences into physical symptoms), and hypochondriasis can also be a problem for some women (ACOG, 2004a).

The effects on the embryo and fetus depend on the severity of the condition. Significant maternal weight loss may be associated with fetal intrauterine growth restriction (IUGR).

Management

Women with a history of nausea and vomiting in a previous pregnancy are advised to regularly take multivitamins before the next conception. Rest is encouraged. The nurse should counsel the woman to avoid foods and sensory stimuli that provoke symptoms (i.e., some women become nauseous when they smell certain foods being prepared) and also to eat small frequent meals of dry, bland foods and include high-protein snacks in their diet. Spicy foods should be avoided. Eating crackers before arising in the morning may be of benefit and ginger capsules have been shown to be effective. If the patient requires hospitalization, intravenous fluids containing dextrose and vitamins are given, and the patient is placed on an NPO status and treated with antiemetics (Box 11-1). Parenteral or enteral feedings may be ordered if the patient is unable to take oral nourishment and if normal weight gain parameters for the gestation of pregnancy are not being achieved (ACOG, 2004a).

Complementary Care: Nausea and vomiting of pregnancy

Ginger, a perennial native to many Asian countries, has been found to be effective in treating nausea and vomiting during pregnancy. The antiemetic effect of this root (taken in a dosage of 1 g per day) is due to its ability to increase gastrointestinal motility. Ginger is available in tablet, capsule, and syrup form. Some concerns about taking ginger during pregnancy have been raised, but to date no significant side effects have been documented.

Elasticized wristbands (i.e., Sea-Bands®) that use a firm object to place pressure on the Neiguan point (acupressure P6 point) are a nonpharmacological, noninvasive method that may lessen the frequency and severity of nausea and vomiting during pregnancy (Hunter et al., 2007).

Hemorrhagic Disorders

Hemorrhagic disorders constitute an obstetric emergency and are a leading cause of maternal death in the United States. Third-trimester vaginal bleeding occurs in 3% to

Box 11-1 Medications for Nausea and Vomiting of Pregnancy

Pyridoxine (vitamin B ₆), 25–75 mg (orally) per day, used alone or in combination with Doxylamine (Unisom), 25 mg (orally) per day
Promethazine (Phenergan) 12.5–25 mg (intravenously, intramuscularly, orally, or rectally) every 4 hours
Dimenhydrinate (Dramamine) 50–100 mg (orally or rectally) every 4–6 hours or 50 mg intravenously (in 50 mL of saline run over 20 minutes) every 4–6 hours
Metoclopramide (Reglan) 5–10 mg (intravenously, intramuscularly or orally) every 8 hours

Sources: ACOG (2004a); Cunningham et al. (2005).

4% of all pregnancies and may be obstetric or nonobstetric in nature (Cunningham et al., 2005). Examples of nonobstetric causes include severe cervicitis, benign and malignant neoplasms, lacerations, and varices.

clinical alert

Early identification of maternal hemorrhage

During pregnancy, the woman's blood volume increases 50% and in the case of multiple gestation, as high as 100%. Due to this expanded blood volume, the patient may be asymptomatic and exhibit vital signs that remain within normal parameters despite a large amount of blood loss. Blood pressure is a very poor indicator of blood volume deficit. The maternal pulse (tachycardia) and/or fetal heart rate (bradycardia or tachycardia) may be the first indicators of maternal instability.

Obstetric Causes of Vaginal Bleeding

PLACENTA PREVIA

Placenta previa is an implantation of the placenta in the lower uterine segment, near or over the internal cervical os. This condition accounts for 20% of all antepartal hemorrhages. There are three recognized variations of placenta previa. With a **complete (total) placenta previa**, the placenta covers the entire cervical os. Since it is associated with the greatest amount of blood loss, a complete placenta previa presents the most serious risk. A **partial previa** describes a placenta that partially occludes the cervical os. A **marginal previa** is characterized by the encroachment of the placenta to the margin of the cervical os (Fig. 11-4). **Placenta accreta**, **percreta**, and **increta** are placentas with abnormally firm attachments to the uterine wall. Unusual placental adherence may accompany a placenta previa.

Placenta previa may be associated with conditions that cause scarring of the uterus such as a prior cesarean section, multiparity, or increased maternal age. A previa may also occur with a large placental mass as seen in multiple gestations and erythroblastosis. Other risk factors include smoking, cocaine use, a prior history of placenta previa, closely spaced pregnancies, African or Asian ethnicity, and maternal age greater than 35 years (Clark, 2004).

Signs and Symptoms

The most common symptom is painless vaginal bleeding. This is believed to occur from small disruptions in the placental attachment during normal development and the subsequent stretching and thinning of the lower uterine segment during the third trimester. Initially, the bleeding is usually a small amount that stops as the uterus contracts to close the open blood vessels. However, bleeding can reoccur at any time and may be associated with profuse hemorrhage and shock that leads to significant maternal and fetal mortality and morbidity. The blood is bright red (Cunningham et al., 2005).

Maternal and Fetal Morbidity and Mortality

Premature delivery is responsible for 60% of perinatal deaths associated with placenta previa. Other fetal risks

Figure 11-4 Placenta previa. A, Complete. B, Partial. C, Marginal.

include preterm premature rupture of the membranes (PPROM), intrauterine growth restriction (IUGR), malpresentation, congenital anomalies, and **vasa previa**. Vasa previa is a condition in which the umbilical cord is implanted into the membranes rather than the placenta. The vessels traverse within the membranes and cross the cervical os before reaching the placenta. The umbilical blood vessels are at risk for laceration. The appearance of bright red blood at the time of rupture of the membranes should alert the nurse to the possibility of a vasa previa. Maternal risks associated with placenta previa are shock, the potential for emergency hysterectomy, and death (Cunningham et al., 2005).

Diagnosis

The timing of the diagnosis of placenta previa has undergone significant change in the last decade. Although third-trimester bleeding was often the first indicator of placenta previa, today, most cases of placenta previa are detected antenatally before the onset of significant bleeding. The common practice of second-trimester abdominal ultrasound for the detection of fetal anomalies has led to this change. However, because most cases of placenta previa diagnosed in the second trimester tend to resolve as the uterus enlarges, management of placenta previa diagnosed in the second trimester differs from that for the same diagnosis made during the third trimester.

In patients diagnosed before 24 weeks' gestation, a repeat ultrasound should be scheduled between 24 and 28 weeks' gestation to confirm the diagnosis of placenta previa. However, if patients experience vaginal bleeding during this interval, they should be managed as presumed cases of placenta previa. Placenta previa should be suspected in all patients who present with bleeding after

24 completed weeks of gestation. Because of the risk of placental perforation, vaginal examinations are not performed. The nurse should advise any patient with a known or suspected previa to inform medical personnel that vaginal exams are prohibited. Abdominal examination generally shows a nontender, soft uterus with normal tone. Leopold maneuvers often reveal the fetus to be in a breech or oblique position or transverse lie because of the abnormal location of the placenta.

Management of the pregnant woman who is experiencing active bleeding associated with a placenta previa requires astute assessment skills so that there is no delay in treatment. Delay can mean the difference between an optimal or poor outcome for the patient and her fetus. Stabilization involves the administration of intravenous fluids and a laboratory workup that includes a complete blood count (CBC), prothrombin time (PT), partial thromboplastin time (PTT), fibrin split products, and fibrinogen. A blood type and crossmatch should be obtained in anticipation of the need for a transfusion. A maternal **Kleihauer–Betke** blood test may be ordered to determine if there has been a transfer of fetal blood cells into the maternal circulation. If the patient is Rh negative and unsensitized, Rh₀(D) immune globulin (RhoGAM) should be administered even if the blood type of the baby cannot be determined (RhoGAM will cause no harm to the woman or her fetus if the fetus is Rh-negative). (See discussion later in this chapter.) The patient is placed on bedrest and the fetus is continuously assessed by electronic fetal monitoring. If time permits, betamethasone (a long-acting corticosteroid) may be administered (to the woman) to promote fetal lung maturity. Labor that cannot be halted, fetal compromise, and life-threatening maternal hemorrhage are indications for immediate delivery regardless of gestational age (Cunningham et al., 2005).

PLACENTAL ABRUPTION

Placenta abruption (**abruptio placentae**) is the premature separation of a normally implanted placenta from the uterine wall. An abruption results in hemorrhage between the uterine wall and the placenta. Fifty percent of abruptions occur before labor and after the 30th week, 15% occur during labor, and 30% are identified only on inspection of the placenta after delivery (Cunningham et al., 2005).

Etiology and Classifications

At the initial point of placental separation, nonclotted blood courses from the site of injury. The enlarging collection of blood may cause further separation of the placenta. Bleeding can be either concealed or revealed (apparent). A concealed hemorrhage occurs in 20% of cases and describes an abruption in which the bleeding is confined within the uterine cavity. The most common abruption is associated with a revealed or external hemorrhage, where the blood dissects downward toward the cervix (Fig. 11-5). Placental abruption may be broadly classified into three grades that correlate with clinical and laboratory findings (Box 11-2).

Perinatal and Maternal Morbidity and Mortality

Maternal mortality from abruptio placentae varies from 0.5% to 5%. The degree of hemorrhage that results from

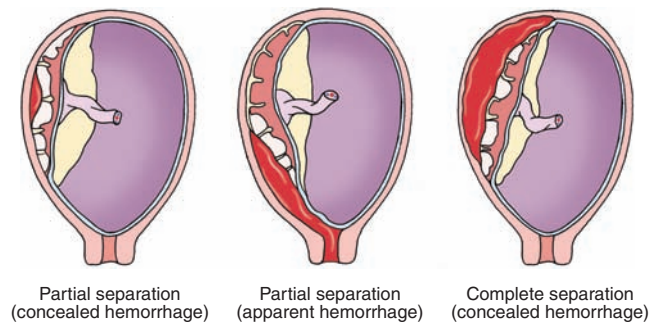

Figure 11-5 Abruptio placentae.

the torn placental vessels can vary from maternal anemia in mild cases to shock, acute renal failure, and maternal death in severe cases. Thirty-five percent of infants whose mothers require an antepartum transfusion will themselves be anemic and require a transfusion after birth. Fetal mortality occurs in about 35% of all placental abruptions and can be as high as 50% to 80% when associated with severe placental abruption. Death results from hypoxia that is related to the decreased placental surface area and maternal hemorrhage (Cunningham et al., 2005).

Signs and Symptoms

The classic presenting sign is third-trimester bleeding associated with severe abdominal pain. Other signs include uterine tenderness and abdominal or back pain, a board-like abdomen and no vaginal bleeding, abnormal contractions and increased uterine tone, fetal compromise as evidenced by late fetal heart rate (FHR) decelerations, bradycardia and lack of variability on the electronic fetal monitor, and fetal demise.

Diagnosis

Vaginal bleeding in the third trimester of pregnancy is the hallmark of placental abruption or placenta previa and should always prompt an investigation to determine its etiology. Diagnosis is made by clinical findings and, when available, ultrasound examination. Recent advances in ultrasound imaging and interpretation have greatly

Box 11-2 Classifications of Abruptio Placentae

Grade 1: Slight vaginal bleeding and some uterine irritability are usually present. Maternal blood pressure is unaffected and the maternal fibrinogen level is normal. The fetal heart rate pattern is normal.

Grade 2: External uterine bleeding is absent to moderate. The uterus is irritable and tetanic or very frequent contractions may be present. Maternal blood pressure is maintained, but the pulse rate may be elevated and postural blood volume deficits may be present. The fibrinogen level may be decreased. The fetal heart rate pattern often shows signs of fetal compromise.

Grade 3: Bleeding is moderate to severe but may be concealed. The uterus is tetanic and painful. Maternal hypotension is frequently present and fetal death has occurred. Fibrinogen levels are often reduced or are less than 150 mg/dL; other coagulation abnormalities (thrombocytopenia, factor depletion) are present.

Source: Cunningham, F., Leveno, K., Bloom, S., Hauth, J., Gilstrap, L., & Wenstrom, K. (2005). *Williams obstetrics* (22nd ed.). New York: McGraw-Hill

improved the diagnosis rate. On ultrasound examination, more than 50% of patients with a confirmed placental abruption will demonstrate evidence of hemorrhage. However, during the acute phase of placental abruption ultrasound findings may not be reliable, so a thorough clinical evaluation of any pregnant woman who presents with bleeding or acute abdominal pain is always indicated (Cunningham et al., 2005).

Management

The potential for rapid deterioration (hemorrhage, disseminated intravascular coagulation [DIC], fetal hypoxia) necessitates delivery in some cases of placental abruption. However, most abruptions are small and noncatastrophic, and therefore do not necessitate immediate delivery. Certain actions, including hospitalization, laboratory studies, continuous monitoring, and ongoing patient support should be initiated when placental abruption is suspected (Box 11-3).

Optimizing Outcomes—Religious beliefs and blood transfusions

Members of Jehovah's Witness do not receive blood products or their derivatives. When bleeding occurs during pregnancy and blood is deemed necessary to save the woman's and/or fetus' life, a very challenging situation exists. Non-blood products may be given but are not always successful. Sometimes a court order is obtained so that blood can be administered to save the life of the woman and/or fetus. The perinatal nurse must be able to respect the family's beliefs and support them during this very difficult time when the health of both the woman and her fetus as well as their religious beliefs are being challenged.

Box 11-3 Care for the Patient Experiencing an Abruptio Placentae

- Hospitalization
- Intravenous placement with a large-bore catheter (16-gauge)
- Labwork: Includes CBC, coagulation studies (fibrinogen, PT, PTT, platelet count, fibrin degradation products), type and screen for 4 units of blood, Kleihauer–Betke for Rh-negative patients. A “clot test” may be performed: a red top tube of blood is drawn, set aside, and checked for clotting. If a clot does not form within 6 minutes or if it forms and lyses within 30 minutes, a coagulation defect is probably present and the fibrinogen level is less than 150 mg/dL.
- Betamethasone may be given to the woman to promote fetal lung maturity when delivery is not imminent.
- Rh(D)-negative patients should receive RhoGAM to prevent isoimmunization.
- Continuous evaluation of intake and output
- Continuous electronic fetal monitoring
- Delivery (cesarean or vaginal birth) may be initiated depending on the status of the mother and the fetus.
- Nursing care is centered on continuous maternal–fetal assessment, with on-going information and emotional support for the patient and her family.

Now Can You—Discuss the management of bleeding during pregnancy?

1. Describe the difference between placenta previa and abruptio placentae?
2. Name three initial steps in the management of the bleeding pregnant patient?
3. Explain why it may be difficult to identify an early maternal hemorrhage?

Preterm Labor

Preterm labor (PTL) is defined as cervical changes and regular uterine contractions occurring between 20 and 37 weeks of pregnancy. Many patients present with preterm contractions, but only those who demonstrate changes in the cervix are diagnosed with preterm labor (ACOG, 2001).

INCIDENCE

Preterm birth, which is a birth that occurs before the completion of 37 weeks of pregnancy, is considered the most acute problem in maternal–child health (American College of Obstetricians and Gynecologists [ACOG]/American Academy of Pediatrics [AAP], 2002). The sequelae of preterm birth has a profound effect on the survival and health of about one in every eight infants born in the United States each year (Freda & Patterson, 2004). From 1981 to 2001, the rate of preterm births in the United States increased by 27%. In 2001, more than 476,000 infants were born at least 3 weeks before their due date (National Center for Health Statistics [NCHS], 2002). In spite of advances in obstetric care, the rate of prematurity has not decreased over the past 40 years and in most industrialized countries, it has slightly increased. The preterm delivery rate in the United States is approximately 11%; in Europe the rate varies between 5% and 7%. A very preterm birth is a birth that occurs before the completion of 32 weeks of pregnancy. In 2003, the very preterm birth rate in the United States was 1.97% (Martin et al., 2005).

ETIOLOGY AND RISK FACTORS

The defining physiological mechanism that triggers the onset of preterm labor is largely unknown but may include decidual hemorrhage (abruption), mechanical factors (uterine overdistention or cervical incompetence), hormonal changes (perhaps mediated by fetal or maternal stress) and bacterial infections (ACOG, 2001). However, a number of risk factors have been associated with preterm labor (Box 11-4).

Collaboration in Caring—Increasing public awareness of the problems of prematurity

The Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN), the American College of Obstetricians and Gynecologists (ACOG), and the American Academy of Pediatrics (AAP) have partnered with the March of Dimes in a multi-million-dollar research, education and awareness campaign to address the problem of prematurity. Educating all women of childbearing age about preterm labor is a crucial component of prevention (March of Dimes, 2005).

MORBIDITY AND MORTALITY

As a result of high-tech neonatal intensive care, advanced technology, and improved medications, the morbidity of babies born after 34 to 35 weeks has decreased and the definition of viability has changed dramatically throughout the past several decades (ACOG, 2002b). The limits of viability keep moving downward in gestation time, and this factor contributes to the increasing numbers of preterm births.

With appropriate medical care, neonatal survival dramatically improves as gestational age increases, with more than 50% of neonates surviving at 25 weeks' gestation, and more than 90% at 28 to 29 weeks' gestation. Short-term neonatal morbidities associated with preterm birth are numerous and include respiratory distress syndrome, intraventricular hemorrhage, periventricular leukomalacia, necrotizing enterocolitis, bronchopulmonary dysplasia, sepsis, and patent ductus arteriosus. Long-term morbidities include cerebral palsy, mental retardation, and retinopathy of prematurity. The risk of these morbidities is directly related to the infant's gestational age and birth weight.

DIAGNOSIS

The diagnosis of preterm labor can be very challenging since many of the symptoms are subtle and common during pregnancy. For example, women experiencing preterm labor may complain of backache, pelvic aching, menstrual-like cramps, increased vaginal discharge, pelvic pressure, urinary frequency, and intestinal cramping with or without diarrhea.

Box 11-4 Various Risk Factors Associated with Preterm Labor and Birth

- History of preterm birth
- Uterine or cervical anomalies
- Multiple gestation
- Hypertension
- Diabetes
- Obesity
- Clotting disorders
- Infection, especially urinary tract infections
- Fetal anomalies
- Premature rupture of membranes
- Vaginal bleeding, especially in the second trimester or in more than one trimester
- Late or no prenatal care
- Illicit drug use
- Smoking
- Alcohol
- Diethylstilbestrol (DES) exposure
- Domestic violence
- Non-Hispanic black race
- Age <17 years or >35 years
- Low socioeconomic status
- Stress
- Long working hours with long periods of standing
- Periodontal disease

Sources: ACOG (2001); Freda & Patterson (2004).

A diagnosis of preterm labor is made when the following criteria are met (ACOG/AAP, 2007):

- A gestation of 20 to 37 weeks
- Documented persistent uterine contractions (4 every 20 minutes or 8 in 1 hour)
- Documented cervical effacement of 80% or greater
- Cervical dilation of more than 0.4 inch (1 cm) or a documented change in dilation

Infection has been implicated as a contributing factor in preterm labor. Prostaglandin production by the amnion, chorion, and decidua is stimulated by cytokines (extracellular factors) that are released by activated macrophages. Group B streptococci, chlamydia, and gonorrhea have been associated with preterm labor and preterm premature rupture of the membranes (Cunningham et al., 2005). It is always prudent for the nurse to obtain a clean-catch, mid-stream, or catheterized urine specimen to identify and treat infection if the patient presents with signs of preterm labor or preterm premature rupture of the membranes.

BIOCHEMICAL MARKERS

Early predictive factors for preterm labor and birth include fetal fibronectin (fFN) and salivary estriol. Fetal fibronectins are proteins produced by the fetal membranes. They are normally secreted in the cervicovaginal fluid until 20 weeks of gestation. Fetal fibronectins are best described as the "glue" that attaches the fetal membranes to the underlying uterine decidua. Their presence between 24 and 34 weeks in a patient with intact membranes suggests an increased risk for preterm labor in both symptomatic and asymptomatic women (Bernhardt & Dorman, 2004). The fFN is retrieved with a sterile cotton-tipped swab placed in the posterior vaginal fornix or in the ectocervical region of the external cervical os for a minimum of 10 seconds. The collection swab is then removed, placed into a manufacturer-supplied medium, and sent to a laboratory that performs the test. Results are reported in 24 to 48 hours. For women whose fetal fibronectin test is negative (e.g., no fFN is detected) the likelihood of giving birth in the following week is less than 1% (Iams & Creasy, 2004).

Observational studies have shown that maternal levels of serum estradiol and salivary estriol increase before the spontaneous onset of term and preterm labor (PTL). Salivary estriol (a biochemical marker under study for its predictive value in preterm labor) is an estrogen produced by fetal trophoblasts. The estriol is derived from adrenal and liver steroid precursors and then converted into estriol in the placenta. Levels of estriol present in maternal saliva have been shown to increase just before preterm labor begins. However, this test has not proven to be very effective since maternal estriol levels normally peak at night. The negative predictive value of both tests is high (95% for fFN; 98% for salivary estriol). Therefore, the tests are better indicators of who will not experience preterm labor rather than of who will experience PTL (ACOG, 2001; Bernhardt & Dorman, 2004).

MANAGEMENT

The two major goals in the management of preterm labor are to inhibit or reduce the strength and frequency of contractions, thus delaying the time of delivery, and to optimize the fetal status before preterm delivery (ACOG,

2003c; Cunningham et al., 2005). **Tocolysis** is the use of medications to inhibit uterine contractions. Drugs used for this purpose (“tocolytics”) include the beta-adrenergic agonists (also called beta-mimetics), magnesium sulfate (MgSO₄), prostaglandin synthetase inhibitors (indomethacin [Indocin]) and calcium channel blockers (nifedipine [Procardia]). The most commonly used tocolytics are the beta-mimetics ritodrine (Yutopar) and terbutaline sulfate (Brethine) and magnesium sulfate, a CNS depressant. Although ritodrine is FDA approved for tocolysis, it is not used for this purpose as frequently as is terbutaline sulfate, which is not FDA approved for tocolysis. The use of these medications is contraindicated under certain conditions (Box 11-5). At present, it is believed that the best reason to use tocolytic drugs is to allow an opportunity to begin the administration of antenatal corticosteroids to accelerate fetal lung maturity. Also, delaying the birth provides time for maternal transport to a facility equipped with a neonatal intensive care unit (ACOG, 2003b). Caring for the patient receiving tocolytic therapy requires the nurse to be cognizant of not only the safety aspects of administering the medication to the pregnant woman but also to the emotional needs of the patient as attempts to halt the preterm labor are being made (Box 11-6).

Family Teaching Guidelines... Preventing Prematurity

Freda and Patterson (2004) suggest that nurses be proactive by educating women about preterm labor and teaching them how to recognize the warning signs and symptoms.

- ◆ Encourage all pregnant women to obtain prenatal care.
- ◆ Educate all pregnant women as to the signs and symptoms of preterm labor.
- ◆ Eliminate the term “Braxton-Hicks” from teaching (women may delay seeking treatment if they believe they are only experiencing Braxton-Hicks contractions).
- ◆ Ask all pregnant women if they have had any symptoms of preterm labor.
- ◆ Screen for vaginal and urogenital infections and treat appropriately.
- ◆ Teach women about the dangers of douching.
- ◆ Assess all pregnant women for intimate partner violence and intervene.
- ◆ Discuss stress levels early in pregnancy, and intervene.
- ◆ Assess all pregnant women for nutritional status and weight gain in pregnancy and intervene as necessary.
- ◆ Assess for illicit drug use, and help the woman get into treatment.
- ◆ Encourage women who have preterm labor symptoms to drink fluids, lie down for 1 hour, and go to the hospital for a vaginal exam if symptoms continue.
- ◆ Remind the woman with symptoms that she should not hesitate to call her provider repeatedly if her symptoms recur.

Now Can You— Care for the patient experiencing preterm labor?

1. Identify five symptoms of preterm labor?
2. Discuss the use of tocolytics in preterm labor?
3. Develop a teaching plan about preterm labor for pregnant women?

Box 11-5 Contraindications to the Use of Tocolytics in Preterm Labor

- Significant maternal hypertension (eclampsia, severe preeclampsia, chronic hypertension)
- Antepartum hemorrhage
- Cardiac disease
- Any medical or obstetric condition that contraindicates prolongation of pregnancy
- Hypersensitivity to a specific tocolytic agent
- Gestational age >37 weeks
- Advanced cervical dilation
- Fetal demise or lethal anomaly
- Chorioamnionitis
- In utero compromise
 - Acute: nonreassuring fetal heart rate pattern
 - Chronic: IUGR or substance abuse

Source: Cunningham, F., Leveno, K., Bloom, S., Hauth, J., Gilstrap, L., & Wenstrom, K. (2005). *Williams obstetrics* (22nd ed.). New York: McGraw-Hill

Box 11-6 Nursing Care of the Patient Receiving Tocolytic Therapy

- Explore the woman’s understanding of what is taking place.
- Include the woman’s partner in all discussions about medications and their effects.
- Provide anticipatory guidance regarding what is likely to happen during medication administration.
- Position the woman on her side for better placental perfusion.
- Explain the side effects and contraindications of the drug.
- Assess blood pressure, pulse, and respirations regularly according to hospital policies (in many institutions every 15 minutes).
- Notify the health care provider if systolic blood pressure is >140 mm Hg or <90 mm Hg.
- Notify the health care provider if diastolic blood pressure is >90 mm Hg or <50 mm Hg.
- Assess for signs of pulmonary edema (chest pain, shortness of breath).
- Assess for the presence of deep tendon reflexes (DTRs).
- Assess output every 1 hour.
- Notify provider if output is <30 mL/hr.
- Limit intake to 2500 mL/day (90 mL/hr).
- Provide psychosocial support and opportunities for the patient to express anxiety.

Premature Rupture of the Membranes

To facilitate an understanding of premature rupture of the membranes (PROM), it is helpful to first define the various terms used:

- **Premature** rupture of the membranes (PROM) is defined as rupture of the membranes before the onset of labor at any gestational age.
- **Preterm** rupture of membranes is defined as rupture of the membranes before 37 completed weeks of gestation. It is a common cause of preterm labor, preterm delivery, and chorioamnionitis.
- **Preterm premature** rupture of the membranes (PPROM) is defined as a combination of both terms—rupture occurs before the 37th completed week of gestation and in the absence of labor. PPRM accounts for 25% of all cases of premature rupture of the amniotic membranes and is responsible for 30% to 40% of all preterm deliveries (Cunningham et al., 2005).

PATHOPHYSIOLOGY

Premature rupture of the membranes is multifactorial. Choriodecidual infection or inflammation appears to play an important role in the etiology of PPRM, especially at early gestational ages. Other factors include decreased amniotic membrane collagen, lower socioeconomic status, cigarette smoking, sexually transmitted infections, prior preterm delivery, prior preterm labor during the current pregnancy, uterine distention (e.g., multiple gestation, hydramnios), cervical cerclage, amniocentesis, and vaginal bleeding in pregnancy (Mercer, 2003). In many cases, the cause is not known.

DIAGNOSIS

Most often, the patient reports a gush or leakage of fluid from the vagina. However, any increased vaginal discharge should be evaluated. The diagnosis is based on the patient's history of leaking vaginal fluid and the finding of a pooling of fluid on sterile speculum examination. Nitrazine and fern tests confirm the diagnosis of PROM. Easily performed, these tests are used to discriminate between vaginal discharge and amniotic fluid. (See Procedure 12-2.) The tampon test may also be used to diagnose PROM. With this test, a blue dye (indigo carmine) is injected into the uterus via amniocentesis. A previously inserted vaginal tampon is then checked in 30 minutes for the presence of blue dye. The level of amniotic fluid in the uterus may also be checked via an abdominal ultrasound examination. Leakage of amniotic fluid is consistent with findings of **oligohydrannios** (decreased amniotic fluid).

MANAGEMENT

The risk of perinatal complications changes dramatically according to the gestational age when rupture of the membranes occurs. Clinical practice varies, and, at present, considerable controversy exists concerning the optimal management of PPRM. However, there is general consensus in regard to the following factors:

- Gestational age should be established based on clinical history and prior ultrasound assessment when available.
- Ultrasound should be performed to assess fetal growth, position, and residual amniotic fluid.

- The woman should be assessed for evidence of advanced labor, chorioamnionitis (intrauterine infection), abruptio placentae, and fetal distress.
- Patients with advanced labor, intrauterine infection, significant vaginal bleeding, or nonreassuring fetal testing are best delivered promptly, regardless of gestational age.

There is further debate over the use of tocolytics, corticosteroids, and antibiotics in patients with PPRM. Tocolysis appears to be of little benefit in PPRM and may be harmful when chorioamnionitis is present. However, in many hospitals, tocolytic therapy is instituted for 48 hours, especially with earlier gestational ages, in order to administer a course of corticosteroids to enhance fetal lung maturity (Cunningham et al., 2005).

Conservative management includes inpatient observation unless the membranes reseal and the leakage of fluid stops. This approach initially consists of prolonged continuous fetal and maternal monitoring combined with modified bedrest to promote amniotic fluid reaccumulation and spontaneous membrane sealing. Delivery of the fetus should be accomplished if signs of infection are present: maternal temperature of 100.4°F (38°C) or greater, foul-smelling vaginal discharge, elevated white blood count, uterine tenderness, and maternal and/or fetal tachycardia.

Without intervention, approximately 50% of patients who have ROM will go into labor within 24 hours, and up to 75% will do so within 48 hours. These rates are inversely correlated to the gestational age at the time of rupture of the membranes. Thus, patients with ROM before 26 weeks' gestational age are more likely to gain an additional week than those greater than 30 weeks' gestation. While maintaining the pregnancy to gain further fetal maturity can be beneficial, prolonged PPRM has been correlated with an increased risk of chorioamnionitis, placental abruption and cord prolapse (Cunningham et al., 2005).

The nurse's role in caring for the patient with PPRM includes explaining to the patient that she will be on full or modified bedrest and her vital signs will be checked at least every 4 hours to detect early signs of a developing infection. If the patient does not exhibit signs of labor, intermittent fetal monitoring is appropriate. Frequent ultrasound examinations are performed to assess amniotic fluid levels. An important component of the nursing care plan centers on providing emotional support to the patient who is understandably worried about the outcome for her baby. The nurse should encourage the woman and her family members to ask questions and express fears and concerns. When the nurse does not have enough information to respond adequately, another health team member who can appropriately answer the patient's questions and address her concerns should be contacted.

Now Can You—Discuss the care of the patient with premature rupture of the membranes?

1. Name three factors associated with premature rupture of membranes?
2. Discuss three major complications that accompany premature rupture of membranes?
3. Describe the Nitrazine, fern and tampon tests?
4. Formulate a plan of care for the patient who has experienced premature rupture of membranes?

Hypertensive Disorders of Pregnancy

Hypertensive disorders are the most common medical complication of pregnancy. The incidence of hypertensive disorders is between 5% and 10%, and this complication is the second leading cause of maternal death in the United States (embolic events are the leading cause) (Martin et al., 2005). Hypertensive disorders contribute significantly to stillbirth and neonatal morbidity and mortality (National High Blood Pressure Education Program Working Group [NHBPEP], 2000; Sibai, Dekker, & Kupfermine, 2005) and can result in maternal cerebral hemorrhage, disseminated intravascular coagulation (DIC), hepatic failure, acute renal failure, pulmonary edema, adult respiratory distress syndrome, aspiration pneumonia, and abruptio placentae (ACOG, 2002a).

CLASSIFICATIONS AND DEFINITIONS

The terminology used to describe the hypertensive disorders of pregnancy is generally associated with imprecise usage. This misuse of terminology often creates confusion for health care professionals who care for women who experience hypertensive complications during pregnancy and childbirth (Sibai et al., 2005). Numerous attempts have been made to accurately describe pregnancy-related hypertensive disorders. The NHBPEP has recommended the following classifications (NHBPEP, 2000):

- Chronic hypertension
- Preeclampsia–eclampsia
- Chronic hypertension with superimposed preeclampsia
- Gestational (or transient) hypertension

Clinically, there are two basic types of hypertension during pregnancy. Distinction between chronic hypertension and pregnancy-induced hypertension (PIH) is based on the timing of the onset of the hypertension. However, NHBPEP advocates discarding the term pregnancy-induced hypertension because it does not differentiate between gestational hypertension, a relatively benign disorder, and the more serious condition of preeclampsia (Peters & Flack, 2004).

Chronic Hypertension

Chronic hypertension is defined as hypertension that is present and observable before pregnancy or hypertension that is diagnosed before the 20th week of gestation. Hypertension is defined as a blood pressure greater than 140/90 mm Hg. Hypertension for which a diagnosis is confirmed for the first time during pregnancy, and which persists beyond the 84th day postpartum, is also classified as chronic hypertension (Roberts, 2004).

Preeclampsia and Eclampsia

Preeclampsia is a pregnancy-specific systemic syndrome clinically defined as an increase in blood pressure (140/90) after 20 weeks' gestation accompanied by proteinuria (NHBPEP, 2000; Peters & Flack, 2004). This increase in blood pressure represents a change from the usual blood pressure findings during pregnancy. Under normal conditions, the blood pressure increases during the first trimester, decreases in the second trimester, and

then returns to nonpregnant values by the end of the third trimester.

At one time, the presence of edema was included in the definition of preeclampsia, but this criterion has been removed since edema is common during pregnancy. However, the sudden onset of severe edema always warrants close evaluation to rule out preeclampsia or other pathological processes such as renal disease. **Eclampsia** is the occurrence of a grand mal seizure in a woman with preeclampsia who has no other cause for seizure (ACOG, 2002a; Roberts, 2004).

Nursing Insight—Recognizing variations in the onset of eclampsia

Approximately one third of cases of eclampsia develop during pregnancy; one third during labor and one third within 72 hours postpartum (Emery, 2005).

Chronic Hypertension with Superimposed Preeclampsia

There is ample evidence that preeclampsia can occur in women who are already hypertensive and that the prognosis for the woman and her fetus is worse for these patients than when either condition exists alone. Distinguishing superimposed preeclampsia from worsening chronic hypertension tests the skills of the clinician and the obstetric nurse. According to Roberts (2004), the following criteria are necessary to establish a diagnosis of superimposed preeclampsia:

1. Hypertension and no proteinuria early in pregnancy (prior to 20 weeks' gestation) and new-onset proteinuria, (defined as the urinary excretion of 0.3 g of protein in a 24-hour specimen) *or*
2. Hypertension and proteinuria before 20 weeks' gestation:
 - A sudden increase in protein—urinary excretion of 0.3 g protein or more in a 24-hour specimen, or two dipstick test results of 2+ (100 mg/dL), with the values recorded at least 4 hours apart, with no evidence of urinary tract infection
 - A sudden increase in blood pressure in a woman whose blood pressure has been well controlled
 - Thrombocytopenia (platelet count lower than 100,000/mm³)
 - An increase in the liver enzymes alanine transaminase (ALT) or aspartate transaminase (AST) to abnormal levels

Gestational (or Transient) Hypertension

This is a nonspecific term used to describe the woman who has a blood pressure elevation detected for the first time during pregnancy, without proteinuria. This term is used only until a more specific diagnosis can be assigned postpartum. If preeclampsia does not develop (e.g., protein does not become present in the urine), and the woman's blood pressure falls into a normal range by 12 weeks postpartum, the diagnosis of transient hypertension of pregnancy can be made (Roberts, 2004).

Preeclampsia

PATHOPHYSIOLOGY

The normal physiological adaptations to pregnancy are altered in the woman who develops preeclampsia. Preeclampsia is a multisystem, vasopressive disease process that targets the cardiovascular, hematologic, hepatic, renal, and central nervous systems.

Preeclampsia is associated with a clinical spectrum of events that range from mild to severe with a potential endpoint of eclampsia. Patients do not suddenly “catch” severe preeclampsia or develop eclampsia but rather progress in a fairly predictable course through the clinical spectrum. In most cases, the progression is relatively slow, and the disorder may never proceed beyond mild preeclampsia. In other situations, the disease can progress more rapidly, and change from a mild to a severe form in a matter of days or weeks. In the most serious cases, the progression can be rapid: mild preeclampsia evolves to severe preeclampsia or eclampsia over hours or days (Roberts, 2004). Hence, the nurse must alert the patient to signs and symptoms that signal a worsening condition and continuously assess the patient for any change.

Although the pathophysiology is poorly understood, it is clear that the blueprint for its development is laid down early in pregnancy. Preeclampsia is a disease of the placenta because it has been documented in pregnancies that involve trophoblastic tissue but no fetus (i.e., a molar pregnancy). In a normal pregnancy, the endovascular trophoblast cells of the placenta transform uterine spiral

arteries to accommodate an increased blood flow. In the presence of preeclampsia, the arterial transformation is incomplete. Women with preeclampsia have a distinctive lesion in the placenta termed “acute atherosclerosis” (fat accumulation in the placental arteries). Their placentas also exhibit a greater degree of infarction (necrosis related to decreased blood supply) than are found in placentas of normotensive women. These pathological changes can lead to decreased placental perfusion and placental hypoxia (Cunningham et al., 2005; NHBPEP, 2000).

Vasospasm and endothelial cell damage are the major underlying pathophysiological events in preeclampsia. Vasospasm may be associated with an elevation in arterial blood pressure and resistance to blood flow. It is unclear whether vasospasm produces damage to the vessels or if damage to the vessels produces vasospasm. Regardless, the restriction of blood flow is associated with endothelial cell damage, and this tissue insult prompts the systemic utilization of platelets and fibrinogen. The widespread vascular changes alter blood flow and result in hypoxic damage to vulnerable organs. Over time, the alterations produce widespread maternal vasospasm that results in decreased perfusion to virtually all organs, including the placenta. Associated physiological events include decreased plasma volume, activation of the coagulation cascade, and alterations in the glomerular endothelium. The increased platelet activation and markers of endothelial activation can predate clinically evident preeclampsia by weeks or even months (Sibai et al., 2005) (Fig. 11-6).

In addition to endothelial damage and vasospasm, women with preeclampsia show an exaggerated response

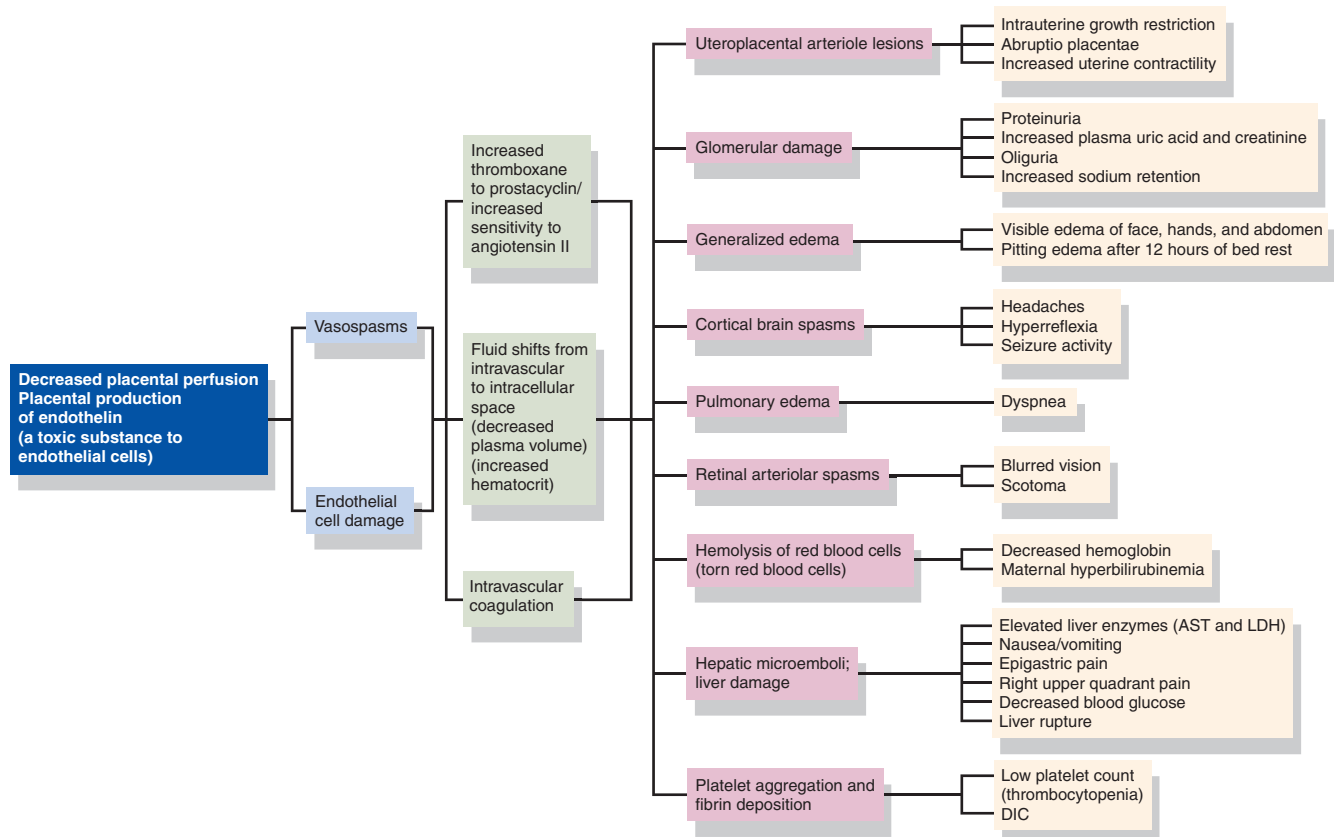

Figure 11-6 Pathophysiological changes of preeclampsia.

to angiotensin II. Angiotensin II is produced by the renin-aldosterone pathway in the kidney when enzymes are released to convert angiotensin I to angiotensin II. Angiotensin II is a potent vasoconstrictor that can trigger arterial hypertension. During a normal pregnancy, the patient's physiological response to angiotensin II is blunted or decreased. In women with preeclampsia, the normal "blunting" does not occur (Sibai et al., 2005).

Pregnancy is normally associated with a low sensitivity to pressor agents, which increase blood pressure. Women with preeclampsia, however, demonstrate an exaggerated response to pressor agents. An imbalance between prostacyclin, a prostaglandin and potent vasodilator, and thromboxane (a compound synthesized in platelets from a prostaglandin), is also thought to occur. Prostacyclin exerts a direct effect on the tone of the arterial smooth muscles. It decreases blood pressure, prevents platelet aggregation (clumping) and promotes uterine blood flow. Thromboxane exerts the opposite effect. It is a potent vasoconstrictor that causes an increase in blood pressure and platelet aggregation (NHBPEP, 2000; Sibai et al., 2005).

Nursing Insight— SPASMS: A memory enhancer when caring for a patient with preeclampsia

- S** Significant blood pressure changes may occur without warning.
- P** Proteinuria is a serious sign of renal involvement.
- A** Arterioles are affected by vasospasms that result in endothelial damage and leakage of intravascular fluid into the interstitial spaces. Edema results.
- S** Significant laboratory changes (most notably, liver function tests [LFTs] and the platelet count) signal worsening of the disease.
- M** Multiple organ systems can be involved: cardiovascular, hematologic, hepatic, renal and central nervous system.
- S** Symptoms appear after 20 weeks of gestation

RISK FACTORS FOR PREECLAMPSIA/ECLAMPSIA

Preeclampsia is a subtle and insidious disease process. Signs and symptoms become apparent relatively late in the course of the disease, usually during the third trimester of pregnancy. Preeclampsia occurs in about 5% to 8% of pregnancies and there is no truly "typical" patient (ACOG, 2002a; Martin et al., 2005).

Risk factors associated with preeclampsia are presented in Box 11-7. Throughout the world, an estimated 50,000 women die each year from preeclampsia. Preeclampsia is more likely to develop in women whose mothers had preeclampsia than in women whose mothers did not. Nulliparity has been confirmed as a risk factor in both large-scale epidemiological studies and in detailed clinical studies. Although some studies have shown an increased risk for preeclampsia in multiparous women with new partners for subsequent pregnancies (Longo et al., 2003) other investigators found that a change of partner did not increase the recurrence rate of preeclampsia (Hjartardottir et al., 2004). Approximately 40% to 50% of multiparous women with a diagnosis of preeclampsia have experienced preeclampsia during a previous pregnancy. Among nulliparous women,

Box 11-7 Risk Factors for Preeclampsia

- Primigravida (6–8 times greater risk)
- Age extremes (<17 years and >35 years)
- Diabetes
- Preexisting hypertension
- Multiple gestation (5 times greater risk)
- Fetal hydrops (10 times greater risk)
- Hydatidiform mole (10 times greater risk)
- Preeclampsia in a previous pregnancy
- Family history
- Obesity
- Immunological factors
- Chronic renal disease
- Rh incompatibility
- African-American ethnicity
- Pregnancies that result from donor insemination, oocyte donation, embryo donation

Sources: ACOG Practice Bulletin No. 33 (2003); Duckitt & Harrington (2005); Sibai, Dekker, & Kupferminc (2005).

black women have a risk of preeclampsia that is twice as high as that of white women; they are also more likely to have hypertension that is independent of pregnancy. Obese women (a body index of 29 or greater) are three times more likely to develop preeclampsia than are nonobese women (Sibai et al., 2005).

Immunological factors, genetic disposition and environmental factors may also contribute to the development of preeclampsia. The high incidence of preeclampsia in many poor countries suggests that an inadequate diet may constitute a risk factor. Dietary inadequacies that have been proposed as relevant to the development of preeclampsia include deficiencies of calcium, zinc, vitamins C and E, and n-3 essential fatty acids (Sibai et al., 2005).

MATERNAL AND FETAL MORBIDITY AND MORTALITY

A number of maternal and fetal complications are likely to develop if preeclampsia progresses from a mild to a severe form. These include placental abruption, acute renal failure, seizures, pulmonary edema, cerebral hemorrhage, hepatic failure, disseminated intravascular coagulation (DIC), IUGR, non-reassuring fetal heart rate pattern on antepartum testing and fetal death. The maternal complications associated with preeclampsia are related to the widespread arteriolar vasoconstriction that affects the brain (seizure and stroke), kidneys (oliguria and renal failure), liver (edema and subcapsular hematoma), and small blood vessels (small ruptures within the walls of the vessels use up large amounts of platelets in an effort to correct the bleeding. This results in thrombocytopenia and DIC) (Cunningham et al., 2005).

The perinatal outcome in preeclampsia is dependent on one or more of the following factors: the gestational age at the onset of the disease process, the presence of a multiple gestation, and the presence of underlying maternal hypertension or renal disease. In patients with mild preeclampsia

at term, the perinatal mortality, incidence of fetal growth restriction, and neonatal morbidity are similar to those associated with normotensive pregnancies. In contrast, both perinatal and maternal morbidity are increased when the disease is severe, particularly when disease develops in the second trimester, and the fetus is quite immature. Maternal death and severe complication rates from preeclampsia are also lowest among women who receive regular prenatal care and are managed by experienced physicians in tertiary centers (August, 2004).

MANAGEMENT OF PREECLAMPSIA/ECLAMPSIA

Once the diagnosis of preeclampsia has been made, delivery of the fetus is the only cure. The primary considerations of therapy must always be the safety of the patient and the delivery of a live, mature newborn who will not require intensive and prolonged neonatal care. Mild preeclampsia, which presents as a maternal blood pressure of 140/90 and +1 to +2 proteinuria on urine dipstick, can often be managed at home after the patient has had a careful assessment of her signs and symptoms, a physical examination, laboratory tests, and evaluation of fetal well-being.

However, the National High Blood Pressure Education Program recommends that for patients with new-onset preeclampsia, the initial examination be performed in the hospital. If the woman's blood pressure and laboratory test results indicate that her care may be safely managed at home, the nurse must make certain that the patient fully understands the signs and symptoms associated with a worsening of the condition. The effects of illness, language, age, culture, beliefs, and support systems must be considered for each patient and appropriate community resources should be explored (Poole, 2004b).

Family Teaching Guidelines... Home Management of the Pregnant Patient with a Hypertensive Disorder

Before discharge, it is important to ascertain that the home environment is conducive to rest and the patient will be able to rest frequently throughout the day. It is essential that the patient can verbalize understanding of the importance of keeping all prenatal appointments and that she must immediately notify her physician or midwife at the first appearance of:

- ◆ Blood pressure values greater than those at the time of hospital discharge— M.D. or CNM should provide parameters
- ◆ Visual changes
- ◆ Epigastric pain
- ◆ Nausea and vomiting
- ◆ Bleeding gums
- ◆ Headaches
- ◆ Increasing edema, especially of the hands and face
- ◆ Decreasing urinary output
- ◆ Decreased fetal movement
- ◆ “Just not feeling right”

Across Care Settings: Promoting bed rest at home

Obtaining an adequate amount of bed rest is not always easy, especially for women who have other children at home and no extended family to help. The nurse may offer suggestions such as lying down and resting while the other children nap or bringing young children into bed and reading them a story or asking a neighbor to watch the children. The woman's partner should also be involved in formulating a plan to help facilitate rest. Church groups may be able to help out with childcare, running errands, or preparing meals for the family. When friends ask what they can do to help, suggest that the woman have a prepared “wish list” of specific actions that would make it easier for her to maintain bedrest. The hospital's social services department should also be contacted and asked for assistance. They are a useful resource that can share information about organizations that can be called upon to help.

Since lying in the lateral side position decreases pressure on the vena cava, the woman is instructed to maintain this position as much as possible. This position also increases venous return, circulatory volume, and placental and renal perfusion. Improving renal blood flow helps decrease angiotensin II levels, promotes diuresis, and lowers blood pressure. Antihypertensive medications have not been shown to improve perinatal outcomes in mild to moderate preeclampsia (blood pressure 140 to 160/90 to 110) and should not be routinely prescribed (NHBPEP, 2000).

critical nursing action Facilitating Effective CPR for the Pregnant Patient

Always instruct pregnant patients never to lie on their backs and explain that the weight of their baby exerts pressure on the large blood vessels and impedes blood flow back to the heart. If the pregnant patient experiences a cardiac arrest, this information is essential. CPR will not be effective if the fetus remains on the large blood vessels. One nurse must take responsibility to displace the uterus to the left while the cardiac compressions are being performed.

The clinical course of severe preeclampsia may be characterized by a progressive deterioration in both the maternal and fetal conditions. Pregnancies complicated by severe preeclampsia have been associated with increased rates of perinatal mortality and significant risks for maternal morbidity and mortality. Because of this fact, there is universal agreement that all patients should be promptly delivered if the disease develops after 34 weeks' gestation or before that time if there is evidence of maternal or fetal compromise. Management of severe preeclampsia includes the following clinical actions (Cunningham et al., 2005; Sibai et al., 2005):

1. Seizure prophylaxis with magnesium sulfate, which has been universally accepted as the drug of choice because of its CNS-depressant action.
2. Antihypertensive medications (Tables 11-1 and 11-2)
 - The use of antihypertensive agents in severe preeclampsia is generally indicated when diastolic blood pressures reach or exceed 110 mm Hg.

Table 11-1 Medications Used to Treat Chronic Severe Hypertension in Pregnancy

Agent (trade name)	Class	Dose	Contraindications and Adverse Effects	Breastfeeding
Alpha-methyldopa (Aldomet)	Central alpha-adrenergic inhibitor	Starting dose = 250 mg po, tid or qid. Maximum dosage of 2–4 g/24 hr	Methyldopa hypersensitivity, history of hepatitis, autonomic dysfunction, lethargy or syncope. Can cause liver damage, fever, Coombs-positive hemolytic anemia	Safe
Labetalol (Trandate, Normodyne)	Alpha-/beta-adrenergic blocker	100–400 mg po, bid or tid maximum dose 2400 mg a day	Labetalol hypersensitivity, bradycardia, asthma, heart block, heart failure. Can cause maternal and fetal bradycardia, hypotension, bronchospasm	Safe
Nifedipine (Adalat, Procardia)	Calcium channel blocker	10–30 mg po tid slow release once a day. Maximum of 90 mg/day	Hypersensitivity to calcium channel blockers, persistent dermatologic reactions, congestive heart failure. Can potentiate cardiac depressive effect of magnesium sulfate	Safe
Furosemide (Lasix)	Loop diuretic	20–80 mg po, qd or bid	Hypersensitivity to furosemide, anuria, or depleted blood count. Can cause profound diuresis with water and electrolyte depletions, sun sensitivity to exposure to sunlight, hyperuricemia and gout, exacerbation of SLE, abdominal cramping, diarrhea, tinnitus, dizziness, pancreatitis, and cholestasis	Safe
Hydrochlorothiazide (HydroDIURIL)	Loop diuretic	25–50 mg po, qd	Anuria, renal disease, liver disease, SLE, hypersensitivity to hydrochlorothiazide or other sulfonamide derived drugs. Can cause weakness, hypotension, pancreatitis, cholestasis, anemia, allergic reactions, electrolyte disturbance, hyperglycemia, hyperuricemia, dizziness, renal dysfunction	Risk is remote, but there are concerns about potential thrombocytopenia in infants.

Table 11-2 Medications Used to Acutely Treat Severe Hypertension in Pregnancy

Agent (Trade Name)	Class	Dosage
Labetalol hydrochloride (Normodyne, Trandate)	Alpha-/beta-adrenergic blocker	IV bolus 20 mg; if no response, double dose and repeat every 15 min, up to a cumulative maximum dose of 300 mg
Hydralazine (Apresoline, Neopresol)	Peripheral/arterial vasodilator	IV bolus 5–10 mg every 15–20 minutes to a maximum dose of 30 mg
Nifedipine (Adalat, Procardia)	Calcium channel blocker	Nifedipine can be given po in doses of 10 mg repeated every 15 minutes to a maximum of 30 mg
Sodium nitroprusside (Nipride, Nitropress)	Vasodilator	0.25 mcg/kg per minute (increase by 0.25 µg/kg/min every 5 minutes) to a maximum of 5 µg/kg per minute

Source: Yankowitz, J. (2004). Pharmacologic treatment of hypertensive disorders during pregnancy. *The Journal of Perinatal & Neonatal Nursing*, 18(3), 230–240. Reproduced with permission.

The goal of therapy is to reduce the risk of cerebral vascular accident, while maintaining uteroplacental perfusion. A decrease in the diastolic pressure to less than 90 mm Hg in the patient with severe hypertension will decrease placental blood flow, often with a decrease in the fetal heart rate (FHR). Management is directed at reducing the diastolic blood pressure to a value of less than 110 mm Hg, but greater than 95 to 100 mm Hg.

- Invasive hemodynamic monitoring may be required if any of the following are present:
 - Oliguria unresponsive to a fluid challenge
 - Pulmonary edema
 - Hypertensive crisis refractory to conventional therapy
 - Cerebral edema
 - Disseminated intravascular coagulation (DIC)
 - Multisystem organ failure

**medication:** Magnesium Sulfate

Magnesium sulfate (mag-nee-zhum sul-fate)

Pregnancy Category: D**Indications:**

Anticonvulsant in severe eclampsia or preeclampsia

Unlabeled Use: Preterm labor**Actions:** Plays an important role in neurotransmission and muscular excitability**Therapeutic Effects:** Resolution of eclampsia**Pharmacokinetics:****ABSORPTION:** IV administration results in complete bioavailability; well absorbed from IM sites**DISTRIBUTION:** Widely distributed. Crosses the placenta and is present in breast milk.**METABOLISM AND EXCRETION:** Excreted primarily by the kidneys**HALF-LIFE:** Unknown**Contraindications and Precautions:****CONTRAINDICATED IN:** Hypermagnesemia/hypocalcemia/anuria/heart block/active labor or within 2 hours of labor (unless used for preeclampsia or eclampsia)**USE CAUTIOUSLY IN:** Any degree of renal insufficiency**Adverse Reactions and Side Effects:**

Central nervous system: Drowsiness

Respiratory system: Decreased respirations

Cardiovascular system: Arrhythmias, hypotension, bradycardia

Gastrointestinal system: Diarrhea

Dermatology system: Flushing, sweating

Metabolic: hypothermia

Interactions: Potentiates neuromuscular blocking agents**Route and Dosage (Eclampsia/Preeclampsia):** Piggyback a solution of 40 g of magnesium sulfate in 1000 mL of lactated Ringer's solution—use an infusion control device (pump) at the ordered rates; loading dose: initial bolus of 4–6 g over 15–30 min; maintenance dose: 1–3 g/hr.**IM:** 4–5 g given in each buttock, can be repeated at 4-hour intervals; use Z-track technique. (Note: IM route rarely used because the absorption rate cannot be controlled and injections are painful and may result in tissue necrosis.)**Time/Action Profile for Anticonvulsant Effect:****IM:** Onset is 60 minutes with peak unknown and duration is 3–4 hours **IV:** onset is immediate with peak unknown and duration is 30 minutes.**Nursing Implications:** Remember that this is a very potent, high alert drug!

Explain purpose and side effects of the medication to the patient and her companion.

Explain that she may feel very warm and become flushed and experience nausea and vomiting, visual blurring, and headaches.

Magnesium sulfate must never be abbreviated (i.e., MgSO₄ is not acceptable) and requires a written order by the physician for administration.

Always use an infusion pump for administration and run the medication piggyback, not as the main line.

Monitor pulse, blood pressure, respirations, and ECG frequently throughout parenteral administration. Respirations should be at least 16/min before each dose.

Monitor neurological status before and throughout therapy.

Institute seizure precautions

Keep the room quiet and darkened to decrease the likelihood of triggering seizure activity

Patellar reflexes should be tested before each parenteral dose of magnesium sulfate. If absent, no additional dose should be administered until a positive response returns.

Monitor intake and output. Urine output should be maintained at a level of at least 100 mL/4 hr.

Serum magnesium levels and renal function should be monitored periodically throughout administration of parenteral magnesium sulfate.

Have 10% calcium gluconate available should toxicity occur.

Administer 10 mL intravenously over 1–3 minutes until signs and symptoms are reversed.

After delivery, monitor the newborn, for hypotension, hyporeflexia, and respiratory depression.

Data from Deglin, J.H., & Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.**clinical alert****Accidental overdose of magnesium sulfate administration can pose a significant risk to both mother and newborn**

Current recommendations to prevent magnesium sulfate accidents:

- A standardized unit protocol should be consistent and include: standing orders addressing the initial bolus and maintenance dose to be administered; how the pump should be programmed; the maintenance IV solutions that will be used and the frequency that the fetus and mother will be assessed.
- Administer IV magnesium sulfate (including the initial bolus) only through a controlled infusion device with free-flow protection.
- Use universal standardized dose prepackaged magnesium sulfate.
- Have a second nurse check the initial magnesium sulfate IV bag and pump settings (and every magnesium sulfate IV bag that is added and each subsequent rate change).
- Use a 100-mL (4 g) or 150-mL (6 g) IV piggyback (IVPB) for the initial bolus instead of bolusing from the main bag with a rate change on the pump.
- Use color-coded tags on the lines as they go into the pumps and into the IV ports.
- Provide 1:1 nursing care for women in labor who are receiving magnesium sulfate.
- When care is transferred to another nurse, have both nurses together at the bedside review the pump settings for both the magnesium sulfate and mainline IV fluids and review written physician orders for magnesium sulfate infusion orders.
- Implement periodic magnesium sulfate overdose drills with airway management and calcium administration with the physician and nurse team members participating together.
- Maintain the calcium antidote in the patient's room in a locked box (Simpson & Knox, 2004).

NURSING ASSESSMENTS

Nursing care centers on extremely accurate, astute observations and assessments. An in-depth understanding of the pharmacological regimens, management plans, and potential complications associated with this disease is also essential. The clinical manifestations of preeclampsia are directly related to the presence of vascular vasospasms. Vasospasms cause endothelial injury, red blood cell destruction, platelet aggregation, increased capillary permeability, increased systemic vascular resistance, and renal and hepatic dysfunction. Hypertension and proteinuria are the most significant indicators of preeclampsia (Poole, 2004b).

IDENTIFYING HYPERTENSION

Preventing hypertension-induced problems in pregnancy requires nurses to use their assessment, advocacy, and counseling skills. Assessment begins with accurate blood pressure measurements. Checking blood pressures should never be treated as a routine, mundane task.

In the past, hypertension indicative of preeclampsia had been defined as an elevation of more than 30 mm Hg systolic or more than 15 mm Hg diastolic above the patient's baseline blood pressure. However, this definition has not been a good prognostic indicator of outcome. The frequently cited "30–15" rule is not part of the criteria for preeclampsia according to the National High Blood Pressure Education Program Working Group. Instead, women who demonstrate a blood pressure elevation of more than 30 mm Hg systolic or more than 15 mm Hg diastolic above the pre-pregnancy baseline "warrant close observation" (ACOG, 2002a; Peters & Flack, 2004).

The nurse needs to remember that blood pressure presents differently in women with preeclampsia. Preeclamptic patients often demonstrate labile (unstable) pressures and a flattening or reversal of normal circadian blood pressure rhythms, with the highest values recorded at night (Cunningham et al., 2005). Because of this variation, hospitalized patients should routinely have a nocturnal blood pressure assessment unless otherwise ordered by the physician. A daily cardiovascular assessment is also an important monitoring component for the hospitalized patient.

Be sure to— Perform a daily cardiovascular assessment on patients with preeclampsia

During the assessment, the nurse should include the following parameters:

- Auscultation of heart sounds, lungs, and breath sounds
- Presence and degree of edema
- Early signs or symptoms of pulmonary edema, such as tachycardia and tachypnea
- Daily weight taken at the same time of the day and on the same scale
- Skin color, temperature, and turgor
- Capillary refill, which may indicate decreased perfusion or vasoconstriction if >3 seconds

SIGNIFICANCE OF PROTEINURIA

Proteinuria is defined as the excretion of 300 mg or more of protein every 24 hours. If 24-hour urine samples are not available, proteinuria is defined as a protein concentration of 300 mg/L or more (>1+ on dipstick) in at least two random urine samples taken at least 4 to 6 hours apart and no more than 7 days apart. However, studies have shown that urinary dipstick determinations as well as random protein to creatinine ratios correlate poorly with the amount of protein found in a 24-hour sample of women with gestational hypertension. Therefore, the definitive test to diagnose proteinuria should be quantitative protein excretion over 24 hours (Sibai et al., 2005).

The purpose of the renal assessment is to identify renal compromise. Due to the vasospasm that accompanies preeclampsia, the expected increases in the glomerular

filtration rate and renal blood flow may not occur, nor the expected decrease in serum creatinine, especially if the disease is severe. Preeclampsia may be associated with a profuse swelling in the kidney glomerular endothelial cell cytoplasm. This pathological change causes glomerular endotheliosis, a lesion that correlates with proteinuria (ACOG, 2002a).

As an important component of hospital care, the nurse assesses urine output every 1 to 4 hours to confirm adequate renal perfusion and oxygenation. A urinary output of 25 to 30 mL/hr or 100 mL/4 hr is normal; a downward trend in output should be reported immediately. A urimeter attached to the Foley catheter tubing is useful in the accurate assessment of the hourly urine output. A 24-hour urine test for total protein may be ordered to monitor for an increase in the excretion of protein, a finding indicative of increasing kidney impairment. The nurse should be aware that if the 24-hour urine specimen (for total protein) shows the presence of protein, a dipstick is not appropriate. Once protein is evident in a 24-hour urine collection, protein will always be present when the urine is tested by the dipstick. Therefore, no new information is obtained. The 24-hour urine sample yields more accurate information because it shows whether or not the urine protein is increasing, decreasing, or remaining the same. When indicated, a high-protein diet may be needed to replace the protein excreted in the urine.

ASSESSING EDEMA

At one time, edema was an important component of the triad considered along with hypertension and proteinuria to diagnose preeclampsia. However, edema is a common finding in pregnancy. Dependent edema in the absence of hypertension or proteinuria is generally related to changes in the interstitial and intravascular hydrostatic pressures that facilitate the movement of intravascular fluid into the tissues. When preeclampsia is present, continuous capillary leakage combined with a decreased colloidal pressure can lead to pulmonary edema. In this situation, intravascular fluid leaks out through holes (caused by vasospasms) in the endothelial lining of the blood vessels. Pulmonary edema can occur very suddenly, especially if the patient receives an overload of intravenous fluid. Because of the potential for rapid development of this life-threatening complication, the nurse must frequently perform a careful assessment of the patient's pulmonary status and meticulously monitor the total intake and output.

CENTRAL NERVOUS SYSTEM ALTERATIONS

Preeclampsia may quickly develop into eclampsia, the convulsive phase of preeclampsia. Before the onset of seizure activity, the patient may complain of headaches, visual disturbances, blurred vision, scotomata (specks or spots in the vision where the patient cannot see; "blind spots"), and, in rare cases, cortical blindness (August, 2004). These symptoms can be indicators of increased CNS irritability that precedes the onset of seizures. A retinal examination often reveals vascular constriction and narrowing of the small arteries. These changes are reflective of the widespread vasoconstriction that is occurring throughout the body. Deep tendon reflexes (DTRs) are also routinely assessed for evidence of irritability and clonus (rapidly alternating muscle

contraction and relaxation), two additional signs of increased CNS irritability.

Optimizing Outcomes— Grading reflexes and checking for clonus

During the assessment, grade maternal reflexes on a 0–4+ scale:

- 4+ Very brisk, hyperactive; often indicative of disease; often associated with clonus
- 3+ Brisker than average; possibly but not necessarily indicative of disease
- 2+ Average; normal
- 1+ Somewhat diminished
- 0 No response

If the reflexes are hyperactive, test for ankle clonus. Support the knee in a partly flexed position. With your other hand, dorsiflex and plantar flex the foot a few times while encouraging the patient to relax, and then sharply dorsiflex the foot and maintain it in dorsiflexion. Look and feel for rhythmic oscillations between dorsiflexion and plantar flexion. Normal is no reaction to this stimulus. Sustained clonus indicates upper motor neuron disease. The ankle plantar flexes and dorsiflexes repetitively and rhythmically (Fig. 11-7) (Dillon, 2007). Clonus is usually noted as “absent” or “present” but it may be rated as:

- Mild (2 movements)
- Moderate (3 to 5 movements)
- Severe (6 or more movements)

A neurological assessment of the patient with preeclampsia includes establishing her level of consciousness (LOC). Determining if the patient is alert and oriented can be accomplished by asking if she knows why she is in the hospital and if she can correctly identify the name of the hospital. It is also important for the nurse to assess for any change in the patient’s behavior or personality. Preeclampsia is an insidious condition and symptoms associated with worsening of the disease can be very subtle. Maintaining a quiet, darkened environment reduces stimuli that may trigger seizure activity. Ensure that seizure precautions (e.g., suction equipment, oxygen administration equipment, emergency medication tray) are in place.

Eclampsia

Eclampsia is the occurrence of grand mal seizures in women who have either gestational hypertension or preeclampsia (Sibia et al., 2005). It is the most common CNS

Figure 11-7 Testing for clonus.

complication of hypertension, and most maternal deaths attributable to hypertension occur in women with eclampsia. Although patients with severe preeclampsia are at the greatest risk for developing seizures, the onset of eclampsia-related seizures in women with mild preeclampsia have been reported. Women in whom eclampsia develops exhibit a wide spectrum of signs and symptoms, ranging from extremely high blood pressure, 4+ proteinuria, generalized edema, and 4+ patellar reflexes to minimal blood pressure elevation, no proteinuria or edema, and normal reflexes (Sibai, 2002).

Maternal complications of eclampsia include cerebral hemorrhage, aspiration pneumonia, hypoxic encephalopathy, coma, thromboembolic events, and maternal death (incidence 0.4% to 14%) (Poole, 2004b). The perinatal death rate in pregnancies complicated by eclampsia is 9% to 23%. Perinatal deaths are closely related to gestational age and most often result from premature delivery, abruptio placentae, and intrauterine asphyxia (Cunningham et al., 2005).

The exact cause of eclamptic seizures is unknown but many etiologies, including cerebral vasospasm with local ischemia, hypertensive encephalopathy with hyperperfusion, vasogenic edema, and endothelial damage, have been proposed (Cunningham et al., 2005). Eclamptic seizures are clonic–tonic in nature and are almost always self-limiting. They seldom last longer than 3 to 4 minutes.

critical nursing action Care of the Pregnant Patient Post-seizure

- Do not attempt to shorten or abolish the initial seizure. Attempts to administer anticonvulsants intravenously without secure venous access can lead to phlebitis and venous thrombosis.
- Prevent maternal injury.
- Maintain adequate oxygenation; administer oxygen via face mask at 10 L/min
- Minimize the risk of aspiration. Position the patient on her side to facilitate drainage. Suction equipment should be ready and working.
- Give adequate magnesium sulfate to control seizures. As soon as possible following the seizure, venous access should be secured with a 4- to 6-g loading bolus of magnesium sulfate given over 15–20 minutes. If the patient seizes following the loading dose, another 2-g bolus may be given intravenously, over 3–5 minutes.
- Correct maternal acidemia. Blood gas analysis allows monitoring of oxygenation and pH status. Respiratory acidemia is possible after a seizure.
- Avoid polytherapy. Maternal respiratory depression, respiratory arrest, or cardiopulmonary arrest is more likely in women who receive polytherapy to arrest a seizure. Remember that anticonvulsants are respiratory depressants and may interact.
- **Be sure to check the fetus or fetuses** (all must be accounted for). After a seizure there may be loss of FHR variability and bradycardia on the fetal monitoring tracing.
- Check the patient for ruptured membranes, contractions, and cervical dilation.
- Prepare for delivery as indicated.
- Support the patient and her family. This is a very frightening event for them and they will need reassurance and to be kept aware of the plan of care and the well-being of their baby (Poole, 2004b).

Be sure to— Document after a patient seizure

Time and length of seizure
 Associated symptoms
 Vital signs including fetal heart assessment
 Presence or absence of uterine contractions
 Any untoward results such as rupture of the membranes or signs of placental abruption
 Medications that were given. Remember to have the physician write or co-sign any verbal orders that were given during the emergency (Poole, 2004b).

case study Kimberly Stallings

Kimberly Stallings is a 25-year-old white married woman pregnant with her first child. Kimberly's family practice physician has been caring for her since her first prenatal visit at 11.4 weeks' gestation. During the initial prenatal visit, the following data was obtained:

Vital signs: temperature: 98.6°F (37.0°C); pulse: 78 beats/min; respirations: 20 breaths/min; blood pressure: 110/70; weight: 146 lbs. (66.4 kg)

A complete physical exam was performed with normal findings and prenatal labs including a thyroid-stimulating hormone level (TSH, because of a positive family history for hypothyroidism) were drawn. During the interview, the nurse inquired about any other family medical problems. Kimberly reported that both her sister and her mother had experienced preeclampsia during pregnancy.

An ultrasound was ordered for pregnancy dating because Kimberly had experienced irregular menstrual periods since discontinuing oral contraceptives.

Kimberly was seen by her doctor every 4 weeks and the pregnancy progressed uneventfully until 4 months later, when she presented to the office with increased blood pressure and swollen legs. Kimberly had noticed an increased swelling that extended up to the knees of both legs. She denied hand or facial swelling, headaches, visual problems, or right upper quadrant (RUQ) pain. Her sister, a chiropractor, had been checking her blood pressure and noted it to be as high as 160–170/100 to 110. At this visit, the following data was obtained:

Blood pressure: 144/96 (sitting). Repeat on left side: 130/76. Weight: 172.5 lbs. (78.4 kg)

Physical exam: General: In no acute distress; abdomen: nontender; fundus at 28–11.8 inches (30 cm) above the symphysis pubis; FHR 150 bpm; cardiovascular: 1+ pedal edema; neurological: reflexes 3+ with no clonus.

Assessment: Mild preeclampsia.

The following lab tests were ordered: CBC with platelet count; liver enzyme determination (AST, ALT, LDH), alkaline phosphatase (ALP); prothrombin time (PT); a chemistry panel (electrolytes: Na⁺, K⁺, Cl⁻, HCO₃⁻, Ca²⁺, Mg²⁺), blood urea nitrogen (BUN), creatinine (Cr), uric acid and a 24-hour urine collection for protein and creatinine clearance. A sonogram (ultrasound) was also ordered to monitor the status of the fetus.

Kimberly was instructed to go home, observe modified bed rest, rest on her left side as much as possible, and call the nurse if she experienced increased edema, headaches, visual disturbances, or RUQ pain. She was told to continue with twice daily blood pressure monitoring and return to the office in 1 week.

On her next office visit 8 days later, Kimberly reported that she had been observing bedrest at home and had noticed that her leg edema was improved. She stated "I can see my ankle

bones again." Her sister had continued to monitor the blood pressure. According to the blood pressure log, Kimberly's systolic blood pressure measurements had been in the 160s and the diastolic measurements were in the 60–70 range. Kimberly denied headaches, visual disturbances, or abdominal pain and remarked that the fetus had been active. At this visit, the following data were obtained:

Blood pressure: 158/98 (sitting); 150/100 (left side); weight: 160 lbs. (72.7 kg); fundal height: 27 cm; FHR: 150–170 bpm; reflexes: 3–4+ with no clonus; urinary protein: 4+ (2000+ mg/dL) on dipstick

Assessment: Severe preeclampsia at 29 4/7 weeks' gestational age

At this point, Kimberly's physician consulted with a maternal fetal medicine specialist, who advised transferring Kimberly to a tertiary care center located 50 miles away. Kimberly was promptly transferred to the tertiary care center and admitted to the obstetrical service.

Critical Thinking Questions

1. What are Kimberly's risk factors for developing preeclampsia?
2. Why did the nurse ask Kimberly about headaches, blurred vision, and right upper quadrant (RUQ) pain?
3. What signs and symptoms prompted Kimberly's physician to consult with the maternal–fetal specialist and arrange for a transfer to a tertiary care center?

◆ See Suggested Answers to Case Studies in the text on the Electronic Study Guide or DavisPlus.

HELLP Syndrome

HELLP is an acronym for: **H**emolysis, **E**levated **L**iver enzymes and **L**ow **P**latelets

Due to the arteriolar vasospasms in the cardiovascular system that occur in preeclampsia, the circulating red blood cells (RBCs) are destroyed as they try to navigate through the constricted vessels (Hemolysis). Vasospasms decrease blood flow to the liver, resulting in tissue ischemia and hemorrhagic necrosis (Elevated Liver enzymes). In response to the endothelial damage caused by the vasospasms (small openings develop in the vessels), platelets aggregate at the site and a fibrin network is set up, leading to a decrease in the circulating platelets (Low Platelets).

HELLP syndrome is a serious complication of preeclampsia that can manifest itself at any time during pregnancy and the puerperium, but like preeclampsia, it is rare before 20 weeks' gestation. However, unlike preeclampsia, HELLP syndrome occurs more often in Caucasians, multiparas, and in women older than 35 years. One third of all cases of HELLP syndrome occur during postpartum, and only 80% of these patients are diagnosed with preeclampsia before delivery (Sibai et al., 2005).

HELLP syndrome is actually a laboratory diagnosis for a variant of severe preeclampsia. The primary presentation is consistent with hepatic dysfunction evidenced by findings from the patient's liver function tests (ACOG, 2002a; Poole, 2004b). HELLP syndrome is characterized by rapidly deteriorating liver function and thrombocytopenia. Liver capsule distention often produces epigastric pain. Though rare, liver rupture is one of the most ominous

consequences of severe preeclampsia/HELLP syndrome, with a reported maternal death rate of more than 30%. The precise cause of liver rupture is unknown, but the prevailing theory postulates that the increased hepatic pressure leads to rupture. It is theorized that endothelial dysfunction with intravascular fibrin deposits and hepatic sinusoidal obstruction leads to intrahepatic vascular congestion, increased intrahepatic pressure, and distention of Glisson's capsule. This pathological process progresses to the development of a subcapsular hepatic hematoma and subsequent liver rupture (ACOG, 2002a; Cunningham et al., 2005).

Therapy for HELLP syndrome centers on improving the platelet count by transfusion of fresh-frozen plasma or platelets and delivery as soon as feasible by vaginal or cesarean birth. Intrapartum nursing care involves continuous maternal–fetal monitoring. Measurement of central venous pressure or pulmonary arterial wedge pressure (Swan–Ganz catheter) may be required to monitor fluid status accurately when pulmonary edema or acute renal failure are present (ACOG, 2002a).

Now Can You— Discuss HELLP syndrome?

1. State what the acronym HELLP stands for?
2. Describe the basic pathology of HELLP syndrome?
3. Discuss the significance of epigastric pain in the patient with HELLP syndrome?

Now Can You— Discuss Hypertensive Complications of Pregnancy?

1. Differentiate among the following conditions: chronic hypertension, preeclampsia, eclampsia, chronic hypertension with superimposed preeclampsia and gestational hypertension?
2. Describe the pathophysiology of preeclampsia?
3. Discuss the indications for use, action, dosage, and side effects of magnesium sulfate?
4. State the specific nursing actions required when caring for the patient receiving magnesium sulfate?

Disseminated Intravascular Coagulopathy

Disseminated intravascular coagulopathy (DIC) is a hematological disorder characterized by a pathological form of clotting that is diffuse and consumes large amounts of clotting factors. DIC causes widespread external or internal bleeding or both (Cunningham et al., 2005). The most common causes of DIC in pregnancy are excessive blood loss with inadequate blood component replacement, placental abruption, amniotic fluid embolism, and severe preeclampsia/HELLP syndrome. Because DIC is a consumptive coagulopathy that results in depletion of the platelets and clotting factors, early diagnosis and prompt and appropriate management are critical in reducing maternal and perinatal death and complication rates (Cunningham et al., 2005; Labelle & Kitchens, 2005).

NURSING CARE

Nursing care includes continued meticulous assessment for signs of bleeding (e.g., petechiae, oozing from injection sites, hematuria). Use of an indwelling catheter for monitoring urinary output is essential because renal failure is a potential consequence of DIC. Vital signs and fetal assessments are monitored frequently and the patient is maintained in a side-lying tilt to enhance blood flow to the uterus. Oxygen may be administered through a rebreathing mask at 8 to 10 L/min and blood and blood products are administered according to physician orders (Labelle & Kitchens, 2005). The patient and her family are emotionally supported and kept informed about the maternal–fetal status. (See Chapters 14, 16, and 33 for further discussion.)

Multiple Gestation

Multiple gestation occurs when a fertilized ovum divides into two separate ova or if ovulation produces two separate ova and each is fertilized. The terminology used to describe the different characteristics of multiple gestations includes the following:

- **Monozygotic:** “Identical twins,” the product of one ovum that split around the end of the first week after fertilization. Accounts for one-third of all twins.
- **Dizygotic:** “Fraternal twins”—two separate ova have been fertilized by two sperm
- **Dichorionic/diamnionic:** Two chorions and two amnions
- **Monochorionic/diamnionic:** One chorion and two amnions
- **Monochorionic/monoamniotic:** One chorion and one amnion—the fetuses share the same living quarters. Associated with a very high (40% to 60%) mortality rate due to cord accidents from entanglement (Cunningham et al., 2005).

INCIDENCE

Multiple gestation (also known as multifetal pregnancy) has increased significantly during the past 10 years and is largely due to advanced maternal age at childbirth and the widespread availability of assisted reproductive technology. “Multiples” account for 3% of all births in the United States. During the past decade there has been a 25% increase in the number of twin births, a 116% increase in triplets, a 149% increase in quadruplets, and a 250% increase in the number of quintuplet or higher order births (Malone & D’Alton, 2004; Martin et al., 2005). Dizygotic twins tend to run in families and are more common in people of African descent. Around the world, the rate of dizygotic twins ranges from 1 in 1000 in Japan to 1 in 20 in several tribes in Nigeria (Cunningham et al., 2005).

ASSOCIATED COMPLICATIONS

Because multiple gestations are associated with a number of maternal and fetal complications, they are considered to be a high-risk pregnancy. Complications may occur during the antepartal, intrapartal, or postpartal period. Preterm labor often results from uterine overdistension and frequently necessitates an early operative delivery. Other complications include preterm labor, gestational diabetes,

increased urinary tract infections, preeclampsia/eclampsia, placenta previa, fetal intrauterine growth restriction (IUGR), abnormal presentation, and umbilical cord prolapse (Cunningham et al., 2005).

MATERNAL AND FETAL MORBIDITY AND MORTALITY

Maternal morbidity is higher in women with multiple gestations and seems to be related to the number of fetuses present. Twin pregnancies are associated with significantly higher risks of hypertension, placental abruption, anemia, and urinary tract infections than are singleton pregnancies (Malone & D'Alton, 2004). Monochorionicity (one chorion instead of separate chorions surrounds the developing multiple gestation), growth restriction, and prematurity pose the main risks to fetuses and neonates in a multiple gestation. The mean duration of a twin gestation is 37 weeks; for triplets and quadruplets the mean duration of gestation is 33 and 31 weeks, respectively. The mean gestational age at delivery for multiple gestations can be misleading because the classification does not reveal the true incidence of extreme prematurity, which has great clinical significance. The incidence of preterm delivery prior to 28 weeks for singletons is 0.7% in the United States. For twins, the incidence increases to 5% and for triplet gestations the incidence is 14%. The perinatal mortality rate for twins is at least threefold higher than with singletons (Malone & D'Alton, 2004).

Perinatal morbidity is also more likely in a multiple gestation. The incidence of a severe handicap in neonatal survivors of multiple gestation is increased from 19.7 per 1000 for singleton survivors to 34.0 and 57.5 per 1000 twin and triplet survivors, respectively. Twins account for between 5% and 10% of all cases of cerebral palsy in the United States (Malone & D'Alton, 2004).

DIAGNOSIS

A positive diagnosis of a multiple gestation can be confirmed by ultrasound examination. Sonography reveals multiple gestational sacs with yolk sacs by 5 weeks of gestation and multiple embryos with cardiac activity by 6 weeks of gestation (Malone & D'Alton, 2004). Rapid uterine growth, excessive maternal weight gain, or palpation of three or more fetal large parts (cranium and breech) on Leopold maneuvers are clinical findings suggestive of multiple gestation. Laboratory tests show elevated levels of human chorionic gonadotropin (hCG), human placental lactogen (hPL), and maternal serum α -fetoprotein (MSAFP) (Cunningham et al., 2005).

MANAGEMENT

Since multiple gestation pregnancies are considered to be high risk, an appropriately trained specialist should ideally manage the obstetric care. Delivery should be planned to take place at a Level III facility with trained personnel who are prepared to deal with maternal or neonatal complications. When a pregnancy is complicated by a multiple gestation, the normal maternal physiological adaptations to pregnancy are heightened. Complications that are associated with these changes help to guide the clinical management. Consideration of maternal–fetal

physiological parameters along with ongoing surveillance is essential in developing an appropriate plan of care.

NURSING IMPLICATIONS

Caring for the patient with a multiple pregnancy can be challenging, especially when complications arise. Hospitalization may be needed due to the increased risk of complications, and the nurse needs to remain cognizant of this fact. As an example, the patient with a multiple gestation who requires tocolytic therapy to prevent preterm birth is at greater risk for complications related to the tocolytic therapy than the patient with a singleton gestation. There is an increased risk of pulmonary edema due to the expanded plasma volume and increased cardiac output. Also, nutritional requirements are increased. Maternal caloric needs are approximately 40% greater for a woman expecting twins and 80% greater for a woman pregnant with triplets or higher multiples (Luke, 2005). Early in the pregnancy, the patient may suffer from severe hyperemesis gravidarum due to higher levels of pregnancy hormones found in multiple pregnancies as compared to singleton pregnancies. This condition can lead to dehydration and poor nutrient intake and require hospitalization for rehydration. At this time, the nurse can refer the patient to a nutritionist and also review foods that might be more appealing to the patient (Bowers & Gromada, 2006).

The nurse must also remain aware that the patients being cared for are the woman (the primary patient) as well as each individual fetus. Serial ultrasounds, nonstress tests, and biophysical profiles will be part of the ongoing assessment for fetal well-being and growth. Fetal surveillance with electronic fetal monitoring may be difficult, especially when there are more than two fetuses. Triplet monitors are available that allow for the tracing of three separate FHRs on a single channel, or two heart rate tracings and a digital read-out for the third fetus. It is best to monitor all fetuses simultaneously and the nurse should label which line corresponds to which ultrasound transducer so that it is clear which fetus is being monitored. The presenting twin is always “A,” with the remaining fetuses (“B,” “C,” etc.) identified by relative ascending positions. Although not common, late pregnancy changes in fetal positions (e.g., male fetus B now in the position of female fetus A) should be noted in the patient record. If no recent ultrasound has been obtained, the nurse should identify each FHR by the appropriate abdominal quadrant (Bowers & Gromada, 2006).

A multiple pregnancy can cause many concerns for the family. They often fear for the well-being of the babies, especially since preterm labor is a major complication with multiples. The thought of the everyday rigors of caring for several newborns at one time can constitute another major cause of stress. If there are other children in the household, the expectant couple may question how they are going to be able to give the older siblings the care and time they will also need. Family finances can be a great concern as well as the affordability of childcare when it is necessary for the mother to return to work. The nurse can be supportive in encouraging families to voice their concerns and address them as appropriately as possible. Helping the family to prepare for the birth of the babies can be of great benefit. The nurse may offer

suggestions that include giving the older children household chores appropriate for their age, alerting the partner's employer of a potential need to adjust the work schedule in order to help out at home or finding someone to help with housekeeping, grocery shopping, laundry, cleaning, and/or childcare. Other team members such as social service can also provide valuable solutions to these concerns. Referring the couple to a "multiples" support group may also be appropriate and welcomed.

 **Now Can You—** Discuss care of the pregnant patient with a multiple gestation?

1. Name five complications associated with a multiple gestation?
2. Describe your plan of care, taking into consideration the maternal fetal physiological parameters of the multiple gestation pregnancy?
3. Identify other team members you would include in your plan of care?

Infections

URINARY TRACT INFECTION

Urinary tract infection (UTI) is the most common bacterial infection in pregnancy. The three most common clinical syndromes associated with UTI are asymptomatic bacteriuria, acute cystitis and acute pyelonephritis (Savoia, 2004).

Pathophysiology

The physiological dilatation of the urinary collecting system that occurs normally during pregnancy is associated with an increase in ascending urinary infections. Mechanical and hormonal changes may lead to hydronephrosis, decreased peristalsis, bladder distention, and incomplete emptying. These events can result in urine stasis or reflux in the bladder and ureters (Cunningham et al., 2005; Savoia, 2004).

The most common infecting organism is *Escherichia coli* (*E. coli*), which is responsible for 75% to 90% of all bacteriuria during pregnancy. Other organisms frequently responsible for UTIs include *Klebsiella*, *Proteus*, *Pseudomonas*, Group B streptococcus, and coagulase-negative staphylococci (Davison & Lindheimer, 2004).

Morbidity

Bacteriuria in pregnancy predisposes the patient to the development of acute pyelonephritis, a condition that poses significant risk to the woman and her fetus (Savoia, 2004). Asymptomatic and untreated bacteriuria has been associated with a number of complications during pregnancy including low birth weight, intrauterine death, preeclampsia, and maternal anemia (Davison & Lindheimer, 2004).

Asymptomatic Bacteriuria

Asymptomatic bacteriuria is defined as the presence of at least 10^5 colony-forming units of bacteria per milliliter of clean, voided, midstream urine in specimens obtained on two separate occasions. As the name implies, the patient does not express any symptoms of a UTI. Asymptomatic bacteriuria occurs in 2% to 11% of pregnancies and if left untreated, approximately 40% of

those infected will develop an acute symptomatic UTI. Treatment includes anti-infectives such as ampicillin (Marcillin) for a 7- to 10-day period. Screening women for asymptomatic bacteriuria on the first prenatal visit constitutes a standard of obstetric care (Davison & Lindheimer, 2004; Savoia, 2004).

Acute Cystitis

Symptomatic lower UTI occurs in 1.3% to 3.4% of pregnant women. Symptoms include urinary frequency, urgency, dysuria, and suprapubic pain. The treatment is the same as for asymptomatic bacteriuria (Savoia, 2004).

 **Nursing Insight—** Anti-infective medications contraindicated during pregnancy

Medications including amoxicillin (Amoxil), ampicillin (Marcillin), and cephalosporins (cephalexin [Keflex]) are safe antibiotics during pregnancy. Sulfonamides should not be used near term because they interfere with protein binding of bilirubin and tetracyclines should never be used because they cause retardation of fetal bone growth and staining of fetal teeth.

Acute Pyelonephritis

Pyelonephritis, an inflammation of the kidney substance and pelvis, occurs in 1% to 2% of pregnant women. This condition presents as flank tenderness on the affected side and is associated with nausea, vomiting, fever, and chills along with the symptoms of a lower UTI. Significant pyuria and bacteriuria are present. Pyelonephritis is treated aggressively with hospitalization and intravenous antibiotics. If left untreated or inadequately treated, septic shock, adult respiratory distress syndrome and/or preterm labor may result (Cunningham et al., 2005; Davison & Lindheimer, 2004).

 **Optimizing Outcomes—** When caring for the patient with a UTI

During pregnancy, a urine specimen is more likely to be contaminated by bacteria that originate in the urethra, vagina, or perineum. This occurs due to a change in pH during pregnancy: the urine becomes more alkaline due to the maternal excretion of bicarbonate; the vagina also becomes alkaline and the vaginal secretions have increased glycogen content, which aids bacterial growth). Before collecting a mid stream specimen, the nurse should instruct the patient about the importance of proper cleansing.

A urinalysis and urine culture and sensitivity (C & S) should be obtained on all patients who present with signs of preterm labor and the nurse must remember that signs of UTI often mimic normal pregnancy complaints (i.e., urgency, frequency). It is important to remind the patient to take **all** of the medication that has been prescribed, even if the symptoms subside and she feels better. A Test of Cure (repeat urine test to evaluate whether or not bacteria is still present) should be obtained once the treatment has been completed.

 **Now Can You—** Discuss the significance of a UTI in the pregnant patient?

1. Describe anatomical and physiological renal system changes during pregnancy that place women at risk for UTIs? Identify the most common organism responsible for a UTI?
2. Explain why pyelonephritis must be treated aggressively?
3. Discuss nursing responsibilities when obtaining a urine specimen from a pregnant patient and identify instructions that should be given to the patient who is treated for a UTI?

Group B Streptococcal Infection

Group B streptococcus (GBS) is a frequent cause of urinary tract infections and chorioamnionitis during pregnancy and a significant cause of endometritis after the pregnancy has ended. It is a major pathogen in neonatal sepsis that can result in significant neonatal morbidity and mortality. Women harbor GBS as part of the normal fecal and vaginal flora. It is estimated that 10% to 30% of women are asymptomatic carriers of the organism. However, the rates vary according to the culture technique used, the number of samples cultured, and the nature of the populations studied. When maternal GBS colonization is present, transmission to the neonate is estimated to occur in approximately 60% of cases. The incidence is approximately 1.8 per 1000 live births (Cunningham et al., 2005; Savoia, 2004).

The onset of neonatal infection may be early (within the first 6 days of life) or late. Infants with early-onset infection generally develop signs (i.e., respiratory distress, septic shock) during the first 12 hours of life. Exposure to the organism occurs either in utero or during labor as the fetus travels down the colonized birth canal. Risk factors for contracting the infection include prematurity, low birth weight, premature rupture of the membranes, prolonged labor, maternal chorioamnionitis, multiple gestation, and GBS bacteremia during pregnancy. The overall rate of neonatal mortality from early onset GBS has declined from 50% in 1977 to approximately 6% currently, although infants of low birth weight continue to be at a substantial risk. Late-onset GBS is community acquired (the route of transmission is less clear and can be nosocomial [acquired while in the hospital], environmental, or maternal) and presents more than a week after birth. The majority of infants with community-acquired GBS are full term and 85% exhibit signs and symptoms of meningitis (Savoia, 2004).

In an effort to protect infants from Group B streptococcus infections, the Centers for Disease Control and Prevention (CDC) has issued guidelines that advocate obtaining vaginal and rectal cultures from all pregnant women between 35 and 37 weeks of pregnancy. Women with positive cultures and those with unknown GBS, ruptured membranes greater than 18 hours, previous preterm delivery (<37 weeks) or a history of a previous infant with GBS disease are treated with a penicillin-based anti-infective agent (Savoia, 2004).

TORCH INFECTIONS

TORCH refers to a group of maternal infectious diseases that cause harm to the embryo–fetus (Table 11-3). The TORCH acronym stands for **T**oxoplasmosis, **R**ubella,

Cytomegalovirus (CMV), and **H**erpes simplex virus type 2 (HSV-2). (Some sources identify the “O” as “other” infections, such as hepatitis B, syphilis, and human immunodeficiency virus.) Maternal exposure to the TORCH infections during the first 12 weeks of gestation is associated with fetal developmental anomalies.

SEXUALLY TRANSMITTED INFECTIONS

Sexually transmitted infections (STIs) can cause serious morbidity and, in some cases, mortality in the mother, fetus, and infant. Following perinatal exposure, newborns are at risk for a number of minor and major complications that include congenital anomalies, mental impairment, and death. Women exposed to STIs are at risk for infertility, ectopic pregnancy, and pregnancy complications (Cunningham et al., 2005).

Chlamydia trachomatis

Chlamydia trachomatis is the most prevalent sexually transmitted infection in the United States. An estimated 3 million cases occur annually (CDC, Workowski, & Berman, 2006). *C. trachomatis* causes genital infections that can be asymptomatic and thus difficult to treat. However, infected women who do experience symptoms usually complain of vaginal discharge, dysuria, and, on occasion, abnormal vaginal bleeding. On speculum examination, the cervix exhibits a distinct mucopurulent discharge along with marked inflammation of the endocervix. Some women also experience an acute urethral syndrome manifested by dysuria, urinary frequency, and the presence of pyuria in a sterile urine specimen. Oral anti-infectives such as erythromycin or penicillin-based agents are used to treat *Chlamydia trachomatis* during pregnancy (Yudkin & Gonik, 2006).

Neonatal infection, most commonly manifested as conjunctivitis and pneumonia, results from exposure to the pathogen during birth. Typically, conjunctivitis occurs during the first 5 to 12 days of life whereas pneumonia does not develop until 1 to 3 months after birth (Rawlins, 2001). Topical antibiotic therapy, routinely administered during the immediate neonatal period, is inadequate for the treatment of a chlamydial infection. Since treatment with erythromycin is only about 80% effective, the newborn requires careful follow-up by the pediatrician (Yudkin & Gonik, 2006).

Neisseria gonorrhoeae

Neisseria gonorrhoeae (gonococci [GC], gonorrhea), a gram-negative diplococcus, is one of the oldest known sexually transmitted infections. It often coexists with chlamydia. The most common site of infection is the genitourinary tract. Infection sites unique to women include the Skene’s and Bartholin’s glands, endocervix, endometrium, and fallopian tubes. Symptoms of infection include vaginal discharge, dysuria, and abnormal vaginal bleeding. A speculum examination often reveals an inflamed, friable (easy to bleed) cervix. Treatment includes either oral or intramuscular cefixime (Suprax) or ceftriaxone (Rocephin) (CDC et al., 2006). Infants born to untreated, infected mothers are at risk for disseminated infection (bacteremia) and **ophthalmia neonatorum** (an eye inflammation) that can result in permanent blindness from perforation of the globe of the eye.

The amniotic infection syndrome is an additional manifestation of gonococcal infection in pregnancy. This entity manifests as placental, fetal membrane, and umbilical cord inflammation that occurs after premature rupture of the membranes (PROM) and is associated with infected oral and gastric aspirate, leukocytosis, neonatal infection, and maternal fever. The syndrome is characterized by PROM, premature delivery, and a high rate of infant morbidity (Gibbs, Sweet, & Duff, 2004).

Syphilis

Syphilis is an acute and chronic infection caused by the spirochete *Treponema pallidum*. It has a long clinical course that begins with an incubation period followed by primary, secondary and tertiary infection. Throughout this time, there is progressive damage to the CNS, cardiovascular system, and musculoskeletal system. Syphilis is transmitted primarily through sexual contact or fetal infection may occur transplacentally. During pregnancy, syphilis usually occurs in women who are young and unmarried and in those who receive little or no prenatal care (Savoia, 2004).

The onset of primary syphilis is usually heralded by the appearance of a chancre, a painless, round, ulcerated lesion with a raised border and indurated (hardened) base. In women, the chancre most commonly appears on the vulva, cervix, and vagina. Penicillin is the treatment of choice for all stages. If left untreated, the disease progresses, becomes chronic, and may lead to death.

Prompt maternal treatment eliminates most fetal syphilis infections, but delayed treatment or failure to obtain treatment may result in fetal effects that range from minor anomalies to preterm birth or fetal death. Damage to the fetus depends on when during gestation the infection occurred and the amount of time elapsed before treatment. Neonatal infection may be present at birth, but not expressed for up to 2 years (“silent infection”) (Askin, 2004). Manifestations of congenital syphilis include rhinitis (snuffles), macular rash on the palms and soles of the feet, osteochondritis (inflammation of the bony epiphysis), perichondritis (inflammation of the membrane that covers the surface of cartilage), hepatosplenomegaly, jaundice, anemia, and thrombocytopenia (Savoia, 2004).

Human Papillomavirus Infection

Human papillomavirus (HPV) is a sexually transmitted virus that causes **condylomata acuminata** (genital warts) and is the primary cause of cervical neoplasia (American Cancer Society, 2006). Approximately 70% of cervical cancers result from infection with HPV (ACOG, 2006). Risk factors associated with HPV infection include early onset of sexual activity, multiple sex partners, cigarette smoking, and long-term use of oral contraceptives (Gibbs et al., 2004).

The prevalence of genital warts is highest among the 16- to 25-year-old age group, which is also the age group with the highest rate of pregnancy. The warts grow more rapidly during pregnancy and may involve the cervix, vagina, or vulva so extensively that vaginal delivery is precluded. The reason for the increase in size and number of the lesions is not known but has been postulated to be the decrease in cell-mediated immunity that occurs during pregnancy (Landry, 2004). Management of these lesions in pregnancy presents difficult problems and treatment includes trichloroacetic acid, dichloroacetic acid, cryotherapy, and

surgical excision. None of these therapies has been shown to be superior to the others. The best approach to treatment during pregnancy may be the excision of the lesions by cautery or the use of cryosurgery. Care must be taken to prevent extensive scarring or sloughing of tissue (CDC et al., 2006; Gibbs et al., 2004).

The risk for transmission of the virus from maternal condylomata acuminata to the neonate has not been established. HPV is present in maternal blood and can be transmitted transplacentally to the fetus, but the incidence is very low according to reported studies (Gibbs et al., 2004).

Nursing Insight— Preventing HPV through vaccination with Gardasil

Nurses can be instrumental in preventing infection caused by the human papillomavirus. The American College of Obstetricians and Gynecologists (ACOG) Committee on Adolescent Health Care and the ACOG Working Group on Immunization recommend that females 9–26 years of age receive vaccination against HPV. Although obstetricians-gynecologists are not likely to care for many girls in this initial vaccination group, ACOG has recommended that the first adolescent reproductive health care visit take place between 13 and 15 years of age. These visits are a strategic time to discuss HPV and the potential benefit of the HPV vaccine and to offer vaccination to those who have not already received it (ACOG, 2006).

HIV and AIDS

Human immunodeficiency virus (HIV) type 1 (HIV-1) infection, with rare exception, causes a slow but relentless destruction of the immune system that ultimately results in acquired immunodeficiency syndrome (AIDS). HIV type 2 (HIV-2) infection has a more variable and benign course. HIV-2 has remained largely confined to West Africa, whereas HIV-1 strains are causing increasing epidemics around the world (Landry, 2004).

HIV-1 infection is an increasing problem among women of childbearing age. AIDS is the fifth leading cause of death among women 25 to 44 years of age and has become a leading cause of death for young children in many parts of the world. Without identification of HIV-infected women and the aggressive use of preventive therapy, 20%-30% of these children will become infected with HIV (CDC, 2006a; Landry, 2004; Moran, 2004a).

TRANSMISSION. Heterosexual unprotected sexual contact now poses the greatest risk to women. Because vaginal mucus can harbor the retrovirus, women are more likely than men to contract HIV infection through heterosexual activity. Factors that increase the risk of transmission include (Moran, 2004a):

- Unprotected sexual intercourse (no condom is used)
- Sexual intercourse during menses
- Increased number of sexual contacts
- Presence of genital sores
- Advanced disease state

The risk of vertical transmission to the fetus or newborn is proportional to the concentration of virus in maternal plasma (viral load). Vertical transmission occurs antepartally when the virus crosses the placenta, intrapartally

when it travels (via the bloodstream) from the vagina up into the uterus during labor or following rupture of the membranes or postpartally through transfer in the breast milk (Lawrence & Lawrence, 2005; Riordan, 2005). Transmission of HIV to the fetus or infant is believed to most often occur late in pregnancy or during labor and birth. Increased rates of transmission also occur with advanced maternal disease and ruptured membranes and after events during labor and delivery that increase fetal exposure to maternal blood (ACOG, 2000). In 2000, ACOG established guidelines to prevent HIV transmission; these guidelines were updated in 2004 (Box 11-8).

Optimizing Outcomes—Decreasing the incidence of STIs in women and children

Nurses should be aware of the signs and symptoms of STIs in order to recognize them and appropriately counsel patients about them.

- Alert the pediatrician to the patient's positive history of an STI.
- Counsel women in a nonjudgmental and compassionate manner about safe sex habits (i.e., the use of condoms).
- Encourage women to obtain routine checkups and promptly report any signs or symptoms of an STI to their provider.
- Instruct the woman undergoing treatment that she must take all of the medication prescribed and keep any follow-up appointments.
- Remind the patient that her partner must also be treated and if he refuses, she must abstain from sex with him until he is treated.
- Remember to always use Universal Precautions.

Box 11-8 Management to Prevent Transmission of HIV Infection

- Patients should be counseled that in the absence of antiretroviral therapy, the risk of vertical transmission is approximately 25%. With zidovudine (ZDV) therapy, the risk is reduced to 5–8%. When care includes both ZDV therapy and scheduled cesarean delivery, the risk is approximately 2%. A risk of 2% or less is seen in those women with viral loads of <1000 copies per milliliter even without delivery via cesarean section.
- Plasma viral loads should be determined at baseline and then every 3 months or following changes in therapy. The patient's most recently determined viral load should be used to direct counseling regarding the mode of delivery.
- Women infected with HIV whose viral loads are >1000 copies per milliliter should be counseled as to the benefits of a scheduled cesarean section in reducing the risk of vertical transmission to the infant.
- Patients should receive antiretroviral chemotherapy during pregnancy according to the accepted guidelines for adults. This therapy should not be interrupted around the time of cesarean delivery. For those patients receiving ZDV, adequate levels of the drug in the blood should be achieved if the infusion is begun 3 hours preoperatively.
- Best clinical estimates of gestational age should be used for planning cesarean delivery. Amniocentesis to determine fetal lung maturity should be avoided whenever possible.
- All women should be clearly informed of the risks associated with cesarean delivery as the preoperative maternal health status affects the degree of the risk of maternal morbidity associated with cesarean delivery.
- The patient's autonomy in making the decision regarding the route of delivery must be respected. A patient's informed decision to undergo vaginal delivery must be honored, with cesarean delivery performed only for other accepted indications and with patient consent.

Source: American College of Obstetricians and Gynecologists (ACOG) Committee Opinion (2000, 2004).

Neonatal Effects	Treatment	Incidence and Prevention	High Risk Potential
Rare transplacental transmission have resulted in miscarriage	Protect neonate from exposure at time of delivery	Estimated 1 million Americans are newly infected with genital HSV annually	Risk factors include female sex, African-American, or Mexican-American ethnic background, older age, low educational level, poverty, cocaine use, and a greater number of lifetime sexual partners
Mortality of 50%-60% if neonatal exposure is with active primary infection	Cultures are done when mother has active lesions	Seroprevalence of HSV is approximately 25%	
Neurologic morbidity such as chorioretinitis, microcephaly, mental retardation, seizures, and apnea	Avoid routine use of scalp electrodes	Approximately 1%-2% of pregnancies	
	If lesions are visible, delivery by cesarean section is the current standard of care	1 in 3000-20,000 live births for the development of neonatal herpes	
	Acyclovir has been used near term to suppress outbreak	Up to 70% of women delivering infected infants have no history of genital herpes	Unprotected sex and having a sexual partner with genital herpes
		Prophylactic treatment with oral acyclovir may be appropriate in women with frequent recurrent infections in pregnancy	
		If symptoms or lesions are present, cesarean delivery should be performed	
		Avoid genital contact when male partner has penile lesions	
		Use condoms	

TUBERCULOSIS

Tuberculosis (TB) is an infectious, communicable disease caused by the tubercle bacillus, *Mycobacterium tuberculosis*. The disease causes inflammatory infiltrations most commonly in the respiratory tract although TB may also affect the gastrointestinal and genitourinary tracts, bones, joints, nervous system, lymph nodes, and skin. Tuberculosis is the most common infectious disease in the world. Since 1992, the number of cases of TB has decreased. However, health care professionals caring for pregnant women and newborns are challenged to remain skilled in screening, identifying, and treating TB infection because the disease remains at epidemic levels in certain areas of the country and in certain populations. Women who are homeless, infected with HIV, IV drug users, or those who have emigrated from countries with a high rate of TB (i.e., Latin America, Asia, Africa) are at highest risk (Cunningham et al., 2005).

Although maternal tuberculosis does not appear to cause congenital malformations, it may lead to fetal infection. TB can spread to the fetus from the maternal blood if the bacilli cross the placenta and enter the umbilical vein. Fetal blood then passes through the liver, and this organ serves as the primary focus for the disease in the fetus and newborn. If the bacilli bypass the fetal liver, the lungs may become the primary infection site. Neonates may become infected at the time of birth by aspiration of infected amniotic fluid or by aspiration of infected blood and tissue if the mother has tuberculosis endometritis. They may also become infected through the traditional airborne route if individuals in the infant's environment have pulmonary tuberculosis (Cunningham et al., 2005; Savoia, 2004).

Initial treatment of active tuberculosis in pregnancy includes isoniazid (INH), ethambutol, and rifampin, medications that are considered to be safe during pregnancy.

Therapy should be continued for 9 months. Breastfeeding is not contraindicated and can begin or can continue during anti-TB therapy since the medications do not cross into the breast milk. However, if the infant is concurrently taking oral antituberculosis therapy, excessive drug levels may be reached in the neonate, and breastfeeding should be avoided (Savoia, 2004).

Optimizing Outcomes—Immunizations during pregnancy

The ideal time to immunize women in order to prevent the spread of disease to the fetus is during the preconceptional period. However, the maternal and fetal benefits of immunization during pregnancy usually outweigh the theoretical risks of adverse effects. The risk for exposure to disease and its deleterious effects on the pregnant woman and the fetus must be balanced against the efficacy of the vaccine and any beneficial effects that may result from it. Nurses can educate their patients regarding the importance of immunizations and documentation of the patient's immunization status should be a part of the permanent medical record.

Inflammatory Disease and Pregnancy

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is a chronic multi-system inflammatory disorder. It is characterized by an autoimmune antibody production that results in an inflammation of the connective tissue in various organs or systems in the body (Yancy, 2004). The disease tends to

affect young women in the second, third, and fourth decades of life but may occur in any age group. The prevalence of SLE is 100 per 100,000 in the general population (Laskin, 2004).

Pathophysiology

The immune system is composed of specialized cells that destroy invading organisms by phagocytosis and antibody and lymphocyte production. When a foreign organism or antigen enters the body, it is consumed by macrophages and then passed on to lymphokines, which present the antigens to the T and B lymphocytes. The B lymphocytes are activated, resulting in the production of an increased number of circulating antibodies that target their specific antigen. The antigen–antibody complex either promotes destruction of the antigen or activates the normal inactive proteins in the complement system. With SLE, the body fails to recognize its own proteins. The clinical manifestations result from inflammation of multiple organ systems, especially the joints, skin, kidneys, nervous system, and serous membranes (Laskin, 2004).

Effects During Pregnancy

Adverse pregnancy outcome is more common in SLE than in any other rheumatic disease. In the pre-steroid era, it was common practice to terminate pregnancy in patients with active SLE. However, with successful treatment of active disease with corticosteroids, this practice has become less frequent. Patients are more likely to have inactive SLE at the onset of pregnancy because of earlier disease diagnosis and more effective pre-pregnancy therapy, as well as appropriate pre-pregnancy counseling (Laskin, 2004). According to Yancy (2004), pregnancy outcome is improved in the following circumstances: SLE has been in remission for at least 6 months; there is no active renal involvement; superimposed preeclampsia does not develop; or there is no evidence of antiphospholipid antibody activity.

The patient with SLE should be seen frequently by both an internist-rheumatologist and a perinatologist specializing in high-risk cases. Assessment of the signs and symptoms of an impending SLE flare-up should be elicited on the patient's history and physical examination, and blood samples obtained for serological evaluation. A rise in the anti-dsDNA antibody titer and a decrease in complement may be predictive of an exacerbation of SLE. The onset of edema and hypertension in pregnancy in these patients is characteristic of both preeclampsia and active SLE-associated nephritis. Since the treatment of these conditions is very different, the importance of an accurate diagnosis is essential (Laskin, 2004).

Perinatal Morbidity and Mortality

When SLE complicates the pregnancy, there is an increased risk of spontaneous abortion, premature rupture of the membranes, preterm labor, preterm birth, stillbirth, and neonatal death (Laskin, 2004; Yancy, 2004). Congenital heart block or congestive heart failure of the fetus or newborn is of particular concern. Maternal autoantibodies may cross the placenta and form immune complexes with fetal autoantigens, promoting fetal tissue destruction. Autoantibodies may initiate injury to fetal cardiac tissue, resulting in conduction disturbances that may be temporary or permanent (Laskin, 2004).

Management

Management of SLE is aggressive and includes immunosuppression of lupus flare with corticosteroid therapy, nonsteroidal anti-inflammatory drugs (NSAIDs), antimalarial agents, azathioprine (AZA), and careful fetal surveillance. If the disease flares during the pregnancy, treatment must be implemented as quickly as possible. The physician assesses the manifestations and extent of the disease exacerbation and selects the safest, most effective therapy. The patient's health must be deemed the first priority and the treatment is planned accordingly (Laskin, 2004). When caring for patients with SLE, nurses should offer support and remain alert for early indicators of SLE exacerbation and pregnancy complications. Patients and their families should be educated about the plan of care, the need for close surveillance, and the importance of effective family planning after the birth.

Hemoglobinopathies of Pregnancy

The major function of the red blood cell (RBC) is to carry hemoglobin, which transports oxygen from the lungs to the tissues. The ability of hemoglobin to bind to oxygen is determined by its structural composition. Normal hemoglobin consists of a heme molecule, which is an iron protoporphyrin, combined with two pairs of globin chains. Significant shortening of RBC survival occurs due to alterations in the structure (i.e., sickle hemoglobin) or quantity (i.e., thalassemia) of the hemoglobin chains. These alterations result from inherited disorders. In their most severe forms, these disorders are associated with hemolytic anemia and progressive multi-organ failure (Duffy, 2004).

Figure 11-8 Comparison of normal hemoglobin and normal red blood cells to sickle hemoglobin (HbS) and sickle red blood cells.

SICKLE CELL DISEASE

Sickle cell disease is the most common hemoglobinopathy in the United States. It is of recessive inheritance and occurs when the gene for the production of hemoglobin S (HbS) is inherited from both parents (homozygous). It is seen most frequently in those of African and Mediterranean descent. Sickle cell anemia is the most prevalent and severe form of the sickle cell diseases (Yancy, 2004).

Pathophysiology

Patients with sickle cell anemia (SCA) suffer from lifelong complications, in part as a result of the markedly shortened life span of their RBCs (Kilpatrick & Laros, 2004). When HbS is exposed to low oxygen tension, it precipitates into long crystals, or polymers, within the red blood cell. With the lowered or absent amount of oxygen, the sickle cell hemoglobin molecule becomes rigid and dehydrated and assumes an abnormal crescent (sickled) shape (Fig. 11-8). The sickled erythrocytes cannot change their shape and are unable to squeeze through the microcirculation. Obstruction results, leading to hypoxia. Progressive tissue and organ damage occur along with painful vaso-occlusive crises and an increased susceptibility to infection (Fig. 11-9). The signs and symptoms, which are related to vascular occlusion, hemolysis (lysis of the RBCs), and infection, are associated with a number of laboratory and clinical findings. Hemoglobin levels usually fall within the range of 6 to 8 g/dL, there is an increase in bilirubin levels due to hemolysis and folate, or iron deficiency results from bone marrow suppression. Clinical signs may include hepatomegaly, cardiomegaly, conjunctival vessel changes, systolic murmurs, and arthritis (Kilpatrick & Laros, 2004).

Effects During Pregnancy

Many pregnancies complicated by sickle cell anemia are associated with poor perinatal outcomes. Severe anemia and frequent vasoocclusive crises may occur during pregnancy and these problems are associated with an increased maternal and perinatal morbidity and mortality. Although maternal mortality is rare in patients with sickle cell anemia, maternal morbidity is great. Infections are common and occur in 50% to 67% of affected women. The respiratory and urinary tracts are the most common sites of infection, and all infections must be promptly treated since fever, dehydration, and acidosis results in further sickling and painful crises (Cunningham et al., 2005).

The rate of spontaneous abortion in pregnancies complicated by sickle cell anemia may be as high as 25% and stillbirth rates have been reported to reach 8% to 10%. Poor perinatal outcome is related to an increased frequency of preterm labor, premature birth, intrauterine infection, preeclampsia and poor placental perfusion (Cunningham et al., 2005).

Management

The care of the maternity patient with sickle cell anemia must be individualized. Ideally, care should be provided in a medical center experienced in treating the multitude of problems that can complicate these pregnancies. Management of care includes the following (Duffy, 2004; Kilpatrick & Laros, 2004):

- Promotion of good dietary habits with a folate supplement of at least 1 mg/d. Iron supplements are not

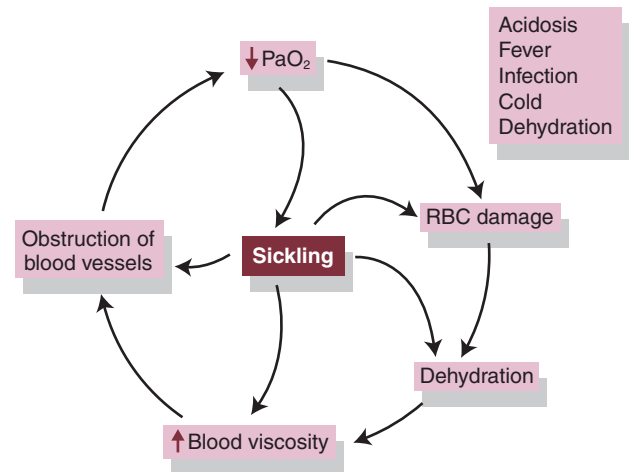

Figure 11-9 The sickling cycle.

routinely given, but serum iron and ferritin levels should be checked monthly and iron supplementation initiated only when the levels are diminished. Of note, the incidence of pica appears to be significantly increased in sickle cell patients. This non-nutritional practice may compromise the iron available for hemoglobin synthesis.

- Early detection of infection and treatment. Urine cultures are performed routinely to detect asymptomatic bacteriuria.
- Prevention of dehydration; intravenous fluids may be indicated.
- Prompt treatment of sickle cell crisis with oxygen, fluids, and pain management; intravenous morphine is usually the drug of choice.

Blood transfusions may be given to increase the hemoglobin to the 10 g/dL range and to reduce the percentage of sickle hemoglobin. This goal is best accomplished by an exchange transfusion: 2 units of blood are removed from the patient and 3 to 4 units of blood are transfused in. With this maneuver, the sickle hemoglobin percentage usually falls to approximately 40%.

- Fetal surveillance. Nonstress tests, biophysical profiles, and Doppler velocimetry begin as early as 26 weeks. Assessment of fundal height and ultrasound are used to monitor appropriate intrauterine growth (Cunningham et al., 2005).

THALASSEMIA

The thalassemia syndromes are named and classified by the type of globin chain that is inadequately produced. The defective chains damage the developing red blood cells by oxidative injury, resulting in chronic hemolysis and, ultimately, in iron overload (Duffy, 2004). The two most common types are α - or β -thalassemia, both of which affect the synthesis of hemoglobin A (Kilpatrick & Laros, 2004).

Thalassemia, also called “Mediterranean anemia,” predominately affects blacks and individuals of Italian, Greek, Middle Eastern, Indian, Asian, and West Indies descent. However, with the increased interethnic mixing and increasing immigration patterns of today, the at-risk populations are changing (Duffy, 2004; Kilpatrick & Laros, 2004).

β -Thalassemia

β -Thalassemia is the most common form of thalassemia. The homozygous state of β -thalassemia is known as “thalassemia major” or “Cooley’s anemia.” Patients with this disorder are transfusion dependent and have marked hepatosplenomegaly and bone changes secondary to increased hematopoiesis. Death generally is caused by infectious or cardiovascular complications before the third decade of life. Female infants who survive to puberty usually have amenorrhea and severely impaired fertility (Kilpatrick & Laros, 2004).

Heterozygous β -thalassemia minor results in various degrees of illness, depending on the rate of β -chain production. The characteristic findings of this disorder include a relatively high RBC count, moderate to marked microcytosis, and a peripheral smear that resembles iron deficiency (Kilpatrick & Laros, 2004). However, there may actually be a severe overload of iron due to the increased iron absorption that results from ineffective erythropoiesis (Poole, 2003).

β -THALASSEMIA AND PREGNANCY. The thalassemia syndromes constitute a group of inherited hemoglobinopathies that require close maternal and fetal surveillance during pregnancy. Ongoing consultations and appropriate treatment by maternal–fetal medicine and hematology specialists are essential throughout the pregnancy. The management is similar to care of patients with sickle cell disease. As with sickle cell disease, iron supplementation should be given only if necessary, because indiscriminate use of iron can lead to hemochromatosis (Cunningham et al., 2005; Poole, 2003).

Rh_o(D) Isoimmunization

Hemolytic disease of the fetus and newborn is a condition in which the life span of the fetal or neonatal RBCs is shortened by the action of maternal antibodies against antigens present on the fetal and neonatal RBCs. Antigens provoke an immune reaction if an incompatible blood cell enters the circulation. The RBCs are agglutinated and destroyed. The two most problematic types are those of the Rh (rhesus) system and the ABO system. Maternal antibodies form in the Rh-negative mother after exposure to Rh-positive fetal blood. Theoretically, no mixing of fetal and maternal blood occurs during pregnancy and childbirth. In reality, however, drops of fetal blood most likely enter the maternal circulation after small placental “accidents.” The development of maternal antibodies, which destroy the fetus’ Rh-positive blood, is termed **isoimmunization** or **sensitization**. In addition to the Rh (rhesus) system, there are more than 400 different antigens found on the surface of red blood cells. The incidence of hemolytic disease in the newborn has dramatically declined with the advent of Rh_o(D) immune globulin (RhoGAM) in the 1960s (Moise, 2004).

PATHOPHYSIOLOGY

For Rh(D) maternal isoimmunization to occur, at least three circumstances must exist:

- The fetus must have Rh(D)-positive erythrocytes, and the mother must have Rh(D)-negative erythrocytes.

- A sufficient number of fetal erythrocytes must gain access to the maternal circulation. This amount can be as little as 0.1 mL.
- The mother must have the immunogenic capacity to produce antibodies directed against the D antigen.

Fetal red blood cells gain access to the maternal circulation during pregnancy, childbirth, and in the immediate postpartum period. Clinical factors such as cesarean birth, multiple gestation, bleeding placenta previa or abruption, manual removal of the placenta, and intrauterine manipulation may increase the chance of substantial hemorrhage.

Rh_o(D) immune globulin (such as RhoGAM) works by coating and destroying fetal cells in the maternal circulation. Rh_o(D) immune globulin (RhoGAM) *must* be given within 72 hours and its effects last for 3 months. To ensure that the correct amount of Rh_o(D) immune globulin (RhoGAM) (sometimes more than one 300-mcg vial is required) is given to the patient, a fetal screen or Kleihauer–Betke blood test is performed on the woman’s blood after it has been determined that the baby is Rh(D) positive. This test estimates the number of fetal RBCs in the mother’s circulation. In most situations, exposure of maternal blood to fetal blood occurs during the third stage of labor at the time of placental separation. The woman’s first child is usually unaffected because the maternal antibodies form after the infant’s birth. However, subsequent Rh(D)-positive fetuses may be affected unless the woman receives Rh_o(D) immune globulin (RhoGAM) to prevent antibody formation. Rh_o(D) (RhoGAM) must be given after the birth of *every* Rh(D)-positive infant (Fig. 11-10). The information presented in Box 11-9 helps to simplify what can be a very confusing clinical situation.

When antibodies to the Rh factor are present in the pregnant patient’s blood (i.e., the woman is sensitized), they freely cross the placenta and destroy the RBCs of the Rh(D)-negative fetus. Over time, the fetus develops an RBC deficiency, the fetal bilirubin levels rise (“icterus gravis”) and severe neurological disease (“bilirubin encephalopathy”) may result. In the fetus, this patho-

Figure 11-10 The Rh isoimmunization sequence. Rh-positive father and Rh-negative mother; Rh-positive fetus. During pregnancy or childbirth, a small amount of fetal blood enters the mother’s circulation. The mother’s immune system produces anti-Rh_o(D) antibodies (triangles). In subsequent pregnancies with an Rh⁺ fetus, the antibodies cross the placenta, enter the fetal circulation and attack the fetal red blood cells, causing hemolysis.

medication: Rh₀(D) Immune Globulin

Rh₀(D) immune globulin (arr aych oh dee im-yoon glob-yoo-lin)
(RhoGAM, HypRho-D, BayRho-D, Gamulin Rh, Rhophylac)

Pregnancy Category: C

Indications: Administered to Rh-negative women who have been exposed to Rh-positive blood by:

- Delivering an Rh₀(D)-positive infant
- Aborting an Rh₀(D)-positive fetus
- Having chorionic villus sampling, amniocentesis, or intraabdominal trauma while carrying an Rh₀(D)-positive fetus
- Accidental transfusion of Rh₀(D)-positive blood

Action: Prevents production of anti Rh₀(D) antibodies in Rh₀(D)-negative patients who were exposed to Rh₀(D)-positive blood by suppressing the immune reaction of the Rh₀(D)-negative woman to the antigen in the Rh₀(D)-positive blood.

Therapeutic Effects: Prevents antibody response and subsequently prevents hemolytic disease of the newborn (erythroblastosis fetalis) in future pregnancies of women who have conceived an Rh₀(D)-positive fetus. Prevention of Rh₀(D) sensitization following transfusion accident.

Pharmacokinetics:

ABSORPTION: Well absorbed from IM sites.

Contraindications and Precautions:

CONTRAINDICATED IN: Rh₀(D)- or Du-positive patients; patients previously sensitized to Rh₀(D) or Du.

Adverse Reactions and Side Effects: Pain at IM site

Route and Dosage: One vial *standard* dose (300 mcg) administered intramuscularly:

- At 28 weeks of pregnancy and within 72 hours of delivery
- Within 72 hours after the termination of a pregnancy of 13 weeks or more of gestation.
- After an accidental transfusion, dosage is calculated based on the volume of blood that was erroneously administered.

One vial *microdose* (50 mcg) within 72 hours after chorionic villus sampling (CVS) or the termination of a pregnancy of less than 13 weeks of gestation

Note: (1) More than 300 mcg of RhoGAM may be indicated after a large transplacental hemorrhage or after a mismatched blood transfusion; (2) Rhophylac can be given IM or IV (prefilled syringes are available).

Nursing Implications:

1. Do not give to infant, to Rh₀(D)-positive individual or to Rh₀(D)-negative individual previously sensitized to the Rh₀(D) antigen. *Note:* There is no more risk than when given to a woman who is not sensitized—if in doubt, administer Rh₀(D) immune globulin.
2. Administer into the deltoid muscle. Should be given within 3 hours but may be given up to 72 hours after delivery, miscarriage, abortion, or transfusion.
3. Explain to the patient the purpose of this medication to protect future Rh₀(D)-positive infants; prior to administering, obtain a signed consent form if required by the agency.
4. Special considerations may be indicated for women who are members of Jehovah's Witnesses because this medication is made from human plasma.

Data from Deglin, J., & Vallerand, A. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

logical process triggers a rapid production of erythroblasts (immature red blood cells) that are unable to carry oxygen. The syndrome associated with this hemolytic process is termed **erythroblastosis fetalis**. Fetal anemia and generalized edema (“hydrops fetalis”) develop and lead to fetal congestive heart failure. (See Chapter 19 for further discussion.)

Box 11-9 Simplifying and Understanding the Rh Factor
RH FACTOR

Rh D-positive: Persons who have the D genotype: the Rh antigen is present on their erythrocytes

RhD-negative: Persons who DO NOT possess the antigen on their red blood cells

Anti-Rh antibodies do not spontaneously occur and are only formed if there is sensitization by RhD-positive cells entering the circulation of the RhD-negative person. The RhD-negative person develops antibodies against the RhD-positive cells. This is why the first pregnancy is not affected, UNLESS the mother was previously sensitized during a miscarriage, amniocentesis, or antepartum hemorrhage.

EXAMPLE

RhD-negative mother gives birth to an RhD-positive baby and some of the baby's blood enters the mother's system at the time of delivery. (It takes only 0.1 mL.) Mother develops antibodies against any future RhD-positive babies.

During the prenatal period, all Rh(D)-negative women receive an antibody titer (indirect Coombs test) to determine whether they are sensitized from a previous exposure to Rh(D)-positive blood. If the test is negative, another antibody titer is obtained at 28 weeks of gestation to rule out sensitization that may have occurred later in the pregnancy. If the woman remains unsensitized, Rh₀(D) immune globulin (RhoGAM) is given as a preventive measure to prevent formation of active antibodies during the remainder of pregnancy. After birth, if the infant is Rh(D) positive, another dose of Rh₀(D) immune globulin is administered. If the infant is Rh(D) negative, no Rh₀(D) immune globulin is necessary.

If the prenatal patient's indirect Coombs test is positive, sensitization has occurred and antibodies against Rh(D)-positive erythrocytes are present in the maternal circulation. In this situation, the patient's antibody titer is repeated frequently throughout pregnancy to identify a rising level. A rise in the maternal antibody titer is indicative of ongoing antibody formation and an increased likelihood of fetal erythrocyte destruction.

When sensitization has occurred, an amniocentesis may be performed periodically throughout pregnancy to assess change in the optical density (ΔOD_{450}) of amniotic fluid. The ΔOD_{450} reflects the amount of bilirubin (bile pigment that remains after RBC destruction) in the amniotic fluid. When the fluid optical density remains low, it could indicate: (1) that the fetus is Rh(D) negative (and thus in no jeopardy) or (2) that the fetus is Rh(D) positive and is presently in no jeopardy. If the ΔOD_{450} is elevated, the fetus is experiencing RBC destruction and is in jeopardy.

Ultrasound evaluations may also be performed to assess for evidence of severe fetal anemia that has occurred due to hemolysis: edema, ascites, an enlarged heart, and hydramnios. An invasive procedure such as percutaneous umbilical blood sampling (discussed later in this chapter) may be performed to quantitatively determine the amount of fetal erythrocyte destruction. When necessary, an intrauterine transfusion of O-negative blood through the umbilical cord may be carried out or, as an alternative, erythrocytes may be transfused into the fetal abdominal cavity for absorption into the circulation.

Be sure to— Administer and document RhoGAM when clinically indicated

Administering and properly documenting Rh_o(D) immune globulin (RhoGAM) is an important nursing action.

If the mother is Rh negative and unsensitized and the baby is Rh positive, always check to be sure the patient has received Rh_o(D) immune globulin (RhoGAM) if indicated before discharge. Make certain that she has received the appropriate dose.

Patients who have miscarried also must be treated. In cases where it is not possible to determine the fetus' or baby's blood type, Rh_o(D) immune globulin (RhoGAM) is still given. Question if an order has not been written.

MANAGEMENT

Prevention of isoimmunization (a rising anti-Rh antibody titer in an Rh-negative woman) is the goal throughout pregnancy. All pregnant women should be tested for ABO and RhD type along with an antibody screen during their first prenatal visit. It is essential that these determinations be made during each subsequent pregnancy, as previous maternal antibody screening is not an adequate assessment. Rh_o(D) immune globulin (RhoGAM) should also be given at any time during the pregnancy when a possibility exists that a patient may be exposed to fetal blood (i.e., CVS, amniocentesis, miscarriage, vaginal bleeding, abortion, ectopic pregnancy).

Optimizing Outcomes— Safe administration of Rh_o(D) immune globulin (RhoGAM)

In a RhD-negative woman who is **nonsensitized**, RhoGAM should be given:

After delivery of an RhD-positive infant. In the United States the standard dose is 300 mcg and it is given within 72 hours of delivery.

Remember to educate your patient as to the reason why she is receiving RhoGAM.

Be sure to give your patient documentation that she has received RhoGAM.

Never give RhoGAM to:

- A Rh(D)-positive woman
- A sensitized Rh(D)-negative woman
- A Rh(D)-negative woman who has given birth to an Rh(D)-negative baby
- The baby or father of the baby!

SUMMARIZING CARE FOR THE SENSITIZED RhD-NEGATIVE PATIENT

Patients with an anti-D antibody titer of greater than 1:4 should be considered Rh sensitized and their pregnancies managed accordingly. The goal is to minimize fetal and neonatal morbidity and mortality. Management includes serial ultrasounds, serial amniocenteses to analyze bilirubin levels in the amniotic fluid, percutaneous umbilical blood sampling (PUBS) to obtain a fetal hematocrit, and intrauterine blood transfusions for a fetal hematocrit less than 30% (Moise, 2004). A delayed manifestation of Rh isoimmunization is

neonatal **kernicterus**, a condition characterized by CNS damage after exposure of the infant brain to hyperbilirubinemia. (See Chapter 19.) The nurse's identification of infants at risk anticipates this danger after birth and allows for early intervention with phototherapy or exchange transfusion before any damage may occur (Duffy, 2004).

ABO

In this condition the **mother is blood group O** and the **baby is either A or B**. This form of blood incompatibility is unrelated to the Rh factor. It is important for nurses to remember that blood group O carries no antigens; group A carries A antigen, and group B carries B antigen. Since the mother already has anti-A and anti-B antibodies present during the first pregnancy, the first child may be affected. IgG antibodies (immunoglobulins that respond to a specific antigen in this case, A or B) can cross the placenta and cause hemolysis of the fetal RBCs.

The Coombs test is performed on the baby's cord blood obtained at the time of birth. A **direct Coombs** identifies the presence of maternal antibodies in the neonate's blood and hemolysis or lysis of RBCs while the **indirect Coombs** detects antibodies against RBCs in the maternal serum. The results are reported as either positive or negative. A positive direct Coombs test must be reported to the pediatrician.

Now Can You— Discuss RhD and ABO isoimmunization?

1. Describe the pathophysiology of RhD isoimmunization?
2. Discuss the importance of preventing maternal isoimmunization?
3. Discuss the action of RhoGAM and the nursing responsibilities required in administering this medication?
4. Explain why ABO sensitization may occur during a first pregnancy?

Respiratory Complications

Pulmonary diseases have become more prevalent in the general population and, therefore, in pregnant women. The normal physiological changes of pregnancy can cause a woman with a history of compromised respirations to develop significant problems. The outcome for a pregnant woman with respiratory complications depends on the adequacy of ventilation and oxygenation as well as the early detection of respiratory compromise. Hypoxia poses a major threat to the fetus (Yancy, 2004).

PNEUMONIA

Although pneumonia is a rare complication of pregnancy, it is the most common nonobstetric infection that causes maternal mortality during the peripartum period. The overall frequency of pneumonia during pregnancy ranges from approximately 1 per 400 to 1 per 1200. The incidence may be increasing primarily as a reflection of the declining general health status of certain segments of the childbearing population (i.e., individuals with AIDS, cystic fibrosis, obesity, and those who smoke) (Mandel & Weinberger, 2004).

Etiology

Streptococcus pneumoniae, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and viruses (e.g., Influenza A and Varicella) are the major causative agents.

Effects on Pregnancy

Pneumonia can complicate pregnancy at any time during gestation. Maternal bacteremia, empyema, a need for mechanical intervention, and death have all been reported. Pneumonia may be associated with poor fetal growth (IUGR), preterm birth, and perinatal loss (Mandel & Weinberger, 2004).

Management

The normal physiological changes in the respiratory system that occur during pregnancy result in a loss of ventilatory reserve. These changes, coupled with pregnancy-related immunosuppression, place the woman and her fetus at an increased risk for respiratory infection. Any pregnant patient suspected of having pneumonia should be managed aggressively with appropriate laboratory testing, clinical surveillance, and medications.

ASTHMA

Asthma is the most common form of lung disease that affects pregnancy; from 0.5% to 8% of pregnant women have this condition (Gardner & Doyle, 2004). Asthma is characterized by a limitation of airflow that is generally more marked during expiration than during inspiration. The obstruction associated with asthma is a reversible process caused by airway inflammation and an increased responsiveness of the airways to a variety of stimuli (e.g., dust, pollen, grass, and cold temperature). The airway response to the stimuli involves contraction of the bronchial smooth muscle, hypersecretion of mucus, and edema of the mucosal surfaces. Collectively, these events contribute to the pathophysiological processes associated with the reversible airway obstruction characteristic of asthma (Mandel & Weinberger, 2004).

Effects on Pregnancy

Asthma is associated with significant risks for both the patient and her fetus. Maternal complications reported among asthmatics include hyperemesis, vaginal bleeding, hypertensive disorders, a predisposition to infections, gestational diabetes, preterm rupture of the membranes and preterm labor, and delivery of a low-birth-weight infant. There is little risk to the fetus with well-controlled maternal asthma and it is safer for pregnant asthmatics to be treated with appropriate medications than to have asthma symptoms and exacerbations. Exacerbations that cause hypoxia and decreased uterine blood flow increase the incidence of intrauterine growth restriction (IUGR), preterm birth, and neonatal mortality (Yancy, 2004).

Signs and Symptoms

A number of classic symptoms are associated with an exacerbation of asthma. These include dyspnea, coughing, wheezing, voice changes, chest tightening, and the presence of scant or copious clear sputum. Lung auscultation usually reveals bilateral expiratory wheezing.

Management

Careful monitoring along with appropriate adjustments in therapy may be required to maintain maternal lung function and ensure an adequate oxygen supply to the fetus. Failure to control asthma during pregnancy may result in hypoxia in both the patient and her fetus. A PO_2 of less than 60 mm Hg places the fetus in jeopardy (National Asthma Education and Prevention Expert Panel, 2005). Guidelines for asthma management have been developed to help ensure maternal–fetal safety and well-being during pregnancy. Goals of therapy include optimal control of asthma symptoms; attainment of normal pulmonary function; prevention and reversal of asthma attacks; and prevention of maternal and fetal complications (Guy, Kirumaki, & Hanania, 2004). Asthma therapy is based on a stepwise classification system designed to control symptoms, avoid acute attacks, and help patients achieve unhampered life styles (Kennedy, 2005).

Medications currently used for asthma are generally well tolerated during pregnancy and appear to be safe for the fetus. Therefore, the management of asthma in the pregnant woman differs little from management in the nonpregnant patient. It is also widely accepted that the fetal risk is higher with poorly controlled maternal asthma than with medications necessary to gain optimal symptom control. Nevertheless, nurses must be aware of available data concerning the use of these drugs during pregnancy (Gluck & Gluck, 2005; Mandel & Weinberger, 2004).

CYSTIC FIBROSIS

Cystic fibrosis (CF) is a chronic, progressive, genetic multisystem disease. It affects nearly 30,000 children and young adults, and occurs in approximately one out of every 3000 Caucasian live births (Brennan & Geddes, 2004). One thousand new cases are diagnosed each year, usually by the age of 3; however, nearly 10% of newly diagnosed cases involve individuals age 18 or older. Since CF is a recessive disorder, a child must inherit a defective gene from each parent. Each time two CF carriers conceive, there is a 25% chance that the child will have CF; a 50% chance that the child will be a carrier; and a 25% chance the child will be a noncarrier. One in 20 Americans (more than 20 million total) is an unknowing carrier of the defective gene for CF (Cystic Fibrosis Foundation, 2005).

The last several decades have witnessed a dramatic increase in the survival of patients with CF. This trend is attributable in large part to earlier diagnosis and intervention, the introduction of pulmonary therapies such as dornase-alpha and high-dose ibuprofen, new airway clearance techniques, effective antipseudomonal antibiotics such as tobramycin for inhalation, improved nutritional management, and dietary recommendations (Kulich et al., 2003). In the United States, the median survival age for persons with CF has increased to 31.1 years for men and 28.3 years for women (Cystic Fibrosis Foundation, 2005; Yankaskas, Marshall, Sufian, Simon, & Rodman, 2004). An increasing number of women with CF are now surviving into the reproductive years and, with meticulous management of their pulmonary function, usually maintain their fertility.

Pathophysiology

The major CF gene product is the protein cystic fibrosis transmembrane regulator (CFTR). When CFTR is not produced or is altered in structure or function as a result of mutations in the CF gene, viscid secretions are produced that primarily affect the respiratory and gastrointestinal systems. An absence or abnormality of the protein results in a blocked or altered chloride channel in the epithelial cell membranes. Chloride ions are trapped within the cell and cause sodium ions and water to diffuse back into the cell, leading to dehydration of the mucus secretions.

Effects on Pregnancy

Factors that may predict a poor outcome for a pregnant woman with CF include prepregnancy evidence of poor nutritional status, significant pulmonary disease with hypoxemia, and pulmonary hypertension. The risk of maternal mortality for those with cor pulmonale and deteriorating pulmonary function in the first trimester is exceptionally high and the couple may be advised to consider termination of the pregnancy. Risks to the fetus include preterm birth, growth restriction due to uteroplacental insufficiency, and CF. The couple must also consider the long-term psychosocial and physical assistance needs that may ensue because of the potential for maternal physical deterioration and/or premature death (Whitty & Dombrowski, 2004).

Optimizing Outcomes— Counseling women with cystic fibrosis

Preconception counseling is essential for women with CF. Because of extremely thick cervical mucus, fewer than one in five women with CF are able to conceive. Women who achieve pregnancy should be advised of the risks, according to their health status. If possible, women should be 90% of their ideal body weight before conception (Whitty & Dombrowski, 2004).

Management

When caring for a pregnant woman with cystic fibrosis, it is important for the nurse to recognize that the fetus is at risk for uteroplacental insufficiency and intrauterine growth restriction. The maternal nutritional status and weight gain during pregnancy greatly affect fetal growth. Ongoing collaboration with the nutritionist is essential, and close attention must be paid to the patient's nutritional status since maldigestion, malabsorption, and malnutrition are all complications of CF (Whitty & Dombrowski, 2004). An early nutritional consultation should be included in the nursing care plan developed for every CF patient. Throughout pregnancy, the nurse and other members of the care team must work closely with the nutritionist to ensure that the caloric requirements are being met. This component of care is especially important when the pregnant patient with CF experiences hyperemesis gravidarum.

Early recognition and prompt treatment of pulmonary infections are also important in the management of the pregnant woman with CF. Diagnostic tests that are helpful for assessing and guiding therapy with CF patients include sputum and culture sensitivity, chest films, spirometry, pulse oximetry, and complete blood counts with a chemistry panel (Whitty & Dombrowski, 2004).

Respiratory management during the preconception and the antenatal period includes baseline pulmonary function tests such as forced vital capacity (FVC), forced expiratory volume (FEV₁) lung volumes, pulse oximetry, and arterial blood gases as indicated. Laboratory values are closely monitored during pregnancy and any deterioration in pulmonary function is promptly addressed. Fetal growth should be monitored by fundal height measurements along with serial ultrasound evaluations of fetal growth and amniotic fluid volume. Doppler flow studies are also used to assess fetal growth and development and general health status. Maternal kick counts should begin at 28 weeks and non-stress tests initiated at 32 weeks to assess fetal well-being (Whitty & Dombrowski, 2004). Management of the pregnant woman with CF requires the involvement of an entire team of professionals: the perinatologist, pulmonologist, neonatologist, nutritionist, social worker, and nurse. When difficulties arise and the family is further challenged, spiritual guidance can be of great comfort and support to the family.

Maternal and consequently fetal oxygenation is of paramount importance during labor and birth. Continuous monitoring of maternal oxygen saturation using pulse oximetry is used to gauge the need for and response to supplemental oxygen therapy. Respiratory depressants, anticholinergic drugs, and inhalation anesthesia should be avoided. Lumbar epidural analgesia is the preferred mode of labor pain relief. The fetal heart rate (FHR) should be continuously monitored during labor and any signs of fetal intolerance (i.e., decelerations and/or a lack of FHR variability) must be promptly addressed (Whitty & Dombrowski, 2004). A critical intrapartum nursing issue centers on the recognition that high-risk couples may have depleted their coping skills due to perinatal complications. The nurse needs to be aware that the anxiety coupled with the stress of labor may be extremely difficult for the patient and her family. The nurse can provide assistance by encouraging the couple to express their emotional concerns, by keeping them informed of changes as the labor progresses, and by encouraging them to freely ask questions.

Now Can You— Discuss respiratory complications during pregnancy?

1. Describe the normal anatomical and physiological changes in the respiratory system during pregnancy and how they affect the patient with asthma and cystic fibrosis?
2. Discuss the fetal effects of maternal oxygen deprivation?
3. Formulate a plan of care for the pregnant patient with a respiratory complication?

Cardiovascular Disease

Cardiovascular disease in women affects 1% to 4% of all pregnancies and remains the primary cause of nonobstetric maternal mortality in the United States (Foley, 2004; Setaro & Caulin-Glaser, 2004). Care of the patient with cardiovascular disease continues to be a great challenge to the obstetrical team despite advances in surgical techniques, medications, and technology, owing to three broad trends (Setaro & Caulin-Glaser, 2004):

- Successful treatment of congenital heart disease has created a new population of clinically complex patients who are able to reach childbearing age.

- There is an increasing trend toward pregnancies in older women who are susceptible to heart diseases acquired in adulthood.
- Immigration from underdeveloped nations has reacquainted Western medicine with a cohort of young childbearing patients who have rheumatic heart disease.

Signs and symptoms of cardiac disease can be similar to physiological changes that normally occur during pregnancy. For example, the pregnant patient may experience heart palpitations associated with the normal increase in blood volume. Women with heart disease may experience heart palpitations due to an arrhythmia. Fatigue, a common complaint during pregnancy, may result from poor cardiac output and myocardial ischemia in patients with heart disease. The incidence of maternal and fetal morbidity and mortality associated with cardiac disease during pregnancy depends on the specific cardiac lesion, the functional abnormality produced by the lesion, and the development of pregnancy-related complications, such as infection, hemorrhage, or preeclampsia (Yancy, 2004).

Categories of cardiac disease during pregnancy include congenital cardiac disease (e.g., atrial septal defect, ventricular septal defect, pulmonic stenosis, congenital aortic stenosis, coarctation of the aorta, tetralogy of Fallot, and Eisenmenger syndrome) and acquired cardiac disease (i.e., lesions that are rheumatic in origin and valvular lesions such as mitral and aortic stenosis). Rheumatic mitral stenosis is the most common clinically significant valvular abnormality in pregnant women and may be associated with pulmonary congestion, edema, and atrial arrhythmias during pregnancy and soon after childbirth. Ischemic cardiac disease (coronary artery disease and myocardial infarction) is rare in pregnancy.

The New York Heart Association (NYHA) classification system is often used to assess the functional ability of the pregnant cardiac patient (Criteria Committee of the NYHA, 1979). Patient cardiac function is divided into four classes:

- | | |
|-----------|---|
| Class I | The patient is asymptomatic and there is no limitation on physical activity. |
| Class II | The patient is asymptomatic at rest, symptomatic with heavy physical activity, and requires slight limitation of activity. |
| Class III | The patient is asymptomatic at rest, symptomatic with minimal physical activity, and physical activity is considerably limited. |
| Class IV | The patient may be symptomatic at rest, is symptomatic with any activity, and has severe limitations on physical activity. |

Patients classified as NYHA I and II generally do well during pregnancy, but those classified as III or IV have a significantly increased risk of morbidity and mortality with pregnancy. However, it must be remembered that any patient with a cardiac history, regardless of classification, must be thoroughly assessed for any signs of decompensation at each prenatal visit.

MANAGEMENT

Management of cardiac disease in pregnancy is frequently complicated by unique social and psychological concerns. Patients with congenital heart disease may have experienced

multiple hospitalizations over the years and be fearful of the medical environment. Some of them never expected to bear children. Often, women with a history of rheumatic heart disease have lived outside the traditional medical care system due to conditions of poverty and cultural differences. Not uncommonly, they are recent immigrants. When caring for any patient with special needs, it is imperative for the nurse to collaborate with other health professionals and community support systems to facilitate the patient's access to care and to ensure her comfort with the health care environment (Easterling & Otto, 2002).

Optimizing Outcomes— Caring for the pregnant woman with cardiac disease

Antepartally, continuity of care with a single provider, frequent prenatal visits, routine screening for bacteriuria, and prophylaxis against anemia are essential. Intrapartal care includes the induction of labor when cervical favorability is present, the avoidance of prolonged labor, second stage pushing and maternal blood loss, and prophylactic antibiotics when the woman is at risk for endocarditis. Postpartal care centers on strict management of blood volume and careful but aggressive diuresis (Easterling & Otto, 2002).

Labor, birth, and the immediate postpartum period provide a time of increased risk due to the rapid volume changes that occur. During labor and birth, epidural anesthesia may be used for most patients with cardiac disease, but care must be taken to avoid hypotension. Positioning the patient in a lateral recumbent position as well as careful administration of intravenous fluids will help to balance the patient's blood pressure. Continuous invasive hemodynamic monitoring is beneficial in evaluating rapid changes in heart rate, cardiac output, and pulmonary capillary wedge pressure (PCWP) (an estimation of left atrial pressure) so that fluid, diuretic, vasodilator, or pressor therapy may be guided (Setaro & Caulin-Glaser, 2004).

Medications that may be indicated for the pregnant cardiac patient include diuretics (e.g., Lasix) to prevent congestive heart failure, digitalis, nitrates (to reduce after-load, the resistance the ventricles must overcome to eject blood during systole), antiarrhythmic agents (e.g., lidocaine), beta blockers (e.g., labetalol), calcium channel blockers (e.g., nifedipine), antibiotics and anticoagulants (heparin–warfarin [Coumadin] is contraindicated because it crosses the placenta). As with any medication being considered for the pregnant patient, a thorough investigation of side effects and potential fetal harm must be evaluated before administration.

Nursing Insight— Recognizing cardiac effects of various obstetric drugs

Obstetric medications such as tocolytics and uterine stimulants can have a major impact on circulatory function. Terbutaline, administered to suppress premature uterine contractions, may stimulate the heart. Adverse effects include chest discomfort, dyspnea, irregular pulse, EKG changes, or pulmonary edema. The nurse should question the use of this medication with any patient with a cardiac history. Prostaglandin is a vasodilator and should not be used in patients with certain cardiac conditions. Oxytocin can cause hypertension and fluid retention and lead to congestive heart failure.

Vaginal birth is advisable for most patients with cardiac disease with care taken to avoid causing stress on the heart during the second stage of labor (pushing). Elective low or outlet forceps may be used to shorten this stage. Cesarean section may limit the stress of vaginal birth in patients with cardiac disease, but this method involves major surgery, blood loss, and the possibility of maternal stress from intubation. Cesarean birth is reserved for situations such as fetal compromise and failure of labor progression.

NURSING IMPLICATIONS FOR THE PREGNANT CARDIAC PATIENT

Due to the intense cardiovascular demands of pregnancy, care of the pregnant cardiac patient presents one of the greatest challenges to the obstetrical nurse. Nursing care should focus on assessment, early detection of problems, and treatment and prevention of complications to both mother and baby. Ideally, these women are cared for in a tertiary care center, but when this is not possible, there should be collaboration between critical care nurses and obstetric nurses. Nursing interventions include:

- Antenatal assessment of weight gain to ensure proper fetal growth while avoiding excessive weight gain which causes increased cardiac workload
- Nutritional counseling (a diet high in iron to prevent anemia and low in sodium to prevent fluid retention)
- Education to avoid/reduce stress and anxiety
- Encouragement of frequent rest periods
- Explanation of fetal surveillance testing
- Stressing the importance of keeping prenatal appointments
- Education regarding the signs and symptoms of complications; when to call the provider

Nursing Insight— Understanding hemodynamic changes in pregnancy

A patient with a cardiac disorder is at greatest risk when hemodynamic changes reach their maximum, between the 28th and 32nd weeks of gestation. The nurse must have knowledge of the disease process and be able to assess the hemodynamic changes that occur during pregnancy.

Intrapartal interventions focus on assessing the patient and fetus for decreased cardiac output and oxygenation and intervening as needed.

critical nursing action Assessing the Cardiac Patient During Labor and Birth

The nurse needs to assess the patient for signs and symptoms of decreased cardiac output:

- Decreased and/or irregular pulse
- Increased respiratory rate
- Dyspnea
- Chest pain
- Abnormal breath sounds: crackles at the base of the lungs
- Decreased blood pressure
- Decreased urinary output (less than 30 mL/hr)
- Edema of the hands, face and feet
- Abnormal heart sounds: diastolic murmur at the heart's apex
- Signs of air hunger: anxiety

- Decreased oxygen saturation: <95%
- Cool, clammy, cyanotic skin
- Increased capillary refill time: >3 seconds
- EKG changes
- Mental changes: disorientation; fatigue; syncope

Oxygen, if required, should be supplied via a re-breather mask at 10 L per minute, intravenous fluids are administered via a pump, and intake and output are meticulously monitored throughout labor. Antibiotic prophylaxis may be indicated for selected patients with cardiac disease because of their increased risk for developing endocarditis as a result of invasive procedures (e.g., invasive hemodynamic monitoring; intrauterine pressure catheter; fetal scalp electrode). Continuous fetal monitoring during labor is also a nursing responsibility. With decreased maternal cardiac output, the fetus will show signs of poor placental perfusion, as evidenced by late decelerations and/or the loss of baseline variability. (See Chapter 12 for further discussion.) Should these indicators develop, improved oxygenation must be delivered to the fetus by giving oxygen to the woman, who should be maintained in a lateral position. Intravenous fluids should be increased with caution to avoid maternal fluid overload.

After delivery of the baby and placenta, large quantities of fluid are rapidly mobilized. The patient with cardiac disease must be continually assessed for decompensation (inability of the heart to maintain a sufficient cardiac output) during the puerperium. Ambulation should be encouraged, as ordered, as soon as possible after birth to prevent deep vein thrombosis. If the mother who is receiving cardiovascular medications chooses to breastfeed, careful clinical observation of the newborn is warranted. Digoxin and beta-adrenergic blockers are generally regarded to be safe during lactation (Setaro & Caulin-Glaser, 2004).

MITRAL VALVE PROLAPSE

Mitral valve prolapse (MVP) is a common condition that affects 2% to 3% of reproductive-aged women; however, it generally does not affect pregnancy (Cunningham et al., 2005). The hemodynamic changes associated with pregnancy may alleviate the murmur of MVP as well as its symptoms. In rare cases, patients experience chest discomfort or rhythm disturbances and should be managed with reassurance. Therapy with beta-adrenergic blockers may be initiated in highly symptomatic patients. If a murmur is audible, antibiotic prophylaxis should be administered at the time of childbirth (Cunningham et al., 2005; Setaro & Caulin-Glaser, 2004).

PERIPARTUM CARDIOMYOPATHY

Peripartum cardiomyopathy (PPCM) is a rare syndrome of heart failure that occurs in late pregnancy or within the first 5 months postpartum. The patient typically has no history of cardiac disease and presents with dyspnea, fatigue, and peripheral or pulmonary edema. Radiological findings are consistent with cardiomegaly. Acute treatment is directed at improving cardiac function. Treatment includes diuretics to decrease preload and relieve pulmonary congestion; digoxin to improve contractility and facilitate rate control when atrial fibrillation is present; beta-adrenergic blockers; anticoagulation with heparin if

the woman is antepartum and Coumadin if postpartum; and fluid and sodium restriction (Easterling & Otto, 2002; Klein & Galan, 2004).

The mortality rate associated with peripartum cardiomyopathy is reported to be 25% to 50%. Within 6 months after childbirth, half of the patients will demonstrate resolution of left ventricular dilation. Of those who do not, 8.5% will die within 4 to 5 years. Death is usually due to progressive heart failure, arrhythmia, or thromboembolism (Easterling & Otto, 2002).

Now Can You— Discuss cardiac complications during pregnancy?

1. Describe the normal anatomical and physiological changes that occur in the cardiovascular system during pregnancy and their impact on the pregnant woman with a cardiac disease?
2. State three important factors in the management of cardiac disease in pregnancy?
3. Identify team members you would include in your plan of care?

Diabetes in Pregnancy

Diabetes during pregnancy encompasses a range of disease entities that include gestational diabetes mellitus (GDM) and overt diabetes mellitus. Diabetes complicates more than 200,000 pregnancies each year in the United States (American Diabetes Association [ADA], 2006; Wallerstedt & Clokey, 2004). Diabetes is a complex health care problem that requires a comprehensive, multidisciplinary approach to ensure a healthy outcome for both the patient and her infant. When working with this population, perinatal nurses are challenged to provide care and education that incorporates diabetes management principles into obstetric care during all phases of childbearing, from pre-conception through the postpartum period.

DEFINITION AND CLASSIFICATION OF DIABETES MELLITUS

Pregestational diabetes mellitus is a chronic metabolic disease characterized by hyperglycemia that results from limited or absent insulin production, deficient insulin action, or a combination of the two (Expert Committee on the Diagnosis and Classification of Diabetes Mellitus [ECDCDM], 2003). Diabetes is divided into two broad categories—type 1 and type 2—that are differentiated according to the primary underlying etiology. Type 1 diabetes (formerly termed “insulin-dependent diabetes mellitus,” or IDDM), is characterized by an autoimmunity directed at the pancreatic beta cells. With Type 1 diabetes, there is an absolute insulin deficiency and the following characteristics are typically present (ECDCDM, 2003):

- It is usually diagnosed in those younger than 30 years of age.
- Acute symptoms precede the diagnosis and include polyuria, polydipsia, and significant weight loss.
- It has an abrupt onset that requires emergency medical attention.
- It accounts for approximately 10% of those diagnosed with diabetes.

Type 2 diabetes, the most prevalent form of the disease, is characterized by a combination of insulin resistance and inadequate insulin production (ECDCDM, 2003). Characteristics of type 2 diabetes include:

- It is diagnosed primarily in adults older than age 30, but with the current obesity epidemic, it is now seen in children.
- The disease is typically symptom free for many years, with a slow onset and a gradual progression of symptoms.
- Individuals with type 2 are not ketosis prone.
- It does not always require insulin and can often be treated with diet, exercise, and/or oral hypoglycemic agents.

GDM is an impairment in carbohydrate metabolism that first manifests during pregnancy. This category may include a small number of previously undiagnosed type 1 and type 2 diabetic women. The following characteristics apply (ECDCDM, 2003):

- Estimated to occur in approximately 4% to 7% of pregnancies; however, the prevalence may range from 1% to 14%, depending on the population studied and the diagnostic test used (ADA, 2006).
- Develops in the latter half of pregnancy as a result of the altered hormonal milieu (Kenshole, 2004).
- Symptoms are usually mild and not life threatening.
- May be treated by either diet or insulin, depending on the blood glucose levels.
- Women diagnosed with GDM are at an increased risk for developing diabetes later in life.

RISK FACTORS FOR GESTATIONAL DIABETES

- Women older than 25 years of age
- Obesity
- Insulin resistance
- Polycystic ovary syndrome
- History of pregnancy-related diabetes mellitus
- History of a large-for-gestational age infant, hydramnios
- Stillbirth, miscarriage, or an infant with congenital anomalies during a previous pregnancy
- Family history of type 2 diabetes (first-degree relative)
- Ethnicity

Ethnocultural Considerations— Gestational Diabetes

An increased incidence of gestational diabetes occurs in Native Americans, African Americans, Hispanic Americans, Asian Americans, and Pacific Islanders (ADA, 2006).

PATHOPHYSIOLOGY

The body requires a constant source of energy, provided mainly by glucose. Once glucose enters a cell, it may undergo oxidative (glycolysis) or nonoxidative metabolism (glycogen synthesis). In response to glucose ingestion, the pancreatic beta cells of the islets of Langerhans secrete insulin, a hormone that promotes the uptake of glucose into the cells. The regulation of plasma glucose levels and the entry of glucose into the cells are of critical importance.

Changes in carbohydrate, protein, and fat metabolism in normal pregnancy are profound, mediated in part by the developing fetus and the production of placental hormones. The first half of pregnancy is considered an “anabolic phase.” It is associated with an increased storage of fat and protein, along with an increase in the secretion of estrogen and progesterone. These physiological events lead to maternal hyperplasia and hyperinsulinemia. The increased insulin production prompts an increased tissue response to insulin and the increased uptake and storage of glycogen and fat in the liver and tissues.

The second half of pregnancy is characterized by a “catabolic phase” associated with the breakdown of protein and fat. During this time there is also an increased insulin resistance due to the heightened production of placental hormones (insulinase and human placental lactogen), cortisol, and growth hormones. These hormones are diabetogenic and act as insulin antagonists. In women who cannot meet the increasing needs for insulin production, this change leads to an altered carbohydrate metabolism and progressive hyperglycemia.

During this time, the developing fetus continuously removes glucose and amino acids, substances that can easily cross the placenta, from the maternal circulation. Because insulin does not cross the placenta, the fetus must increase its own insulin production. Fetal hyperinsulinemia develops and acts as a growth hormone that contributes to an increase in fetal size (macrosomia), and a decrease in pulmonary surfactant production. Macrosomia occurs in 20% to 25% of diabetic pregnancies. When the pregnant woman’s blood glucose levels remain abnormally elevated, there is a constant transport of maternal glucose across the placenta. This “glucose load” prompts the fetus to produce insulin at a greater rate in order to utilize the glucose.

Nursing Insight— Anticipating changes in insulin needs during pregnancy

During the first trimester, maternal blood glucose levels are normally reduced and the insulin response to glucose is enhanced. The woman with well-controlled pregestational diabetes may need a decrease in her insulin dosage to avoid hypoglycemia. During the second and third trimesters, as the insulin requirements steadily increase, the insulin dosage must be adjusted to prevent hyperglycemia. Maternal insulin resistance begins around 14 weeks of gestation and continues to increase until it stabilizes during the final weeks of pregnancy.

MATERNAL AND PERINATAL MORBIDITY AND MORTALITY

The changes in the maternal milieu that characterize the diabetic state can have profound effects on the growth and development of the fetus, increase the risk of perinatal morbidity and mortality, and exert adverse effects throughout life. The physiological adaptations induced by pregnancy can unmask latent maternal diabetes or result in transient worsening of preexisting vascular compromise (Kenshole, 2004). Diabetic women are four times more likely to develop preeclampsia or eclampsia than are nondiabetic women and twice as likely to experience a spontaneous abortion. The rates of infection, hydramnios, postpartum hemorrhage, and

cesarean birth are increased. In the long term, GDM is also associated with impaired insulin tolerance and the manifestation of diabetes in later life (Cunningham et al., 2005).

Major fetal effects associated with diabetes include a fivefold increase in perinatal death and a two to threefold increase in the rate of congenital malformations. Early in pregnancy, the fetus is at risk for congenital malformations and poor fetal growth. The risk of major congenital defects is 4% to 8% greater with type 1 or 2 diabetes. Congenital defects result from the teratogenic effects of hyperglycemia during the time of organogenesis during the early gestational weeks. Late in pregnancy, the fetus is at risk for growth abnormalities and sudden intrauterine death (Cunningham et al., 2005).

Control of maternal glucose levels (<7.0% in overtly diabetic women) is an important factor in determining fetal outcome. The **glycosylated hemoglobin A_{1c}** (HbA_{1c}) level is commonly assessed to guide adjustments in the treatment plan throughout pregnancy. Since the maternal serum HbA_{1c} reflects the degree of glycemic control during the preceding 5 to 6 weeks, the test is repeated every trimester. Good diabetic control is reflected by a HbA_{1c} value of 2.5% to 5.9%; a HbA_{1c} value greater than 8% is indicative of poor diabetic control. In the absence of pre-pregnancy and prenatal care, the rate of perinatal mortality for the diabetic patient and her fetus may be as high as 40%. However, with close, meticulous care, the perinatal mortality rate can be reduced to 3% to 5% (Cunningham et al., 2005).

Ketoacidosis

Diabetic ketoacidosis (DKA) is an accumulation of ketones in the blood that results from hyperglycemia. This condition, which can lead to metabolic acidosis, has become a less common occurrence since the implementation of meticulous antenatal care and protocols that stress the strict metabolic control of maternal blood glucose levels. Early recognition of the signs and symptoms of DKA helps to improve both maternal and fetal outcome. As occurs in the nonpregnant state, clinical signs of volume depletion follow the symptoms of hyperglycemia, which include polydipsia and polyuria. Malaise, headache, nausea, and vomiting are common patient complaints. A distinctive feature of diabetic ketoacidosis during pregnancy is that it can occur with remarkably low blood glucose levels (barely exceeding 200 mg/dL, compared with 300 to 350 mg/dL in the nonpregnant state) and requires emergency management to prevent maternal coma or death. Ketoacidosis that occurs at any time during pregnancy may result in fetal death and it is a common cause of preterm labor (Cunningham et al., 2005).

clinical alert

Maternal diabetes and preterm labor

Magnesium sulfate is the drug of choice for diabetic women who experience preterm labor. The use of terbutaline sulfate (Brethine) or antenatal corticosteroids to accelerate fetal lung maturation can cause significant maternal hyperglycemia and precipitate DKA. Patients must be closely followed in an acute care setting for at least 48 to 72 hours after corticosteroids have been given. An intravenous insulin infusion will usually be required and is adjusted on the basis of frequent capillary glucose measurements (Landon, Catalano, & Gabbe, 2002).

SCREENING AND DIAGNOSIS

Since 1970, much has been learned about the important relationship between maternal glycemic control before and during pregnancy and fetal outcomes. The perinatal mortality rate has simultaneously improved as an intensive approach to the diabetic pregnancy has become standard. The American College of Obstetricians and Gynecologists (ACOG) recommends that all pregnant women should be screened for diabetes during the 24th and 28th weeks of gestation. Women with risk factors (age >40, family history of a first-degree relative with diabetes; prior macrosomic, malformed, and/or stillborn infant; obesity; hypertension; or glycosuria) should be screened earlier in pregnancy (ACOG, 2001a). The American Diabetes Association (ADA) recommends selective diabetes screening during pregnancy, eliminating the need to screen women who have no risk factors. Screening is recommended for pregnant women with risk factors that include age greater than 25 years, obesity, family history of type 2 diabetes, and a history of a poor obstetric outcome (ADA, 2006).

In the United States, most centers use the following diagnostic recommendations and criteria established by the National Diabetes Data Group:

- The Glucose Challenge Test (Glucola screening): A 50-g oral glucose solution is administered to the woman and a blood sample is taken 1 hour after it is consumed. Patients with a 1-hour plasma glucose value of 140 mg/dL or higher should be further evaluated with the formal 3-hour oral glucose tolerance test (OGTT).
- The 3-hour OGTT requires the fasting patient to ingest 100 g of glucose with blood drawn at 1-hour intervals. Before the test, the woman should avoid caffeine (it may increase glucose levels) and refrain from smoking at least 12 hours before and during the test. The diagnosis of GDM is made when two values or more of the threshold are above the norm. According to the American Diabetes Association (2006), the normal plasma values are:

Fasting blood sugar	<95 mg/dL
1 hour	<180 mg/dL
2 hour	<155 mg/dL
3 hour	<140 mg/dL

MANAGEMENT

The goal of modern glycemic management during the diabetic pregnancy is to maintain blood glucose levels as close to normal (euglycemia) as possible. Euglycemia is a normal blood glucose level in the range of 65 to 105 mg/dL preprandially. Two-hour postprandial blood glucose levels should be less than 130 mg/dL (ADA, 2006). Metabolic monitoring during pregnancy is directed at detecting hyperglycemia and making all necessary pharmacological, dietary, or activity adjustments in order to minimize any adverse effects to the fetus. Home blood glucose monitoring with a glucose reflectance meter or biosensor monitor is a widely accepted method for monitoring blood glucose levels and an essential tool for helping the woman to assess her degree of blood glucose control. Patients monitor their blood glucose levels daily, record the findings, and bring their blood glucose logs with them to each prenatal appointment.

Ongoing fetal surveillance is of utmost importance. Maternal care requires the cooperative efforts of a clinical team that includes the obstetrician, internist, endocrinologist, diabetes educator, neonatologist, dietitian, and nurse. Patient education is essential to ensure that the woman understands her diabetic state and the need to adhere to treatment so that an optimal outcome is achieved (Fig. 11-11). Social services, home nursing visitation, and spiritual support are often involved as well.

Optimizing Outcomes— Diet and exercise for the patient with GDM

Diet and exercise are important components of care for the woman with GDM. Typically, the patient is placed on a standard diabetic diet that is calculated to include 30 kcal/kg per day, based on a normal preconceptional weight. For the obese woman, the diet may be calculated to include up to 25 kcal/kg per day (Chan & Winkle, 2006). Ongoing nutritional counseling is essential. Physical activity such as walking and swimming is also important for the woman with GDM. Exercise helps to lower blood glucose levels and may decrease the need for insulin (ADA, 2006).

Nursing Insight— Planning care for the woman with GDM

Although diet and exercise are the mainstays of care for the woman with gestational diabetes mellitus, up to 20% will require insulin during pregnancy to maintain euglycemia. If fasting blood glucose levels exceed 105 mg/dL, insulin therapy is initiated (ADA, 2006). (Oral hypoglycemic agents are contraindicated during pregnancy.)

Now Can You— Discuss diabetes management during pregnancy?

1. State three risk factors for gestational diabetes?
2. Discuss the effects of maternal diabetes on fetal growth and development?
3. Describe how you would educate the pregnant patient about the importance of diabetes screening?

The Thyroid Gland and Pregnancy

Thyroid disorders are relatively common among pregnant women. The hormonal changes and increasing metabolic demands of pregnancy bring about complex compensatory alterations in maternal thyroid function. Human chorionic gonadotropin (hCG), which is at its highest levels in early pregnancy, possesses intrinsic, weak thyroid-stimulating activity. Thyroid-stimulating hormone (TSH) levels fall during the first trimester, and this decrease parallels the rise in the production of hCG.

HYPERTHYROIDISM

Signs and Symptoms

The signs and symptoms of mild to moderate hyperthyroidism are common during pregnancy (heat intolerance, diaphoresis, fatigue, anxiety, emotional lability, tachycardia,

Nursing Care Plan Gestational Diabetes Mellitus

Nursing Diagnosis: Nutrition, Imbalanced: Less than Body Requirements related to impaired carbohydrate metabolism during pregnancy

Measurable Short-term Goal: The patient will plan a balanced diet and exercise program to follow during pregnancy

Measurable Long-term Goal: The patient will obtain and metabolize sufficient nutrients for maternal and fetal needs and to maintain appropriate blood glucose levels during pregnancy

NOC Outcomes:

Diabetes Self-Management (1619) Personal actions to manage diabetes mellitus and prevent disease progression.

Nutritional Status: Nutrient Intake (1009)
Adequacy of usual pattern of nutrient intake.

NIC Interventions:

Nutrition Therapy (1120)
Nutrition Counseling (5246)

Nursing Interventions:

1. Assess the patient's understanding of gestational diabetes and provide additional information as needed about changes in carbohydrate metabolism during pregnancy and how these may affect the patient and her fetus.

RATIONALE: Teaching is based on the patient's need for information to help promote active participation in self care.

2. Refer patient to a registered dietician and reinforce the recommended diet parameters with patient at each visit: an additional 300 calories per day are needed in the second and third trimesters; 40–50% from complex carbohydrates, 10–20% from protein, and 30% from fats; avoid concentrated sweets; nutrients should be divided each day between three meals and three snacks.

RATIONALE: The diet is planned to maintain a normoglycemic state during pregnancy based on the patient's lifestyle and individual food preferences.

3. Encourage the patient to engage in 30 minutes of daily exercise appropriate for her pregnancy such as walking or swimming.

RATIONALE: Regular exercise helps maintain lower blood glucose levels

4. Ask patient to keep a daily log of her diet and exercise. Review at each prenatal visit and offer support and encouragement to continue regimen.

RATIONALE: A written log allows the patient to monitor her own progress as well as providing a record of interventions to compare with blood glucose levels.

5. Inform patient that she will need to have her blood glucose checked weekly in the office and if it is still high after about 2 weeks of diet and exercise, she may need to begin insulin therapy.

RATIONALE: Dietary changes and exercise may not be enough to maintain carbohydrate balance. Anticipatory guidance helps motivate the patient and prepare her for possible change.

6. Monitor fetal growth and well-being. Instruct patient in a method for fetal kick counts beginning at 28 weeks and prepare her for weekly NSTs from 34 weeks until birth.

RATIONALE: Maternal hyperglycemia may result in fetal macrosomia. The fetus of a diabetic mother is at higher risk for complications.

and a wide pulse pressure). However, weight loss, tachycardia greater than 100 beats per minute, and diffuse goiter are clinical features suggestive of hyperthyroidism. Gastrointestinal symptoms (i.e., severe nausea, excessive vomiting, and diarrhea), cardiomyopathy, lymphadenopathy, and congestive heart failure can also accompany thyrotoxicosis (excessive thyroid activity) in pregnancy (Cunningham et al., 2005; Nader, 2004). Establishing a diagnosis of maternal hyperthyroidism can be challenging due to the myriad of metabolic and hormonal changes that normally take place during pregnancy. However, a depressed maternal serum TSH concentration and an elevated free thyroxine (T_4) level are useful in confirming the diagnosis. Although difficult,

prompt diagnosis of hyperthyroidism is imperative because of the potential for serious maternal and fetal complications. Research suggests that uncontrolled hyperthyroidism during pregnancy may be associated with increased preeclampsia, preterm labor, low birth weight, and neonatal mortality (Cunningham et al., 2005; Nader, 2004).

Treatment

Treatment for hyperthyroidism includes the use of antithyroid medications such as the thioamides, propylthiouracil (PTU—the drug of choice), or methimazole (Tapazole). Symptomatic improvement usually occurs within 2 weeks after the initiation of therapy although the

Name _____ Date of birth _____ Age _____
 Diabetes type _____ Age @ diagnosis _____ Expected date of confinement _____ Educator _____

 The pregnant woman with diabetes will demonstrate the following:

Expected Outcome	Date
Understands diabetes, role of glucose and insulin transport	
Understands significance to pregnancy of 3-hour glucose tolerance test results (GDM)	
Understands effect pregnancy has on diabetes control, including role of placental hormones	
Understands potential outcomes of uncontrolled blood glucose—macrosomia, polyhydramnios, respiratory distress syndrome, preterm delivery, intrauterine fetal death, neonatal hypoglycemia, ketoacidosis, birth trauma, cesarean delivery	
Understands significance of hemoglobin A1C for spontaneous abortion and congenital defects	
Uses glucose meter, including quality controls	
Uses autolancet to obtain blood sample with appropriate disposal	
Understands diabetes/diet/diary and role of exercise, with safety guidelines	
Records technique of blood glucose values and abnormal reactions	
Understands glycemic goals for treatment	
Knows onset and peak times of prescribed insulin	
Inspects and stores insulin correctly	
Draws up insulin correctly (single and mixed)	
Identifies timing of injection, injection sites, rotation and technique, and appropriate syringe disposal	
Identifies signs and symptoms of hypoglycemia	
Treats hypoglycemia with documented low (written guidelines)	
Has support person with knowledge of glucagon use and appropriate administration—provided Rx with two refills	
Identifies signs and symptoms of ketoacidosis; reports persistent nausea/vomiting, illness, infection, persistent hyperglycemia, or recurrent insulin reactions	
Checks ketones daily with first void (pregestational) and with blood glucose values >180 mg/dL	
Understands sick day management (written guidelines)	
Schedules antepartum testing	
Understands significance of GDM for future pregnancy, development of overt diabetes mellitus later in life, appropriate follow-up, need for follow-up testing, preconception control, and risk-minimizing interventions	
Understands significance of diabetes and development of long-term complications related to poor control	

Level of comprehension _____ Learning impediments _____

Figure 11-11 Diabetic education checklist.

medication does not become fully effective for 6 to 8 weeks. During treatment, the patient's free T_4 levels are obtained on a monthly basis and the findings are used to taper the dosage to achieve the smallest effective level to prevent unnecessary fetal hypothyroidism. When unresponsive to drug therapy, surgery (subtotal thyroidectomy) may be necessary. Since the surgery is associated with an increased risk of pregnancy loss and preterm labor, it is performed only for cases of severe hyperthyroidism. The use of radioactive iodine for diagnosis or treatment of hyperthyroidism is contraindicated during pregnancy because it may adversely affect the fetal thyroid (Golden & Burrow, 2004). When caring for patients with hyperthyroidism, the nurse must carefully monitor maternal weight gain and fetal growth.

HYPOTHYROIDISM

Symptoms

The symptoms of hypothyroidism are insidious and can be masked by the hypermetabolic state associated with pregnancy. Maternal symptoms can include modest weight gain, a decrease in exercise capacity, lethargy, cold intolerance, constipation, hoarseness, hair loss, brittle nails and dry skin. Laboratory confirmation is made from an elevated TSH level and low to normal T_3 and T_4 values (Cunningham et al., 2005; Nader, 2004).

Treatment

Hypothyroidism must be treated promptly as there is an increased risk for maternal preeclampsia, placental abruption, and stillbirth. Fetal neurological development can be severely affected by decreased levels of thyroid hormone. Treatment involves the use of a thyroid hormone supplement (i.e., levothyroxine [Synthroid]) with the dose adjusted every 4 weeks until the TSH level reaches the lower end of the normal range for pregnancy (Nader, 2004).

Venous Thrombosis and Pulmonary Embolism

Venous thromboembolic diseases include superficial and deep vein thrombophlebitis (DVT), pulmonary embolus (PE), septic pelvic thrombophlebitis, and thrombosis. These conditions account for one half of all obstetric morbidity. Pulmonary embolism, the leading cause of maternal mortality, accounts for 17% of all maternal deaths (Whitty & Dombrowski, 2004). The most common form of thrombosis that occurs during pregnancy involves veins of the calf, thigh, and pelvis. The most important aspect of lower extremity and pelvic venous thrombosis is that it can lead to pulmonary embolism, which poses a major threat to the pregnant woman (Cunningham et al., 2005).

PATHOPHYSIOLOGY

Thrombosis is thought to be the consequence of alterations in the vessel wall, slowing of blood flow (or stasis), and changes in blood components. Pregnancy presents the ideal state in which all three of these components may exist. Trauma to the vessel wall may occur during childbirth with alterations in the clot-inhibiting endothelial surface. Blood flow from the legs and pelvic veins are slowed during pregnancy because of pressure exerted on the iliac veins by the gravid uterus and by the relaxation of the smooth muscles in response to increased progesterone.

Finally, changes in blood components occur during pregnancy whereby some clotting factors are increased while other anticoagulant and fibrinolytic system factors are decreased.

INCIDENCE AND RISK FACTORS

When compared with nonpregnant women of similar age, the likelihood of venous thromboembolism during normal pregnancy and the puerperium is increased by a factor of five. Venous thromboembolism (VTE) occurs in 0.5 to 3 per 1000 pregnancies. An untreated DVT is associated with a 15% to 25% incidence of pulmonary embolus, which is associated with a 12% to 15% maternal mortality rate (McPhedran, 2004). A number of factors such as preeclampsia, advanced age, increased parity, multiple gestation, obesity, and dehydration place women at high risk for thromboembolic disease during pregnancy. When assessing the pregnant patient, the nurse must be aware of the characteristic signs and symptoms associated with thromboembolic disease.

Critical Nursing Action Recognizing Thromboembolism

During the examination, the nurse assesses for the presence of the following signs and symptoms that may be indicative of thromboembolism (Cunningham et al., 2005; McPhedran, 2004):

- Pain, tenderness, warmth
- Swelling of the lower extremity which is asymmetric with a difference of greater than 0.8 inch (2 cm) between the normal and affected leg. Swelling of the thigh is especially relevant because the risk of pulmonary embolism is associated with femoral or iliac phlebitis.
- Color change, especially in the left leg
- A palpable cord underlying the region of pain and tenderness
- Positive Homans' sign

Symptoms of a pulmonary embolism

- Tachypnea
- Dyspnea
- Pleuritic chest pain
- Atelectatic rales
- Cough
- Fever
- Diaphoresis
- Tachycardia
- Hemoptysis
- Cyanosis
- Heart gallop or murmur
- Anxiety
- Apprehension

The diagnosis can be very challenging as some of the signs and symptoms are normal during pregnancy (e.g., lower extremity edema). Doppler ultrasound technique has become the diagnostic study of choice in cases of proximal vein occlusion. Venography has not been used often in pregnancy because of possible hazards to the fetus, but it is a useful tool when results of other studies are equivocal (Laros, 2004). If there is a suspicion of PE, the ventilation–perfusion (VQ) scan results in minimal radiation exposure to the fetus. An entirely normal perfusion scan rules out PE (Refuerzo, Hechtman, Redman, & Whitty, 2004). Management involves a combination of strategies including medications (i.e., anticoagulant therapy with heparin), bed rest with elevation of the involved extremity, and the application of warm, moist heat.

Now Can You—Discuss thromboembolism during pregnancy?

1. Describe why pregnancy is an ideal state for the development of thromboembolism?
2. Name five signs and symptoms to consider when assessing your pregnant patient for thromboembolism?
3. Formulate a plan of care for the patient with a diagnosis of thromboembolism?

Psychiatric Complications During Pregnancy

The recognition and management of depression and psychoses during pregnancy and the puerperium are of critical importance. Particularly in the United States, these disorders often are underrecognized and undertreated, and this factor potentially contributes to the likelihood of devastating effects on the child, the mother, the family, and society (Parry, 2004).

CONSULTING WITH THE PREGNANT PSYCHIATRIC PATIENT

Psychiatric complications during pregnancy can represent an exacerbation of an ongoing psychiatric disorder, a resurgence of previously remitted symptoms, or the onset of a new illness. Millions of women suffer from mental illness during their childbearing years, and more than 50% of pregnancies are unplanned in this population. These facts highlight the importance of prenatal counseling with regard to the natural history of various psychiatric disorders during pregnancy as well as the potential associated with fetal exposure to psychotropic agents and/or maternal mental illness (Epperson & Czarkowski, 2004).

Consultations with pregnant women who suffer from a psychiatric disorder, regardless of the diagnosis, should include discussion of the following facts (Epperson & Czarkowski, 2004):

- Psychoactive medications readily cross the placenta.
- There are potential risks associated with untreated maternal psychiatric illness as well as exposure to psychotropic medications. (Risks may include poor attention to prenatal care, substance abuse, and deliberate self-harm).

- Many women experience relapse or worsening of symptoms if pharmacologic treatment is not continued or instituted when necessary. (Maternal anxiety and stress have been shown to have adverse effects on pregnancy outcome, infant/child neurodevelopment, and maternal postnatal mental health.)

DEPRESSION

The incidence of depression during pregnancy is estimated to be 10% to 13%. Women at risk for antepartum and/or postpartum depression are those with a personal or family history of affective disorders (unipolar and bipolar), few social supports, marital conflict, or significant life events (Epperson & Czarkowski, 2004; Records & Rice, 2007).

Bipolar Disorder

The course of bipolar disorder is particularly unpredictable during pregnancy. There have been reports of heightened risk of depressive or manic relapse in women who rapidly discontinued their lithium treatment, in comparison with those who underwent a slow, controlled tapering off over 4 weeks. Regardless of how rapidly lithium doses were tapered, the risk of relapse illness in these women was 52% during pregnancy and 70% during the puerperium (Pigarelli, Kraus, & Potter, 2005).

Anxiety Disorders

Anxiety disorders including panic disorder, generalized anxiety disorder, obsessive-compulsive disorder (OCD), and posttraumatic stress disorder (PTSD) are common during the childbearing years. Childbearing has been associated with the onset or worsening of panic disorder or OCD (Epperson & Czarkowski, 2004).

Eating Disorders

Eating disorders in pregnant women have both physiologic and psychologic effects on the outcome of the pregnancy and on subsequent infant development. Anorexia nervosa has been associated with higher rates of perinatal mortality, obstetric complications, and congenital anomalies. Bulimia nervosa has been associated with extreme maternal weight gain, and preeclampsia and eclampsia (Epperson & Czarkowski, 2004).

MANAGEMENT

The importance of the detection of psychiatric problems in the pregnant population cannot be overemphasized. The health and welfare of not only the mother is at stake but also that of the entire family. Nurses are often the first care providers to recognize indicators of psychiatric difficulties in their patients. Strategies to help identify mental health problems during pregnancy may include (Epperson & Czarkowski, 2004; Parry, 2004):

- Placing psychoeducational materials throughout all patient areas
- Routinely inquiring about the patient's and her family's psychiatric history during the initial interview
- Administering the Edinburgh Postnatal Depression Scale (or a similar tool)
- Assessing the woman's access to social and family supports

- Referring the woman to community resources such as home health visitation and the local mental health agency

“What to say” — When screening for depression during pregnancy

The U.S. and Canadian Task Forces on Preventive Health Care recommend using the following two “probe questions” to screen women for depression during pregnancy:

- “Over the past two weeks have you felt down, depressed or helpless?”
- “Over the past two weeks have you felt little interest or pleasure in doing things?” (Records & Rice, 2007).

Substance Abuse in Pregnancy

Drug and alcohol use during pregnancy is a common phenomenon and a significant public health issue. Studies of substance abuse during pregnancy have documented a high incidence of adverse and, sometimes, catastrophic perinatal outcomes associated with intrauterine drug and alcohol exposure. Nurses are responsible for having up-to-date knowledge of the effects of alcohol, tobacco, and other drugs in pregnancy and for performing skilled and compassionate assessments of pregnant and postpartum women without criticizing their behavior or alienating them from their sources of health care.

According to the National Pregnancy and Health Survey, approximately 19% of women used alcohol during pregnancy; 5% used an illicit drug at least once during pregnancy, including marijuana (3%) and cocaine (1%). The Pregnancy Risk Assessment Monitoring System (PRAMS) estimated that women's alcohol use during pregnancy ranged from 3% to 10%. Findings from the Maternal Life Study, which oversampled very low-birth-weight infants, revealed that 35% of pregnant females reported alcohol use and 8% reported marijuana use during pregnancy. Meconium toxicology screens tested positive for cocaine or opioids in 11% of infants screened (Brady & Ashley, 2005).

SUBSTANCE ADDICTION

Pregnancy does not occur in a vacuum but rather it is an event that is superimposed on the context and circumstances of women's lives. Substance abusing women have a high incidence of social (intimate partner violence, risk-taking sexual behaviors) and psychologic (low self-esteem) conditions that affect their health status, their ability to engage in prenatal care, and their ability to succeed in drug abuse treatment. These social and psychologic conditions become more important considerations when the biologic and psychologic stress of pregnancy is added to an already fragile system (Mason & Lee, 2004).

Nurses face difficult ethical dilemmas when caring for pregnant and parenting women who use harmful substances. The conflict may be viewed as one that exists between the women's right to autonomy over her body and behavior and the nurse's obligation to prevent harm

to the fetus or child (Kearney, Wellman, & Freda, 1999). Nurses in prenatal care and acute care settings are responsible for thoroughly assessing psychosocial risks and conducting mutual goal setting with pregnant patients to minimize the harm associated with these risks. Support and respect should be offered regardless of the woman's decisions about her health care or self-care. A nonjudgmental, concerned, and empathetic environment should be provided so that the patient feels encouraged to express her feelings and concerns about herself, her drug use, and her unborn child (Kearney et al., 1999; Moran, 2004b).

Now Can You— Discuss issues associated with substance abuse during pregnancy?

1. Name five behaviors that may signal a substance abuse problem?
2. Discuss how substance abuse can affect the course and outcome of pregnancy?
3. Discuss the ethical dilemmas faced by the perinatal nurse who is caring for the pregnant woman with a substance abuse problem?

Antepartum Fetal Assessment

Fetal assessment is an integral component of prenatal care. Careful assessment of fetal well-being enhances perinatal outcome through early identification and intervention for fetal compromise. The goal of antepartum fetal surveillance is to prevent fetal death and to help ensure the best possible fetal outcome. A number of tests can be performed during pregnancy to monitor fetal growth, development, and well-being. Antenatal assessment during the first and second trimester is directed primarily at the diagnosis of fetal congenital anomalies while the goal of third trimester assessment is to determine the quality of the intrauterine environment for the maturing fetus.

CHORIONIC VILLUS SAMPLING

Chorionic villus sampling (CVS) is an invasive procedure that can be used to obtain a fetal karyotype. Because the villi arise from trophoblast cells, their chromosome structure is identical to that of the fetus. CVS is performed between 10 and 12 weeks' gestation and results are available quickly due to the rapid proliferation of the chorionic villi cells. Using ultrasound guidance to locate the chorion cells, a thin catheter is inserted vaginally into the intrauterine cavity. An alternative technique involves the abdominal or intravaginal insertion of a biopsy needle. A small quantity of chorionic villi is then aspirated from the placenta. The risk of complications associated with CVS is 1 in 200. Risks include infection (in 0.5% of cases), fetal loss (in 0.3% of cases), rupture of membranes (in 0.1% of cases), Rh isoimmunization, and possible fetal limb reduction (Gilbert & Harmon, 2003).

PERCUTANEOUS UMBILICAL BLOOD SAMPLING

Percutaneous umbilical blood sampling (PUBS) is an invasive procedure that is performed to obtain a sample of fetal blood for karyotyping and to test for anemia, isoimmunization, metabolic disorders, and infection. Under

ultrasound guidance, a needle is inserted through the maternal abdomen and into the fetal umbilical cord. Use of a fetal blood sample for karyotyping allows for more rapid test results than when fetal skin cells are used, as with amniocentesis. Complications include cord laceration, thromboembolism, preterm labor, premature rupture of the membranes, and infection (Jenkins & Wapner, 2004).

AMNIOCENTESIS

Amniocentesis is an invasive procedure that involves the removal of amniotic fluid. Under ultrasound guidance, a needle is inserted through the maternal abdomen and into the amniotic sac (Fig. 11-12). Amniocentesis may be performed beginning at 12 weeks' gestation. Components of the amniotic fluid, including fetal cells, may be analyzed for chromosomal abnormalities, fetal lung maturity, infection, and the presence of bilirubin in Rh-sensitized pregnancies. Later in the pregnancy, amniotic fluid reduction (via amniocentesis) may be performed for temporary alleviation of maternal symptoms associated with hydramnios (excessive amniotic fluid). Complications associated with amniocentesis include rupture of the membranes, preterm labor, infection, fetal injury, and fetal death. If the woman has Rh₀(D)-negative blood, Rh₀(D) immune globulin should be administered following the amniocentesis to prevent isoimmunization.

Amniocentesis is frequently performed late in pregnancy to provide information concerning fetal lung maturity. **Lecithin** and **sphingomyelin** are the protein components of surfactant, the lung enzyme that is formed by the alveoli beginning around the 22nd week of gestation. After amniocentesis, the **lecithin/sphingomyelin ratio (L/S ratio)** may be quickly determined by a "shake test" or sent to the laboratory for a quantified analysis. An L/S ratio of 2:1, which typically occurs by 35 weeks' gestation, is traditionally accepted as lung maturity (a ratio of 3:1 in the infant of a diabetic mother).

Phosphatidylglycerol and **desaturated phosphatidylcholine** are two other compounds that are found in surfactant after approximately 35 to 36 weeks of gestation. Since these two substances are present only with

Figure 11-12. Amniocentesis.

lung maturity, their presence in the amniotic fluid sample is another indicator that respiratory distress syndrome will not occur in the neonate.

ADDITIONAL INVASIVE TESTS

Amnioscopy

Amnioscopy involves the use of an amnioscope (a small fetoscope) to visually inspect the amniotic fluid through the cervix and membranes. Most often this procedure is performed to detect meconium staining. It carries a risk of membrane rupture.

Fetoscopy

Fetoscopy is a method of visualizing the fetus with a fetoscope, an extremely narrow, hollow tube inserted through an amniocentesis technique. It is sometimes used to assess fetal well-being, obtain fetal tissue and blood samples, and perform fetal surgery, but not before 17 weeks of gestation. The procedure carries a risk of premature labor and infection.

ULTRASONOGRAPHY

Ultrasonography is the use of high-frequency (>20,000 Hz) sound waves to detect differences in tissue density and visualize outlines of structures in the body. Widely used in modern obstetrics, ultrasonography is an important component of antepartum fetal assessment and surveillance. The examination can be done abdominally (after application of a transmission gel, a transducer is moved over the skin) or transvaginally (a lubricated transducer probe is placed in the vagina) during pregnancy. The abdominal technique is more useful after the first trimester when the gravid uterus becomes an abdominal organ. The sound frequencies that bounce back from the uterus are displayed on an oscilloscope screen as a three-dimensional visual image. During the painless examination, the patient should be positioned so that she (and her support person, if present) can observe the images, if they wish to do so.

Nursing Insight— Levels of ultrasonography

There are three levels of ultrasonography examinations: standard, limited, and specialized.

Ultrasonographers or other health care professionals who have received special training may perform the *standard* examination, which is used to detect fetal viability, assess the gestational age, determine the presentation of the fetus, locate the placenta, assess amniotic fluid volume (AFV), and examine the fetus for certain anatomic abnormalities. The *limited* examination is performed for a specific indication, such as determining the fetal presentation during labor or evaluating fetal heart activity when it cannot be detected by other methods. The *specialized* examination is performed to evaluate a fetus suspected to have an anatomical or physiological abnormality. This level of examination is generally performed by specialists in high-risk perinatal centers (ACOG, 2004).

During the first trimester, ultrasound may be used to confirm the viability and age of the pregnancy, determine the number, size, and location of the gestational sacs, identify uterine abnormalities (and rule out an ectopic

pregnancy), and locate the presence of an intrauterine contraceptive device. Fetal heart rate activity can be observed as early as 6 to 7 weeks via real-time echo sonography. In the second and third trimesters, ultrasound is frequently used to confirm fetal viability and gestational age, monitor fetal growth, AFV, placental location and maturity, and assess uterine fibroid tumors and cervical length. Serial measurements are useful in providing an accurate determination of fetal age. Ultrasound is an essential component of the biophysical profile and fetal Doppler studies (discussed later).

Optimizing Outcomes— Accurately determining fetal age with ultrasonography

Ultrasonography examinations provide an accurate estimate of fetal age during the first 20 weeks of gestation because most normal fetuses grow at approximately the same rate. Throughout the gestational period, fetal age determination may be made by the following sonographic measurements: (1) gestational sac dimensions (around 8 weeks); (2) crown–rump length (CRL) (around 7–12 weeks); (3) biparietal diameter (BPD) (after 12 weeks); and (4) femur length (after 12 weeks). The accuracy of gestational age assessment increases as the fetus ages because more than one structure is measured.

KICK COUNTS

Counting fetal movements or “kick counts” has been proposed as a primary method of fetal surveillance for all pregnancies. This method of fetal assessment has many benefits. It is easy to perform, readily available to the woman, and has no associated costs. The patient is instructed to lie on her side and count the number of times that she feels the fetus move. Many variations have been developed but there are two major methods for performing kick counts:

- The first method is done while the woman lies on her side. She counts and records 10 distinct movements in a period of up to 2 hours. Once 10 movements have been perceived, the count may be discontinued.
- With the second method, the patient counts and records fetal movements for 1 hour three times per week. The count is to be considered reassuring if it equals or exceeds the woman’s previously established baseline.

DOPPLER ULTRASOUND BLOOD FLOW STUDIES (UMBILICAL VELOCIMETRY)

Doppler ultrasound is used to study blood flow in the umbilical vessels of the fetus, placental circulation, fetal cardiac motion, and maternal uterine circulation. This technology is useful in managing pregnancies at risk because of hypertension, diabetes mellitus, IUGR, multiple fetuses or preterm labor. A noninvasive Doppler wave measures the velocity of red blood cell movement through the uterine and fetal vessels. Assessment of the blood flow through the uterine vessels is useful in determining vascular resistance in women at risk for developing placental insufficiency. Decreased velocity is associated with poor neonatal outcome (Jasper, 2004).

FETAL BIOPHYSICAL PROFILE

The fetal **biophysical profile** (BPP) is a noninvasive “fetal physical examination” that is more accurate in predicting fetal well-being than any single assessment. It combines electronic fetal heart rate monitoring with ultrasonography to evaluate fetal well-being. The fetus responds to central hypoxia by alterations in movement, muscle tone, breathing, and heart rate patterns. A finding of normal fetal biophysical parameters indicates that the central nervous system is functional and therefore the fetus is not hypoxic. The BPP comprises the following five components and is based on a 30 minute time period (Harmon, 2004):

- Nonstress test
- Fetal breathing movements (one or more episodes of rhythmic fetal breathing movements for 30 seconds)
- Fetal movement (three or more discrete body or limb movements)
- Fetal tone (one or more episodes of extension of a fetal extremity with return to flexion, or opening or closing of a hand)
- Determination of the amniotic fluid volume (a single vertical pocket of amniotic fluid exceeding 0.8 inch (2 cm) is considered evidence of adequate amniotic fluid)

Each of the five components is assigned a score of 2 (normal or present) or 0 (abnormal). A score of 8 to 10 is reassuring while a score of 6 is considered “equivocal” and the test should be repeated within 24 hours in the case of a preterm infant; the term infant should be promptly delivered. When the score is 0 to 4/10, especially in the fetus with IUGR that has reduced amniotic fluid and in whom serial observations have previously been normal, delivery should commence without any delay (Harmon, 2004).

NONSTRESS TEST

The nonstress test (NST) is one of the most common methods of antenatal screening. It involves the use of electronic fetal monitoring (EFM) for approximately 20 minutes. The NST is based on the premise that a normal fetus moves at various intervals and that the CNS and myocardium responds to movement. The response is demonstrated by an acceleration of the FHR (the FHR “reacts”). Loss of heart rate reactivity is associated most commonly with a fetal sleep cycle but may result from any cause of central nervous system depression, including fetal hypoxia, acidosis, and some congenital anomalies (Harmon, 2004; Tucker, 2004).

Reactivity is also based on gestational age; 32 to 34 weeks is considered to be the appropriate age for reactivity to occur. Before this gestational age, a very large percentage of fetuses will not meet the acceptable criteria: a FHR acceleration of 15 beats per minute (bpm) that lasts for 15 seconds (ACOG, 1999). Fetuses less than 32 weeks are more likely not to meet the criteria for a reactive nonstress test. When the preterm fetus is monitored, consideration should be given to the effect of the gestational age on the size of the accelerations: a FHR acceleration of 10 bpm that lasts for 10 seconds is acceptable at 32 weeks. Once a fetus has a reactive tracing, however, it should remain reactive. Women with risk factors (e.g., diabetes,

uteroplacental insufficiency) undergo frequent non stress testing, often twice weekly (Cunningham et al., 2005).

With the patient in the lateral tilt position, the nurse applies the external electronic fetal monitor and observes the tracing for evidence of fetal heart rate accelerations of at least 15 bpm above the baseline heart rate. At least two FHR accelerations sustained for at least 15 seconds should occur over a 20-minute time period. If these criteria are met, the test is satisfactory and termed a “reactive test.” The test may be extended for another 20 minutes if needed. If the reactive criteria are not met (e.g., the FHR accelerations do not reach 15 bpm or do not last for 15 seconds) over a 40-minute period, the test is considered to be “nonreactive.” Depending on the fetal age, a nonreactive NST result should be followed by a contraction stress test or a biophysical profile (ACOG, 1999). An “unsatisfactory” NST result occurs if there is inadequate fetal activity or if the data cannot be interpreted.

ACOUSTIC STIMULATION/VIBROACOUSTIC STIMULATION

Acoustic (sound) **stimulation** and **vibroacoustic** (vibration and sound) **stimulation** may be used as an adjunct to the NST to elicit an acceleration of the fetal heart rate. A hand-held instrument such as an artificial larynx (especially designed for this purpose) is positioned on the maternal abdomen and a low-frequency vibration and a buzzing sound are emitted. The stimulus is applied for 1 to 3 seconds in an attempt to awaken the fetus and may be repeated up to three times with a 1-minute rest period between attempts. A fetus that shows no response to the applied stimulus may be neurologically compromised or acidotic and requires further evaluation (ACOG, 1999).

CONTRACTION STRESS TEST

The **contraction stress test (CST)** evaluates the FHR response to uterine contractions. The CST is based on the premise that fetal oxygenation that is only marginally adequate with the uterus at rest is transiently worsened by uterine contractions (Jasper, 2004). The nurse uses the electronic fetal monitor to obtain a baseline FHR tracing for 20 minutes. If spontaneous uterine contractions do not occur during this time, uterine stimulation is produced through IV oxytocin infusion (beginning with 0.5 milliunits/min and increasing the dose by 0.5 milliunits/min at 15- to 30-minute intervals) or patient nipple self-stimulation, until three contractions of at least 40 seconds duration occur within a 10-minute time frame. CSTs are evaluated according to the presence or absence of late FHR decelerations. A late deceleration, associated with fetal hypoxia, is one that begins at the peak of the contraction and persists after the conclusion of the contraction. The test is considered negative (normal) if there is no evidence of late or significant variable decelerations; a positive CST (abnormal) is one in which there are late decelerations after 50% of contractions, even if the frequency is less than three in 10 minutes. An equivocal or suspicious result indicates the presence of non-persistent late decelerations or decelerations associated with hyperstimulation (contractions occur less than 2 minutes apart or last longer than 90 seconds) (ACOG, 1999; Harmon, 2004). Additional information is needed when this finding occurs.

Since the CST is based on the presence of uterine contractions, there are several contraindications to the test. Patients who have experienced third trimester bleeding from placenta previa or marginal abruption placenta, women who have had a previous cesarean birth with a classical incision (vertical incision that extends into the uterine fundus), and those with premature rupture of the membranes, cervical incompetence or multiple gestation are not candidates for a CST.

ELECTRONIC FETAL HEART RATE MONITORING

Electronic fetal heart rate monitoring (EFM) uses electronic techniques to give an ongoing assessment of fetal well-being. EFM provides information related to the response of the fetal heart rate in the presence or absence of uterine contractions. Electronic monitoring of the fetal heart rate can be accomplished by either external or internal means. EFM is discussed in greater detail in Chapter 12.

Now Can You— Discuss methods of antepartum fetal surveillance?

1. Differentiate among chorionic villus sampling, percutaneous umbilical sampling and amniocentesis?
2. Identify two methods for conducting kick counts?
3. List the fetal parameters assessed in a biophysical profile?
4. Discuss how the NST is performed and describe what is meant by a “reactive” and a “nonreactive” test result?

Special Conditions and Circumstances that May Complicate Pregnancy

THE PREGNANT WOMAN WHO REQUIRES ANTENATAL BED REST

The patient whose antenatal course is compromised by obstetrical complications that require bed rest faces even more challenges. Maloni (2002) has written extensively about the deleterious effects of bed rest on body systems and addresses problems such as muscle wasting, failure to gain weight, and cardiovascular and psychological difficulties. Lack of weight bearing and inactivity make muscles weak. Dizziness, difficulty regulating blood pressure, and fainting are common symptoms in the patient confined to bed rest.

In most situations, regular home visitation by a community health nurse is an important component of care (Fig. 11-13). The nurse caring for the patient with a high-risk pregnancy needs to remain cognizant of the fact that depending on the circumstances, the woman’s libido is often unaffected and she and her partner will need guidance regarding “safe” practices that promote intimacy without threatening the pregnancy. Also, as the pregnancy progresses, the woman on bed rest is presented with the same maternal tasks (Rubin, 1976), as is any other woman who is approaching motherhood. The woman’s physical condition may cause difficulty in mastering the tasks. For example, Rubin observed that a pregnant woman is drawn to the company of other pregnant women, not only for acceptance but also to promote a greater understanding of interpersonal behavior during this special stage of her life.

Figure 11-13 Visiting patients confined to bed rest at home is an important nursing intervention.

These normal feelings and activities can be jeopardized by hospitalization and the woman’s subsequent removal from the comforting patterns and rhythm of day-to-day life. Hospitalization, especially when prolonged, can create many additional problems, since hospitalized patients often suffer from loneliness, boredom, powerlessness, anxiety, anger, and depression.

Maloni, Brezinski-Tomasi, and Johnson (2001) reported that women confined to bed rest felt like prisoners and often experienced guilt over the extra responsibilities foisted upon their partners. In addition, childcare, with the necessary involvement of multiple providers and the disruption of usual routines, was viewed as a major concern. Financial strain and its impact on family well-being was also an issue. Referral to social services and other community resources may be helpful in assisting the couple with financial matters and other aspects of home care.

Nursing interventions that can be instituted to help the family adjust to the stress of a complicated pregnancy include the involvement of high-risk pregnancy or other specialty support groups, professional counseling when appropriate, and religious support when desired. The educational needs of the pregnant woman who is experiencing a high risk pregnancy are essentially the same as those of any childbearing woman. Whenever possible, nurses should encourage their patients to participate in prenatal classes, seek lactation counseling, learn about infant care, and attend self-care classes. The nurse may arrange for the couple to attend childbirth education classes in either a group or private setting. For most, participating in a group promotes a feeling of normalcy. Family members, particularly the woman’s partner, should be included, as they can share infant care responsibilities and provide emotional support.

“Sidelines,” a national support group, provides resources such as a helpful bedside checklist that describes a variety of activities for women confined to bed rest. This organization may be contacted at www.sidelines.org.

The recognition that high-risk couples may have depleted their coping skills due to perinatal complications constitutes an important nursing issue, especially during the intrapartum period. The nurse needs to be aware that the anxiety and stress of labor may be extremely difficult for the couple. The nurse can assist and empower the

patient and her partner by encouraging them to express their emotional concerns, by keeping them informed of changes in the woman's condition and by encouraging them to ask questions.

Depending on the circumstances, the postpartum period may be very difficult as well, due to physical and emotional exhaustion, especially if antenatal hospitalization was required. Adverse symptoms associated with weeks of bed rest are often not resolved by 6 weeks postpartum (Maloni & Park, 2005). The woman may not be able to care for her infant as she would like, and this situation can quickly lead to feelings of helplessness, frustration, and disappointment. The nurse needs to remain supportive, conduct an ongoing assessment of the family's coping skills, monitor the extent of maternal–infant attachment, and engage the appropriate hospital and community resources.

Now Can You— Discuss care for the patient on antenatal bed rest?

1. State six complications of antenatal bed rest?
2. Formulate a plan of care to meet the physiological, psychological and social needs of the pregnant patient on bed rest?
3. Identify team members to be included in your plan of care when caring for the pregnant patient on bed rest?
4. Describe how antenatal bed rest can affect the patient after childbirth (postpartum)?

ADOLESCENT PREGNANT PATIENT

Although teen pregnancies have been decreasing steadily during the past decade, the United States still has the highest teen pregnancy rate among all developed countries (Hoyert, Mathews, Menacker, Strobino, & Guyer, 2006). With early and thorough prenatal care, adolescents older than the age of 15 years experience no greater risks than those of the general pregnant population. Although the incidence of certain complications may be higher because of age extremes, the nursing diagnoses, interventions, and evaluations remain relatively unchanged from those for the general pregnant population with the same complications (Smith, 2004). Examples of nursing diagnoses for several complications of pregnancy are presented in Box 11-10.

Box 11-10 Examples of Nursing Diagnoses for Selected Complications of Pregnancy

- Risk for injury, maternal or fetal, related to inadequate prenatal care and screening
- Fear related to uncertain outcome of the pregnancy
- Risk for deficient fluid volume related to bleeding during pregnancy
- Risk for infection related to preterm rupture of the membranes
- Risk for injury to fetus related to uteroplacental insufficiency
- Ineffective tissue perfusion related to hypertension
- Risk for injury to self and fetus related to chronic substance abuse
- Interrupted family processes related to adolescent pregnancy
- Deficient diversional activity related to imposed bed rest

Prenatal medical and behavioral risk factors can severely complicate adolescent pregnancy and result in poor birth outcomes, particularly when late or inadequate prenatal care occurs. Prenatal medical and behavioral risks for the adolescent population include (Gilliam, Tapia, & Goldstein, 2003):

- Preterm labor and birth—especially when combined with low socioeconomic status, single parent, smoker, illicit drug use, pre-pregnant weight less than 100 lbs. (45.5 kg), poor weight gain during pregnancy, and inadequate prenatal care.
- Anemia
- Preeclampsia/eclampsia
- Repeated exposure to sexually transmitted infections
- Chronic or asymptomatic urinary tract infections
- Acute pyelonephritis
- Intrauterine growth restriction

The nurse's need for good communication skills when working with adolescents cannot be overstated since these young women often lack trust in medical personnel and fear that their behaviors might be judged. Without good communication, the nurse is unable to make an accurate assessment of the adolescent's knowledge about the importance of quality, consistent prenatal care. Without good communication, the professional nurse–patient relationship is neither established nor developed and the prenatal plan of care is jeopardized.

ADVANCED AGE PREGNANT PATIENT

Many women are now choosing to delay childbirth until later years. The implementation of infertility technology has broadened the boundaries of the reproductive age. Both socioeconomic circumstances and the nature of the older mother have changed with time. The older maternity patient today is at significantly lower risk than her contemporary of two decades ago, who tended to be the mother of many children, having commenced childbearing many years earlier. However, the nurse must be aware of special considerations such as an increased likelihood of chronic diseases (e.g., diabetes, hypertension) when planning care for the woman who has become pregnant after the age of 35 years. (See Chapter 9 for further discussion.)

Nursing Insight— Recognizing potential problems associated with mature mothers

Pregnant women older than age 35 are more likely to experience obstetric complications such as placenta previa, abruptio placentae, prolonged labor, cesarean birth, and mortality. The fetus is at a greater risk for low birth weight, macrosomia, chromosomal abnormalities, congenital malformations, and neonatal mortality.

THE PREGNANT PATIENT WHO HAS SUFFERED TRAUMA

Trauma is the fourth leading cause of death worldwide and the leading nonobstetric cause of maternal death during pregnancy (Weinberg et al., 2005). Motor vehicle accidents account for more than one half of maternal

trauma incidents. About 50% of fetal deaths result from maternal trauma, and most of these are due to motor vehicle accidents (Mattox & Goetzl, 2005). Blunt trauma is caused by the following conditions (Haney, 2004):

- Motor-vehicle collisions in which force is applied to the abdomen from direct impact or as a result of secondary injury from abdominal organs. Abruption of the placenta and/or preterm labor may result from the trauma.
- Accidental falls are usually more common in the third trimester as the woman's center of gravity becomes increasingly displaced.
- Assaults involving intimate partner violence (the incidence increases during pregnancy), gunshot and stabbing wounds.

Optimizing Outcomes— Considerations when caring for the obstetric trauma patient

Maternal stabilization is the initial goal in resuscitation. Resuscitation during pregnancy proceeds as with any other trauma. Trauma in pregnancy involves at least two patients (more in the case of multiple gestation). The fetal heart rate is often the first vital sign to change. All pregnant trauma patients need continuous fetal monitoring. Risk factors predictive of fetal death include ejection during an automobile crash, motorcycle and pedestrian collisions, abnormal heart fetal heart rate patterns, maternal tachycardia, and maternal death (Haney, 2004).

Be sure to— Take care with documentation

Document your nursing care by writing accurate and factual notes. Make certain you have described your assessment, plan of care, interventions, and evaluation for your plan of care. Frequently, trauma cases involve litigation. Well-documented records protect both the patient and the health care system.

SURGERY DURING PREGNANCY

Surgery for nonobstetric reasons occurs in about 1% to 2% of pregnant women. This figure is most likely an underestimated number since many women may not know that they are pregnant at the time of surgery (Callahan, 2004).

Maternal and Fetal Risks During Surgery

Anesthetic considerations are of prime importance when surgery becomes necessary during pregnancy. General anesthesia is a more complex issue during pregnancy because of the increase in maternal blood volume and cardiac output. Surgery risks are related to the possibility of increased maternal morbidity associated with pregnancy-induced changes in the cardiovascular, respiratory, hematologic, and gastrointestinal systems. Normal physiological changes that occur during pregnancy can adversely affect the use of anesthesia and the safety of the surgical procedure. Surgery carries a possibility of increased fetal risks due to an intraoperative decrease in uteroplacental blood flow (leading to fetal hypoxia), along with possible

teratogenic effects from the anesthetic agents. The risk of spontaneous abortion associated with maternal surgery is approximately 8% during the first trimester and 6.9% in the second trimester. Extra-abdominal surgery is less likely to be complicated by spontaneous abortion (Burtness, 2004; Callahan, 2004).

CANCER DURING PREGNANCY

The incidence of cancer is low during the childbearing years. During pregnancy, the incidence of cancer is similar to that of nonpregnant women of childbearing age. Cancer complicates 1 out of 1000 pregnancies and accounts for 5% of deaths that occur during pregnancy. Because more women today choose to delay childbearing, the co-occurrence of pregnancy and cancer may increase (Burtness, 2004). The prognosis best correlates with the anatomic extent of the disease at the time of diagnosis. Cancer in the pregnant woman does not appear to metastasize to the fetus because of the placenta's effectiveness as a barrier against spread and also because the fetus may be capable of resisting the invasion of malignant cells.

During pregnancy the diagnosis of cancer can be difficult for the following reasons: many of the presenting symptoms of cancer are often attributed to the pregnancy; many of the physiologic and anatomic alterations of pregnancy can compromise the physical examination; many serum tumor markers (β -hCG, α fetoprotein, CA 125) are normally increased during pregnancy; and the ability to perform either imaging studies or invasive diagnostic procedures is often altered (Gabbe, Niebyl, & Simpson, 2007).

Care of the pregnant patient with cancer is related a number of factors:

- Gestational age of the pregnancy
- Stage of the cancer and the associated prognosis
- Potential for the cancer treatment to have adverse effects on the fetus, including the potential for long-term occult problems
- Risk to the patient of delaying therapy to permit fetal viability
- Risk to the fetus of early delivery to allow more timely cancer therapy; and the possible need to terminate an early pregnancy to allow an optimal opportunity to treat the patient and cure the malignancy.

OBESITY

Obesity has reached epidemic proportions in the United States, and nearly one third of reproductive-aged women are considered to be obese. In pregnancy, obesity is associated with a higher incidence of antepartum complications such as diabetes and hypertension, and with peripartum complications including macrosomia, prolonged labor, shoulder dystocia, and higher cesarean rates. Cesarean delivery is often complicated by excessive operative blood loss (greater than 1000 mL), difficult anesthesia intubations and operative times greater than 2 hours duration. Postoperative wound complications, including infection, delayed healing, operative injury, the need for blood transfusions, thromboembolism, and hysterectomy are also increased in obese women and result in prolonged hospitalization and increased costs.

Nursing Insight— Differentiating between “overweight” and “obese”

A pregnant woman is considered *overweight* if she is 20% above ideal weight or has a BMI over 26.1; she is considered *obese* if her weight exceeds 200 lbs. (91 kg), if she is 50% over ideal body weight for height or if her BMI is above 29.

Dieting for weight loss during pregnancy is not recommended because if carbohydrates are restricted too much, the body will burn fat and protein for energy. This can result in inadequate protein available for the fetus and lead to ketoacidosis. Dietary counseling should focus on reduced carbohydrates (daily caloric intake should not go below 1500 to 1800 calories per day), education to recognize nutritious food choices and the value of daily exercise. During the postpartum period, the woman should receive continued nutritional counseling and support with realistic goals for weight loss.

Be sure to— Voice concerns about difficulties with FHR monitoring

As a nurse using electronic fetal monitoring, you must be able to obtain a FHR strip that can be interpreted. Monitoring the obese patient can be very challenging. If you are having difficulty monitoring the fetal heart and/or uterine contractions, bring your concerns to the physician or midwife. In the event of a malpractice claim, the fetal monitoring strips can be used as evidence as to whether the standard of care was or was not met.

Obese patients often suffer from low self-esteem and are embarrassed by their size. Health care providers must always strive to preserve the patient's dignity and treat her with respect. Remarks should never be made as to the need for a “bigger bed” or blood pressure cuff. Requesting that extra personnel be available in the labor room to aid with a fetal shoulder dystocia or to help the patient to get out of bed postpartum should be made discreetly.

THE PATIENT WITH A DISABILITY

The pregnant woman with a disability often faces two major concerns: her ability to maintain her own health and her fetus' health throughout pregnancy, childbirth, and during the postpartum period; and the fear of not being able to physically care for her baby. The first concern, universally shared by all mothers, has added significance for the woman with a disability due to the possible interactions between the pregnancy and her disability. The disabled woman's experience of pregnancy, birth, and postpartum is shaped by what she brings to this period of transition as well as her prior experiences with the health care system. The woman's specific disability, her resources, and unique approach to pregnancy and birth are all factors that help shape her overall childbearing experience (Carty, 1998).

While pregnancy and childbirth can be very challenging for the woman with a disability, it provides the nurse with a wonderful opportunity to help make this event a special, memorable time in her life. Care must be well planned and individualized because many women with

disabilities face unpredictability in their symptoms and in their day-to-day abilities. The nurse can develop a well organized plan of care by ensuring that there is documentation of the patient's specific needs, concerns, and desires for her labor and birth and that this information is readily available to all appropriate personnel.

Early in the pregnancy, a referral to the clinical nurse specialist or nurse manager on the birth unit allows the care plan and specific needs to be noted and prepared. Special equipment (i.e., mattress, commode) may need to be ordered and if there are mobility issues, a notation made that this patient will need assignment to a handicap accessible room. Staff nurses may also need to be educated about how to appropriately care for the patient. Advance notice may facilitate development of a nursing schedule that allows the same team to provide continuity of care throughout the woman's hospital stay. Other members of the health team (e.g., physical therapist, occupational therapist, lactation consultant, visiting nurse) should also be involved in the plan of care and kept aware of the patient's needs. If the patient has a service dog, all staff should be aware that it is permissible for the dog to be in the hospital. Furthermore, the staff should understand that the dog provides an important service for the patient, is “working” and should not be played with. While the woman and her dog are in the hospital, a family member should assume responsibility for the dog's needs. Many special devices are available to assist new mothers who have hearing or mobility impairments.

INTIMATE PARTNER VIOLENCE DURING PREGNANCY

Intimate partner violence (IPV), family violence, battering, and spousal abuse are all terms used to describe a pattern of assaultive and coercive behaviors. The true incidence of IPV perpetuated against women in the United States is unknown because much of it remains undetected and unreported. However, it is estimated that battered women account for up to 35% of all women seeking care in an emergency room (Mattson, 2004). Pregnancy is often the trigger for the beginning or escalation of violence in a relationship, and many chronically abused women report an increase in violence directed at them during pregnancy. There are many theories to account for this behavior. For example, the stress of pregnancy may strain a troubled relationship beyond normal coping abilities. The abuser may harbor jealousy against the fetus. Physical violence may be an attempt to end the pregnancy; and frequently, the battered pregnant woman is unlikely to have a strong social support network upon which she can rely (Mattson, 2004).

Characteristically, the abuser targets different maternal body parts during pregnancy. Pregnant women are likely to have more multiple injury sites than nonpregnant women and the abuse is often directed to the breasts, genitalia, and abdomen. The risk of injury to the fetus is very high due to the chance of placental injury that can result in an abruption.

Pregnant teenagers are particularly vulnerable because of their need to rely on others for the basics of life. Often those they rely on are their abusers. Incest, rape, child abuse, gang (group) fighting, stalking, and IPV from both male and female partners have been described. Nurses can

help teenagers with violence only if they know that the teenagers are experiencing it. Thus, nurses need to be able to gain their young patients' trust and confidence so that they feel comfortable sharing their problems. Assessment, safety planning, documentation, and follow-up are all essential components of providing care for women who are experiencing violence, no matter what their age. The medical record is often the source of information that can raise suspicions of abuse, and a number of assessment forms specifically designed to elicit information regarding patterns of abuse have been developed. (See Chapter 9 for further discussion.)

Now Can You— Discuss abuse during pregnancy?

1. Explain why pregnancy is often the trigger for the beginning or escalation of intimate partner violence?
2. Describe the body areas that are usually targeted during pregnancy?
3. Discuss your nursing plan of care when you suspect that your patient has been abused?

summary points

- ◆ Complications that arise during pregnancy are often challenging and demand the perinatal nurse's skills, knowledge, and expertise, combined with the nursing process, to first identify the pregnant patient at risk and then formulate, implement, and evaluate an appropriate, holistic plan of care.
- ◆ Anticipatory nursing care is invaluable in preventing a complication from becoming a major health crisis.
- ◆ Alterations of signs and symptoms from the expected clinical progression during pregnancy must be immediately conveyed to the primary healthcare provider so that an appropriate management plan may be activated.
- ◆ The nurse must always remain cognizant of the important role the patient's family, culture, language, and religious beliefs play in her adjustment to motherhood and overall well being.
- ◆ By providing culturally competent care to childbearing families, many potential complications can be identified in a timely manner to allow for effective treatment and improved outcomes.
- ◆ Meticulous documentation of the patient's plan of care and response to the plan of care cannot be overemphasized.

review questions

Multiple Choice

1. The perinatal nurse describes for the woman/family who have experienced an 11-week miscarriage and desire information that the majority of miscarriages are caused by:
 - A. Nausea and vomiting in early pregnancy
 - B. Prenatal stress
 - C. Chromosomal abnormalities
 - D. Umbilical cord accidents

2. The perinatal nurse uses the acronym "SPASMS" to teach a new nurse about preeclampsia. The "P" refers to:
 - A. Pregnancy
 - B. Proteinuria
 - C. Pelvic circulation
 - D. Pressure

True or False

3. The perinatal nurse knows that the most common medical complications of pregnancy are those related to hypertension.
4. The perinatal nurse is aware that the most accurate determination of gestational age is based on the date of the last menstrual period and an early ultrasound examination.

Select All that Apply

5. The clinic nurse recognizes that a woman's risk factors for an ectopic pregnancy include:
 - A. The use of oral contraceptive pills
 - B. A previous history of a dilatation and curettage
 - C. A history of *Chlamydia trachomatis* infection
 - D. A history of rubella
6. The perinatal nurse provides additional time for the clinic appointment for Janet and her partner. Janet has just experienced a spontaneous abortion. The perinatal nurse knows that it is critical to provide:
 - A. Time to listen to their grief
 - B. Information about support groups
 - C. A referral to an obstetrician if requested
 - D. Appropriate contraceptive information
7. The perinatal nurse knows that risk factors for preeclampsia include:
 - A. Maternal history of preeclampsia
 - B. Body mass index (BMI) greater than thirty
 - C. Nulliparity
 - D. History of a previous cesarean birth

Fill-in-the-Blank

8. As part of the surgical follow-up for removal of a molar pregnancy, the nurse schedules _____ hCG levels beginning at biweekly, then monthly for at least _____ months.
9. The perinatal nurse completes a _____ test on fluid obtained from a speculum examination on a woman at 35 weeks' gestation who describes a spontaneous rupture of the membranes.
10. The perinatal nurse knows that _____ bleeding related to disruption in _____ attachment is the most common presentation for _____.

CONCEPT MAP

Bleeding Disorders

- Placenta previa
- Placental abruption
- DIC

Psychiatric

Exacerbation:
Resurgence:
New onset:

- Depression
- Anxiety
- Eating disorder
- Substance abuse or addiction

Infections

- UTIs
 - Bacturia, cystitis, pyelonephritis
- Group B strep
- TORCH
- STIs
 - Gonorrhea, syphilis, HPV, HIV/AIDS
- TB

Respiratory

- Pneumonia
- Asthma
- Cystic fibrosis

Family Teaching Guidelines:

- Preventing preterm birth
- Home care for patient with hypertensive disorder

Critical Nursing Actions:

- Maternal positioning in CPR
- Correct maternal/fetal care post maternal seizure
- Assess for decreased cardiac output during labor in maternal cardiovascular disease hx

Nursing Insight:

- Pneumonic for preeclampsia: SPASMS
- Vaccine for HPV
- OB meds that can affect maternal C/V diseases
- Risk for hemodynamic changes greater in wks 28–32

Ethnocultural Considerations:

- Beliefs related to pregnancy itself
- Preferences for provider's gender
- Culturally significant foods
- Need for interpreter
- Gestational diabetes → more prevalent in certain ethnic groups

Optimizing Outcomes:

- Offer tests with history of habitual spontaneous abortions
- Support religious beliefs related to transfusions
- Administer RhoGAM correctly

Complementary Care:

- Ginger for nausea and vomiting

Clinical Alert:

- Expanded volume in pregnancy can mask sx of hemorrhage
- Serious consequences occur with overdose of magnesium sulfate
- Have calcium gluconate (antidote) at bedside

Now Can You:

- Discuss the management of bleeding during pregnancy
- Identify 3 symptoms of preterm labor/PROM
- Discuss Rh₀(D) and ABO isoimmunization
- Discuss major disease processes that affect maternal health during pregnancy
- Identify how unique conditions complicate pregnancy

The Birth Experience

The Process of Labor and Birth

chapter 12

To my labor and delivery nurse:

On February 24th you helped us welcome our darling daughter into the world. In fact you practically delivered her yourself. My labor and delivery moved along quite quickly. Through it all you somehow managed to always say and do the right thing. I have taken great pleasure in telling people what a really good labor and birth experience I had. You played a key role in that. While we know it's your job and all that, we thought you still deserved to know that your contribution to our daughter's birth was important and will always be a part of our memory. Years from now when we are telling her about her birth, your name is sure to come up. Thanks again!

—Anonymous

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Discuss various theories concerning the onset of labor.
- ◆ Describe signs and symptoms of impending labor.
- ◆ Distinguish between true and false labor.
- ◆ Contrast advantages and disadvantages of various childbirth settings.
- ◆ Describe the “5 P’s” and how each influences labor and birth.
- ◆ Differentiate among the four stages of labor according to the duration and work accomplished, contraction patterns, and maternal behaviors.
- ◆ Identify nursing interventions for each stage of labor.
- ◆ List five nursing diagnoses applicable to childbearing women.

moving toward evidence-based practice Choice of Elective Cesarean Birth

Wax, J. R., Cartin, A., Pinette, M. G., & Blackstone, J. (2005). Patient choice cesarean – Maine experience. *Birth, 32*(3), 203–206.

The literature, as reported by the researchers, states that there has been a 42% increase in the number of elective cesarean procedures performed from 1999 to 2002, which accounted for 1.5–2.21% of all live births during that period.

The purpose of this study was to examine obstetricians' attitudes and practices with respect to patient choice of elective cesarean section. Questionnaires were sent to all (110) American College of Obstetricians and Gynecologists (ACOG) practicing Fellows and Junior Fellows in one northeastern state.

Physicians were asked whether they had ever performed a patient-requested cesarean section and, if so, how many were performed during the previous year. They were also asked what they considered as acceptable reasons for performing the procedure.

In addition, the physicians were also asked whether they would prefer this method of childbirth for themselves (if female) or for their partner (if male) and reasons for their choice.

If the respondent physicians had not performed any patient-requested cesarean deliveries, they were asked if they would be

(continued)

moving toward evidence-based practice (continued)

willing to perform the procedure if requested, if they had ever refused a request to perform the procedure, and, if so, the number of refusals during the previous year.

The questionnaires were completed and returned by 78 of the 110 physicians. Sixty respondents reported that they had previously performed or would be willing to perform an elective cesarean section.

Acceptable indications for performing elective cesarean deliveries included (in descending order of choice):

- Avoidance of damage to the woman's urinary tract system
- A woman who had experienced a previous adverse birth experience
- Avoidance of damage to anal continence
- Concern regarding fetal injury or death
- Maternal fear of childbirth
- Preservation of sexual function (26.7%); pelvic organ prolapse
- Pain
- Convenience
- Certainty of the delivering practitioner

The data also revealed that:

- Thirty-one physicians reported that they had performed elective cesarean deliveries and had averaged fewer than five procedures during the previous year.

- Of the 40 physicians who reported that they had not performed an elective cesarean delivery, 29 stated that they would be willing to do so if asked.
- The remaining 11 stated that they would be unwilling to perform any elective cesarean delivery.
- Of those who were willing to perform elective cesarean deliveries, only 15 stated that they would choose this surgery for themselves or for their partner.
- Female physician respondents younger than 35 years of age were more likely to select an elective cesarean birth for themselves than female physician respondents older than 35 years of age
- The majority of the respondents stated that medical evidence supporting elective cesarean delivery was available.

The researchers concluded that even though the majority of physicians were willing to perform elective cesarean procedures for their patients, few preferred this method for themselves or for their partners.

1. What might be considered as limitations to this study?
2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

The journey from conception to birth is one of ongoing development and adaptation for the woman, the fetus, and the family. Physiological, psychological, and emotional changes that take place during pregnancy help to prepare the woman for labor and birth. Near the end of the pregnancy, the fetus continues to develop physiological abilities that facilitate successful adaptation for the transition from in utero life to the outside environment.

Each woman's labor and birth experience is uniquely shaped by a myriad of factors. Throughout this journey, the actions of nurses play a vital role in supporting the patient, the fetus, and the family. This chapter presents the processes of labor and birth, and the important roles of nurses during each stage.

Theories Concerning Labor Onset

For the majority of women, the onset of labor usually occurs between the 38th and 42nd weeks of pregnancy. For most of the pregnancy, the uterus stays in a relaxed state and the cervix remains closed and firm to maintain the pregnancy. Toward the end of pregnancy, there is a complete reversal where the uterus becomes more excitable and cervical softening (ripening) occurs. The cervical changes result from the breakdown of collagen fibers, which produce a decrease in the binding capacity. This

change, coupled with an increase in cervical water content, causes weakening and softening. Although many theories regarding the origin of labor have been proposed, no one theory can account for the onset of labor in all women. Instead, a combination of maternal and fetal factors most likely interacts to bring about the initiation of labor (Box 12-1).

The Process of Labor and Birth

A number of forces affect the progress of labor and help to bring about childbirth. These critical factors are often referred to as the "P's" of labor:

- Powers (physiological forces)
- Passageway (maternal pelvis)
- Passenger (fetus and placenta)
- Passageway + Passenger and their relationship (engagement, attitude, position)
- Psychosocial influences (previous experiences, emotional status)

Position of the laboring patient is sometimes designated as a separate critical "P." In this chapter, maternal positions to facilitate labor and enhance comfort are included in the discussion under promoting comfort during labor. The coordination of the various factors that affect labor is essential for the labor and birth to progress in a successful manner.

Box 12-1 Theories Regarding the Onset of Labor**MATERNAL FACTORS**

- **Uterine muscle stretching**, which causes a release of prostaglandins.
- **Pressure on the cervix**, which stimulates the release of oxytocin by the maternal posterior pituitary gland.
- **Oxytocin stimulation** increases significantly during labor and works together with prostaglandins to activate uterine contractions.
- **Increase in the ratio of estrogen to progesterone:** As term approaches, biochemical changes cause a decreased availability of progesterone (relaxes smooth muscle) to the uterine myometrial cells. With rising estrogen levels, the uterus becomes more excited and contractions begin.

FETAL FACTORS

- **Placental aging** and deterioration triggers the initiation of contractions.
- **Fetal cortisol concentration** increases. This results in a decrease in the production of placental progesterone and an increase in the release of prostaglandins.
- **Fetal membranes** produce prostaglandins, which aid in the stimulation of uterine contractions.

POWERS

The powers are the physiological forces of labor and birth that include the uterine contractions and the maternal pushing efforts. The uterine muscular contractions, primarily responsible for causing cervical effacement and dilation, also move the fetus down toward the birth canal during the first stage of labor. Uterine contractions are considered the primary force of labor. Once the cervix is fully dilated, the maternal pushing efforts serve as an additional force. During the second stage of labor, use of the maternal abdominal muscles for pushing (the *secondary force* of labor) adds to the primary force to facilitate childbirth.

Characteristics of Uterine Contractions

Contractions are a rhythmic tightening of the uterus that occurs intermittently. Over time, this action shortens the individual uterine muscle fibers and aids in the process of cervical effacement and dilation, birth, and postpartal **involution** (the reduction in uterine size after birth). Each contraction consists of three distinct components: the **increment** (building of the contraction), the **acme** (peak of the contraction) and the **decrement** (decrease in the contraction).

Between contractions, the uterus normally returns to a state of complete relaxation. This rest period allows the uterine muscles to relax and provides the woman with a short recovery period that helps her to avoid exhaustion. In addition, uterine relaxation between contractions is important for fetal oxygenation as it allows for blood flow from the uterus to the placenta to be restored.

Contractions bring about changes in the uterine musculature. The upper portion of the uterus becomes thicker

and more active. The lower uterine segment becomes thin-walled and passive. The boundary between the upper and lower uterine segments becomes marked by a ridge on the inner uterine surface, known as the “physiological retraction ring.”

With each contraction, the uterus elongates. Elongation causes a straightening of the fetal body so that the upper body is pressed against the fundus and the lower, presenting part is pushed toward the lower uterine segment and the cervix. The pressure exerted by the fetus is called the fetal axis pressure. As the uterus elongates, the longitudinal muscle fibers are stretched upward over the presenting part. This force, along with the hydrostatic pressure of the fetal membranes, causes the cervix to dilate (open).

Assessment of Uterine Contractions

Contractions are often described in terms of their frequency, duration, and intensity. The **frequency** of a contraction is measured from the beginning of one contraction to the beginning of the next contraction. The **duration** of a contraction is measured from the start of one contraction to the end of the same contraction. The **intensity** of a contraction is most frequently measured by uterine palpation and is described in terms of mild, moderate, and strong (Fig. 12-1).

Palpation is a noninvasive procedure, and requires the nurse to place the fingertips of one hand on the fundus of the uterus where most contractions can be felt. The nurse applies gentle pressure and keeps the hand in the same place (moving the hand over the uterus may stimulate additional contractions, therefore interfering with the ability to accurately assess labor progress). Gentle palpation of the uterine fundus can determine the firmness of the uterus and whether there is an ability to indent the uterus at the acme (peak) of the contraction. Palpating the intensity of contractions is often compared to palpating one's nose (mild intensity), chin (moderate intensity), or forehead (strong intensity). When the uterine fundus remains soft at the acme of a contraction, the contraction intensity is described as “mild.” Conversely, when there is an inability to indent the uterus at the acme of a contraction, the contraction intensity is described as “strong.” “Moderate” contraction intensity falls somewhere in between and is characterized by a firm fundus that is difficult to indent with the fingertips. Several contractions must be evaluated to accurately determine the frequency, duration, and intensity.

Contractions may also be measured via electronic monitoring. Monitoring may be external or internal, and this modality can provide a continuous assessment of uterine activity. External contraction monitoring uses a **tocodynamometer**, which is a pressure-sensitive device that is applied against the uterine fundus. When the uterus contracts, the pressure that is exerted against the “toco” is measured and recorded on graph paper. External monitoring may be continuous or intermittent. It provides information about the frequency and duration of contractions, but may not give accurate data regarding the intensity of contractions because there are many variables (i.e., maternal position, obesity, and the placement of the monitor on the uterus) that can affect the tracing. Contraction intensity is best assessed with palpation.

Figure 12-1 Counting contractions. Contraction frequency is the time from the beginning of one contraction to the beginning of the next contraction. Contraction duration is the time from the beginning to the end of the same contraction.

Another method to measure the intensity of uterine contractions is an invasive procedure that involves the use of an internal monitor. If the amniotic membranes have ruptured, an internal pressure catheter is inserted through the cervix and into the uterus to measure the internal pressure generated during the contraction. Normally, the resting pressure in the uterus (between contractions) is 10 to 12 mm Hg. During the acme, contraction intensity ranges from 25 to 40 mm Hg during early labor, 50 to 70 mm Hg during active labor, 70 to 90 mm Hg during transition, and 70 to 100 mm Hg during maternal pushing in the second stage. Internal uterine pressure monitoring is most often used with high-risk pregnancies when accurate measurement of uterine activity is required. Since internal monitoring is an invasive procedure, it is associated with a slight risk of infection. (See Chapter 14 for further discussion.)

During early labor, uterine contractions are characteristically weak and irregular. They usually last for about 30 seconds and occur every 5 to 7 minutes. As the labor pattern becomes established, the uterine contractions typically become regular in frequency, longer in duration, and increased in intensity. The duration of contractions increases to about 60 seconds, and they occur every 2 to 3 minutes. The contractions are involuntary and are most efficient when there is a regular, rhythmic, coordinated labor pattern. The woman in labor is unable to control contraction frequency, duration, or intensity.

Uterine contractions also bring about changes in the pelvic floor musculature. The forces of labor cause the levator ani muscles and fascia of the pelvic floor to draw the rectum and vagina upward and forward. During descent, the fetal head exerts increasing pressure and causes thinning of the perineal body from 5 cm to less than 1 cm in thickness. Continued pressure causes the maternal anus to evert and the interior rectal wall is exposed as the fetal head descends forward (Cunningham et al., 2005).

Now Can You— Evaluate uterine contractions?

1. Discuss what is meant by the “powers” of labor?
2. Describe the terms used to evaluate contractions?
3. Identify two methods used to assess the intensity of contractions?

The coordinated efforts of the contractions help to bring about effacement and dilatation of the cervix. **Effacement** is the process of shortening and thinning of the cervix. As contractions occur, the cervix becomes progressively shorter until the cervical canal eventually disappears. The amount of cervical effacement is usually expressed as a percentage related to the length of the cervical canal, as compared to a noneffaced cervix. For example, if a cervix has thinned to half the normal length of a cervix it is considered to be 50% effaced. **Dilatation** is the opening and enlargement of the cervix that progressively occurs throughout the first stage of labor. Cervical dilatation is expressed in centimeters and full dilatation is approximately 10 cm. With continued uterine contractions, the cervix eventually opens large enough to allow the fetal head to come through. At this point, the cervix is considered fully dilated or completely dilated and measures 10 cm (Fig. 12-2).

The first stage of labor, which begins with the onset of true labor, concludes when cervical effacement and dilatation are complete. Effacement and dilatation occur concurrently but at different rates. In a nulliparous patient, most cervical effacement is completed early during the process of cervical dilatation whereas the multiparous cervix is often patulous (distended) before effacement begins.

Effacement and dilatation are evaluated by a vaginal examination performed by a qualified practitioner such as a maternity nurse who has received specialized training in this procedure (Procedure 12-1). The vaginal examination provides important information regarding the diameter of the opening of the cervix, which ranges from 1 cm (not dilated) to 10 cm (fully dilated), the status of the amniotic membranes (ruptured or intact), and the fetal presentation and the station, or

Figure 12-2 Cervical effacement and dilation. The membranes are intact. *A.* Before labor. *B.* Early effacement. *C.* Complete (100%) effacement. The fetal head is well applied to the cervix. *D.* Complete dilation (10 cm). Note the overlapping of the cranial bones.

the extent of the fetal descent through the maternal pelvis. Once the cervix is fully dilated and retracted up into the lower uterine segment, it can no longer be palpated.

Maternal Pushing Efforts

After the cervix has become fully dilated, the laboring woman usually experiences an involuntary “bearing down” sensation that assists with the expulsion of the fetus. At this time, the woman can use her abdominal muscles to aid in the expulsion. It is important to remember that the cervix must be fully dilated before the patient is encouraged to push. Bearing down on a partially dilated cervix can cause cervical edema and damage and adversely affect the progress of the labor. For most women, the urge to bear down generally occurs when the fetal head reaches the pelvic floor. Women who have a strong urge to push often do so more effectively than women who force themselves to push without experiencing any sensations of pressure.

PASSAGEWAY

The passageway consists of the maternal pelvis and the soft tissues. The bony pelvis through which the fetus must pass is divided into three sections: the inlet, midpelvis (pelvic cavity), and outlet. Each of these pelvic components has a unique shape and dimension through which the fetus must maneuver to be born vaginally. In human females, the four classic types of pelvis are the gynecoid, android, platypelloid, and anthropoid. (See Chapter 5 for further discussion.)

PASSENGER

The passenger is referred to as the fetus and the fetal membranes. In the majority (96%) of pregnancies, the fetus presents in a head-first position. The fetal skull, usually the largest body structure, is also the least flexible part of the fetus. However, because of the sutures and fontanels, there is some flexibility in the fetal skull. These structures allow the cranial bones the capability of movement and they overlap in response to the powers of labor. The overlapping or overriding of the cranial bones is called **molding**.

A & P review The Fetal Skull

The fetal skull, or cranium, consists of three major components: the face, the base of the skull, and the vault of the cranium (roof). The facial bones and the cranial base are fused and fixed. The cranial base is made up of two temporal bones and each has a sphenoid and ethmoid bone.

The cranial vault is composed of five bones: two frontal bones, two parietal bones, and the occipital bone. These bones, which are not fused, meet at the **sutures**. The sutures of the fetal skull are composed of strong but flexible connective tissue that fills the spaces that lie between the cranial bones.

The sagittal suture lies between the parietal bones and runs in an anteroposterior direction between the fontanels, dividing the head into a right and a left side. The lambdoidal suture extends from the posterior fontanel and separates the occipital bones from the parietal bones. The coronal sutures are located between the frontal and parietal bones. They extend from the anterior fontanel laterally and separate the parietal from the frontal bones. The frontal (mitotic) suture lies between the frontal bones and extends from the anterior fontanel to the prominence between the eyebrows.

Two membrane-filled spaces are present where the suture lines meet. These spaces are referred to as the anterior and posterior **fontanels**. The anterior fontanel is the larger of the two and measures approximately 0.8×1.2 inch (2×3 cm). It is diamond shaped and is positioned where the sagittal, frontal, and coronal sutures intersect. The anterior fontanel remains open until approximately 18 months of age to allow normal brain growth to occur. The posterior fontanel is triangular in shape and is much smaller than the anterior fontanel. It measures approximately 0.8 inch (2 cm) at its widest point. The posterior fontanel is positioned where the lambdoidal and sagittal sutures meet. Shaped like a small triangle, it closes at approximately 6 to 8 weeks after birth. The location of the fontanels assists the examiner in determining the position of the fetal skull during a

Procedure 12-1 Performing the Intrapartal Vaginal Examination

Purpose

Vaginal examination may be performed during the intrapartal period for many reasons including: assessment of cervical dilation, effacement and station, position and presentation of fetus, rupture of the membranes, and prolapse of the umbilical cord.

Equipment

- Sterile examination gloves (clean gloves may be used if the membranes are intact)
- Sterile lubricant
- Antiseptic solution and light source (if required)
- Disposable wipes

Steps

1. Wash and dry your hands. Explain the procedure and purpose of the examination to the patient.

RATIONALE: Hand washing helps to prevent the spread of microorganisms. Explanations help to decrease anxiety and promote patient understanding and cooperation.

2. Assess for latex allergies.

RATIONALE: To prevent injury from latex exposure; if patient has a latex allergy, use nonlatex gloves.

3. Ensure privacy.

RATIONALE: Privacy promotes comfort and self-esteem.

4. Assemble necessary equipment including clean gloves (if the membranes are intact) or sterile examination gloves (if the membranes are ruptured), sterile lubricant, antiseptic solution (if required).

5. Position the patient in a supine position with a small pillow or towel under her hip to prevent supine hypotension. Instruct the patient to relax and position herself with her thighs flexed and abducted.

RATIONALE: Relaxation decreases muscle tension and enhances patient comfort. Proper positioning facilitates the examination by providing access to the perineum.

6. Don sterile gloves (clean gloves may be used if the membranes are intact).
7. Inspect the perineum for any redness, irritation, or vesicles.
8. Using the nondominant hand, spread the labia majora and continue assessment of the genitalia. Note the presence of any discharge including blood or amniotic fluid.

RATIONALE: Positioning the hand in this manner facilitates good visualization of the perineum. The presence of lesions may be indicative of an infection and possibly preclude a vaginal birth. The presence of amniotic fluid implies that the membranes have ruptured. Bleeding may be a sign of placenta previa. Do not perform a vaginal examination if a placenta previa is suspected.

9. Gently insert the lubricated gloved index and third fingers into the vagina in the direction of the posterior wall until they touch the cervix. The uterus may be stabilized by placing the nondominant hand on the woman's abdomen.

RATIONALE: This position facilitates the examination by allowing the fingertips to point toward the umbilicus and find the cervix.

10. Assess the cervix for effacement and the amount of dilation.

11. Assess for intact membranes; if fluid is expressed, test for amniotic fluid.

12. Palpate the presenting part.

RATIONALE: It is necessary to determine the presenting part in order to assess fetal position and evaluate fetal descent.

13. Assess fetal descent and station by identifying the position of the posterior fontanel.

14. Withdraw the fingers. Assist the patient in wiping her perineum from front to back to remove lubricant or secretions. Help her to resume a comfortable position.

RATIONALE: Wiping from front to back prevents the transfer of rectal contamination toward the vagina.

15. Inform the patient of the findings from the examination.

16. Wash hands.

17. Document the procedure on the patient's chart and on the fetal monitor strip (if a fetal monitor is being used). Include the assessment findings and the patient's tolerance of the procedure.

RATIONALE: Documentation provides a record for communication and evaluation of patient care.

Documentation

6/18/09. 12:35: Vaginal examination performed for assessment of labor. Cervix 4 cm dilated, 100% effaced, station 0. No membranes felt, patient leaking clear fluid from the vagina, position OA. Procedure tolerated well by patient, fetal heart rate 152 bpm post examination.

-L. Lopez, RN

vaginal examination. Important landmarks of the fetal skull are presented in Figure 12-3. ♦

The fetal skull contains several important landmarks (Box 12-2). There is much variation among the skull diameters. As molding occurs during labor, some skull diameters shorten while others lengthen. The head diameters are measured between the various skull landmarks. Most fetuses enter the maternal pelvis in the cephalic presentation but a number of variations are possible. The biparietal diameter is the major transverse diameter of the fetal head. It is measured between the two parietal bones and averages 3.7 inches (9.5 cm) in a term fetus. The anteroposterior diameter of the fetal head varies according to the degree of flexion. During labor, the most favorable situation occurs when the head becomes fully flexed and the anteroposterior diameter is the suboccipitobregmatic, which averages 3.7 inches (9.5 cm).

Box 12-2 Landmarks of the Fetal Skull

- Mentum:** fetal chin
- Sinciput:** anterior area known as the “brow”
- Bregma:** large, diamond-shaped anterior fontanel
- Vertex:** the area between the anterior and the posterior fontanels
- Posterior fontanel:** the intersection between the posterior cranial sutures
- Occiput:** the area of the fetal skull that is occupied by the occipital bone, beneath the posterior fontanel (Fig. 12-3).

Now Can You— Discuss various factors associated with the process of labor?

1. Define effacement and dilation?
2. Explain what is meant by the “passageway”?
3. Describe anatomical landmarks of the fetal skull?

Fetal Lie

The **fetal lie** refers to the relationship of the long axis of the woman to the long axis of the fetus (Fig. 12-4). If the head to tailbone axis of the fetus is the same as the woman’s, the

Figure 12-4 The fetal lie refers to the relationship of the long axis of the woman to the long axis of the fetus. A. Longitudinal lie. B. Transverse lie. C. Oblique lie.

Figure 12-3 Bones, fontanels, and sutures of the fetal head. An understanding of the placement and relationships of these structures is essential in making an accurate assessment during the labor process.

fetus is in a **longitudinal lie**. In more than 99% of pregnancies, the lie is longitudinal. In the longitudinal lie, either the fetal head or the fetal buttocks enter the pelvis first. If the head to tailbone axis of the fetus is at a 90-degree angle to the woman, the fetus is in a **transverse** (horizontal) **lie**. A transverse lie occurs in fewer than 1% of pregnancies. An **oblique lie** is one that is at some angle between the longitudinal and the transverse lie.

Fetal Attitude

The fetal **attitude** describes the relationship of the fetus' body parts to one another. The fetus normally assumes an attitude of flexion. In this attitude, the fetal head is flexed so that the chin touches the chest, the arms are flexed and folded across the chest, the thighs are flexed on the abdomen, and the calves are flexed against the posterior aspects of the thighs. This is commonly referred to as the "fetal position."

In moderate flexion, the fetal chin is not touching the chest but is in an alert of "military position." This position causes the occipital frontal diameter to present to the birth canal. An attitude of moderate flexion usually does not interfere with labor because during descent and flexion the fetal head flexes fully. The fetus in partial extension presents the brow or face of the head to the birth canal.

Flexion of the fetal head (where the chin touches the chest) is the preferred position for birth because it allows the smallest anteroposterior diameter of the fetal skull to enter into the maternal pelvis. Any other position of the fetal head (other than that of complete flexion) will present with a larger anteroposterior diameter, which can ultimately contribute to a longer, more difficult labor (Fig. 12-5).

Fetal Presentation

The fetal **presentation** refers to the fetal part that enters the pelvic inlet first and leads through the birth canal during labor. The fetal presentation may be cephalic, breech,

Figure 12-5 The fetal attitude describes the relationship of the fetal body parts to one another. A. Flexion (vertex). B. Moderate flexion (military). C. Extension.

or shoulder. The part of the fetal body first felt by the examining finger during a vaginal examination is the "**presenting part**." The presenting part is determined by the fetal lie and attitude.

CEPHALIC PRESENTATION. A **cephalic presentation** identifies that the fetal head will be first to come into contact with the maternal cervix. Cephalic presentations constitute the most desirable position for birth and occur in approximately 95% of pregnancies. There are four types of cephalic presentations (Fig. 12-6):

Vertex. The fetal head presents fully flexed. This is the most frequent and optimal presentation as it allows the smallest suboccipitalbregmatic diameter to present. It is called a "vertex presentation."

Military. In the military position, the fetal head presents in a neutral position, which is neither flexed nor extended. The occipitofrontal diameter presents to the maternal pelvis and the top of the head is the presenting part.

Brow. In the brow position, the fetal head is partly extended. This is an unstable presentation that converts to

Figure 12-6 There are four types of cephalic presentation; the vertex presentation with complete flexion is optimal. Fetal presentation refers to the fetal body part that first enters the maternal pelvis.

a vertex if the head flexes, or to a face presentation if the head extends. The occipitontal diameter (the largest anteroposterior diameter) presents to the maternal pelvis and the sinciput (fore and upper part of the cranium) is the presenting part.

Face. In the face presentation, the fetal head is fully extended and the occiput is near the fetal spine. The submentobregmatic diameter presents to the maternal pelvis and the face is the presenting part.

The following advantages are associated with a cephalic presentation:

- The fetal head is usually the largest part of the infant. Once the fetal head is born, the rest of the body usually delivers without complications.
- The fetal head is capable of molding. There is sufficient time during labor and descent for molding of the fetal head to occur. Molding helps the fetus to maneuver through the maternal birth passage.
- The fetal head is smooth and round, which is the optimal shape to apply pressure to the cervix and aid in dilation.

Other presentations (e.g., breech, shoulder) are associated with difficult, prolonged labor and often require cesarean births. They are called malpresentations.

Now Can You— Discuss passenger characteristics important during labor?

1. Define “fetal lie” and identify three types of fetal lie?
2. Explain what is meant by “fetal attitude”?
3. Describe three advantages associated with a cephalic presentation?

BREECH PRESENTATION. A **breech** presentation occurs when the fetal buttocks enter the maternal pelvis first. Breech presentations occur in approximately 3% of births and are classified according to the attitude of the fetal hips and knees. Breech presentations are more likely to occur in preterm births or in the presence of a fetal abnormality such as hydrocephaly (head enlargement due to fluid) that prevents the head from entering the pelvis. They are also associated with abnormalities of the maternal uterus or pelvis. Since many factors can compromise the normal labor and birth process associated with breech presentations, delivery is usually accomplished via cesarean section. There are three types of breech presentations (Fig. 12-7):

Frank. The frank breech is the most common of all breech presentations. In the frank breech position, the fetal legs are completely extended up toward the fetal shoulders. The hips are flexed, the knees are extended, and the fetal buttocks present first in the maternal pelvis.

Complete (Full). The complete, or full, breech position is the same as the flexed position with the fetal buttocks presenting first. The legs are typically flexed. Essentially, this position is a reversal of the common cephalic presentation.

Footling. In the footling breech position, one or both of the fetal leg(s) are extended with one foot (“single footling”) or both feet (“double footling”) presenting first into the maternal pelvis.

Figure 12-7 There are three types of a breech presentation. A. Frank. B. Complete or full. C. Footling breech (single or double).

Several disadvantages are associated with a breech presentation:

- An increased risk for umbilical cord prolapse because the presenting part may not be covering the cervix (i.e., footling breech)
- The presenting part (buttocks, feet) is not as smooth and hard as the fetal head and is less effective in dilating the cervix
- Once the fetal body (abdomen) is delivered, the umbilical cord can become compressed. The fetus must then be delivered expeditiously to prevent hypoxia. Rapid delivery may be difficult since the fetal head is usually the largest body part and in this situation, there is no time to allow for molding.

In response to adverse outcomes that have been associated with vaginal breech births, the American College of Obstetricians and Gynecologists (ACOG, 2006) has published a Committee Opinion concerning planned breech deliveries.

SHOULDER PRESENTATION. The shoulder presentation is a transverse lie (Fig. 12-8). This presentation is rare and occurs in fewer than 1% of births. When a transverse lie is present, the maternal abdomen appears large from side to side, rather than up and down. In addition, the woman may demonstrate a lower than expected (for the gestational age) fundal height measurement. Although the shoulder is usually the presenting part, the fetal arm back, abdomen, or side may present in a transverse lie. This presentation occurs most often with preterm birth, high parity, prematurely ruptured membranes, hydramnios, and placenta previa. It is important for the nurse to promptly identify a transverse lie or shoulder presentation since the infant will almost always require a cesarean birth.

Figure 12-8 Shoulder presentation.

where research and practice meet: The Planned Vaginal Breech Delivery

The American College of Obstetricians and Gynecologists (ACOG) published a Committee Opinion in July 2006, advising that in light of recent published studies that further clarify the long-term risks of vaginal breech delivery, “the mode of delivery should depend on the experience of the health care provider... Cesarean delivery will be the preferred mode for most physicians because of the diminishing expertise in vaginal breech delivery”. A Randomized Controlled Trial (RCT) that included 2088 women found that perinatal mortality, neonatal mortality, or serious neonatal morbidity was significantly lower for the planned cesarean section group than for the planned vaginal birth group (Hannah et al., 2000). Currently, the standard of care in most practices is to deliver all breeches by cesarean section to avoid the potential complications of vaginal breech deliveries such as cord prolapse, head entrapment, birth asphyxia and birth trauma (Hacker, Moore, & Gambone, 2004).

Now Can You— Discuss the breech and shoulder presentations?

1. Identify three types of breech presentations?
2. Explain three disadvantages of a breech presentation?
3. Describe how the nurse could identify a shoulder presentation?

PASSAGEWAY + PASSENGER

The passageway and the passenger have been identified as two of the factors that affect labor. The next “P” is the relationship between the passageway (maternal pelvis) and the passenger (fetus and membranes). The nurse assesses the relationship between the two when determining the engagement, station, and fetal position.

Engagement

Engagement is said to have occurred when the widest diameter of the fetal presenting part has passed through the pelvic inlet. In a cephalic presentation, the largest diameter is the biparietal; in breech presentations, it is the intertrochanteric diameter. Engagement can be determined by external palpation or by vaginal examination. In primigravidas, engagement usually occurs

approximately 2 weeks before the due date. In multiparas, engagement may occur many weeks before the onset of labor or it may take place during labor. Although engagement confirms the adequacy of the pelvic inlet, it is not an indicator of the adequacy of the midpelvis and outlet.

Station

Station refers to the level of the presenting part in relation to the maternal ischial spines. In the normal female pelvis, the ischial spines represent the narrowest diameter through which the fetus must pass. The ischial spines, blunted prominences located in the midpelvis, have been designated as a landmark to identify station zero. To visualize the location of station zero, an imaginary line may be drawn between the ischial spines. Engagement has occurred when the presenting part is at station zero. When the presenting part lies above the maternal ischial spines, it is at a minus station. Therefore, a station of minus 5 (–5) cm indicates that the presenting part is at the pelvic inlet. Positive numbers indicate that the presenting part has descended past the ischial spines. A presenting part below the level of the ischial spines is considered to be a positive station. A station of +4 cm indicates that the presenting part is at the pelvic outlet (Fig. 12-9). During labor, the presenting part should continue to descend into the pelvis, indicating labor progress. As labor advances and the presenting part descends, the station should also progress to a numerically higher positive station. If the station does not change in the presence of strong, regular contractions, this finding may indicate a problem with the relationship between the maternal pelvis and the fetus (“cephalopelvic disproportion”).

Position

Position refers to the location of a fixed reference point on the fetal presenting part in relation to a specific quadrant of the maternal pelvis (Fig. 12-10). The presenting part can be right anterior, left anterior, right posterior, and left posterior. These four quadrants designate whether the presenting part is directed toward the front, back, right, or left of the passageway.

Figure 12-9 Station.

Figure 12-10 Fetal presentations and positions. The position refers to how the presenting fetal part is positioned in relation to a specific quadrant of the maternal pelvis: front, back, or side.

Four landmarks of the fetus are used to describe the relationship of the presenting part to the maternal pelvis. In a vertex presentation, the occiput (O) is used. For a face presentation, the chin (M for mentum) is used. In a breech presentation, the sacrum (S) is used, and for a shoulder presentation, (A) for acromion process of the shoulder is used. Fetal position may be described as:

- Right (R) or left (L) side of the maternal pelvis
- The landmark of the presenting part: occiput (O), mentum (M), sacrum (S), acromion process (A)
- Anterior (A), posterior (P), transverse (T): This designation depends on whether the landmark is in the front, back, or side of the maternal pelvis

It is important for the nurse to assess the position of the fetus to identify whether the fetus is in an optimal position for a vaginal birth. To do so, the nurse uses inspection and palpation of the maternal abdomen and vaginal examination. Use of the abbreviated notations (listed above) helps to convey essential information to other members of the health care team. For example, when the fetal occiput is directed toward the maternal back (a posterior lie) and to the right of the birth passageway, the nurse would chart “ROP,” to indicate right occiput–posterior. The fetal position most common, and most favorable for birth, is the right occiput–anterior (ROA). Identification of a malpresentation such as a foaling breech or transverse lie is important, as the presence

of a malpresentation may signal the need for a cesarean delivery. Identification of a posterior lie may identify the potential for a longer labor as the fetus may attempt to rotate to an OA position. In addition, the nurse must be aware that the fetal position will vary as the fetus changes position to move through the different diameters of the maternal pelvis.

In some situations, the physician may have the option to attempt a fetal rotation. Prenatally, an external cephalic version may be performed in an attempt to rotate an identified breech presentation. A forceps rotation from a transverse or posterior position to an anterior position may also be indicated during a prolonged second stage of labor. However, as with any procedure, these maneuvers are associated with risks and benefits that must be presented to the patient for informed consent. (See Chapter 14 for further discussion.)

critical nursing action Determining and Documenting Fetal Position

During the assessment, the nurse determines that the fetal occiput is in the right anterior quadrant of the maternal pelvis. The position is correctly documented as ROA. If the fetus were presenting in the frank breech position with the buttocks positioned to the left maternal posterior quadrant, the position would be correctly documented as LSP (left sacrum posterior).

Now Can You— Discuss the passageway and passenger?

1. Define engagement and identify when engagement has occurred?
2. List the four fetal landmarks used to describe the relationship of the presenting part?
3. Discuss why it is important for the nurse to assess fetal position during labor?

PSYCHOSOCIAL INFLUENCES

The first four P's discussed address the physical forces of labor. The last "P" (psychosocial influences) acknowledges the many other critical factors that have an effect on parents such as their readiness for labor and birth, level of educational preparedness, previous experience with labor and birth, emotional readiness, cultural influences, and ethnicity. Transition into the maternal role, and most likely, into the paternal role as well, is facilitated by a positive childbirth experience. A number of internal and external influences can affect the woman's psychological well-being during labor and birth.

Culturally oriented views of childbirth help to shape the woman's expectations and ongoing perceptions of the birth experience. The nurse's understanding of the cultural values and expectations attached to childbirth provide a meaningful framework upon which to plan and deliver sensitive, appropriate care. Cultural considerations for the laboring woman encompass many elements of the birth experience including choice of a birth support person, strategies for coping with contractions, pain expression and relief and food preferences.

Nursing Insight— Assessing cultural influences of the laboring patient

To provide culturally sensitive care to the laboring patient, the nurse should consider:

- The patient's and family's level of comfort with the nurse's "language" and whether an interpreter is needed
- Who is the designated birth support person and what will be the extent of this person's role
- The patient's level of comfort with touch
- If any special rituals or practices will be used during the childbirth experience

Studies have revealed that marked anxiety, fear, and fatigue can adversely affect the woman's ability to cope with the demands of labor. A negative childbirth experience can have far-reaching implications, interfering with bonding and maternal role attainment.

Emotional factors can have physiological implications as well. Maternal catecholamines (chemicals that affect the nervous and cardiovascular systems, metabolic rate, temperature, and smooth muscle) are often stimulated as a response to anxiety and fear and can inhibit uterine contractions and impede placental blood flow. During labor, the nurse's ongoing assessment of the maternal psyche along with appropriate interventions can help facilitate therapeutic communication to decrease or eliminate anxiety and fear through discussion and support.

Now Can You— Discuss the psychosocial influences of labor?

1. Describe why maternal psyche and cultural influences are important factors during labor?
2. Identify three culturally oriented nursing assessments for the laboring woman?
3. Discuss how maternal emotions can adversely affect the process of labor?

Signs and Symptoms of Impending Labor

Before the onset of labor, a number of physiological changes occur that signal the readiness for labor and birth. These changes are usually noted by the primigravid woman at about 38 weeks of gestation. In multigravidas, they may not take place until labor begins. It is important for nurses to empower pregnant women and their families by teaching them about the signs and symptoms of impending labor. Providing guidelines about when to contact the health care provider or come to the birth facility helps to demystify the sometimes confusing events that surround birth and lessen the anxieties that can accompany the onset of labor.

LIGHTENING

At about 38 weeks in the primigravid pregnancy, the presenting part (usually the fetal head) settles downward into the pelvic cavity, causing the uterus to move downward as well. This process, called **lightening**, marks the beginning of engagement. As the uterus moves downward, the woman may state that her baby has "dropped." She may also report changes in the appearance of her abdomen such as a flattening of the upper area and an enhanced protrusion of the lower area. This downward settling of the uterus may decrease the upward pressure on the diaphragm and result in easier breathing. The downward settling may also lead to the following maternal symptoms:

- Leg cramps or pains
- Increased pelvic pressure
- Increased urinary frequency
- Increased venous stasis, causing edema in the lower extremities
- Increased vaginal secretions, due to congestion in the vaginal mucosa

BRAXTON-HICKS CONTRACTIONS

As the pregnancy approaches term, most women become more aware of irregular contractions called Braxton-Hicks contractions. As the contractions increase in frequency (they may occur as often as every 10 to 20 minutes), they may be associated with increased discomfort. Braxton-Hicks contractions are usually felt in the abdomen or groin region and patients may mistake them for true labor. It is believed that these contractions contribute to the preparation of the cervix and uterus for the advent of true labor. Braxton-Hicks contractions do not lead to dilation or effacement of the cervix, and thus are often termed "**false labor.**"

CERVICAL CHANGES

In the nonpregnant woman, the cervix is normally rigid. In preparation for passage of the fetus, the cervix undergoes many physiological changes. The cervix softens (“cervical ripening”), stretches, and thins, and eventually is taken up into the lower segment of the uterus. This softening and thinning is called cervical effacement.

BLOODY SHOW

During pregnancy the cervix is plugged with mucus. The mucus plug acts as a protective barrier for the uterus and its contents throughout the pregnancy. As the cervix begins to soften, stretch, and thin through effacement, there may be rupture of the small cervical capillaries. The added pressure created by engagement of the presenting part may lead to the expulsion of a blood-tinged mucus plug, called **bloody show**. Its presence often indicates that labor will begin within 24 to 48 hours. Late in pregnancy, vaginal examination that involves cervical manipulation may also produce a bloody discharge that can be confused with bloody show.

RUPTURE OF THE MEMBRANES

About 12% of pregnant women experience spontaneous rupture of the amniotic sac (“ruptured membranes” or “ruptured bag of waters”) prior to the onset of labor. In the majority of pregnancies, the amniotic membranes rupture once labor is well established, either spontaneously or by **amniotomy**, the artificial rupture of the membranes by the primary care provider. Rupture of the membranes is a critical event in pregnancy. Assessment by the woman if rupture occurs at home, or by the nurse if it occurs in the birthing unit, is essential. If the membranes do rupture at home, the woman should be taught to immediately contact the nurse at the provider’s office or at the birthing center who will advise her to report for an examination. It is important for the woman to note the color, amount, and odor of the amniotic fluid. The fluid should be clear and odorless. Often it contains white specks (vernix caseosa) and fetal hair (lanugo). A yellow-green tinged amniotic fluid may indicate infection or fetal passage of meconium and this finding always signals the need for further assessment and fetal heart rate monitoring. Urinary incontinence (frequently associated with urgency, coughing, and sneezing) is sometimes confused with ruptured membranes. The presence of amniotic fluid can be confirmed by a Nitrazine tape test or by a fern test (Procedure 12-2).

ENERGY SPURT

Toward the end of the pregnancy, some women experience a sudden increase in energy coupled with a desire to complete household preparations for the new baby. Some refer to this energy spurt as “nesting.” The energy spurt may be related to an increase in the hormone adrenaline, which is needed to support the woman during the work of labor. Women should be cautioned not to overexert themselves doing household chores and instead to “store up” their energy for the childbirth process.

WEIGHT LOSS

Before the onset of labor, changes in the levels of estrogen and progesterone can lead to electrolyte shifts and may result in a reduction in fluid retention. The increased fluid loss can lead to a weight loss of up to 3 pounds (0.5 to 1.5 kg).

GASTROINTESTINAL DISTURBANCES

Some women experience gastrointestinal disturbances (diarrhea, nausea, vomiting or indigestion) as a sign of impending labor. The etiology of the gastrointestinal disturbances is generally unknown.

Distinguishing True Labor from False Labor

Recognizing the difference between true and false labor is important for the pregnant woman and her nurse (Table 12-1). True labor contractions lead to progressive dilation and effacement of the cervix. True labor contractions occur with regularity, and increase in frequency, duration, and intensity. The pain of true labor usually begins in the woman’s lower back region, and radiates to the abdomen. The pain often intensifies with activity such as walking. In contrast, false labor contractions are irregular and usually do not change in intensity and duration. False labor does not lead to dilation and effacement of the cervix. The pain of false labor is usually felt in the abdominal region, and often stops with activities such as walking, position changes, and hot showers or other comfort measures.

Determining whether labor is true or false is an important assessment. Depending upon the findings, the nurse can help validate the next steps the woman should take. Any pregnant woman who arrives at the birth unit complaining of contractions must be carefully evaluated. After the assessment, if the maternity nurse confirms normal findings and intact membranes, the woman is sent home. For many, this can be a disappointing and frustrating experience. It is important for the nurse to provide reassurance that distinguishing true from false labor is difficult. Signs and symptoms of true labor should be reviewed in a sensitive, supportive manner, and the patient should be instructed about when to return to the birth unit.

Table 12-1 Distinguishing True from False Labor

True Labor	False Labor
<ul style="list-style-type: none"> • Contractions are at regular intervals. 	<ul style="list-style-type: none"> • Contractions are irregular.
<ul style="list-style-type: none"> • Contractions increase in frequency, duration, and intensity. 	<ul style="list-style-type: none"> • Usually there is no increase in frequency, duration, or intensity of contractions.
<ul style="list-style-type: none"> • Pains usually begin in lower back, radiating to the abdomen. 	<ul style="list-style-type: none"> • Pains usually occur in the abdominal region.
<ul style="list-style-type: none"> • Dilation and effacement of the cervix are progressive. 	<ul style="list-style-type: none"> • There is no change in the cervix.
<ul style="list-style-type: none"> • Activity such as walking usually increases labor pains. 	<ul style="list-style-type: none"> • Walking may lessen the pain.

Procedure 12-2 Assessing for Amniotic Fluid

Purpose

Assessing for the presence of amniotic fluid helps determine whether the membranes have ruptured. There are two tests commonly used to detect amniotic fluid: the Nitrazine tape test and the fern test.

Equipment

- Nitrazine test tape
- Sterile gloves
- Sterile speculum
- Sterile cotton swab and glass slide
- Microscope

Steps

1. Wash and dry hands and explain the procedure and purpose of the examination to the patient, noting what she will experience, and what the results will indicate.
RATIONALE: *Hand washing helps to prevent the spread of microorganisms. Explanations help to decrease anxiety and promote patient understanding and cooperation.*
2. Assess for latex allergies.
RATIONALE: *To prevent injury from latex exposure; if the patient has a latex allergy, use nonlatex gloves.*
3. Ask the patient if she has noticed any leakage of fluid from her vagina.
4. Assess for the presence of amniotic fluid before other tests that require the use of lubricant (such as vaginal examination).
RATIONALE: *Lubricant may alter the pH of amniotic fluid and contaminate the test result.*
5. Don sterile gloves. With one hand, spread the labia to expose the vaginal opening. With the other hand, place a 2-inch (5 cm) piece of Nitrazine tape against the vaginal opening, ensuring contact with enough fluid to wet the tape. Alternately, a sterile cotton-tipped applicator may be used to obtain fluid from the vagina. The applicator is then touched to the Nitrazine tape.

6. Remove the tape. Compare the color of the tape with the color guide on the Nitrazine tape container. If the tape turns blue-green, gray or deep blue, amniotic fluid is present. If the tape remains beige, no amniotic fluid has been detected.
RATIONALE: *Amniotic fluid is alkaline, with a pH of 6.5 to 7.5. Urine and vaginal secretions are usually acidic.*

Caution: Blood, *Trichomonas vaginalis*, and other substances may also turn the nitrazine test strip alkaline or blue.

7. When the Nitrazine test has not confirmed the presence of amniotic fluid, the nurse may insert a speculum and sterile cotton swab to collect a sample of fluid from the posterior vagina. The swab is smeared on a glass slide and allowed to dry. The glass slide is then placed on the microscope. The presence of a ferning pattern confirms the presence of amniotic fluid. The fern test is often indicated if premature rupture of the membranes (PROM) is suspected.
RATIONALE: *Dried amniotic fluid shows a fern pattern due to its high estrogen content.*

8. Document the findings on the admission or labor record.
9. Inform the patient of the findings.

Documentation

8/30/09. 0430 Sterile speculum exam performed, large amount of clear, nonmalodorous fluid noted in vagina. Specimen obtained, fern test positive. Procedure tolerated well by patient, fetal heart rate 148 bpm by auscultation.

-L. Lopez, R.N.

“What to say” — Questions to ask the patient who calls the birth unit

A pregnant woman calls the birth unit to determine if she should come in for an evaluation or remain at home. The nurse conducts the telephone assessment by asking the following questions:

- “What is your due date?”
- “Are your membranes ruptured?” or “Did your water break?” and “Are you having any bleeding or vaginal discharge?”
- “Describe your contractions: When did they start? How frequent? How long? How strong?”

- “Is the fetus active?”
- “What helps with the discomfort?”
- “Who is with you?”

Now Can You— Identify true labor?

1. List four signs that may signify impending labor?
2. Compare and contrast signs of true labor versus false labor? Discuss how they can be differentiated?
3. Explain when a woman experiencing contractions at term should be instructed to go to the hospital?

Childbirth Settings and Labor Support

The decision about where to give birth is influenced by several factors: geographical location, socioeconomic status, the patient's preference, and the absence or presence of pregnancy complications. The size of the community often dictates the type and number of maternity health care facilities and the available primary care providers who may include family physicians, obstetricians, and certified nurse midwives (CNMs).

Large urban centers have hospitals with birthing units or birthing centers. Some of the units may offer labor options such as whirlpool baths. Other settings may provide a home-like environment for the expectant couple. Taking a tour of the available birth settings as part of prenatal education classes can help the pregnant woman and her partner develop an understanding of what to expect during the childbirth experience.

The woman's socioeconomic status and whether or not she has health insurance also affect the choices available for labor and birth. Some pregnant women who have no pregnancy complications may choose to have their prenatal care and birth managed by a CNM, and they may also plan for a home birth.

The patient usually determines whether or not a support person accompanies her to the birthing unit and remains throughout the labor and birth. This decision is based on personal preferences, and may reflect cultural or religious practices. The woman's partner or the baby's father is the most common labor support person, although the woman's mother or friend may also serve as a support person especially if the patient is single. The nurse can identify the patient's preference for a support person by asking a question such as, "Who is the main person that you want to stay with you during labor?"

In some centers, women may use a **doula** as a labor support person. The doula is a woman who has received professional training and is experienced in childbirth. The doula's role is to provide continuous information and physical and emotional support to the woman and her

partner before, during, and immediately after the birth. She does not function in a clinical role but instead specializes in providing comfort measures to decrease the woman's anxiety. Breathing techniques, application of hot and cold, and massage are strategies often used to enhance comfort and the progress of labor.

The doula assists the family in gathering information concerning the labor process and available options before childbirth. If a cesarean birth is required, the doula may accompany the laboring woman into the surgical suite. Doulas also provide some postpartum services. In some situations, the family hires the doula. Doulas can be paid hospital employees or volunteer doulas may be available in certain settings. When needed, the bilingual doula can be an essential team member in helping to promote a positive childbirth experience for the woman and her family.

Now Can You— Discuss childbirth settings and support persons?

1. Discuss various childbirth settings and factors that may influence the woman's choice?
2. Describe the role of a doula?

Routine Hospital and Birth Center Admission Procedures

In the third trimester it is important for the prenatal care nurse to explain the differences between true and false labor, and to teach the patient about when to go to the birthing center. Table 12-2 summarizes the circumstances that warrant going to the birthing center. The nurse should reinforce this information during each prenatal visit.

Be sure to— Understand federal regulations that relate to obstetric care

The federal regulation known as *The Emergency Medical Treatment and Active Labor Act (EMTALA)* was created to ensure that all women receive emergency treatment or active labor care whenever such treatment is sought. Under the EMTALA regulation, true labor is considered to be an emergency medical condition. Thus the nurse working in a birthing unit must be familiar with the full range of responsibilities included in the EMTALA regulations: (1) provide services to pregnant women when an urgent pregnancy problem such as labor, rupture of the membranes, decreased fetal movement, or recent trauma is experienced and (2) fully document all relevant information to include assessment findings, interventions implemented and the patient's response to the care provided. Any pregnant woman who presents to an obstetric triage is considered to be experiencing "true labor" until a qualified health care provider determines that she is not (Angelini & Mahlmeister, 2005; Caliendo, Millbauer, Moore, & Kitchen, 2004).

where research and practice meet: Home-like Birth Settings

In this Cochrane review of home-like versus conventional institutional settings for birth, Hodnett, Downe, Edwards, and Walsh (2005) reviewed six trials of 8677 women. The findings revealed a number of benefits associated with home-like settings for childbirth: increased maternal satisfaction with the intrapartum care; increased initiation and continuation of breastfeeding; an increased incidence of spontaneous vaginal births; and a reduced likelihood of medical interventions including analgesia/anesthesia and episiotomies. Despite these positive findings, the review also demonstrated an association between home-like birth settings and increased perinatal mortality. The authors concluded that although a home-like birth setting with its focus on normality is associated with modest benefits, care providers need to monitor patients closely for complications, regardless of the setting for labor and birth.

Table 12-2 Providing Patient Guidelines for Reporting to the Birthing Center

Questions to Ask the Patient	Guidelines for Admission
Describe your contractions: frequency, duration, and intensity?	Primigravida: Contractions are regular, occur about every 5 minutes for at least 1 hour. Multipara: Contractions are regular, occur about every 10 minutes for at least 1 hour.
Have your membranes ruptured?	Any gush of fluid needs to be evaluated, even if there are no contractions.
Is there any vaginal bleeding?	The mucus plug or “bloody show” is usually pink or dark red. Any bright red bleeding requires immediate evaluation.
Has there been a decrease in the movement of the baby?	Any decrease in fetal movement signals the need to report to the birthing center.
Has there been any change in your health?	Any cause for worry or anxiety in the pregnant woman needs to be explored by the nurse and may lead to admission.

Once the woman arrives at the birthing center, the role of the nurse is twofold: to establish a positive relationship with the patient and her family and support person and to assess the status of the patient and her fetus.

ESTABLISHING A POSITIVE RELATIONSHIP

The onset of labor is a time of many emotions for the woman and her family. There can be excitement, fear, and anxiety. The role of the nurse in recognizing these emotions and creating a caring, trusting relationship is paramount to a positive birth experience. The nurse needs to respect individual differences in the woman’s knowledge and understanding of childbirth, as well as recognize the cultural or religious practices that may influence the experience. The nurse needs to remain nonjudgmental, particularly with patients who have not had adequate prenatal care or who have made unhealthy lifestyle choices during the pregnancy.

To foster a positive and therapeutic relationship, the nurse creates an atmosphere that encourages questions and the sharing of information. Some women have prepared written childbirth plans that describe their expectations of the experience. Getting to know each patient’s expectations for her childbirth experience constitutes an important element in the relationship. The nurse must also recognize when an interpreter is needed to assist in the understanding and exchange of information.

Touch is an integral aspect of the nurse–patient relationship during labor and birth. Touch can convey caring and provide comfort. The nurse continuously assesses the patient’s response to touch and provides intimate care that is culturally sensitive.

COLLECTING ADMISSION DATA

The nurse uses multiple sources and data collection methods to compile a comprehensive database to plan and deliver individualized care to the woman in labor. The prenatal record provides data regarding the current pregnancy and previous pregnancies and birth outcomes for the multiparous woman. Measurements such as maternal weight gain, fundal height, blood pressure, fetal heart rate patterns, laboratory values such as blood type and Rh factor, results from diagnostic tests such as amniocentesis, non-stress tests, and ultrasound examinations provide the basis for determining intrapartur risk.

The admission interview provides the nurse with information about the woman’s reason for coming to the birthing center, her understanding and expectations of the labor and birth process, her subjective experience of the labor, as well as psychosocial and cultural factors that can impact her birth experience. The fetal assessment, including presentation, fetal heart rate (FHR), and movement provides essential data regarding fetal well-being. Maternal vital signs, particularly blood pressure and temperature, as well as the assessment of current labor status (uterine contraction patterns, cervical dilatation, and effacement, fetal station, rupture of membranes) provide important baseline labor data. A systematic physical assessment provides the nurse and other care providers with overall health data, and various laboratory tests, such as hematocrit, blood glucose, and HIV status, give further direction for the individual plan of care.

Initial Admission Assessments

For women who have received prenatal care, the prenatal care record is sent to the birthing center prior to the expected due date. The information is stored and readily available when the laboring patient reports there for care. Women without a prenatal care record require a more extensive assessment upon admission to the birth setting.

THE FOCUSED ASSESSMENT

On admission to the birthing unit, the nurse initiates a focused assessment to determine the condition of the mother and fetus and the progression of the labor. The data collected answers these critical questions and helps the nurse to establish priorities for care:

- Is this true labor, and if so, is birth imminent?
- Are there any factors that increase risk to the mother or fetus?

The nurse assesses the fetus’ well-being by recording the FHR and noting the FHR in response to uterine contractions. The nurse also assesses fetal movement. If the woman reports that her membranes have ruptured, the nurse validates the presence of amniotic fluid using Nitrazine tape (see Procedure 12-2), and examines the amniotic fluid for color and odor.

The nurse assesses the patient's vital signs to establish a baseline for comparison during the labor and birth. An elevation in blood pressure may be a sign of pregnancy-induced hypertension (PIH). An elevated temperature may signal infection. The nurse also assesses the progression of the labor by monitoring the pattern of uterine contractions for frequency, duration, and intensity. The nurse further assesses the labor status by evaluating cervical dilatation and effacement, and fetal station, presentation, and position.

A patient who states “I feel like pushing” may be indicating that the birth is imminent. Important questions to ask this patient upon admission include the following:

- What is your name? Your support person's name?
- Have you received prenatal care? Who is your care provider?
- How many pregnancies and births have you had? Were the deliveries vaginal or cesarean? Were there any difficulties with previous deliveries?
- What is your due date? When was your last normal menstrual period?
- Have your membranes ruptured? What time? Describe the fluid.
- Have you had any complications with this pregnancy?
- Do you have any allergies?
- Describe your contractions—mild, moderate, or intense. When did your contractions begin? How are you coping?
- Are you taking any medications—prescribed and/or over-the-counter? Do you use illegal/street drugs? Do you smoke? Do you drink alcoholic beverages?
- When did you last eat or drink anything and what was it?
- Have you prepared a birth plan? Do you have any cultural preferences related to your labor and birth?

If the nurse determines that the fetal or maternal assessments are not normal, or that the birth is imminent, the physician or primary care provider is notified immediately. If the assessments are normal, and birth does not appear to be imminent, the nurse can then complete a more thorough admission assessment, which would include a systematic physical assessment.

THE PSYCHOSOCIAL ASSESSMENT

An important, yet sometimes challenging part of the data collection is the psychosocial assessment. Understanding the woman's behavioral responses to the pregnancy and childbirth experience allows the nurse to support and strengthen the identified coping mechanisms. Obtaining information that addresses questions such as “What was the previous birth experience like?” “How is the patient handling the labor pain?” and “Who is providing labor support for her?” helps the nurse to better meet the patient's and her support person's needs.

The nurse completes a social assessment, collecting information about the woman's family and support systems and living conditions. Questions about family violence can be particularly difficult. If the nurse suspects partner abuse, the patient should be interviewed alone in a private place where she feels safe.

Assessing the woman's social and lifestyle habits can also be difficult. Questions about drug and alcohol use

and sexually transmitted infections are often embarrassing. The nurse can facilitate the sharing of this information through the establishment of a caring and nonjudgmental relationship with the patient.

“What to say” — Asking the difficult questions

Asking closed-ended questions such as “Do you drink alcohol?” may elicit a quick “No” response. Asking more directed and open questions such as “How many drinks do you have each day?” may encourage a more detailed response. The nurse should remember that a caring and nonjudgmental attitude, in a private, nonthreatening environment, helps to foster a trusting nurse–patient relationship.

THE CULTURAL ASSESSMENT

To provide care that is culturally relevant, the nurse must assess the patient's cultural preferences, practices, and values related to labor and childbirth. Issues such as care provider gender preference, comfort level with intimate touch, and the presence or absence of a labor support person may be culturally determined. The woman's responses to the labor pain, her acceptance or rejection of labor support interventions, and her emotional responses to the newborn can be culturally based.

LABORATORY TESTS

Laboratory testing is a routine component of the admission process. Tests for blood type and Rh factor, complete blood count, hemoglobin and hematocrit, and blood glucose are generally obtained. Blood tests for syphilis, hepatitis B, and HIV are also collected. The urine specimen is tested for the presence of protein, glucose, and ketones.

Documentation of Admission

Each birth setting has documentation forms and set protocols to be completed with patient admissions. Collecting a complete health and childbirth history and performing a physical examination of the patient and her fetus provide an essential foundation for the care and support to be given during labor and birth. Once the admission assessments have been completed, the nurse documents the information using the birth setting's recording procedures, notifies the patient's primary care provider of the admission status, and receives orders. Critical information to relay to the physician or nurse-midwife includes:

- Patient's name and age
- Gravidity and parity
- Gestational age and estimated date of delivery
- Labor status: pattern of contractions, cervical dilatation and effacement, fetal presentation and station
- Status of membranes
- Fetal heart rate and response to contractions
- Patient's vital signs, especially blood pressure and temperature
- Any identified risk to maternal or fetal well-being
- Patient's coping ability in response to labor

After admission, the patient and her fetus are assessed frequently to monitor both the progression of labor and the responses of both to the labor. Throughout each stage of labor, ongoing maternal assessments include vital signs, intake and output, pattern of contractions, cervical dilation and effacement, and response to labor. Fetal assessments, which primarily center on the response to labor, involve intermittent or continuous FHR monitoring.

First Stage of Labor

The first stage of labor is often referred to as the stage of dilation. This stage begins with the onset of regular uterine contractions and ends with complete dilation of the cervix. The onset of labor is often made retrospectively since the woman may not always recognize when true labor actually begins. The contractions often start slowly and are fairly tolerable. Over time, contractions tend to increase in frequency, duration, and intensity as the first stage of labor progresses. The first stage of labor is most often the longest stage and its duration can vary considerably among women. The first stage of labor is divided into three distinct phases: latent, active, and transition. Multiparous women tend to progress through the childbirth process much more rapidly than do nulliparous women. Factors such as analgesia, maternal and fetal position, the woman's body size and her level of physical fitness can also affect the length of labor.

LATENT PHASE

The **latent phase** of labor begins with the establishment of regular contractions (labor pains). Labor pains are often initially felt as sensations similar to painful menstrual cramping and are usually accompanied by low back pain. Contractions during this phase are typically about 5 minutes apart, last 30 to 45 seconds, and are considered to be mild. During this phase, the woman is usually excited about labor commencing and she remains chatty and sociable. Often this phase of labor is completed at home. During the latent phase cervical effacement and early dilation (0 to 3 cm) occurs. The latent phase of labor can last as long as 10 to 14 hours as the contractions are mild and cervical changes occur slowly.

ACTIVE PHASE

The **active phase** of labor is characterized by more active contractions. The contractions become more frequent (every 3 to 5 minutes), last longer (60 seconds), and are of a moderate to strong intensity. During the active labor phase, the woman becomes more focused on each contraction and tends to draw inward in an attempt to cope with the increasing demands of the labor. Cervical dilation during this phase advances more quickly as the contractions are often more efficient. While the length of the active phase is variable, nulliparous women generally progress at an average speed of 1 cm of dilation per hour and multiparas at 1.5 cm of cervical dilation per hour.

TRANSITION PHASE

The **transition phase** is the most intense phase of labor. Transition is characterized by frequent, strong contractions that occur every 2 to 3 minutes and last 60 to

90 seconds on average. Fortunately, this phase often does not take long because dilation usually progresses at a pace equal to or faster than active labor (1 cm/hr for a nullipara and 1.5 cm/hr for a multipara). During the transition phase, the laboring woman may feel that she can no longer continue or she may question her ability to cope with much more. Other sensations that a woman may feel during transition include rectal pressure, an increased urge to bear down, an increase in bloody show, and spontaneous rupture of the membranes (if they have not already ruptured). Table 12-3 presents a summary of the characteristics of the first and second stages of labor.

A labor curve assessment tool, often referred to as a "Friedman curve," is a graph used to help identify whether a patient's labor is progressing in a normal pattern (Fig. 12-11). Composite normal labor patterns are graphically presented for the multiparous and nulliparous patient. The labor curve assessment tool contains categories that include the time of day, amount of cervical dilation, and effacement and hours of labor that have elapsed. The patient's own labor progress is plotted on the graph to allow a comparison between her progress and the norm.

Now Can You— Identify characteristics of the first and second stages of labor?

1. Define the characteristics of the first and second stages of labor including contractions, dilation, and maternal response?
2. Describe the three phases of the first stage of labor and the changes that occur during each phase?
3. Explain the value of using a labor curve assessment tool?

NURSING CARE DURING THE FIRST STAGE OF LABOR

Cunningham and associates (2005) noted that there are two opposing priorities in the ideal management of labor:

- Birthing should be recognized as a normal physiological process and should be treated as such.
- Intrapartum complications can arise quickly and unexpectedly and therefore should be anticipated.

There are several key roles for the nurse who is providing care for the woman in labor. It is essential that the nurse continually assess the patient and her fetus to ensure a safe delivery, help to facilitate a positive birth experience, assist in the satisfactory management of pain, and advocate for the patient's needs.

It is important to remember that nursing interventions must first be safe and consistent with the current standard of care. Interventions are also tailored to meet the individual needs and preferences of the woman in labor. The patient's needs may quickly change throughout the process of labor. For example, during early labor the woman may be very independent and in little need of assistance. During active labor or transition, the needs often become very different. Research has shown that during labor, support by nurses has a positive effect on maternal and fetal outcomes.

Table 12-3 Characteristics of the First and Second Stages of Labor

	First Stage	Second Stage
Definition	Commences with the onset of regular contractions and ends with full dilation (10 cm) of the cervix	Begins with full dilation of the cervix (10 cm) and ends with the expulsion (birth) of the fetus.
Contractions	Latent: 5–10 minutes, may be irregular in frequency, duration 30–40 seconds, mild to moderate strength Active: Regular pattern established (2–5 minutes apart), 40–60 seconds duration and moderate to strong by palpation Transition: 2–3 minutes apart lasting 60–90 seconds, strong by palpation.	Contractions continue at a similar rate as during the transition phase; 2–3 minutes apart lasting 60 seconds and strong by palpation.
Dilation	Latent: 0–3 cm Active: 4–7 cm Transition: 8–10 cm	Fully dilated
Physical discomforts	Latent: Contractions often begin as painful menstrual-like cramps or low back ache Active: Increasing discomfort as contractions become stronger and more regular. May have backache. Transition: Increasing discomfort as contractions are very strong with little time for relaxation in between. As the fetal head descends there may be an increase in rectal pressure and the urge to push.	May have an urge to push that increases as the fetal head descends. Many women prefer to push so that they can use the contractions and work with them. When head is crowning may feel intense pain, burning.
Maternal behaviors	Latent: Pain often well controlled; various behaviors may be present: excited, talkative, confident, anxious, withdrawn Stage may be completed at home. Active: Needs to focus more on staying in control and managing the pain; often requires coaching at this stage; quieter and more inwardly focused Transition: Most intense phase. Often difficult to cope; may experience various emotions: irritable, agitated, hopeless (“can’t do it”); tired (sleeps between contractions)	Often during this stage many women get a “second wind” as they see that they are making progress and are embarking on a new (labor) phase. Intense concentration with pushing efforts.

Composite Normal Dilation Curves

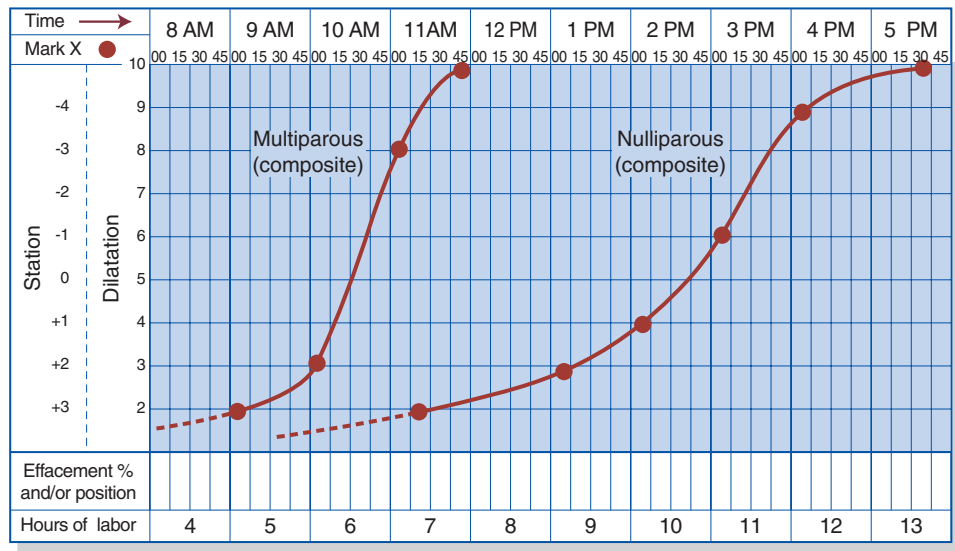

Figure 12-11 A labor curve assessment tool, often referred to as a “Friedman curve,” helps to identify whether a patient’s labor is progressing in a normal pattern.

where research and practice meet: Benefits of Continuous Labor Support

A recent systematic review that included 15 trials involving 12,791 women in 11 countries was conducted to assess the effects of continuous one-to-one labor support on mothers and their infants (Hodnett, Gates, Hofmeyr, & Sakala, 2006). The researchers found that women who were provided with one-to-one continuous support in labor were more likely to give birth without using analgesia or anesthesia, more likely to experience a spontaneous vaginal birth, and less likely to report dissatisfaction with their childbirth experience. Additional findings were that the positive effects of continuous one-to-one support increased when the support occurred from women who did not have any other responsibilities other than providing support to the laboring woman. Further, support begun early in the labor process appeared to be more effective than support initiated later in labor. Early and continuous support for women in labor should be encouraged whenever possible as an essential component of standard care.

Labor Support

Whenever possible, continuous labor support should be given to women in labor. Providing this level of care has been associated with positive outcomes for mothers and infants and there have been no documented harmful or adverse effects. Continuous labor support can be provided by professional nurses or by lay people.

PRESENCE

Presence is one method of providing continuous support. Offering one's presence in labor can be defined simply as "physically being with the woman." Women find that having a nurse present can be reassuring because they recognize that assistance is available when needed. Studies have demonstrated that "women want the nurse to be available,

to be emotionally involved, to help create a special moment, to hear and respond to their concerns, to share the responsibilities for keeping them safe, and to act as a go-between for their family and the medical institution" (MacKinnon, McIntyre, & Quance, 2005, p. 32). Unfortunately, other studies have demonstrated that nurses may not be actually providing this type of care for several different reasons such as inadequate staffing, lack of time, lack of training, hospital practices that emphasize technological care, and resistance from physicians (Simkin, 2002). Nurses are especially adept in providing therapeutic labor support because their educational background emphasizes a caring, holistic approach that centers not only on knowledge of the labor process and supportive techniques but also on empowerment of the woman experiencing childbirth.

PROMOTION OF COMFORT

Position Changes

In labor, frequent position changes are beneficial in helping to promote the descent of the fetus. The nurse may assist the laboring woman to various positions and activities such as walking, standing, sitting, squatting, leaning over a piece of furniture, or assuming a hands and knees position (Fig. 12-12). Maternal preferences can guide the nurse in assessing which positions or activities the woman finds most comfortable. Each position is associated with advantages and disadvantages (Box 12-3). During early labor, women are often encouraged to remain ambulatory since activity has been shown to enhance the normal progression of labor.

As labor advances the woman may feel tired and in need of some relaxation between contractions. Sitting in a chair and reclining on the side are two positions that often bring comfort. Changes in the patient's status such as continuous fetal monitoring, premature rupture of the membranes, or epidural analgesia may necessitate a need for bed rest. In these situations, the nurse should encourage the laboring woman to rest on her left side

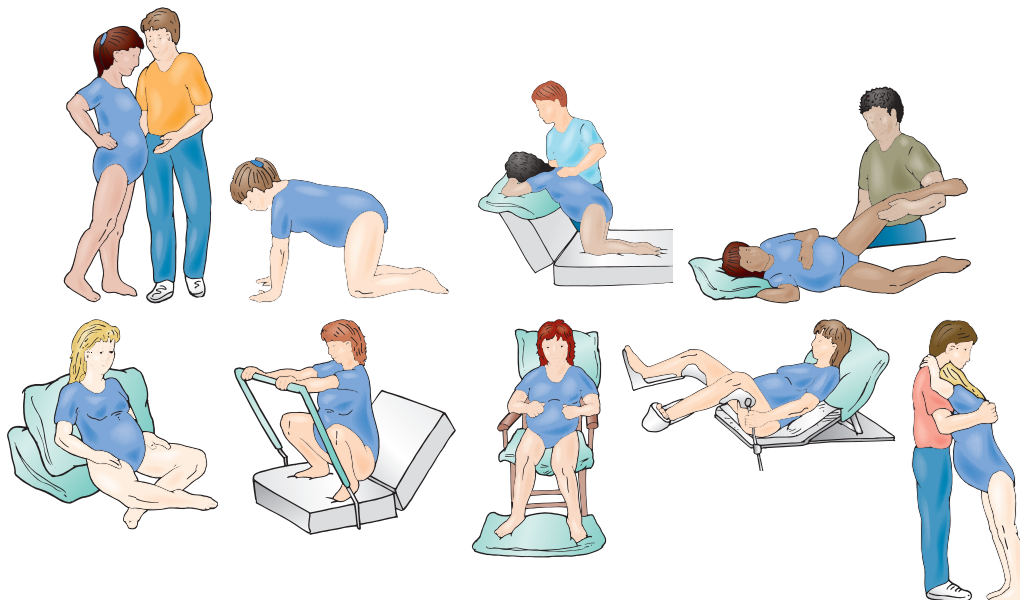

Figure 12-12 Various positions for labor and birth.

Box 12-3 Advantages and Disadvantages of Various Positions for Labor

WALKING/STANDING

Utilizes gravity, facilitates descent, places fetus in alignment with pelvis, may decrease the length of labor by enhancing the effect of contractions.

May be tiring, requires telemetry for continuous electronic fetal monitoring, may not be possible with regional anesthesia.

SITTING

Utilizes gravity, increases pelvic diameter and shortens second-stage labor, avoids supine hypotension syndrome, decreases back pain, enhances communication with partner and allows for ready access to back and sacrum for massage and counterpressure.

Labor may be slowed if not alternated with other positions, may intensify suprapubic pain and cause edema of the vulva or cervix.

HANDS AND KNEES POSITION

Stimulates rotation of fetus from a posterior to an anterior position, relieves backache and rectal pressure, facilitates pelvic rocking and pelvic mobility.

May be tiring or embarrassing, difficult to keep external fetal monitor in place, may not be possible with regional anesthesia.

SQUATTING

Utilizes gravity, increases pelvic diameter, relieves backache, promotes fetal descent and rotation, facilitates second-stage pushing.

May impede descent before engagement has occurred, may be tiring, uncomfortable, or embarrassing, may increase perineal and cervical edema.

to facilitate optimal uteroplacental blood flow. In addition, position changes should be encouraged even if the woman must remain in bed. If bed rest is necessary, the nurse may be able to assist the woman into a variety of positions in bed. Sitting, getting on hands and knees, or resting on alternate sides may be desirable, depending on the patient's condition and preferences. It is important to avoid the supine position since the pressure of the uterus on the maternal spine can cause compression of the inferior vena cava and lead to decreased blood pressure and diminished uteroplacental blood flow.

Personal Comfort Measures

Nurses can provide personal comfort measures for the laboring woman based on her preferences and needs. For example, assistance with basic hygiene, back rubs, ice chips, or application of a cold cloth may be quite comforting. Family members and support persons should be encouraged to remain with the woman and help to meet her personal comfort needs.

ENVIRONMENT. The woman or her family may prefer to have the lights dimmed to create a relaxing atmosphere. Conversely, other women and families may prefer to have the sun streaming into the room. During active labor the woman may verbalize heat intolerance (being too hot) due to the physical work and energy expenditure required in labor. An electric fan may be beneficial in providing a cooling breeze. Nurses must remember to turn off the fan or assess the room temperature during childbirth to ensure that the infant does not get unnecessarily chilled.

PERSONAL HYGIENE. As needed, the nurse can help promote the patient's sense of cleanliness and well-being by changing pads, linens, or gown especially if the woman is leaking amniotic fluid or bloody show. Many women who remain ambulatory are able to perform their own personal care. However, if the laboring woman is confined to bed or exhausted from the exertion of labor, full assistance should be provided.

Frequent mouth care should be encouraged since dry mouth is common during labor. Providing fluids to drink, ice chips, popsicles, or hard candy may help to alleviate the symptoms. In addition, the use of mouthwash or brushing the teeth may be especially beneficial following vomiting. Nurses should be aware that different institutional policies exist regarding oral intake in labor and remain knowledgeable of the policies and procedures that affect their practice.

ELIMINATION. A full bladder can inhibit the descent of the fetus and contribute to increased pain with contractions. Encouraging and assisting the woman to the toilet (or bedpan) to void at least every 2 hours is recommended. If the woman is unable to void and has a distended bladder a urinary catheter may be required.

SUPPORTIVE RELAXATION TECHNIQUES. During labor, the nurse may encourage, assist, or teach the woman about different interventions to help decrease pain and relieve anxiety. Relaxation techniques may include visualization, focal points, imagery, hydrotherapy, and breathing techniques. In addition, patients may bring items from home to enhance relaxation such as music, a picture, or a stuffed animal. (See Chapter 13 for further discussion.)

where research and practice meet: Taiwanese Women's Perceptions of Helpful and Nonhelpful Nursing Behaviors During Labor

A major role of the labor and delivery nurse is to create a positive and satisfying birth experience. In order to determine what nursing interventions laboring women found most helpful, a study of Taiwanese women's perspectives about their encounters with obstetric nurses during labor was conducted. The results indicated that the majority (68%) of the women reported having received only helpful nursing behaviors, as compared with other study participants who reported both helpful and nonhelpful nursing interventions. Nursing interventions that were identified as helpful include: performing roles of emotional support provider, comforter, information/advice provider, professional technical skills provider, and advocate. The women who reported having received both helpful and nonhelpful nursing interventions (38%) stated that their nurses failed to provide emotional support or comfort measures, give adequate or correct information/advice, or perform technical duties. The results of this research are similar to findings from other studies conducted with North American women. The findings suggest that nursing interventions can have either a positive or negative effect on women's overall birthing experiences. This research identifies desirable personal qualities of labor nurses and many professional tasks that they should perform. During the birth experience, ideal nursing interventions should include the provision of ongoing emotional support and comfort, information and advice, professional and technical skills, and, in every activity, the nurse should serve as a patient advocate (Chen, Wang, & Chang, 2001).

Now Can You— Provide comforting nursing care during labor?

1. List four examples of nursing interventions that patients have identified as helpful in promoting comfort and relaxation?
2. Identify three beneficial positions for the laboring woman who is confined to bed rest?
3. Describe what is meant by “presence”?

ANTICIPATORY GUIDANCE

Providing anticipatory guidance for the woman and her family constitutes an essential role of the obstetric nurse. Regardless of whether or not they have attended prenatal classes, most women and their families have many questions. Anticipatory guidance should be provided throughout the childbirth experience. Women and families usually want to know what to expect. While the nurse cannot predict exactly what will happen, helpful information can be provided in general terms. For example, a woman in early active labor may comment: “These contractions are getting stronger, how strong will they get?” The nurse can empower the woman by identifying the progress she has made to that point. Explaining how the contractions have gradually become stronger and emphasizing how successful the patient has been in adjusting to the changes provides factual feedback and positive reinforcement of the progress made. In addition, the nurse may suggest comfort measures such as relaxing in a whirlpool bath or shower for later on when the contractions become stronger.

“What to say” — Positive, encouraging words during labor

During labor the patient needs encouragement with positive words regarding what she is doing well even when she may not be coping at her optimal ability. Nurses must be careful not to use language that may be discouraging for the woman such as “This is just the beginning. It is going to get much worse.” Instead, nurses should offer comments such as “Try focusing on one contraction at a time” or “See if you can concentrate on relaxing more between the contractions” followed by “That is really great, keep going, excellent, now let’s try that again with the next one.”

Keeping the woman and her family informed about the process of labor and birth is a constant and ever changing task. For example, during the transition phase the nurse may be teaching the woman breathing techniques to avoid pushing with a partially dilated cervix. In a matter of minutes, the patient can reach full cervical dilation. The nurse then teaches her how to push and may need to assist the woman into an effective pushing position.

CARING FOR THE BIRTH PARTNER

Obviously, most of the nurse’s attention focuses on the woman in labor. Efforts also should be made to help the support person feel welcome and included whenever possible according to the woman’s wishes. Orientation to the birth unit is helpful in identifying where to locate

items such as towels and washcloths, kitchen supplies (ice chips), and the restroom.

Assessment of the degree of involvement the support person would like to assume is also important. It is helpful to determine whether or not the patient and labor partner have attended childbirth preparation classes and give respect to the support person for their identified wishes and or limitations. In some cultures, assistance at the birth might be considered “woman’s work” and the laboring woman instead seeks support from a sister, mother, and aunt while the husband stays at home or assumes more of an observational role.

ENSURING CULTURE-CENTERED CARE

Providing care that is culturally appropriate is as important in caring for laboring women and their families as with any other patients. It is unrealistic to expect nurses to be knowledgeable about the cultural traditions and customs of all patients. However, it is important for nurses to remain open minded and aware that there are a myriad of values, attitudes, beliefs, and practices regarding childbearing that vary among cultures just as there may be wide variations within cultures. Body language and communication approaches provide examples of how differences in cultural practices can be applied when caring for a woman and her family during the childbirth experience.

Ethnocultural Considerations— Cultural differences in communication

Eye contact: North American nurses have been taught that eye contact is an integral part of the communication process when communicating with patients. Some cultures do not maintain eye contact as they consider eye contact to be impolite or aggressive.

Silence: Some individuals find silence to be uncomfortable and may make efforts to communicate when there are gaps in a conversation. However, labor may be a time where it is inappropriate to be carrying on a conversation. Silence can be seen as a sign of respect for the laboring woman and the effort that she may be using to stay focused.

Touch: Often during the care of laboring women, nurses will use touch as a sign of caring and empathy. Wide variations in meaning can be attributed to touch among cultures. It is recommended to always ask the patient prior to touching her and assess her response to being touched.

Space: The concept of personal space varies among individuals and cultures. An awareness of personal space boundaries is essential; the individual patient will help the nurse to identify what she finds acceptable.

Care provider and labor support gender: Variations exist within cultures regarding norms relating to gender. Some cultures require a female care provider for the woman in labor. Other cultures require that a female labor companion accompany the woman in labor while the husband assumes a passive role.

Sick role behavior: Sick role behavior can vary among individuals and cultures. In some cultures it may be unacceptable to shout out during labor and the woman may be very stoic even though she is in extreme pain. Other cultures consider the childbearing year to be a time that requires intense assistance. In these situations, it is appropriate for the mother or sister to come live with the family to help care for the mother and infant.

Nursing Care Plan Young Primigravida in Labor

Allison is a 16-year-old gravida 1 para 0 who presents to the birth unit in early active labor accompanied by her mother. Allison appears quite fearful as she frequently asks, “what is that for?,” “what are you going to do with that?,” and “will it hurt?” On further questioning the nurse determines that Allison did not attend prenatal classes and has never been hospitalized.

Nursing Diagnosis: Deficient Knowledge related to hospitalization for labor and birth as manifested by frequent questions, no attendance at prenatal classes, and no previous hospitalizations.

Measurable Short-term Goal: The patient will have increased knowledge about labor and birth/hospital procedures.

Measurable Long-term Goal: The patient will have decreased anxiety related to hospitalization.

NOC Outcome:

Knowledge: Labor and Delivery (1817) Extent of understanding conveyed about labor and vaginal delivery

NIC Interventions:

Childbirth Preparation (6760)
Teaching: Individual (5606)

Nursing Interventions:

1. Establish rapport with the patient and her mother.
RATIONALE: The support and understanding of the nurse will help decrease the patient’s anxiety to facilitate learning. Including the mother in teaching provides an additional source of information and comfort for the patient.
2. Describe aspects of the admission process and standard care for labor patients with rationales.
RATIONALE: Explaining to the patient what will occur and the reasons why they are important will increase the patient’s knowledge and may alleviate some of her anxiety.
3. Orient the patient to the unit/room/birthing area.
RATIONALE: Orientation to the hospital environment may assist in making the patient feel more comfortable with her surroundings.
4. Describe any procedures before performing them, including rationales, risks, and benefits.
RATIONALE: This allows the patient to participate in her own care and make decisions based on knowledge.
5. Explain the nature of uterine contractions, cervical dilation, and labor progress.
RATIONALE: This knowledge will reduce the patient’s anxiety, which may also reduce perceived pain.
6. Teach the patient and her mother breathing and relaxation techniques that may be used as labor advances.
RATIONALE: Anticipatory guidance provides the patient with tools to use during labor.
7. Teach support person(s) measures to comfort the patient during labor (specify, e.g., back rub, cool cloth, position changes, massage, imagery, use of birthing ball).
RATIONALE: Providing presence conveys support and respect for the patient. Continuous support should be on-going to prevent the patient from being left alone during labor.
8. Offer words of encouragement and suggestions for coping strategies as labor advances.
RATIONALE: Empowers the patient to gain better control over her situation and helps to diminish fear and anxiety.

Assessment of the Fetus During Labor and Birth

Assessment of the fetus during labor and birth is a fundamental component of caring for a woman in labor. Intrapartal assessment of the fetus should be included in the maternal assessments at admission and remain ongoing throughout the intrapartal period. Fetal assessments include the identification of fetal position and presentation, and the evaluation of the fetal status.

Nurses use a variety of assessment techniques including observation, palpation, and auscultation. When assessing a woman in labor, the nurse is able to use observation and interview skills from the moment the woman comes through the door. Astute observation assists the nurse in assessing the patient’s level of pain, her coping abilities,

her contraction frequency, and the effectiveness of her support person. However, the nurse is unable to use direct observation skills to assess the status of the fetus. Therefore, it is critical that fetal assessment be a priority when the patient enters the intrapartal unit.

FETAL POSITION

There are four central ways to identify fetal position and some methods are more accurate than others. The nurse may attempt to identify the fetal presentation in the following ways:

- Abdominal palpation (Leopold maneuvers)
- Location of the point of auscultation of the FHR
- Vaginal examination
- Ultrasound

Leopold Maneuvers and Point of FHR Auscultation

Leopold maneuvers are a systematic way of palpating the maternal abdomen to assess the fetal position. In addition, through the identification of fetal position, Leopold maneuvers can also assist the nurse to identify the location in which to auscultate the fetal heart tones. Performing Leopold maneuvers is a skill that requires practice and is not always accurate in identifying fetal position. Factors such as maternal obesity, hydramnios, and multiple gestation can increase the difficulty of identifying fetal position by Leopold maneuvers. (See Chapter 9 for further discussion.)

Critical Nursing Action Prevent Supine Hypotension

Much of the fetal assessment involves the maternal abdomen. Avoid positioning the patient flat on her back. Instead, slightly elevate the head of the bed or place a wedge under the patient's hip to prevent compression of the maternal vena cava caused by the gravid uterus.

Vaginal Examination

Another method of assessing the fetal position is by vaginal examination (see Procedure 12-1). The examiner may be able to palpate the fontanel or cranial suture to identify that the fetus is in a cephalic presentation. The landmarks may also be used to further identify the degree of flexion and the specific presentation such as vertex. If the membranes are intact or if the cervix is minimally dilated the examiner may not be able to identify the position of the fetus.

Ultrasound Examination

Ultrasound may be used when the practitioner is unable to identify the position by abdominal palpation or when it is necessary to determine the fetal position with the most accuracy. If a breech presentation is suspected during labor, an ultrasound examination may be performed to confirm the fetal presentation prior to performing a cesarean section.

Now Can You— Discuss determination of fetal position during labor?

1. Identify and describe three methods used to determine fetal position?
2. Outline the major steps involved in performing an intrapartal vaginal examination?

ASSESSMENT OF THE FETAL HEART RATE

Much debate exists regarding the optimal method for evaluating the FHR in labor with the use of continuous or intermittent electronic fetal monitoring and intermittent auscultation. In addition, there is considerable variation among the methods of fetal monitoring used routinely in practice and the scientific evidence to support clinical practice. There is no consensus in the literature that electronic fetal monitoring provides superior assessment over intermittent auscultation (IA) in low-risk women. However, in practice, many low-risk women continue to be electronically monitored during labor. In addition, there is evidence to support the assertion that continuous electronic fetal monitoring can be associated with negative outcomes (Thacker, Stroup, & Chang, 2005).

Across Care Settings: Variations in practice environments for perinatal nurses

Since diverse policies are found in different practice environments, nurses are encouraged to seek relevant policies and procedures within their individual health care organizations to guide their practice. It is important that the nurse practice within the standards set by the employer institution. The nurse is professionally accountable and has a legal responsibility to be knowledgeable of the current standards that affect practice. Perinatal nurses should be fully cognizant of the institutional policies concerning fetal heart surveillance during labor. Pertinent information generally includes the method of assessment, qualifications for those performing the technique, nurse to patient ratio, frequency and duration of assessment for specific stages of labor and defined risk categories, indications for specific methods, when to notify the primary care provider, and documentation (Goodwin, 2000).

Table 12-4 identifies recommendations for fetal monitoring generated by various professional organizations. This information further underscores the diversity of professional standards related to the issue of FHR monitoring.

Auscultation of Fetal Heart Sounds

Fetal heart sounds are best heard over the fetal back when the fetus is in the flexed position, as this is the part in closest contact with the uterine wall. Where to auscultate the

Table 12-4 Professional Organizations and Fetal Monitoring Recommendations

Professional Organization	Recommendations
AWHONN (Association of Women's Health, Obstetric and Neonatal Nurses, 2000, 2003b)	Supports both the use of IA and uterine palpation as an appropriate method of fetal assessment for both antepartum and intrapartum patients and the judicious, appropriate application of EFM intrapartally. Risk assessment of the mother and fetus should guide the use of technology.
ACOG (American College of Obstetrics and Gynecology, 2005)	Recommends that either EFM or electronic IA be used during the labors of low-risk pregnant women.
SOGC (Society of Obstetricians and Gynaecologists of Canada, 2005)	Recommends IA as the preferred method of fetal surveillance of low-risk pregnancies and that there is insufficient evidence to justify the use of continuous EFM in routine practice.

IA = intermittent auscultation; EFM = electronic fetal monitoring.

fetal heart sounds depends on the fetal position (back to maternal left or right side; breech versus cephalic) (Fig. 12-13). Finding the best location to auscultate fetal heart sounds facilitates another method to identify or confirm fetal position. Typically, with a cephalic presentation, the fetal heart sounds are heard below the level of the maternal umbilicus. In a ROA position, the heart sounds are heard loudest in the right lower quadrant. Conversely, with a breech presentation, the fetal heart sounds are often auscultated above the level of the umbilicus. In a LSA position, the fetal heart sounds should be heard loudest in the upper left quadrant.

Regardless of the method used to assess fetal well-being in labor, nurses need to be extremely attentive to the fetal heart sounds. In addition, nurses must be knowledgeable regarding the identification of reassuring versus non-reassuring FHR sounds and the appropriate interventions that may be required.

INTERMITTENT AUSCULTATION. Intermittent auscultation (IA) of the fetal heart rate is frequently the recommended method for evaluating fetal status in women who have been identified as low risk. The fetal heart rate can be auscultated with a fetoscope or Doppler instrument and should be assessed for the baseline FHR, regular or irregular rhythm pattern, and the presence of accelerations (discussed later). In addition, the nurse should be able to identify reassuring and non-reassuring FHR patterns and recognize the implications and interventions that may be required. Intermittent auscultation is conducted using a fetoscope or Doppler instrument (Procedure 12-3).

Optimizing Outcomes— Recognizing reassuring and non-reassuring FHR patterns

The use of intermittent auscultation to monitor FHR during labor requires the nurse to recognize characteristics of reassuring and non-reassuring patterns.

Reassuring FHR characteristics:

- Normal FHR baseline (110–160 bpm)
- Presence of accelerations

Non-reassuring FHR characteristics:

- Abnormal FHR baseline (<110 or >160 bpm)
- Presence of decelerations (ACOG, 2005)

Now Can You— Assess FHR by auscultation?

1. Describe situations in which intermittent auscultation of the FHR is indicated?
2. List the characteristics of a reassuring FHR monitored by intermittent auscultation?

Electronic Fetal Monitoring

Electronic fetal monitoring (EFM) may be conducted on an intermittent or continuous basis. In a large number of American and Canadian hospitals, women are routinely monitored on admission for a short period of time to assess fetal well-being and then the monitoring is conducted periodically throughout labor. This practice is referred to as

Figure 12-13 Identifying where to auscultate fetal heart sounds depends on the fetal position.

“intermittent” fetal monitoring. However, the evidence base supporting this practice has not demonstrated improved outcomes (Thacker, Stroup, & Chang, 2005). Thacker and colleagues (2005) reported that EFM, as compared to IA, has not been associated with a decrease in neonatal mortality or morbidity although EFM has been associated with increased rates of cesarean section, operative vaginal birth and the use of obstetrical anesthesia. At present, more than 85% of laboring women in the United States are monitored electronically for at least part of their labor (Martin et al., 2005). The continued use of EFM over intermittent FHR auscultation is believed to be related to concerns about liability and the increased nurse-to-patient ratio required with IA (Wood, 2003). In view of the fact that all fetal surveillance methods have limitations, some professionals assert that the current evidence supports a return to the use of IA for low-risk laboring women (Dildy, 2005).
