Situations where EFM is recommended continuously for assessing fetal well-being include the presence of a high-risk pregnancy, induction of labor with oxytocin, when IA identifies a non-reassuring FHR or if the institution is unable to provide IA. EFM can be performed externally or internally. The external EFM involves a process that is very similar to the non-stress test (NST) (see Chapter 11). The external monitor is composed of a Doppler ultrasound transducer and tocodynanometer that is applied to the maternal abdomen to monitor and display the FHR and contractions (Fig. 12-14). Although the use of an external transducer requires that the woman remain confined to a bed or chair, portable telemetry units allow patients to ambulate during electronic monitoring. The nurse is able to observe the FHR and uterine contraction patterns at a centrally located electronic display station. Some facilities are equipped with monitoring units that can be used when the woman is submerged in water.

The internal fetal monitor is composed of a spiral electrode that must be inserted into the fetal scalp or presenting part during a vaginal examination (Fig. 12-15). The cardiac signal is transmitted through the spiral electrode and a fetal electrocardiogram tracing is produced. Uterine activity is assessed by a solid or fluid-filled intrauterine pressure catheter (IUPC) that is introduced into the uterine cavity. The IUPC can measure contraction frequency, duration, and

Procedure 12-3 Auscultating the Fetal Heart Tones During Labor

Purpose

Auscultation, an auditory method of monitoring the fetal heart tones, is performed intermittently during labor to assess the fetus. Auscultation allows the laboring woman greater freedom because she is not attached to a machine and does not have to wear belts to secure the ultrasound transducer and the tocotransducer. Intermittent auscultation does not provide a printed record of the fetal heart rate for other members of the health care team to review. Auscultation also does not provide an assessment of fetal heart rate variability or of other subtle changes in the fetal heart rate.

Equipment

- Fetoscope or hand-held Doppler ultrasound with gel (“Doppler”)
- Disposable wipes

Steps

1. Wash and dry hands and explain procedure and purpose of the examination to the patient.
RATIONALE: *Hand washing helps to prevent the spread of microorganisms. Explanations help to decrease anxiety, and promote patient understanding and cooperation.*
2. Help the patient assume a comfortable position that provides access to the abdomen.
3. Palpate the maternal abdomen using Leopold maneuvers to identify the fetal position to aid in obtaining the location of the fetal heart tones. Note that the fetal heart tones are heard most loudly over the fetal back.
4. Palpate the fundus of the uterus for the presence of uterine contractions. At the end of a uterine contraction, place the fetoscope or Doppler over the location of the fetal back. Adjust the fetoscope or Doppler if necessary to obtain a clearly audible FHR. Depending on fetal position, the fetal heart sounds may be soft and muffled or loud and clear.

5. Listen for audible fetal heart sounds. Note that two distinctly different sounds can be heard: fetal heart tones that result from blood moving through the placenta and umbilical cord (funic soufflé) and the uterine soufflé, which is the same rate as the maternal pulse.
6. Palpate the maternal radial pulse to ensure that the auscultated fetal heart sounds are at a different rate than the maternal pulse.
7. Auscultate the fetal heart sounds for the rate and rhythm. The greatest accuracy for assessment of the fetal heart rate occurs when listening for 1 minute.

Note: During active labor, 30-second intervals may be more feasible.

8. Count the FHR for 30–60 seconds between contractions to determine the baseline rate.
RATIONALE: *The baseline rate can be assessed only during the absence of uterine activity.*
9. Interpret the fetal heart rate: Is the baseline normal between 110 and 160 bpm? Is there tachycardia (baseline >160 bpm) or bradycardia (baseline <110/bpm)? Is the rhythm regular or irregular? Can you note the presence of accelerations or decelerations?
10. Repeat the procedure as indicated according to agency policy.
11. Inform the patient of the findings.
12. Document the fetal heart rate according to agency policy.

Documentation

5/15/09 1030: Fetal heart rate obtained by fetoscope at 144 bpm and regular. Acceleration of the fetal heart rate noted. Patient coping well in active labor. Contractions 3 min apart, 60-second duration with moderate intensity.

-L. Lopez, RN

intensity. The internal method is a more accurate form of fetal monitoring. However, owing to the invasive nature of the procedure, internal EFM is often reserved for high-risk pregnancies (situations in which external fetal monitoring is insufficient in obtaining the FHR or in situations where there is evidence of a non-reassuring fetal heart rate). The application of an internal electrode requires that the membranes be ruptured and that the cervix has sufficiently dilated.

The interpretation of the fetal heart rate pattern requires a holistic assessment of the maternal risk factors, uterine activity, and FHR patterns including baseline, variability and the presence of accelerations, and the identification of any decelerations. Members of the obstetrical team must maintain close communication and reach mutual consensus

regarding interpretation of fetal heart patterns. Often, nurses who practice in labor and delivery units obtain advanced training and education regarding fetal monitoring to aid in accurate interpretation.

Optimizing Outcomes— Standards for the interpretation of FHR patterns

In 1997, the National Institute of Child Health and Human Development (NICHD) published a proposed nomenclature system for EFM interpretation. Standardized definitions for FHR monitoring were presented (NICHD, 1997). Concerns regarding enhancing communication among various caregivers and patient safety (Simpson, 2004) as well as concerns about research validity have led to the

Figure 12-14 External fetal monitor.

Figure 12-15 Internal fetal monitor.

adoption of the NICHD terminology by the American College of Obstetricians and Gynecologists (ACOG, 2005) and Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN, 2003a).

Baseline Fetal Heart Rate

The **baseline fetal heart rate** (FHR) is referred to as the average fetal heart rate observed between contractions over a 10-minute period (Fig. 12-16). The recorded baseline excludes periodic FHR changes that are evidenced by increased variability or accelerations. The normal baseline fetal heart rate at term is 110 to 160 beats per minute (bpm). There are two abnormal variations of the baseline: tachycardia (baseline above 160 bpm); and bradycardia (baseline below 110 bpm) (ACOG, 2005).

TACHYCARDIA. **Tachycardia** is generally defined as a sustained baseline fetal heart rate greater than 160 beats per minute for a duration of 10 minutes or longer. A number of conditions are associated with fetal tachycardia:

- Fetal hypoxia: The fetus attempts to compensate for reduced blood flow by increasing sympathetic stimulation of the central nervous system (CNS).

Figure 12-16 The normal baseline fetal heart rate at term is 110 to 160 bpm. *Top.* Fetal heart rate. *Bottom.* Uterine contractions.

- Maternal fever: An increase in maternal temperature accelerates fetal metabolism, thus increasing the FHR. This situation may be seen in a laboring woman who becomes dehydrated or has an increased temperature following prolonged exposure in a warm bath or whirlpool.
- Maternal medications: Both parasympathetic drugs (i.e., atropine, scopolamine) and beta-sympathetic drugs (tocolytic drugs used to halt contractions) can have a stimulant effect and increase the fetal heart rate.
- Infection: Tachycardia may be an initial sign of uterine infection (amnionitis) and may precede an increased maternal temperature by 1 to 2 hours.
- Fetal anemia: In response to a decrease in hemoglobin, the FHR increases to compensate and improve tissue metabolism.
- Maternal hyperthyroidism: Thyroid-stimulating hormone (TSH) may cross the placenta and stimulate the fetal heart rate (Tucker, 2004).

BRADYCARDIA. **Bradycardia** is defined as a sustained (greater than 10 minutes) baseline FHR of less than 110 to 120 bpm. Fetal bradycardia may be associated with:

- Late hypoxia: Myocardial activity becomes depressed and lowers the fetal heart rate.
- Medications: Beta-adrenergic blocking drugs (e.g., propranolol [Inderal]).
- Maternal hypotension: Results in decreased blood flow to the fetus and can lower the FHR. Maternal hypotension can result from positioning (i.e., supine hypotension) and is a common side effect associated with an epidural or spinal anesthetic.
- Prolonged umbilical cord compression: Stimulates fetal baroreceptors that cause vagal stimulation and a decreased FHR.
- Bradyarrhythmias: With complete heart block, the FHR baseline is often as low as 70 to 90 bpm (Tucker, 2004).

VARIABILITY

Variability of the FHR is manifested by fluctuations in the baseline fetal heart rate observed on the fetal monitor. The pattern denotes an irregular, changing FHR rather than a

straight line that indicates few changes in the rate. The variability of the FHR is a result of the interplay between the fetal sympathetic nervous system, which assists to increase the heart rate and the parasympathetic nervous system, which acts to decrease the heart rate.

Variability can further be classified as short-term or long-term variability. Short-term variability is the beat to beat changes in the FHR and is most accurately assessed with an internal electrode. Long-term variability refers to the changes in fetal heart rate over a longer period of time such as 1 minute. The absence of or undetected variability is considered non-reassuring. Health care providers are able to assess the overall amount of (long-term) variability and describe it as absent, minimal, moderate, or marked (Table 12-5).

The presence of adequate (moderate) variability is an important indicator of fetal well-being. FHR variability is indicative of an adequately oxygenated neurological pathway in which impulses are transmitted from the fetal brain to the cardiac conduction system (Fox, Kilpatrick, King, & Parer, 2000). An electronic fetal monitor tracing that records the FHR as a changing, jagged line is reflective of an adequately oxygenated, responsive fetal brain and fetal heart.

Conversely, the absence of variability may indicate normal variations such as fetal sleep (the sleep state should not last longer than 30 minutes), a response to certain drugs that depress the CNS, such as analgesics (meperidine [Demerol]), tranquilizers (diazepam [Valium]), barbiturates (secobarbital [Seconal] and pentobarbital [Nembutal]), ataractics (promethazine [Phenergan]), and general anesthetics or a pathological condition such as hypoxia, a CNS abnormality, or acidemia.

ACCELERATIONS

An **acceleration** is defined as an increase in the FHR of 15 bpm above the fetal heart baseline that lasts for at least 15 to 30 seconds. Accelerations are considered a sign of fetal well-being when they accompany fetal movement. Thus, when a fetus is active in utero, accelerations are

Table 12-5 Classifications of FHR Variability and Possible Causes

Variability	Amplitude of FHR Changes	Causes
Absent	Undetectable	May represent fetal cerebral asphyxia. Warrants immediate evaluation.
Minimal	>2–<5 beats per minute (bpm)	May be related to narcotics, tranquilizers, magnesium sulfate, barbiturates, anesthetic agents, prematurity or fetal sleep.
Moderate	6–25 bpm	Reassuring; indicates fetal well-being
Marked	>25 bpm	Marked variability is believed to be a less common response to fetal hypoxia.

Figure 12-17 Top. Fetal heart rate accelerations. Bottom. Uterine contractions.

normally present. Consequently, when the fetus is sleeping or not moving, limited FHR accelerations may be noted.

When contractions are present, accelerations are often noted as a response to the contraction. This type of periodic FHR acceleration with contractions is thought to be a compensatory accelerative response to a transient decrease in blood flow to the fetus. Accelerations may occur before, during, or after a contraction. Accelerations are often associated with a normal FHR baseline and normal variability (Fig. 12-17).

DECELERATIONS

Decelerations are defined as any decrease in FHR below the baseline FHR. Decelerations are further defined according to their onset and are characterized as early, variable, and late.

Early Decelerations

Early decelerations are characterized by a deceleration in the FHR that resembles a mirror image to the contraction. Therefore, the onset of the deceleration begins near the onset of the contraction, the lowest part of the deceleration occurs at the peak of contraction, and the FHR returns to baseline by the end of the contraction. Early decelerations are usually repetitive and are commonly observed during active labor and descent of the fetus (Fig. 12-18).

Figure 12-18 Top. Early decelerations. Bottom. Uterine contractions.

Early decelerations are considered benign and are usually well tolerated by the fetus. They are believed to be related to fetal head compression and the resulting vagal stimulation that slows the FHR. They may occur during vaginal examinations, uterine contractions, and during placement of the internal mode of fetal monitoring. Early decelerations are viewed as a reassuring FHR pattern when accompanied by normal baseline FHR and normal variability.

Variable Decelerations

Variable decelerations, as the name implies, are decelerations that are variable in terms of their onset, frequency, duration, and intensity. The decrease in FHR below the baseline is 15 bpm or more, lasts at least 15 seconds, and returns to the baseline in less than 2 minutes from the time of onset (NICHD, 1997) (Fig. 12-19). The deceleration is unrelated to the presence of uterine contractions. Variable decelerations are thought to be a result of umbilical cord compression. Thus, the degree by which the cord is compressed (partially versus completely) can affect the severity of the deceleration. For example, a cord that is briefly compressed by the fetus may be manifest as a very abrupt decrease in the FHR with a rapid return to baseline. Conversely, a cord that is tightly wrapped around the fetal neck (**nuchal cord**) progressively becomes more compressed as the fetus descends into the maternal pelvis. This situation is most likely to result in longer, more severe decelerations. In general, brief, occasional decelerations are often considered benign whereas repetitive, worsening variable decelerations are cause for concern and always warrant further investigation.

The American College of Obstetricians and Gynecologists (ACOG, 2005) classifies variable decelerations as significant when the FHR falls below 70 bpm and lasts longer than 60 seconds. In addition, the Society of Obstetricians and Gynaecologists of Canada (SOGC, 2005) concurs and further identifies “non-reassuring” or “atypical” variable decelerations as:

- Deceleration to less than 70 bpm lasting greater than 60 seconds
- Loss of variability in the baseline FHR and in the trough of the deceleration
- Biphasic deceleration
- Slow return to baseline

Figure 12-19 Top. Variable decelerations. Bottom. Uterine contractions.

- Continuation of a baseline at a lower level that before the deceleration
- The presence of fetal tachycardia

Optimizing Outcomes— Amnioinfusion to relieve cord compression

Amnioinfusion is the infusion of warmed normal saline into the uterus via sterile catheter (IUPC). Amnioinfusion may be used in an attempt to reduce the severity of variable decelerations caused by cord compression. The nurse assists with the procedure by assembling the equipment; monitoring the FHR, contraction status, and maternal temperature; and by verifying that the infused fluid is exiting the uterus.

Late Decelerations

The patterns of late decelerations typically mirror the contraction, and this characteristic is similar in appearance to early decelerations. With late decelerations, the deceleration has a late onset and begins around the peak of the contraction (Fig. 12-20). This type of deceleration does not resolve until after the contraction has ended. Late decelerations indicate the presence of **uteroplacental insufficiency**, a decline in placental function. Normally, the fetus can withstand repeated contractions with sufficient oxygenation. However, in this circumstance a decrease in blood flow from the uterus to the placenta results in fetal hypoxia and late decelerations.

Late decelerations require prompt attention and reporting. The longer the late decelerations persist, the more serious they become. Immediate attempts should be made to correct the cause of the late decelerations if possible. For example, late decelerations in the presence of an oxytocin infusion may signal a need to immediately discontinue the oxytocin infusion, especially if uterine hyperstimulation is suspected. Nursing interventions that should be implemented immediately include reporting the late decelerations, changing the maternal position, discontinuing the oxytocin infusion, increasing the intravenous fluids, and administering oxygen by mask.

Figure 12-20 Top. Late decelerations. Bottom. Uterine contractions.

It is important to note that late decelerations can present very obviously or very subtly. In addition, late decelerations are often accompanied by other non-reassuring fetal heart patterns such as a loss of or decrease in variability.

Nursing Insight— Potential causes of uteroplacental insufficiency

Late decelerations that are caused by uteroplacental insufficiency may be related to uterine hyperstimulation with oxytocin, postdate or preterm pregnancy, amnionitis, preeclampsia, small for gestational age (SGA) fetus, placenta previa, abruptio placentae, maternal diabetes, conduction anesthesia that causes maternal hypotension, maternal cardiac disease and maternal anemia.

INTERPRETATION OF FHR TRACINGS

A systematic approach to the interpretation of FHR tracings ensures that all possibilities are considered. Most institutions have established protocols to guide electronic fetal heart monitoring methods and to maintain consistency in the interpretation of FHR patterns. When assessing FHR tracings, nurses should consider factors such as contraction frequency and intensity, stage of labor, and the earlier FHR pattern.

critical nursing action Interpreting Fetal Monitor Tracings

To aid in the interpretation of EFM tracings, the nurse should consider the following parameters:

- **Uterine activity:** What is the frequency, duration, and intensity of contractions?
- **Labor progress:** What is the stage of labor? What is the dilation, effacement, station, presentation, and position?
- **Baseline FHR:** What is the baseline FHR? Is tachycardia or bradycardia present?
- **Baseline variability:** What is the variability of the FHR (absent, minimal, moderate, marked, or other)?
- **Periodic changes in FHR:** Are there any FHR changes from the baseline? Are accelerations present? Are any decelerations present? If decelerations are present are they early, variable, late, or prolonged?
- **Maternal history and condition:** Are there any pre-existing conditions that increase risk for this pregnancy? Are there any intrapartum high-risk factors (e.g., meconium) that should be noted?

Based on a systematic interpretation, FHR tracings are generally classified as reassuring or non-reassuring (Box 12-4). This classification helps to determine the need for interventions. In general, a reassuring (normal) FHR tracing is generally associated with fetal well-being. Routine assessment of the fetal heart rate is conducted according to the birth center protocol. A non-reassuring tracing indicates an urgent need to notify the physician (or nurse midwife) and implement appropriate interventions.

Box 12-4 Characteristics of Reassuring and Non-reassuring FHR Patterns by EFM

REASSURING PATTERNS

- Normal baseline FHR
- Presence of short-term and long-term variability
- Presence of accelerations with fetal movement or contractions
- Early decelerations may be noted in active labor

NON-REASSURING PATTERNS

- Absence of variability (short-term and long-term)
- Late decelerations
- Severe variable decelerations
- Prolonged decelerations
- Severe bradycardia or tachycardia

Source: Tucker, S. (2004). *Pocket guide to fetal monitoring and assessment* (5th ed.). St. Louis, MO: C.V. Mosby.

It is important to note that when non-reassuring FHR patterns are identified, there is often a combination of more than one non-reassuring feature such as late decelerations and decreased variability or tachycardia and absent variability. When a non-reassuring FHR pattern is present, it is imperative to intervene immediately in an effort to correct the problem and prevent the worsening of symptoms.

Optimizing Outcomes— Communicating about FHR patterns

In clinical practice, various guidelines exist concerning the management of FHR tracings. Accurate, consistent, and timely communication among health care providers is always required to optimize outcomes for the patient and her fetus.

Be sure to— Use appropriate terminology during documentation of FHR auscultation

When documenting the findings from FHR auscultation, descriptive terms associated with EFM such as “marked variability” or “variable deceleration” should be avoided because these terms reflect visual descriptions of the patterns produced on the monitor tracing. Terms that are numerically defined (i.e., “bradycardia,” “tachycardia”) may be used. When auscultated, FHR must be described as a baseline number or range and as having a regular or irregular rhythm. The presence or absence of accelerations or decelerations that occur during and after contractions should be noted (AWHONN, 2000; 2003b).

NURSING INTERVENTIONS AND DIAGNOSES

Early decelerations are considered to be benign and no action is necessary. However, it is important to identify them so that they can be differentiated from late or variable decelerations. Depending on the cause, interventions

for variable and late decelerations include lateral position changes (to displace the weight of the gravid uterus off the inferior vena cava), oxygen administration at 8 to 10 L per minute by face mask, palpation of the uterus for hyperstimulation, discontinuation of oxytocin if infusing, increasing the rate of the maintenance intravenous solution, and assisting with fetal oxygen saturation monitoring if ordered. Possible nursing diagnoses include impaired fetal gas exchange related to umbilical cord compression or placental insufficiency; decreased maternal cardiac output related to supine hypotension secondary to position; and anxiety related to lack of knowledge concerning fetal monitoring/fetal well-being during labor.

Now Can You— Assess FHR patterns detected by EFM?

1. Describe situations when electronic fetal monitoring instead of intermittent auscultation is indicated?
2. Define the following frequently used terminology: baseline fetal heart rate, variability, acceleration, deceleration?
3. Describe the assessment of a reassuring and a non-reassuring fetal heart rate?
4. List four nursing interventions for variable and late decelerations?

Second Stage of Labor

The second stage of labor commences with full dilation of the cervix and ends with the birth of the infant. Often the woman or nurse may suspect that the woman has entered the second stage of labor because of the patient's urge to push or the presence of involuntary bearing down efforts. The contractions often remain very similar to those experienced during the transition stage. They continue to occur frequently and are very intense. The woman may exhibit varying emotions during the second stage. Some patients may get a spurt of energy or a "second wind" to help them get through the second stage. Others may be nervous or fearful of the new sensations that they are feeling. Encouragement and support from the labor nurse and

support person are crucial at this stage. The woman is not to be left alone during this time, and continuous support should be provided. It is important to encourage the patient to rest between pushing in order to maintain her energy throughout the second stage.

The duration of the second stage is variable and may be influenced by several factors such as parity; the type and amount of analgesia or anesthesia administered; the frequency, intensity, and duration of contractions; maternal efforts in pushing, and the support the patient receives. For nulliparous women, the second stage often involves 1 to 2 hours of pushing. Multiparous women typically experience a much shorter second stage and childbirth may occur within minutes following full cervical dilation.

PROMOTING EFFECTIVE PUSHING

Women push most effectively when they experience the urge to bear down and push. The urge to push is believed to be stimulated by the Ferguson reflex as the presenting part stretches the pelvic floor muscles. Thus, the maternal urge to push may be more related to the station of the presenting part rather than to the dilation of the cervix.

Differing practices exist regarding the promotion of pushing during the second stage. Many practitioners believe that pushing should be encouraged only when the woman has the urge to push, instead of when full cervical dilation has been reached. Some women (i.e., those with an epidural analgesia or other types of anesthesia) may have no urge to bear down. When this situation occurs, a process called "laboring down" may be used. "Laboring down" allows the woman to rest as the fetus descends. Pushing is postponed until the urge to push is experienced. Research suggests that there is a decrease in maternal fatigue and an increase in fetal oxygenation when women delay pushing until they feel the urge (Minato, 2000; Roberts, 2003). It has been proposed that the decision concerning when to initiate pushing should be based on the individual maternal response rather than on standardized routine practices. Furthermore, the duration of active maternal pushing has been found to be more closely related to the neonate's condition at birth than the duration of the second stage of labor (Cesario, 2004; Minato, 2000; Roberts, 2002).

There are generally two methods of pushing during the second stage of labor: closed-glottis and open-glottis pushing. Closed-glottis pushing, also referred to as "directed pushing," is the traditional method, in which women are encouraged to begin pushing at full cervical dilation regardless of the urge to bear down. The woman is encouraged to take a deep breath and hold it for at least 10 seconds while pushing as hard and as long as she is able throughout the contraction. Simpson and Creehan (2001) identify this practice as outdated and physiologically inappropriate. They assert that there is a lack of scientific evidence to support closed-glottis pushing and point out that this practice has been associated with adverse outcomes including fetal hypoxia, acidemia, and lower neonatal Apgar scores. The poor outcomes are believed to result from prolonged maternal breath holding that ultimately affect uteroplacental blood flow.

Open-glottis pushing, also referred to as "involuntary pushing," is another method of pushing. With this technique, the laboring woman is encouraged to hold her

where research and practice meet: Use of EFM

Researchers evaluated nine randomized controlled trials that included 18,561 low- and high-risk pregnant women from diverse countries to compare the efficacy and safety of routine continuous EFM during labor with intermittent auscultation. Overall, there was a statistically significant decrease in the incidence of neonatal seizures in infants subjected to EFM. They found no significant differences between patients who received electronic fetal monitoring or intermittent auscultation during labor on: Apgar scores of infants at 1 minute of less than 7 or less than 4, rate of admission to neonatal intensive care units, perinatal deaths, or the development of cerebral palsy. However, there was an increased rate of cesarean delivery and operative vaginal delivery with the use of EFM. Implications for clinical practice include the following: (1) EFM may exert a preventative effect on neonatal seizures and (2) the use of EFM appears to increase the rate of maternal operative deliveries, a factor that may balance or outweigh the potential benefits of its use (Thacker, Stroup, & Chang, 2005).

breath for only 5 to 6 seconds during pushing and to take several breaths between each bearing down effort. In addition, women are allowed to exhale throughout the bearing down attempts. This process is believed to produce no compromise to the uteroplacental blood flow and therefore is thought to invoke less stress on the fetus.

Variations in pushing techniques are found in clinical practice. Regardless of the process used for second-stage pushing, laboring women require continuous support and encouragement from their health care provider(s). It is important to calmly provide easy-to-understand, consistent information to avoid confusion. It is also important to remember that the patient and her partner can become anxious and confused if several people attempt to give directions at the same time.

ACHIEVING A POSITION OF COMFORT

During the second stage, comfort measures remain equally important and many of the interventions and positioning identified for the first stage of labor can be implemented during the second stage as well. Many factors (e.g., the woman's personal preferences, the use of analgesia or anesthesia, the preferences of the health care practitioner, and the imminence of birth) have an influence on the optimal maternal position during this stage. When pushing, women are encouraged whenever possible to maintain an upright or semi-upright position, such as squatting, sitting, standing, kneeling, on all fours, or sitting on the toilet.

Pushing when in an upright position allows the use of gravity to promote fetal descent and has been associated with a shortened labor. Positions such as squatting and kneeling may also help to increase the dimensions of the maternal pelvis. Assuming a hands and knees position or leaning over a table or chair helps to take pressure off the maternal spine and often reduces backache commonly associated with a fetal occipital–posterior position (see Fig. 12-12).

Now Can You— Discuss comfort measures and pushing techniques for the second stage of labor?

1. List three comfort measures used during the first stage of labor that would also be effective during the second stage of labor?
2. Discuss how the nurse can advocate for a patient who does not have the urge to push in the second stage?
3. List two positions for pushing and provide one advantage of each?

PREPARATION FOR THE BIRTH

As the fetus descends, the woman experiences an increasing urge to bear down due to pressure of the fetal head on the sacral and obturator nerves. As the patient pushes, contraction of the abdominal muscles exerts intra-abdominal pressure. With the maternal bearing down efforts and further descent of the fetus, the nurse may notice bulging of the perineum and rectum. As the fetal head progresses downward, the perineum begins to stretch, thin out, and move anteriorly. The amount of bloody show may increase at this time and the labia begin to part with each contraction. The fetal head, which may be observable at the vaginal

introitus, often appears to recede between contractions. As the contractions and maternal pushing efforts continue, the presenting part descends farther.

Crowning, which means that birth is imminent, occurs when the fetal head is encircled by the vaginal introitus (Fig. 12-21). Some women may complain of a burning sensation as the perineum is stretched. This experience can be frightening for the woman and it is important for the nurse to identify it as a normal sensation. The woman may also feel intense pressure in the rectum and a need to evacuate her bowels. Again, the nurse should confirm the normalcy of these sensations and continue to offer encouragement and support. If the woman does pass stool, she should be cleaned in a timely manner. Some women may feel as though they are losing control and a variety of emotions (e.g., irritability, fear, embarrassment, and helplessness) may be displayed. These behaviors can be frightening to the support person as well. The nurse needs to continue to encourage and reinforce to the woman and her support person that these reactions are normal and that progress is being made.

EPISIOTOMY

Episiotomy is a surgical incision of the perineum that is performed to enlarge the vaginal orifice during the second stage of labor (Carroli & Belizan, 2006). The frequency of routine episiotomy has decreased over the last 20 years as the benefits of performing routine episiotomy began to be questioned. In the 1980s, the episiotomy rate was reported to be approximately 64 out of 100 births. At that time, many physicians routinely performed episiotomies based on the belief that surgical enlargement of the vaginal opening would prevent intrapartum complications such as protracted second stage of labor, fetal trauma, and severe lacerations, and later maternal problems such as cystocele, rectocele, dyspareunia, and uterine prolapse.

Many women questioned the use of routine episiotomy and current practices have changed to reflect existing evidence that routine episiotomy has not been associated with better outcomes over selective episiotomy. In studies where episiotomy had been performed for medical indications, the results demonstrated positive benefits. When medically indicated, episiotomy was associated with decreased posterior perineal trauma and suturing and

Figure 12-21 Crowning.

fewer complications. No differences were found in maternal pain experience or the incidence of severe vaginal perineal trauma when routine and selective episiotomies were compared. There was an increased risk of anterior perineal trauma associated with selective episiotomy (Carroll & Belizan, 2006). Many practitioners currently reserve the use of episiotomy for medical indications, which include instrumentation during birth (forceps or vacuum), a need to expedite the birth (evidence of fetal compromise), or in the event of maternal exhaustion.

Two different methods are used for the episiotomy. The most common method is the midline or median episiotomy. An incision is made from the vaginal opening downward toward the rectum. A midline episiotomy is easily repaired, heals quickly, and is associated with less postoperative pain than a mediolateral episiotomy. However, the primary disadvantage of a midline episiotomy is the risk of third- and fourth-degree lacerations with extension through the rectal sphincter. The mediolateral episiotomy is less common. An incision is made from the vagina to the 5 o'clock or 7 o'clock position (the maternal left mediolateral or right mediolateral position). Compared to a midline incision, the mediolateral episiotomy is associated with a smaller risk of fourth-degree lacerations although third-degree lacerations may occur. The amount of blood loss is usually greater, the surgical repair is more difficult, and there is increased pain postpartum (Fig. 12-22).

Complementary Care: Methods to decrease perineal trauma

Various strategies to decrease the risk of perineal trauma during the second stage of labor have been implemented and evaluated. These include perineal massage (antenatal and intrapartal), application of warm compresses, use of lubricating oils, and manual support. However, research has demonstrated variable results and further investigation is indicated. Maternal positioning for birth has also shown variable results regarding its effect on perineal trauma. Soong and Barnes (2005) found that women who gave birth in a semirecumbent position had an increased need for sutures for perineal lacerations than women who gave

Figure 12-22 An episiotomy is a surgical incision of the perineum that is performed to facilitate birth. The most common method is the midline or median episiotomy. An incision is made from the vaginal opening downward toward the rectum.

birth in an “all fours” position. In addition, women who received regional anesthesia also demonstrated an increased need for suturing than women who gave birth in a lateral position.

Nurses should be aware of the potential benefits and risks associated with various techniques intended to help minimize perineal trauma. It is important for nurses to remain open-minded, encouraging, and supportive of patients who wish to utilize alternate methods to help facilitate perineal stretching.

Now Can You— Discuss factors associated with impending childbirth?

1. Explain the significance of crowning?
2. Discuss the controversies surrounding routine episiotomy?
3. Identify three strategies that may be effective in reducing perineal trauma during childbirth?

Birth

As the fetal head is crowning, the perineum is stretched very thin and the anus stretches and protrudes. With continued maternal pushing efforts, the fetal head extends under the symphysis pubis and is born. The practitioner assisting at the birth may prefer to coach the patient regarding pushing and breathing, as the birth of the head should occur in a controlled manner in an attempt to limit injury to the perineum. Once the anterior shoulder reaches the pelvic outlet, it rotates to the midline and is delivered from under the pubic arch. The posterior shoulder is guided over the perineum, and the body follows.

THE CARDINAL MOVEMENTS

The **cardinal movements**, or mechanisms of labor, have been used to describe how the fetus (in a vertex presentation) passes through the birth canal and the positional changes required to facilitate birth (Fig. 12-23). The cardinal movements are presented in the order in which they occur.

Descent

Four forces facilitate **descent**, which is the progression of the fetal head into the maternal pelvis: (1) pressure of the amniotic fluid; (2) direct pressure of the uterine fundus on the fetal breech; (3) contraction of the maternal abdominal muscles; and (4) extension and straightening of the fetal body. The fetal head enters the maternal inlet in the occiput transverse or the oblique position because the pelvic inlet is widest from side to side. The sagittal suture is equidistant from the maternal symphysis pubis and sacral promontory. The degree of fetal descent is measured by stations.

Flexion

Flexion occurs as the fetal head descends and comes into contact with the soft tissues of the pelvis, the muscles of the maternal pelvic floor, and the cervix. The resistance encountered with these structures causes the fetal chin to flex downward onto the chest. This position allows the smallest fetal diameters to enter the maternal pelvis.

Figure 12-23 The cardinal movements, or mechanisms of labor.

Internal Rotation

To fit into the maternal pelvic cavity, which is widest in the anteroposterior diameter, the fetal head must rotate. As the occiput of the fetal head comes into contact with the levator ani muscles and surrounding fascia, it meets with resistance. This causes the occiput to rotate, usually from left to right, and the sagittal suture aligns with the long axis of the maternal pelvis (the anteroposterior pelvic diameter).

Extension

As the fetal head passes under the maternal symphysis pubis, it meets with resistance from the pelvic floor. The head pivots and extends with each maternal pushing effort. The head is born in extension as the occiput slides under the symphysis and the face is directed toward the rectum. The fetal brow, nose, and chin then emerge.

Restitution

Internal rotation causes the fetal shoulders to enter the maternal pelvis in an oblique position. After the head is delivered in the extended position, it rotates briefly to the position it occupied when it was engaged in the inlet. This movement is termed restitution. The 45-degree turn of the fetal head facilitates realignment with the long axis of the body.

External Rotation

As restitution continues, the shoulders align in the anteroposterior diameter, causing the head to continue to turn farther to one side (external rotation). The fetal trunk moves through the pelvis with the anterior shoulders descending first.

Expulsion

After external rotation, maternal pushing efforts bring the anterior shoulder under the symphysis pubis. Lateral flexion of the shoulder and head occurs and the anterior, then posterior, shoulder is born. Once the shoulders are delivered, the rest of the body quickly follows.

CLAMPING THE UMBILICAL CORD

Much controversy exists concerning the issue of when and how to clamp the umbilical cord. When the newborn is held above the level of the placenta, a transfer of blood occurs from the newborn back to the placenta. Conversely, delaying the umbilical cord clamping and holding the newborn below the level of the placenta can result in a transfer of 50 to 100 mL of blood from the placenta to the newborn. The additional blood may be beneficial in reducing infant iron deficiency, although this practice

may also contribute to polycythemia and potential hyperbilirubinemia.

The primary care provider places two Kelly clamps on the umbilical cord, and may invite the father or birth support person to cut the cord between the two clamps. Either the primary care provider or the nurse then places a plastic clamp on the umbilical cord approximately 0.5 to 1 inch (1.2 to 2.5 cm) from the newborn's abdomen, being careful to not catch the abdominal skin in the clamp. The nurse observes the cut cord for the presence of three blood vessels: two arteries and one vein. Samples of cord blood are collected for laboratory analysis. Some parents request to have their newborn's cord blood "banked" in the event that the stem cells in the cord blood may be required in the future for the treatment of a family illness. A vaginal birth sequence is presented in Figure 12-24.

Possible Nursing Diagnoses for the Intrapartal Patient

Examples of common nursing diagnoses during labor and birth are listed below. It is important to be cognizant of individual differences among patients. While these are common nursing diagnoses, they will vary among individuals and stages of labor.

- Pain related to increasing frequency, duration, and intensity of contractions
- Knowledge deficit related to pain management techniques for active labor
- Anxiety related to the previous birth experience
- Fatigue related to a prolonged latent phase labor
- Risk for infection related to prolonged rupture of membranes

- Impaired fetal gas exchange related to umbilical cord compression
- Decreased maternal cardiac output related to supine hypotension secondary to maternal position

 **Now Can You—** Discuss cardinal movements and umbilical cord clamping?

1. Describe what is meant by the cardinal movements?
2. Compare and contrast early versus late clamping of the umbilical cord?

Third and Fourth Stages of Labor

Nursing care during the third and fourth stages of labor is focused on providing immediate care for the newborn in the adjustment to extrauterine life, assisting with the delivery of the placenta, monitoring and assisting the mother with the physiological adjustments of labor and birth, and facilitating the attachment between the mother and baby. Characteristics of the third and fourth stages of labor are presented in Table 12-6.

Third Stage of Labor

The third stage of labor is the period of time from the birth of the baby to the complete delivery of the placenta. This stage usually lasts 5 to 10 minutes, and may last up to 30 minutes. Once the baby is born, the uterine cavity immediately becomes smaller. The change in the interior dimension of the uterus results in a reduction in the size of the placental attachment site. This event leads to the

Table 12-6 Characteristics of the Third and Fourth Stages of Labor

	Third Stage	Fourth Stage
Description	Begins with the birth of the infant and ends with the delivery of the placenta. Usually takes 5–10 minutes, and may take up to 30 minutes.	A time of physiological adaptation that begins following delivery of the placenta and lasts 1–2 hours.
Contractions	The uterus should be firmly contracted.	The uterus should be firmly contracted.
Assessment	Uterus becomes globelike.	Uterus remains firmly contracted.
	Uterus rises upward.	Lochia rubra, bright red blood flow with occasional small clots.
	Umbilical cord descends further.	Vital signs return to prelabor values.
	Gush of blood as placenta detaches.	
Physical discomforts	Some discomfort or cramping as the placenta is expelled.	Some experience perineal discomfort usually related to trauma from the episiotomy or tearing, or hemorrhoids.
Maternal behaviors	Focus on infant well-being.	Excited, tired.
	Crying common. Expressions of relief.	Bonding and attachment with infant.
	Culturally influenced.	Initiation of breastfeeding.
		Culturally influenced.

Figure 12-24 Vaginal birth sequence. *A.* Pushing in an upright position allows the use of gravity to promote fetal descent. *B.* Crowning. *C.* Birth of the head. *D.* Birth of the shoulders. *E.* The infant is shown to the new parents. *F.* The baby's father cuts the umbilical cord.

separation of the placenta from the uterus. The following clinical indicators signal that separation of the placenta from the uterus has occurred:

- The uterus becomes spherical in shape.
- The uterus rises upward in the abdomen due to the descent of the placenta into the vagina.
- The umbilical cord descends further through the vagina.
- A gush of blood occurs once the placenta detaches from the uterus.

The placenta is expelled in either the Schultze or Duncan manner (Fig. 12-25). The **Schultze mechanism** (“shiny Schultze”) occurs when the placenta separates from the inside to the outer margins with the shiny, fetal side of the placenta presenting first. It is the most common method of placental expulsion. The **Duncan mechanism** occurs when the placenta separates from the outer margins inward, rolls up, and presents sideways. Since the placental surface is rough, the Duncan mechanism is commonly called “dirty Duncan.”

As the placenta separates from the uterine wall, it is important that the uterus continues to contract. The contractions minimize the bleeding that results from the open blood vessels left at the placental attachment site. Failure of the uterus to contract adequately with separation of the placenta can result in excessive blood loss or hemorrhage. To enhance the uterine contractions after expulsion of the placenta, oxytocic medications are often given. Oxytocin is administered either by the intravenous (IV) route or by intramuscular (IM) injection.

NURSING CARE OF THE MOTHER DURING THE THIRD STAGE OF LABOR

After the birth of the infant, the nurse observes for signs that the placenta has separated from the wall of the uterus. The uterus is palpated to determine the rise upward as well as the characteristic change in shape from one resembling a disk to that of a globe. The nurse may ask the woman to push again, to facilitate in the delivery of the placenta. If 30 minutes have elapsed from completion of

medication: Oxytocin

Oxytocin (ox-i-toe-sin)

Pitocin, Syntocinon

Pregnancy Category: X (intranasal), UK (IV, IM)

Indications:

Induction of labor at term
Facilitation of uterine contractions at term
Facilitation of threatened abortion
Control of postpartum bleeding after expulsion of placenta

Actions: Stimulates uterine smooth muscle producing uterine contractions similar to those in spontaneous labor (administered intravenously). Stimulates mammary gland smooth muscle facilitating lactation (administered intranasally). Has vasopressor and diuretic effects.

Therapeutic Effects: Induces labor. Reduces postpartum bleeding. Induces breast milk letdown.

Pharmacokinetics:

ABSORPTION: Well-absorbed from the nasal mucosa when administered intranasally.

DISTRIBUTION: Through extracellular fluid. Small amounts reach fetal circulation.

METABOLISM: Metabolized rapidly in kidneys and liver.

EXCRETION: Small amounts excreted in urine, half-life 3–9 minutes.

Contraindications and Precautions:

Contraindicated in CPD or deliveries that require conversion (i.e., transverse lie). Use with caution in first and second stages of labor.

Adverse Reactions and Side Effects: Maternal adverse reactions are associated with IV use only. Painful contractions and increased uterine motility most common. May contribute to maternal coma, seizures, hypotension. May contribute to fetal asphyxia or arrhythmias.

Route and Dosage: May be added to IV for labor induction or given IV or IM to control postpartum bleeding (do not administer IM and IV routes simultaneously). Intranasal spray is administered 2–3 minutes before planned breastfeeding.

Nursing Implications:

Fetal maturity, presentation, and maternal pelvic adequacy should be assessed before administration to induce labor.

Monitor contractions, resting uterine tone, and FHR frequently.

Monitor uterus for firmness and early detection of boggy.

Monitor lochia for signs of excessive bleeding.

Adapted from Deglin, J.H., and Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

Figure 12-25 Third stage of labor: separation and expulsion of the placenta. A. Schultze mechanism. B. Duncan mechanism.

the second stage of labor and the placenta has not yet been expelled, it is considered to be “retained”. (See Chapter 14 for further discussion.)

Oxytocic medications such as Pitocin and Syntocinon are often administered at the time of the delivery of the placenta. These drugs are used to stimulate uterine contractions, thereby minimizing the bleeding from the placental attachment site and reducing the risk of postpartum hemorrhage. The nurse administers oxytocic medications according to institutional protocol. If a peripheral intravenous infusion has been established, oxytocin 10 to 20 units may be added to the intravenous infusion. If no intravenous infusion is present, 10 units of oxytocin may be administered intramuscularly. In situations where there is excessive blood loss, the physician may order up to 40 units of oxytocin per liter of intravenous infusion fluid. Other medications such as methylergonovine maleate (Methergine) or carboprost tromethamine (Hemabate) may be given intramuscularly to control blood loss. During this time the nurse continues to assess the volume of blood loss and monitor the patient’s vital signs, paying close attention to the blood pressure and heart rate.

Once the placenta has been delivered, the nurse carefully examines it to ensure that all cotyledons are intact (Fig. 12-26). If any part of the placenta is missing, the nurse immediately reports this finding to the attending physician. Because retained placental fragments can contribute to postpartum hemorrhage or infection, the physician may perform a manual exploration of the uterus to remove any remaining placental tissue.

Emotional Support

The birth of the newborn is an emotional experience for the patient and her support person. Hearing the infant’s first cry can evoke tears, laughter, and feelings of relief,

Figure 12-26 Examination of the placenta.

accomplishment, and amazement. The nurse can support the mother and birth partner by promoting contact with the infant. The stable newborn can be placed on the maternal abdomen, and as soon as possible, the nurse can help the mother into a comfortable position to hold the infant.

Initiating Infant Attachment

Once the birth has taken place, the time that immediately follows is ideal for fostering attachment between the mother, her birth partner, and the newborn. The infant is in a stage of alertness during the first hour after birth and is responsive to voice, touch, and gaze. The nurse can facilitate eye-to-eye contact between the patient and her neonate by dimming the room lights. This occasion also provides an excellent time to initiate breastfeeding if the mother wishes to do so.

Immediate Nursing Care of the Newborn

Once the newborn has been born, the primary care provider (physician or certified nurse midwife) places the infant on the mother’s abdomen (if the infant is stable), in a modified Trendelenburg position. This immediate contact between mother and newborn provides reassurance to the mother regarding the overall well-being of the baby, and begins the attachment process.

Birth signals the transition from fetus to newborn. Several physiological adaptations must occur to facilitate the adjustment of the newborn to the extrauterine environment. Of primary importance is the initiation of the newborn’s respirations, a process that results in the replacement of fetal lung fluid with air. In most situations, the actions of drying the newborn and performing nasopharyngeal suctioning, if needed, provide adequate stimulation to initiate the newborn’s respiratory effort. While respirations are being established, the newborn’s cardiovascular system is also undergoing major adaptations to allow the flow of deoxygenated blood into the lungs for gas exchange. Fetal circulation transitions to neonatal circulation after closure of the ductus arteriosus, the foramen ovale, and the ductus venosus. (See Chapter 17 for further discussion of the physiological transitions in the newborn.)

The modified Trendelenburg position facilitates the drainage of mucus from the newborn’s nasopharynx and trachea. The nurse suction the newborn’s nose and mouth with a bulb syringe as needed. Preventing heat loss in the neonate constitutes an important nursing role. Before the infant is placed on the mother’s abdomen, the nurse dries the infant, discards the wet linens, and applies warm blankets. Skin-to-skin contact between the mother and baby also helps to maintain the newborn’s temperature.

THE APGAR SCORING SYSTEM

The nurse assesses this transition stage after one minute and again after 5 minutes, using the **Apgar Scoring System** (Apgar, 1966). The Apgar scoring system evaluates

five signs of newborn cardiopulmonary adaptation and neuromuscular function: heart rate, respiratory effort, muscle tone, reflex irritability, and color (Table 12-7).

HEART RATE. The priority assessment of the newborn is the heart rate. On auscultation or palpation, the nurse recognizes an absent heart rate or heart rate less than 100 bpm as a signal for resuscitation.

RESPIRATORY EFFORT. The newborn's vigorous cry best indicates adequate respiratory effort, the next most important assessment after birth. A weak or absent cry is a signal for intervention.

MUSCLE TONE. The nurse determines the newborn's muscle tone by assessing the response to the extension of the extremities. Good muscle tone is noted when the extremities return to a position of flexion.

REFLEX IRRITABILITY. The nurse assesses reflex irritability by observing the newborn's response to stimuli such as a gentle stroking motion along the spine or flicking the soles of the feet. When this stimulation elicits a cry, the score is 2. A grimace in response to stimulation scores 1, and no response is a score of 0.

COLOR. The nurse assesses skin color for pallor and cyanosis. Most newborns exhibit cyanosis of the extremities at the 1-minute Apgar check, and this normal finding is termed **acrocyanosis**. A score of 2 indicates that the infant's skin is completely pink. Newborns with darker pigmented skin are assessed for pallor and acrocyanosis.

IDENTIFICATION OF THE NEWBORN

Another important nursing action involves placing matching identification bands on the infant and the mother. Some hospitals also provide identification bands for the father or other designated birth support person. The infant's identification bands are placed snugly enough so that when the initial weight loss occurs, the ID band does not fall off. Agency protocols may also direct the nurse to footprint the newborn. (See Chapter 18 for further discussion.)

Table 12-7 The Apgar Scoring System

Physiological Parameter	Score		
	0	1	2
Heart Rate	Absent	Slow: below 100	Above 100
Respiratory Effort	Absent	Slow; irregular, weak cry	Good; strong cry
Muscle Tone	Flaccid	Some flexion of extremities	Well flexed
Reflex Irritability	No response	Grimace	Vigorous cry
Color	Blue, pale	Pink body, blue extremities	Completely pink

Range of Apgar Score: from 0 to 10
 A score of 8–10 reflects a newborn in good condition that usually requires only nasopharyngeal suctioning. A score less than 8 may warrant further resuscitation measures.

While the newborn rests upon the mother's abdomen, the nurse performs a head-to-toe assessment to detect any abnormalities. The nurse observes the infant's overall size relative to the gestational age, noting the shape and size of the head and chest. The color of the skin, presence of vernix and lanugo, and any evidence of trauma are also noted. (See Chapter 18 for further discussion.)

Now Can You— Discuss essential nursing actions during the third stage of labor?

1. Name three clinical indicators that signal placental separation during the third stage of labor?
2. Explain what is meant by “shiny Schultze” and “dirty Duncan”?
3. Describe essential nursing actions concerning the oxytocin infusion, placenta inspection, and immediate newborn care?

Fourth Stage of Labor

The fourth stage of labor is the period of maternal physiological adjustment that occurs from the time of delivery of the placenta through the first 1 to 2 hours after birth. Monitoring of the mother and infant takes place frequently during this time.

NURSING CARE DURING THE FOURTH STAGE OF LABOR

While the physician examines the mother's perineum, cervix, and vagina for evidence of tears, the nurse assesses the uterus for firmness, height, and position. To perform fundal palpation, the left hand is placed directly above the symphysis pubis and gentle downward pressure is exerted. The right hand is cupped around the uterine fundus (Fig. 12-27). On palpation, the uterus is expected to feel firm and be positioned in the midline, at or just below the umbilicus. It can be described as closely

Figure 12-27 Fundal palpation during the fourth stage of labor. The left hand is placed directly above the symphysis pubis and exerts gentle downward pressure; the right hand is cupped around the uterine fundus.

approximating the size of a grapefruit. A full bladder or excessive blood in the uterus may cause it to be displaced from the midline.

If the uterus feels soft or “boggy” on palpation, this finding may indicate that excessive blood and/or clots have pooled in the uterus. The nurse immediately begins to massage the uterus until it becomes firm. To perform uterine fundal massage correctly, the nurse uses two hands. One hand applies firm pressure to the fundus to express the blood clots; the other hand supports the lower aspect of the uterus to protect the ligaments from damage.

While monitoring the firmness and position of the uterus, the nurse also assesses the bloody vaginal discharge or **lochia**, noting the color, amount, and presence of clots. The first lochia that appears is bright red, and is called **lochia rubra**. The amount of lochia is determined by examining the soaking of the perineal pads and the frequency of pad changes required. One soaked pad within the first postpartal hour is considered the normal maximum flow. Small blood clots are common; large clots are not normal. A steady trickle of blood or blood pooling under the mother’s buttocks can be a sign of trauma to the perineum or birth canal.

The nurse also assesses the mother’s vital signs frequently, generally every 5 to 15 minutes. The blood pressure should return to the prelabor level and the pulse rate should be slower than that recorded during the labor experience. A rising pulse rate or a decreasing blood pressure are indicators of excessive blood loss. The temperature is also assessed at the beginning of the fourth stage of labor, and on transfer from the birthing room to the postpartum area. A rise in temperature and an increase in the pulse may be early indicators of postpartum infection.

The nurse monitors maternal urine output. A full, distended bladder can displace the uterus and impede its ability to contract adequately, potentially leading to hemorrhage. Trauma to the urethra or bladder during childbirth may impair the mother’s perception of the urge to void.

critical nursing action Fourth-Stage Risk Signs

The nurse must be alert to the following risk signs that may occur during the fourth stage of labor: hypotension, tachycardia, excessive bleeding, or a boggy noncontracting uterus. These signs are associated with hemorrhage and must be reported immediately. If the uterus is boggy, the nurse must immediately initiate fundal massage and continue until the uterus becomes firm.

Comfort

It is not unusual for the mother to experience extreme shivering during the fourth stage of labor. The nurse can offer a heated blanket or warm beverage as comfort measures. The work of labor has expended considerable maternal energy, and providing a light meal and fluids can help replace lost calories. The process of labor is also extremely fatiguing, and the nurse can encourage both the mother and her birth partner to rest.

Figure 12-28 Family members share a special time with the newborn.

Promoting Attachment and Breastfeeding

The first hour after the birth is an ideal time to promote parent–infant attachment. During this time the stable newborn is in a state of alertness and is responsive to voice and touch. The nurse can support this attachment by completing many maternal and newborn assessments while the infant is held by the parents. Providing a private, quiet environment enhances the opportunity for parent–infant eye contact. Some parents may wish to include siblings or other family members in this experience (Fig. 12-28).

The mother may wish to initiate breastfeeding at this time. The nipple stimulation associated with maternal breastfeeding is beneficial in two ways: it initiates the process of lactation and assists in the process of uterine involution by triggering the release of endogenous oxytocin. As with any interactions with childbearing families, it is important for the nurse to be aware of and respect the family’s cultural practices.

Now Can You— Discuss the fourth stage of labor?

1. Explain what is meant by the fourth stage of labor?
2. Describe essential nursing assessments and appropriate interventions during the fourth stage of labor?
3. Name two nursing actions to promote infant attachment during the fourth stage of labor?

case study The Birth Experience of a Multigravida

Tina Sanchez is a 26-year-old Mexican-American gravida 2 para 1 who comes to the birthing unit with her husband Thomas. On arrival, Tina describes her contractions as starting approximately 2 hours earlier, regular and of moderate strength. You note that while she is walking to her room she has two contractions that are approximately 4 minutes apart and 60 seconds long. Tina is coping well with the contractions. She tells you in between contractions that with her first baby 3 years ago she was induced and confined to bed with an electronic monitor and does not want that this time if possible.

critical thinking questions

1. What type of information do you need to obtain from Tina and her husband?
2. What are your priority nursing assessments?
3. How would you respond to Tina's request not to be confined to bed?

The nurse completes the assessment of Tina and the admission history between contractions. Tina has experienced a healthy pregnancy and is considered low risk. The institution policy promotes intermittent auscultation for low-risk patients in active labor. Tina's contractions are growing longer in duration and becoming stronger in intensity. Tina states: "I don't know how long I am going to be able to do this, it is getting harder."

4. What evaluation of the FHR would you make during intermittent auscultation?
5. How would you respond to Tina, considering that at this time she appears to be coping well?

6. What type of comfort measures could you suggest?

While ambulating in the room, Tina experiences a large gush of greenish-brown fluid from her vagina.

7. What are your priority nursing assessments?

The amniotic fluid is noted to be meconium stained, a finding that is an indication for continuous fetal monitoring. The nurse explains the findings to Tina and Thomas and places Tina on the electronic FHR monitor. The fetal heart tracing shows a baseline rate of 140 bpm with accelerations to 160 bpm. The variability is normal and no decelerations are noted.

8. Are these findings normal or pathological? What further interventions are required?

Thirty minutes later Tina is fully dilated and begins to push with each contraction. The FHR is now decreasing with each contraction and resembles the mirror image of the contraction.

9. What stage of labor has Tina now entered?

10. What is your interpretation of the FHR at this time?

11. What type of nursing interventions would you anticipate for Tina?

Tina gives birth to a healthy baby girl 20 minutes later. The infant is suctioned well at the perineum and examined by the pediatrician due to the presence of meconium in the amniotic fluid. The infant is pink with acrocyanosis and does not demonstrate any signs of respiratory difficulties and is quickly returned to the proud parents.

12. Considering that the newborn infant has acrocyanosis, what is the highest possible Apgar score this infant could receive?

13. What are your priority nursing interventions for the newborn, Tina, and the family?

- ◆ See Suggested Answers to Case Studies in the text on the Electronic Study Guide or DavisPlus.

summary points

- ◆ Each patient's labor and birth experience is unique, and nurses play a vital role in facilitating a positive outcome for the patient, infant, and family.
- ◆ Nurses recognize that the labor and birth experience is influenced by a myriad of factors such as maternal age and well-being, social support, and cultural and religious beliefs and practices.
- ◆ Nurses need a strong knowledge base about the physiological processes of labor and birth in order to provide safe and effective care.
- ◆ In each of the four stages of labor, the nurse uses well-developed assessment skills to recognize the normal progression of labor, to identify potential risks to the patient and fetus, and to identify how and when to intervene and consult with other health care providers.
- ◆ The overall goal of intrapartum nursing care is to promote comfort and safety of the patient, the fetus, and the newborn infant.
- ◆ A positive nurse-patient relationship in which the woman feels cared for and informed will empower her in coping with her labor.
- ◆ Nurses include the patient and her support person(s) in the planning and delivery of care.
- ◆ The nursing care given throughout labor and birth is an important determinant of the woman's overall perception of her childbirth experience.

review questions**Multiple Choice**

1. When describing the "powers" of labor to a new nurse, the perinatal nurse discusses the uterine contractions and the:
 - A. Woman's pushing efforts
 - B. Unique musculature of the uterus
 - C. Position of the fetus
 - D. Hormonal influences regulating labor
2. The perinatal nurse assesses Diane, a 22-year-old primigravida who has just arrived at the birth facility for labor assessment. Diane describes contractions that are 7 to 10 minutes apart, and felt in the abdomen. She states that the contractions "feel better" when she is walking. This is most likely:
 - A. True labor
 - B. Transition
 - C. Early labor
 - D. False labor
3. The perinatal nurse describes for the student nurse the lettering used to designate fetal position. The correct use includes:
 - A. "P" indicating fetal pelvis location
 - B. "P" indicating posterior maternal pelvis
 - C. "M" indicating fetal mandible
 - D. "A" indicating maternal anus

Fill-in-the-Blank

4. The perinatal nurse describes labor contractions as composed of three distinct parts: an increment or _____, an _____ or peak and the decrement or _____ in the contraction.
5. The perinatal nurse teaches the new nurse about fetal lie. The perinatal nurse describes fetal lie as the relationship of the _____ axis of the woman to the _____ axis of the fetus.
6. The perinatal nurse knows that offering relaxation techniques such as massage and assistance with breathing can decrease the production of _____, which can _____ uterine blood flow during labor.

True or False

7. The perinatal nurse knows that the fetus is normally in a flexed position prior to birth.

Select All that Apply

8. The perinatal nurse knows to assess for the uterine relaxation that occurs between contractions. This period of uterine relaxation is important for:
 - A. Fetal oxygenation
 - B. Maternal rest
 - C. Lactic acid production
 - D. Oxytocin production
9. The perinatal nurse describes the latent phase of labor to the new nurse. Characteristics of this phase include:
 - A. Cervical dilation from 0 to 3 cm
 - B. Excitement and nervousness
 - C. Moderate to strong contractions
 - D. Admission to the hospital
10. The perinatal nurse describes for the student nurse the risks associated with a breech birth which include:
 - A. Cord prolapse
 - B. Birth trauma
 - C. Shoulder dystocia
 - D. Vaginal bleeding

CONCEPT MAP

Promoting Patient Comfort During Labor and Birth

chapter 13

Natural childbirth means that no drugs will be put into the mother's body during delivery—the father can have all he wants.

—Bill Cosby

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Describe the unique characteristics of pain associated with childbirth.
- ◆ Discuss sociocultural factors that shape the woman's pain experience during labor and childbirth.
- ◆ Identify nonpharmacological methods to promote comfort during labor and birth.
- ◆ Compare pharmacological interventions used for discomfort and pain during different stages of labor.
- ◆ Summarize the possible complications associated with regional and general anesthesia.
- ◆ Discuss the nurse's role in ensuring maternal-fetal safety while promoting comfort during labor and birth.

moving toward evidence-based practice Use of a Doula to Support Women in Labor

Campbell, D.A., Lake, M.F., Falk, M., & Backstand, J.R. (2006). A randomized control trial of continuous support in labor by a lay doula. *JOGNN*, 35(4), 456–463.

Previous meta-analysis of randomized clinical trials have found that there is a reduction in the number of cesarean deliveries, length of labor, and use of analgesia along with increased infant Apgar scores in women who receive continuous support during labor. One form of support can be provided by a doula, who is a female support for women in labor. She is not a physician, nurse, or midwife and does not provide medical treatment. In addition, her presence is not intended to take the place of the male partner or other family members who may be present during labor.

The purpose of the study was to compare labor outcomes of nulliparous women accompanied by a doula with the labor outcomes of nulliparous women who received standard care and did not have the support of a doula, regardless of support from the male partner or other family members. The outcomes under investigation included:

- Length of labor, which was defined as the time from the onset of regular contractions to the birth of the neonate.

The onset of regular contractions was determined by the nurse or reported by the patient. The actual time of birth was obtained from the woman's medical record.

- Type of birth
- Type and timing of administration of analgesia or anesthesia
- Apgar scores at 1 and 5 minutes.

The study took place in a tertiary perinatal care hospital that provides care for underinsured low-income women. A convenience sample of 600 nulliparous women met the criteria for the study: low-risk, singleton pregnancy. Male partners and/or additional family members were allowed to provide support during labor.

Three hundred women who were randomly assigned to the experimental group identified a female friend or family member who was willing to serve as a lay doula.

(continued)

moving toward evidence-based practice (continued)

A research assistant who was certified as a doula met with the pregnant women and their female support for two-2-hour sessions to teach traditional doula supportive techniques.

Data analysis of the 586 women who completed the study revealed the following:

Of the 586 of the original 600 women who completed the study,

- Fifty-six percent of the women in each group were Caucasian.
- Thirty-six percent of women in the experimental (doula) group and 29% in the control (non-doula) group were black.
- Fewer than 1% in both groups described themselves as Indian, Chinese, or Filipino; 6.4% in the experimental (doula) group and 12% in the control (non-doula) group described their ethnicity as “other.”
- The participants’ ages ranged from 14 to 40 years at the time of birth. The mean age was 22.2 years for the

experimental (doula) group and 22.6 years for the control (non-doula) group.

- The experimental (doula) group experienced shorter labors, greater cervical dilation at the time of administration of epidural anesthesia (if used), and higher infant Apgar scores at 1 and 5 minutes.
- No difference was found between the two groups in the number of cesarean births, duration of the second stage of labor or type of analgesia/anesthesia administered.

The researchers concluded that providing low-income pregnant women with an option to choose a female friend to train and serve as a doula shortens the labor process and improves maternal and neonatal outcomes.

1. What might be considered as limitations to this study?
2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

When a laboring woman experiences discomfort and pain, there are many interventions that nurses can implement to help reduce anxiety and promote comfort. There is an increasingly accepted perspective that certain physiological processes are normally associated with a certain level of pain, and that the pain serves a useful purpose. The pain of childbirth, for example, may serve to warn the woman to seek a safe haven and obtain help. Ideally, these actions help to ensure that the birth takes place in safe surroundings and facilitate a positive outcome, whether childbirth takes place at home, in a free-standing birth center, or at a hospital. However, this perspective should not be confused with the belief that childbirth should not be painful. To deny that discomfort or pain exists during childbirth is patently unrealistic. The nurse, the laboring woman, and her support person(s) all benefit from an understanding of the physiological and psychological processes that underlie the experience of pain. Becoming familiar with strategies for managing or diminishing the pain of childbirth empowers the laboring woman to make informed decisions about the various pain management measures she will use. This chapter discusses the physiology of childbirth pain, theories related to pain perception, cultural and psychological factors that affect childbirth pain, non-pharmacological and pharmacological pain management interventions, and implications for nursing care.

Optimizing Outcomes— Helping to achieve *Healthy People 2010* national goals

Because the use of anesthesia and analgesia during childbirth can increase maternal mortality, several of the *Healthy*

People 2010 national goals relate to pain relief during labor. One such goal is:

- Reduce the maternal mortality rate to no more than 3.3 per 100,000 live births from a baseline of 7.1 maternal deaths in 1998.

Nurses can help the nation achieve this goal by educating women about the benefits of prepared childbirth. During labor, nurses can educate, reassure, and continuously monitor patients and assist them in the use of nonpharmacological pain relief methods to enhance comfort and reduce the total amount of analgesics needed.

The Physiology of Pain During Labor and Birth

DEFINING PAIN

Pain is a complex, multidimensional experience. According to Padfield and colleagues (2003), pain is defined as whatever the person who is experiencing it says it is. The International Association for the Study of Pain defines pain as an unpleasant sensory and emotional experience arising from actual or potential tissue damage or described in terms of such damage. Pain includes not only the perception of an uncomfortable stimulus but also the response to that perception (Venes, 2009). The expression of pain is influenced by a number of psychosocial and cultural factors. For example, in some cultures it is permissible for the woman in labor to freely verbalize her pain. In others, the laboring woman must be stoic and keep her emotions to herself.

The pain experienced during childbirth is an unpleasant sensation that is usually localized to the back and the

abdomen. For most, the pain associated with childbirth intensifies an already highly emotional experience for both the laboring woman and her support person. How well the laboring woman is able to cope with her pain significantly affects the overall birth experience.

During the assessment, the nurse may identify physiological and psychological changes that are indicative of maternal pain. These include an increased pulse rate and blood pressure, changes in mood, increased anxiety and stress, marked agitation, confusion, decreased urine output, decreased intestinal motility, and guarding of the target area of discomfort. Pain affects the patient's physiologic, behavioral, sensory, and cognitive responses. It is frequently intensified by fear, anxiety, and fatigue.

The experience of pain is shaped by many factors such as the patient's age, educational background, state of wellness, prior experiences, sociocultural background, degree of family and social support, and mastery of coping mechanisms. Nurses must simply accept what the patient says about her pain experience. The pain is real for each woman and occurs wherever she reports it to hurt. Despite the presence or absence of physiological indicators of pain, only the patient can validate with certainty her present level of discomfort.

Nursing Insight— Recognizing the unique characteristics of childbirth pain

When caring for laboring women, nurses must recognize that unlike other sources of pain, childbirth pain:

- Is part of a normal process (not associated with illness or injury)
- Can be anticipated, and thus prepared for (through childbirth education and the practice of distraction techniques and comfort measures)
- Has an end point (the baby's birth brings relief on a physical and emotional level)

PHYSICAL CAUSES OF PAIN RELATED TO LABOR AND BIRTH

Pain Neurology

The pain associated with labor and birth has both visceral and somatic origins (Lowe, 2002). Uterine contractions during the first stage of labor bring about cervical dilation and effacement. During each contraction, arteries that supply the myometrium are compressed, causing uterine ischemia (oxygen deficit that results from decreased blood flow). During the first stage of labor, pain impulses are transmitted via the T11 and T12 spinal nerve segments and accessory lower thoracic and upper lumbar sympathetic nerves. These nerves originate in the uterus.

Visceral pain describes the predominant discomfort experienced during the first stage of labor. It is related to changes in the cervix (i.e., dilation and effacement), distention of the lower uterine segment and uterine ischemia. Visceral pain is a slow, deep, poorly localized pain that occurs over the lower abdomen. It is commonly described as a dull aching pain. Laboring women may also experience **referred pain**. Referred pain describes pain that originates in the uterus and then radiates to the

abdominal wall, the lumbosacral area of the back, the iliac crests, the gluteus maximus, and down the thighs. Usually, the discomfort is felt only during contractions. A period of pain relief occurs between contractions although some women report continued nonremitting pain even during the interval between contractions (Lowe, 2002).

Somatic pain, a faster, well localized intense, sharp, burning, prickling pain, occurs during the second stage of labor. Somatic pain is associated with stretching and distention of the perineal body to allow for birth. It is also related to distention and traction placed on the peritoneum and uterocervical supportive tissue during contractions and can result from soft tissue lacerations that frequently occur in the cervix, vagina, or perineum. Somatic pain may also occur from the maternal expulsive forces during the second, or "pushing" stage of labor or by fetal pressure on the bladder, bowel, or other pelvic structures. During the second stage of labor, pain impulses are transmitted via the pudendal nerve through S2 to S4 spinal nerve segments and the parasympathetic system (Lowe, 2002).

During the third stage of labor, and in the early postpartum period, discomfort is associated with uterine contractions. The pain experienced during this time is similar to that associated with the first stage of labor.

PAIN PERCEPTION AND EXPRESSION

Although pain is a universal experience, how a woman reacts to and expresses pain is highly personal and subjective. One's perception of and response to pain is colored by many factors including gender, culture, ethnicity, and past experiences. Research from the disciplines of psychology, anthropology, and sociology has offered insights into the influence of one's primary social group on the meaning of pain and verbal and nonverbal expressions of pain.

Optimizing Outcomes— Recognizing cultural influences on the experience of pain

When providing care, nurses must recognize that culture strongly influences how one perceives and copes with pain. Women from certain cultures seek pain relief through prayer; others rely on herbal remedies, the application of cold or warmth, acupuncture, the "laying on of hands," and therapeutic massage. Assessment of cultural beliefs and practices, questions to identify specific needs and encouragement and support to use safe interventions is key in providing culturally sensitive care that empowers the patient to maintain her sense of control over her labor and childbirth experience.

For example, a primigravid Haitian woman may respond to painful uterine contractions with crying, loud screams, and hysteria (Colin & Paperwalla, 2003). Laboring Cambodian women, usually attended by a female relative rather than the male partner, tend to be quiet and sedate during labor and birth (Kulig, 2003). The Mexican American woman in labor is likely to be very vocal. Family members other than the baby's father frequently assist with emotional and verbal support (Lagana & Gonzalez-Ramirez, 2003). In any clinical setting, it is helpful for the nurse to identify the ethnic groups most often cared for and develop an awareness of culturally specific childbirth

practices and pain behaviors. However, the nurse should be cautious not to stereotype patients and must remain sensitive to individual variations in women's choices for dealing with pain during the childbirth process. Approaching each woman's response to her labor and pain with acceptance and support is key to a therapeutic nursing relationship.

Ethnocultural Considerations—Realities of the cultural model

When caring for women, nurses must be aware that a potential limitation of relying solely on a cultural perspective comes from neglecting to recognize women's individuality in how they conform to traditional values and norms. Cultural models of health care frequently stereotype women who share the same cultural heritage. In so doing, they may immobilize health providers who seek to change unfavorable health care situations in the name of protection of the cultural heritage (Meleis, 2003).

Pain is expressed in a number of physiological and affective ways. During labor and childbirth, the sympathetic nervous system responds to pain with increased levels of catecholamines (e.g., epinephrine and norepinephrine—biologically active substances that produce a marked effect on the nervous and cardiovascular systems, metabolic rate, temperature, and smooth muscle). There is a rise in blood pressure and heart rate. Increased maternal oxygen consumption results in an altered respiratory pattern that may produce hyperventilation and respiratory alkalosis. The woman may become diaphoretic, and nausea and vomiting are common during the active phase of labor. Throughout this process, decreased placental perfusion and uterine activity can potentially prolong labor and adversely affect fetal well-being.

Visceral and somatic pain has been described as burning, prickling, stabbing, heavy, pulling, pointing, sharp, stinging, and throbbing. On an emotional, or affective level, maternal pain during childbirth has been characterized as exhausting, nauseating, annoying and sickening (Lowe, 2002). Outward signs of suffering tend to be universal and are exhibited in varying degrees. Patients in pain cry, scream, clench and wring their hands, moan, groan, clench their jaws, and in other ways demonstrate increasing anxiety with a reduced perceptual field.

FACTORS THAT AFFECT MATERNAL PAIN RESPONSE

Physical, physiologic, and psychological influences affect the laboring woman's perception and tolerance of pain. Physical factors include labor intensity, cervical readiness, fetal position, pelvic dimensions, fatigue, and medical interventions.

Physical Factors

A brief, intense labor is often associated with a greater level of discomfort and pain because the contractions are highly efficient in accomplishing cervical changes (effacement and dilation) and fetal progress (descent). Also, a shortened labor may diminish the woman's options for

pharmacological methods of pain relief. When cervical changes (softening, some dilation and effacement) have occurred before the onset of labor, the cervix opens more readily. Theoretically, fewer contractions are needed to achieve dilation and effacement.

When the fetus is in an unfavorable position, the labor is likely to be longer and associated with a greater amount of discomfort. For example, when the fetus is in an occiput posterior position, the woman experiences intense pain during contractions as the fetal occiput is pressed against the maternal sacrum. The pain associated with "back labor" persists between contractions and is unremitting until the fetus rotates to a more favorable position (e.g., occiput anterior). The size and shape of the maternal pelvis influences the progress, and thus the level of discomfort and pain associated with the labor. Structural abnormalities may cause the labor to be prolonged and may contribute to fetal malpresentation.

Maternal fatigue adversely affects the ability to tolerate pain and the effective use of coping techniques and strategies to remain in control. Fatigue can hamper the woman's ability to concentrate and prevent her from using imagery, focal points, breathing techniques, and other methods of distraction. Lack of refreshing sleep is not unusual during the last weeks of pregnancy; a well-rested woman who experiences a prolonged labor can quickly become exhausted long before the birth takes place.

Certain care provider interventions, such as intravenous and fetal monitoring equipment, can intensify the discomfort naturally associated with labor. At times, these methods may also interfere with maternal mobility and the ability to assume a position of comfort. Labor induction and augmentation, amniotomy and vaginal examinations may also be associated with intensifying labor discomfort.

Physiological Factors

Physiological forces influence the laboring woman's pain response. If there is a history of dysmenorrhea, increased childbirth pain may be related to higher levels of circulating prostaglandins. Laboring in an upright, instead of supine, position may help alleviate discomfort. Freedom to ambulate and assume a position of comfort during labor has been shown to be beneficial in reducing pain and muscle tension. Furthermore, the opportunity to choose positions for labor empowers the woman with a greater sense of control over her situation. In addition, the fetal size in relation to the maternal pelvic dimensions may also affect the level of pain intensity (Lowe, 2002; Simkin & O'Hara, 2002).

Although the physiological role is not well understood, the level of circulating endorphins is believed to have an important effect on the laboring woman's sense of well-being. **Endorphins** are endogenous opioids secreted by the pituitary gland. Endorphins act as opiates and produce analgesia by binding at opiate receptor sites involved in pain perception. In this manner, endorphins increase the threshold for pain. Beta-endorphin is the most active compound. When present in higher levels, endorphins are believed to increase the laboring woman's ability to tolerate pain; increased endorphin levels have been demonstrated with spontaneous, natural childbirth (Righard, 2001).

Psychological Factors

A number of psychological forces such as anxiety, fear, previous experiences, support systems, and childbirth preparation influence perception of and response to pain. Maternal anxiety during labor triggers the release of catecholamines, which increase the amount of pelvic pain stimuli sent to the brain, resulting in an intensified perception of pain (Lowe, 2002). As muscle tension increases, the effectiveness of the uterine contractions decreases and maternal discomfort and pain are intensified. Over time, the cycle of anxiety → tension → pain diminishes the progress of labor. At the same time, the woman's self-confidence in her ability to cope with the pain erodes and therapeutic interventions to help reduce pain and discomfort become less effective.

The woman's previous experience with pain and childbirth also influences her pain perception and ability to cope during labor. For most young, healthy women, childbirth often represents the first exposure to prolonged, intense pain. During early labor, sensory pain tends to be more pronounced in the nulliparous patient because the reproductive tract structures are less pliant and flexible. Multiparous patients may experience greater sensory pain during the transition phase of the first stage of labor because their pliable reproductive tract structures allow for a more rapid fetal descent accompanied by a heightened intensity in pain. During the first stage of labor, affective pain is usually greater for nulliparous women but is decreased for both nulliparous and multiparous women during the second stage (Lowe, 2002).

The patient's personal experience with a previous childbirth also influences her pain perception. A prior negative experience marked by misery and pain may produce an expectation of a repeated negative experience that is filled with fear and dread. A woman whose prior childbirth experience was satisfying is more likely to approach the present birth with a positive attitude and confidence in her ability to cope with the pain and discomfort.

The physical environment that envelops the birth experience should be considered as well. "Environment" encompasses those present as well as the physical space where the labor takes place. When indicated, labor support persons should be encouraged to serve as the patient's advocate in communicating desires, expectations and concerns and in providing physical comfort measures. Women prefer to be cared for in a home-style setting by trusted, familiar caregivers (Hodnett, 2002).

Nursing Insight— Environmental strategies to enhance comfort during labor

The labor environment should provide privacy, comfort, and a sense of security. Allowing patients to determine the amount of noise, light, and temperature in their room fosters relaxation and a sense of control over their situation. Ideally, the room has an abundance of space that freely allows for patient and staff mobility, equipment (preferably hidden from view unless needed) and comfort measures such as birth balls, reclining chairs, tubs, and showers.

Now Can You— Discuss characteristics of pain during labor and birth?

1. Identify three distinct characteristics of childbirth pain?
2. Differentiate among visceral, somatic, and referred pain and discuss when these pain types are most likely to occur during labor?
3. Discuss the physical, physiological, and psychological factors that influence the laboring woman's experience of pain?

THE EFFECTS OF PREPARED CHILDBIRTH ON PAIN PATHWAYS

Prepared childbirth provides the patient and her partner with an understanding of what to expect during childbirth and empowers them to become knowledgeable consumers of health care who can make informed choices concerning their childbearing experience. Accessible through many avenues, childbirth education is offered by most care providers, and may also be obtained in written or online materials, or through participation in formal childbirth education classes. In most areas, a variety of classes are available to provide general or specialized information. Prenatal classes focus on fetal growth and maternal changes and often place emphasis on health promotion through nutrition, exercise, stress reduction, and adequate rest. Other classes are intended to prepare the expectant couple for the labor process, and much time is spent exploring nonpharmacological and pharmacological measures for pain relief. These classes generally focus on educating the woman and her support person(s) about strategies such as position changes, breathing techniques, massage, and other methods to achieve relaxation and enhance comfort during labor. Classes for women with a planned cesarean birth are also available, and for those who wish to breastfeed, hospital maternity programs and local lactation support groups frequently provide focused breastfeeding classes.

To enhance understanding of how methods learned through prepared childbirth work to promote comfort during labor, it is helpful to review pain pathways and the gate control theory of pain. Pain may be viewed as a multidimensional phenomenon that encompasses the following five dimensions: affective, physiological, behavioral, sensory, and cognitive. The neural pathway for pain involves four processes: transduction, transmission, perception, and modulation. Transduction is the conversion of a mechanical, thermal, or chemical stimulus into a neuronal action potential. Transduction occurs at the nociceptors, nerves that receive and transmit painful stimuli. Stated another way, incoming noxious stimuli are converted to electrical activity at the sensory endings of the peripheral nerves. Transmission is the movement of the pain impulse from the site of transduction (e.g., uterine contractions) to the brain. Perception is the development of the sensory, subjective and emotional experience identified by the individual as pain. Perception occurs when the patient feels the pain and responds to it, and modulation involves the activation of descending pathways that exert either inhibitory or facilitatory effects on the transmission of pain (Lowe, 2002).

Sometimes it is possible for painful stimuli to be ignored. Groups of certain nerve cells located in the spinal

cord, brainstem, and cerebral cortex have the ability to modulate, or alter, pain impulses through a blocking mechanism. According to the **gate-control theory** of pain control (Melzack & Wall, 1965), pain sensations travel along sensory nerve pathways to the brain—but only a certain number of sensations, or “messages” can pass through the nerve pathways at one time. Methods of distraction learned and practiced in prepared childbirth classes such as breathing patterns, massage, music, and the use of focal points and imagery reduce or completely block the capacity of the nerve pathways to transmit pain. It is believed that these physical and psychological distractions work by “shutting the gate” in the spinal cord so that pain signals are unable to reach the brain.

When the laboring woman is actively involved in neuromuscular and motor activity, there is an increase in spinal cord activity that further modifies the transmission of pain. For example, the cognitive effort channeled into concentration on breathing patterns, focal points, and imagery requires selective and directed cortical activity that activates and closes the gating mechanism. The gate-control theory helps to explain how methods such as hypnosis and the various pain relief techniques taught in childbirth education classes help to diminish the laboring woman’s perception of pain.

BENEFITS OF COMFORT AND SUPPORT ON PAIN PERCEPTION

In the traditional medical model, pain and discomfort during labor have largely been viewed as a negative component that should be eliminated. An alternative approach views labor as a natural process that challenges women to seek activities of comfort that will allow them to transcend the pain to achieve the satisfaction and contentment of birth. Feeling safe, secure, comforted, and in control empowers the laboring woman to find strength in dealing with her discomfort and pain. Nurses can facilitate comfort by providing a caring, supportive, therapeutic presence.

Support during labor and birth has a major impact on the woman’s birth experience. Support includes both nonpharmacological and pharmacological measures. The nurse’s attitude, expressions of caring, and supportive actions play a significant role in the woman’s perception of pain and in her overall childbearing experience. Patients who feel they have control over their situation (self-efficacy) and who are actively engaged in the decision-making process concerning

interventions and pain relief measures during labor and birth report a greater sense of satisfaction with their birth experience (Hodnett, 2002). When support is perceived to be ongoing and individualized throughout labor, women require fewer pain medications and interventions and experience improved outcomes (Simkin & O’Hara, 2002).

Optimizing Outcomes— Assessment of pain during labor

Throughout the process of labor and birth, the nurse continuously assesses the patient and addresses her needs for comfort measures. Conducting an initial and ongoing pain assessment lays the foundation for intrapartal nursing care. Once the beginning assessment has been completed, the nurse uses the information to develop an individualized plan of care that includes pain relief interventions acceptable to the patient. A number of tools have been developed to facilitate pain assessment during labor; these may be modified or adapted as needed (Fig. 13-1).

Providing Comfort and Pain Relief

Methods to provide comfort and relieve pain are of paramount importance for the childbearing couple. The woman’s perception of her overall birth experience is greatly influenced by her ability to cope with pain in whatever manner is acceptable to her. Nonpharmacological pain relief measures are for the most part inexpensive, easy to use, safe, and readily available. They also allow the patient to gain an enhanced sense of control over her childbirth experience. Despite their effectiveness, however, none of the various techniques are more effective than methods of epidural analgesia. Nurses play a key role in educating women and their support persons about the various nonpharmacological and pharmacological pain relief methods available. During labor, women should be encouraged to try a variety of pain relief measures, including pharmacological methods, if needed. Factual information and ongoing support empowers the patient to make informed choices and to participate fully in the decision-making process.

Another important component of childbirth preparation concerns the choice of the birth setting. Many communities offer several options for where the childbirth

Pain Assessment During Labor			
Patient's Name _____	Date _____	Age _____	Room _____

will take place. Often during the first prepared childbirth class, expectant couples are encouraged to explore community options for the childbirth setting that best “fits” with their desired childbirth experience.

Across Care Settings: Childbirth options in the local community

Encouraging expectant couples to explore options for the childbirth setting is an important component of prenatal education. As consumers of health care, patients should seek a primary care provider and facility that will safely meet their childbirth needs. Depending on the locale, the community may have a large city hospital, a small community hospital, a birth center, or a practicing group of certified nurse midwives (CNMs) that provides care during home births. When considering a birth facility, the woman may wish to ask the following questions:

1. Where does my primary care provider have childbirth privileges?
2. Does the facility offer personal Jacuzzis? Traditional bathtubs? Showers?
3. Does the facility have birth balls? Could I bring my own birth ball?
4. Would the facility allow me to play my own music during labor and birth?
5. How many labor support persons may be with me when I give birth?
6. Does the facility permit the use of aromatherapy?
7. Does the facility have transcutaneous electrical nerve stimulation (TENS) units available?
8. At what point would I be allowed to receive an epidural?
9. What medications would be available during my labor?

Now Can You— Discuss a pain control theory, pain perception, and considerations for the childbirth setting?

1. Discuss the basic premise of the gate control theory of pain control?
2. Explain how comfort and support during labor decrease the woman’s perception of discomfort and pain?
3. Identify four questions the expectant couple may wish to ask to help determine their choice of childbirth setting?

NONPHARMACOLOGICAL PAIN RELIEF MEASURES

Maternal Position and Movement

One way the nurse can facilitate relaxation is by helping the patient to find a position of comfort. Movement and changes in maternal position are important strategies for facilitating labor and childbirth. As the patient changes positions, gravity assists the fetus’ descent down the birth canal. Slow dancing during labor is an activity that the expectant couple may enjoy. Most find slow dancing to special music from their own collection to be comforting and relaxing. When the couple assumes the slow dance position, the woman can lean on her coach (this helps to support her), and they can sway and dance together through the contractions.

Laboring women may also wish to use a “squatting bar” or assume a squatting position at the edge of the bed. The

squatting position helps to open the pelvic outlet, which facilitates the fetus’ downward movement. Assuming a hands and knees position is comforting for women who have back labor or whose fetus is in a posterior position. The hands and knees position decreases the patient’s back pressure and helps the fetus to rotate into an anterior position. Many hospital birthing suites offer wireless telemetry units that provide continuous monitoring while the patient ambulates at her leisure (Fig. 13-2).

The “birth ball” may be also used to promote comfort during labor. Essentially, the birth ball is a large, firm yet pliable physical therapy ball or gymnastic ball that provides support for the laboring woman. The patient carefully sits on the birth ball and rhythmically rocks back and forth or moves the ball around in a circular motion. Assuming a sitting position on the birth ball facilitates a supported squatting position that opens the pelvis to allow fetal descent in preparation for birth. Warm compresses applied to the back and perineum while balancing on the ball enhance relaxation and promote comfort (Fig. 13-3). The birth ball should be large enough to allow the woman to sit comfortably on it with her knees bent at a 90-degree angle with her feet flat on the floor and approximately 2 feet apart (Perez, 2000). The woman may also place the birth ball against the wall behind the small of her back and gently lunge from side to side to open the pelvis. When needed, assuming a kneeling position while leaning forward on the birth ball may encourage the rotation of the fetus from a posterior to an anterior position.

Breathing Techniques

During childbirth education classes, the pregnant woman and her labor coach learn about conscious breathing patterns that involve slowed respirations to enhance relaxation. Specific breathing methods are also taught as attention

Figure 13-2 Use of a wireless telemetry unit allows the woman to ambulate during labor.

Figure 13-3 The coach applies counterpressure and warm compresses to the woman's lower back as she balances on the birth ball.

focusing and distraction techniques to help relieve discomfort and pain during labor. Distraction helps to reduce the woman's perception of pain. The labor "coach," or support person, assists the woman by learning to palpate her body to identify muscle tenseness, by signaling the onset of contractions, and by monitoring her effective use of the breathing techniques. Techniques learned in class are practiced at home so that when labor begins, the couple is prepared to use relaxation and breathing patterns as a strategy to help diminish discomfort and pain (Fig. 13-4).

Figure 13-4 Practice of relaxation techniques and breathing exercises help to prepare the couple for labor and birth.

The woman is instructed to take a slow, deep cleansing breath in through the nose and out through the mouth at the beginning of every contraction. During early labor, when the woman is no longer able to walk or talk through contractions, she may wish to begin using *slow-paced* breathing. With this pattern, following a cleansing breath, the woman begins to slowly breathe in and out through her mouth while her coach slowly counts out loud. The breathing rate is approximately half the woman's normal breathing rate—6 to 8 breaths per minute. With this pattern, she is prompted to slowly breathe in while the coach counts "one, two, three, four," and then slowly breathe out to the same rhythm as the coach counts "one, two, three, four."

As the labor progresses, and the contractions increase in frequency and intensity, the patient may need to change to a *modified-paced* breathing pattern. This breathing technique is shallower and approximately twice the woman's normal rate of breathing—32 to 40 breaths per minute. After a deep cleansing breath, the woman inhales slowly, but exhales at faster pace. For example, the coach may instruct her to take a cleansing breath, then breathe in to a count of one, two, three, four and breathe out to a count of one, two, three. All contractions should end with another deep cleansing breath. The modified paced breathing pattern requires more concentration and is believed to block more painful stimuli than the slow-paced breathing pattern (Perinatal Education Associates, 2006). The woman may wish to combine the slow and modified paced breathing: use the slow-paced breathing at the beginning and end of the contractions; and the modified-paced breathing during the contraction intensity. Combining the patterns helps to conserve maternal energy and lessens fatigue and the likelihood of hyperventilation.

During the transition phase of labor, when contractions are most intense, patients usually find it difficult to concentrate on breathing techniques. At this time, the *pattern-paced* breathing technique, which requires increased concentration, is helpful. With this breathing pattern, following a cleansing breath, the woman begins with a 3:1 pattern: breathe in, breathe out; breathe in, breathe out; breathe in, then blow (as if blowing out a candle). This sequence is repeated throughout the contraction. As needed, the ratio may be increased to 4:1. As with the other breathing patterns, a cleansing breath is taken at the end of the contraction. The patient can use and modify any of the breathing techniques that work best for her at any stage of her labor.

“What to say” — *When the patient needs assistance refocusing during labor*

While in the transition phase of labor, the laboring patient screams out “I quit, I cannot do this anymore, I have no more energy, I can't do this.” At this point, comfort measures are ineffective. Instead, the nurse can help the patient stay focused on dealing with each contraction by offering words of support and encouragement with statements such as:

“You are doing a great job!”

“You are almost there!”

“I can see your baby's head—reach down and feel it!”

“You can do it!”

Optimizing Outcomes— Recognizing hyperventilation

The pattern-paced breathing technique may result in maternal hyperventilation. The nurse should alert the patient and her support person to symptoms of respiratory alkalosis: light-headedness, dizziness, tingling of the fingers, or circumoral numbness. Strategies to eliminate respiratory alkalosis focus on replacement of the bicarbonate ion by rebreathing carbon dioxide. This can be accomplished by instructing the woman to breathe into a paper bag held tightly around the mouth and nose or, if no bag is available, instructing her to breathe into her cupped hands.

During the second-stage pushing phase of labor, patients should be encouraged to use whatever breathing pattern is comfortable and relaxing. To ensure optimal blood flow to the fetus, prolonged breath holding during pushing should be avoided. When needed, the urge to push may be controlled by a breathing pattern that consists of panting breaths or by slow exhalation through pursed lips (Perinatal Education Associates, 2006).

It is important for the pregnant woman and her coach to practice all breathing techniques before the onset of labor. The practice helps to increase their comfort level with the techniques and increases the likelihood that they will be able to use them effectively during labor. The breathing and relaxation techniques can be practiced together at home and at any time to reduce stress. When necessary, couples that are unfamiliar with breathing strategies can be taught during labor. Breathing techniques offer a form of distraction since the woman who is concentrating on slow paced breathing cannot focus on her pain. The breathing patterns are also beneficial in increasing blood flow to the fetus.

Music

Music can help to create a relaxing environment and boost spirits. During labor, music provides comfort and decreases maternal anxiety by stimulating the release of endorphins. For most couples, quiet, soothing music works best. Compact disc players are often available in hospital birthing suites and free-standing birth centers and patients are encouraged to supply music of their choice. A headset or earphones used with the compact disc player or patient's personal iPod may be even more effective because environmental sounds are tuned out. Comforting music during labor promotes maternal relaxation, thereby increasing oxygen intake. Some women find that music enhances their ability to remain focused during contractions. Music alone may also provide pain relief during labor, although further research is needed (Smith, Collins, Cyna, & Crowther, 2005). In some birth settings, patients are allowed to bring personal videos or DVDs from home to enjoy as another strategy for distraction during labor.

Relaxation

Various relaxation techniques are used to help decrease anxiety during labor. When the nurse, patient, and her labor support person(s) are successful in diminishing the patient's level of anxiety, stress and tension are also reduced. When tension is reduced, the woman breathes more deeply, resulting in improved maternal and fetal oxygenation. When the laboring woman experiences increased anxiety, stress levels and tension build and trigger a cascade of events that

heighten the sensation of pain. Pain also impedes the patient's ability to relax. The nurse's ongoing assessment of maternal pain should be conducted throughout labor and birth. The use of a standardized pain assessment tool facilitates the evaluation and allows for an easy reassessment of pain following therapeutic interventions. Use of a patient self-assessment tool is preferable because it ensures that the management of pain is based on the subjective nature of the woman's pain rather than on the nurse's judgment alone.

Nursing Insight— Use of a visual analog scale for the assessment of pain

A visual analog scale for pain assessment is helpful because the patient is able to indicate on a line how intense she perceives her pain to be: the choices range from "no pain" to "pain as bad as it could possibly be." Other scales that present drawings that range from happy, smiling faces to sad, crying faces are also available. The nurse should ask the woman to rate her pain on the scale before and after pain-relief measures to evaluate their effectiveness.

Other Attention-Focusing Strategies

Guided imagery is a state of intense, focused concentration that one uses to create persuasive mental images. Guided imagery distracts the laboring woman and transports her to a place that is special to her. The nurse or labor support person assists with guided imagery by asking the laboring woman to focus on a place where she likes to be. Many patients choose the beach or the mountains as their special locale. Next, the nurse or the labor support person verbalizes sights and sounds of that unique place in an attempt to relax and distract the patient. Often, the labor support person can describe the special place in a meaningful, calming way. For example, the coach may say:

Close your eyes, get comfortable in your chair (or bed), take yourself to the beach. You are standing on the edge of the water. You hear the sounds of the waves rolling in. The water gently laps at your feet. The waves roll in, and the waves roll out. You smell the salty air. Feel the warm sun on your face, the sun is getting warmer and warmer. The waves roll in and out, and the sun is getting warmer. Listen, the sea gulls are flying overhead, you hear them crying out, and you hear the peaceful sound of the waves rolling in and out. You glow with the warm sun on your face, and you feel the gentle breezes against your skin. The waves roll in and out.

Focal points also distract the patient. A focal point may be a picture, photograph, stuffed animal, piece of needlework, or clock on the wall. The laboring woman concentrates or "focuses" on the object while breathing during the contractions. Patients are encouraged to bring the object that will serve as a focal point with them to the hospital or birth center. Focal points enhance concentration and help distract from the discomfort associated with contractions.

Massage and Touch

Massage and touch are techniques that have long been used to facilitate comfort and relaxation during labor. The patient's labor support person or nurse can perform simple hand massage to help decrease tension. Back massage is especially beneficial for the discomfort of back labor.

Effleurage, taken from the French word *effleurer* (to touch lightly) is a gentle stroking technique performed in rhythm with contractions. The patient or her labor support person massages the abdomen using light circular motions. Effleurage is helpful in distracting the patient from her contractions. Massage of the hands, feet, and back may be effective in diminishing tension and in enhancing comfort. Throughout the labor experience, patients and their partners should be encouraged to experiment with various techniques to determine what methods work best for them.

Counterpressure is often effective in enhancing the woman's ability to cope with discomfort from internal pressure and lower back pain. This technique involves use of the labor support person's fist or heel of the hand to apply steady pressure to the sacral area. Counterpressure is especially helpful when maternal back pain results from pressure of the occiput against spinal nerves when the fetal head is in a posterior position. This technique brings pain relief as the counterpressure lifts the occiput off of the spinal nerves.

Therapeutic touch is based on the use of "prana," the body's energy fields. Prana is believed to be deficient in some individuals who experience pain. Specially trained persons use laying-on of hands to provide therapeutic touch to redirect the energy fields thought to be associated with the pain (Scheiber & Selby, 2000). Although the benefits of therapeutic touch in enhancing relaxation and in reducing anxiety and pain have been documented (Marks, 2000), the effectiveness of this modality for pain relief during labor is not known.

Healing touch is also based on use of the body's energy fields. This modality employs a combination of techniques from multiple disciplines. Persons trained in healing touch are taught energetic diagnosis and treatment forms and how to document the patient's response and progress. It is believed that the various techniques align and balance the human energy field, enhancing the body's ability to heal itself. Although healing touch has been used during labor, no studies have been published to document its effectiveness (Hover-Kramer, Mentgen, & Scandrett-Hibdon, 2001).

Hydrotherapy

Hydrotherapy (water therapy) is the use of warm water to promote comfort and relaxation. Hydrotherapy may involve showering or soaking in a regular tub or whirlpool bath. When showering is the selected method of hydrotherapy, the patient stands in a warm shower and allows the water to gently glide over her abdomen. Alternatively, she may wish to sit in a shower chair. The nurse or labor coach may use a hand-held sprayer to direct a steady stream of water over the abdomen or back. Throughout this time, the support person provides reassurance and encouragement, assists with breathing techniques during contractions, and offers touch and massage. The flow of warm water enhances feelings of relaxation and helps to decrease muscle tension. Reduced discomfort and increased relaxation often empowers the woman to have more control over her labor.

Immersion in a tub of warm water filled up to shoulder level is also beneficial in promoting comfort and relaxation. For most, the buoyancy provided by the

water provides welcomed relief from labor discomfort and pain. The production of maternal catecholamines is decreased, prompting an increase in the release of oxytocin (stimulates uterine contractions) and endorphins (reduces the perception of pain). If the woman is experiencing "back labor" from a fetal occiput posterior or transverse position, she may be assisted into a side-lying or hands-and-knees position in the tub. These positions enhance comfort and help to facilitate fetal rotation into an occiput anterior position.

Whirlpool tubs ("jet hydrotherapy") are available in many birth settings, although some institutions require prior approval for use from the patient's primary care provider. The pulsating flow of warm water from the whirlpool jets is soothing and delivers continuous massage to the patient's legs, abdomen, and back. The rhythm of the water flowing in the shower or whirlpool tub provides a soothing sound that aids in relaxation.

During hydrotherapy, fetal heart rate (FHR) monitoring may be intermittent or continuous. It may be conducted via Doppler technique, fetoscope, or use of a wireless external monitor device. Internal electrode placement may not be used with whirlpool baths. In some settings, women with ruptured membranes are allowed to use jet hydrotherapy, provided that the amniotic fluid is clear.

Patients may stay in the tub as long as desired; most remain for 40 to 60 minutes. During that time, if the maternal temperature or FHR increase, if the labor slows or becomes too intense, or if the comforting effects of the water are diminished, patients may come out of the tub and return at a later time. For many, repeated immersions are more effective in relieving pain than a long, continuous exposure to the water. During tub hydrotherapy, the nurse or labor partner can offer comforting, cool washcloths for the face and fluids to promote hydration (Mackey, 2001; Simkin & O'Hara, 2002). To avoid overheating, the water temperature should be maintained at 96.8° to 100.4°F (36° to 38°C) (Florence & Palmer, 2003).

Hypnotherapy

Hypnotherapy is a structured technique that enables the patient to achieve a state of heightened awareness and focused concentration that can be used to alter the perception of pain. With this modality, emphasis is placed on promoting maternal relaxation while decreasing fear, anxiety, and the perception of pain. To accomplish this, the woman may be given direct suggestions about pain relief or indirect suggestions that she is experiencing decreased discomfort (Ketterhagen, VandeVusse, & Berner, 2002). Education about the method and continued practice during the prenatal period are essential in the successful use of hypnotherapy during labor and birth (Gentz, 2001). Hypnotherapy involves the induction of a state of great mental and physical relaxation that can be therapeutic in the management of pain control (Potter, 2006).

Aromatherapy

Aromatherapy is the use of essential oils, derived from plants, flowers, herbs, and trees, whose aroma is thought to have a therapeutic effect in treating illnesses and promoting health and well-being. The fragrances of rose, lavender, frankincense, and bergamot oils are believed to promote comfort and relaxation and decrease pain. Patients

may use the scented oils by adding a few drops to a warm tub bath, or to body compresses and massage lotions or to an aromatherapy lamp used to add fragrance to the room. Drops of lavender and other essential oils may also be massaged into the woman's temples or forehead or placed on a pillow to induce relaxation (Simkin & Bolding, 2004).

clinical alert

When using aromatherapy

Nurses must be aware that the essential oils used in aromatherapy should never be applied to the skin in a full-strength form. Instead, the oils must be diluted, usually in a vegetable oil base, before application. Patients should be cautioned that not all aromatherapy oils are safe to use during pregnancy; some oils, when inhaled, cause side effects such as nausea and headache (Gentz, 2001).

Figure 13-5 A cool washcloth placed on the forehead provides comfort during labor.

Complementary Care: Yoga to reduce discomfort during labor

Prenatal yoga classes, which focus on breathing techniques and enhanced relaxation, are becoming increasingly popular. Physiologically, yoga increases the efficiency of the heart, slows the respiratory rate, and lowers blood pressure. For many, yoga helps decrease stress and anxiety during the prenatal period and provides coping strategies that can be used during labor. The practice of yoga during pregnancy helps women learn to decrease the urge to tighten muscles in response to pain. This response promotes the release of oxytocin to enhance the progress of labor. Poses used in prenatal yoga also facilitate the descent of the fetus and often decrease back pain. Women should always check with their primary care provider before beginning prenatal yoga. For many, attending a prenatal yoga class in the community is a healthy way to meet other women who are beginning a new chapter in their life.

Application of Heat and Cold

The application of heat and cold can promote comfort and help decrease pain during labor and birth. The two modalities may be used alternately to enhance their effects. Heat exerts a therapeutic effect by relieving muscle ischemia and increasing blood flow to the area of discomfort. Warm washcloths applied to the perineum help to relieve the discomfort associated with stretching. Socks or bags that are sewn from cloth can be filled with uncooked rice and heated in a microwave oven. Once warmed, the bags radiate soothing heat that helps to diminish pain. The rice bags may be placed on the patient's neck, back, or wherever the discomfort is felt. When desired, lavender oil, a comforting aroma to many, may be added to the homemade rice bag before heating.

Cold washcloths or ice packs placed on the forehead, chest, or face may be comforting to laboring women who feel warm (Fig. 13-5). Cold packs may also be applied to areas of pain where they exert a therapeutic effect by reducing muscle temperature and relieving muscle spasms. The nurse should be aware that some patients' cultural beliefs may not permit the use of cold therapy during labor (Simkin & Bolding, 2004).

Optimizing Outcomes—When using heat and cold for pain relief during labor

Nurses should avoid the application of heat or cold over body areas that have been anesthetized because of the risk for tissue damage. Hot and cold packs should be used only after one to two layers of cloth have been placed between the pack and the patient's skin (Simkin & Bolding, 2004).

Biofeedback

Biofeedback has been used for many years to enhance relaxation and help patients to gain control over their pain. It is based on the concept that the mind controls the body: if one can recognize physical signals, certain internal physiological events can be changed. During the prenatal period, the woman is taught body awareness, how to recognize responses to stimuli, and various relaxation techniques. She practices using strategies such as concentration, focal points, and breathing to control her response to uncomfortable stimuli. The labor partner learns to recognize cues (e.g., grimacing, tensing, frowning, moaning, and breath holding) indicative of pain and uses verbal feedback and touch to help the woman to achieve relaxation. Formal biofeedback, which involves the use of a recording device to measure physiological responses, requires special training by a skilled biofeedback therapist. Body signals (e.g., skin temperature, blood flow, and muscle tension) that indicate pain and stress are sent via attached electrodes back to the biofeedback unit. The unit then alerts the patient who uses various techniques to decrease the tension and discomfort.

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) involves the delivery of an electric current through electrodes that are applied to the skin over the painful region of a peripheral nerve (Simkin & Bolding, 2004). The TENS unit relieves pain by producing counterirritation on the nociceptors. Normally, two pairs of flat electrodes are placed on either side of the patient's thoracic and sacral spine. Continuous low-intensity electrical impulses are delivered through a battery-operated device. During a contraction, patients are instructed to turn the knobs on

the unit to increase the degree of stimulation from a low intensity to a high intensity. High-intensity levels maintained for at least 1 minute facilitate the release of endorphins. Most women report a pleasant buzzing or tingling sensation that offsets the pain. The TENS unit is especially beneficial for relief of low back pain. The doctor or certified nurse midwife prescribes the use of a TENS unit, which may initially be applied by a physical therapist. The nurse explains the use of the device, assists with its application, and evaluates its effectiveness.

Intradermal Water Block

Intradermal water block is a technique that involves the use of a small (e.g., 25-gauge) needle to inject small amounts (e.g., 0.05 to 0.1 mL) of sterile water into four locations on the patient's lower back to relieve back pain. This method may be used during early labor to delay the initiation of pharmacological pain relief methods. Patients experience a brief stinging sensation immediately after the injections, but the back pain is generally relieved for 45 minutes to 2 hours. Although the mechanism of action is not fully understood, the technique is believed to work by producing counterirritation (pain in one specific area is reduced while skin in close proximity is irritated), gate control, or by increasing circulating endorphins. Once the beneficial effects have diminished, the treatment may be repeated or another pain relief method may be instituted (Gentz, 2001; Simkin & O'Hara, 2002).

Acupressure and Acupuncture

Acupressure, sometimes called "Chinese massage," involves the application of pressure, or heat or cold to identified acupuncture points to decrease the sensation of pain. The points contain an increased density of neuroreceptors and increased electrical conductivity. It is believed that the technique's effectiveness is related to the gate-control theory of pain and an increased release of endorphins. Pressure may be applied by the support person's hands, tennis balls, or by the application of pressure bands—cloth-covered elastic bands that contain rigid plastic inserts—to provide the pressure. During labor, pressure is applied to various acupressure points, which are located on the neck, shoulders, wrists, lower back, hips, area below the kneecaps, ankles, toenails, and soles of the feet. A commonly identified point used for women in labor is Co4 (Hoku or Hegu point), which is located between the first and second metacarpal bones on the back of the hand. Another acupressure point is located between the inner anklebone and the Achilles' tendon. Applying pressure for 1 minute on each ankle is believed to be beneficial in relieving labor pain.

Acupuncture is a therapy used in traditional Chinese medicine for healing and comfort. It is based on the theory that illness results from an imbalance of energy. This method involves the insertion of fine, sterile, stainless steel needles into specific points in the body (i.e., those associated with labor pain) to control the flow of "chi," or life energy. Activation of the insertion points is believed to trigger the release of endorphins. Acupuncture should be performed only by a trained, certified acupuncturist. Although acupuncture is considered to be safe, it is an invasive therapy that carries a risk of infection (Smith et al., 2005).

Collaboration in Caring— Acupressure and acupuncture as modalities for labor pain relief

Not as widely accepted in the United States as in some countries, interest in acupressure and acupuncture as a method of inducing labor and relieving labor pain is increasing as more individuals seek holistic practices and alternative medicine (Allaire, 2001). Today, there are more than 40 schools and colleges of acupuncture that offer training in the technique. While the practice of acupuncture requires a considerable amount of education and training, the certified nurse midwife may work with an acupressurist/acupuncturist to become skilled in the manual massage of acupuncture and acupressure points, as well as shiatsu (the application of pressure to acupuncture sites) and other touch therapies.

Now Can You— Discuss nonpharmacological methods of pain relief during labor?

1. Demonstrate three breathing patterns for labor and explain when each is likely to be most benefit?
2. Identify four signs of hyperventilation and describe nursing interventions to facilitate restoration of the patient's oxygen-carbon dioxide balance?
3. Briefly discuss the use of guided imagery, touch, hydrotherapy, application of heat and cold, and transcutaneous electrical nerve stimulation as nonpharmacological methods to reduce discomfort and pain during labor?

Pharmacological Pain Relief Measures

Pharmacological methods of pain control should be initiated before the pain intensifies to the point that catecholamines are released and labor is prolonged. A combination of nonpharmacological and pharmacological measures provides pain relief, enhances the patient's comfort and sense of control over her situation, and promotes a positive child-bearing experience for the woman and her family. During early labor, nonpharmacological methods alone are often satisfactory for relaxation and pain relief. As labor progresses, contractions and discomfort intensify, often necessitating the addition of pharmacological agents for pain control. Because nonpharmacological measures promote relaxation and potentiate the effects of analgesic agents, less pharmacological intervention is usually required (Faucher & Brucker, 2000).

Be sure to— Ensure the patient is informed about available pharmacological methods of pain relief

The nursing role of patient advocate includes ensuring that the woman understands the alternative methods of pain relief that are available in the birth facility and, when indicated, by asking the primary care provider for further details or clarification. Obtaining an informed consent for interventions means that the procedure and its advantages and disadvantages are fully explained; the patient must agree with the plan of care as it is described

Nursing Care Plan Patient Who Plans to Use Nonpharmacological Methods of Pain Relief During Labor

Ann is a 28 year old gravida 2, para 1, who was admitted 45 minutes ago. Ann's cervix is 4 cm dilated and 100% effaced, the station is -2 and her membranes are intact. Uterine contractions occur every 3 minutes, last 45–50 seconds and are of moderate intensity. The fetal heart rate averages 140–145 beats per minute and has no non-reassuring patterns. Ann complains of low back pressure and pain. She and her husband Raul have prepared a birth plan; they attended childbirth preparation classes and state they feel comfortable with using the methods learned.

Nursing Diagnosis: Coping, Readiness for Enhanced related to intention and preparation to meet the demands of childbirth

Measurable Short-term Goal: Ann will demonstrate a relaxed facial and body posture during contractions.

Measurable Long-term Goal: Ann will successfully use relaxation and breathing techniques learned in childbirth class throughout her labor.

NOC Outcomes:

- Personal Well-Being (2002) Extent of positive perception of one's health status and life circumstances
- Coping (1302) Personal actions to manage stressors that tax an individual's resources

NIC Interventions:

- Coping Enhancement (5230)
- Support System Enhancement (5440)

Nursing Interventions:

1. Review the birth plan with Ann and Raul, answering any questions and providing additional information as needed. Inform other caregivers of the couple's plans for their labor and birth.
RATIONALE: Appraisal of the couple's expectations allows the opportunity to provide factual information and offer support in an accepting environment.
2. Ensure a comforting environment: offer warmed blankets, an electric or hand held fan; adjust the room thermostat as needed.
RATIONALE: A comfortable environment enhances relaxation and increases the patient's ability to focus on her coping skills.
3. Provide Ann's preferred music as desired; use soft lighting; ensure the focal point is within easy view; avoid conducting assessments and procedures during contractions; ensure that bed linens are soft, clean, and dry.
RATIONALE: Listening to favorite music may distract the patient from discomfort and external noises. Environmental distractions and unnecessary stimulants interfere with the successful use of learned techniques to manage labor discomfort.
4. Assist Raul in helping Ann to find a position of comfort; encourage position changes every 30–60 minutes and unless contraindicated, encourage ambulation, sitting in a chair or use of a birth ball.
RATIONALE: Assistance empowers Raul to participate actively in the labor and birth experience. Position changes enhance maternal comfort by reducing muscle tension and facilitate fetal descent.
5. Encourage Raul to perform back rubs or provide counterpressure as learned in childbirth classes, according to Ann's desires.
RATIONALE: Back rubs and counterpressure provide comfort from pain associated with back labor by stimulating the large-diameter fibers and interfering with the transmission of pain impulses to the brain.
6. Keep Ann and Raul informed of the progress of labor.
RATIONALE: Ongoing information helps to decrease anxiety and fear, which increase the perception of pain and decrease pain tolerance; news of labor progress provides an incentive to continue with efforts to cope with labor.

to her; and the patient's consent must be given freely without coercion or manipulation from her health care provider (Lowe, 2004).

SEDATIVES AND ANTIEMETICS

Sedatives are agents that relieve anxiety and induce sleep. They are primarily used during the early latent phase of labor, when the cervix is long, closed, and

thick and rest has been prescribed for the patient. Sedatives may also be used to augment analgesics and reduce nausea after the administration of opioids. Sedatives induce sleep for a few hours. Once the woman awakens, either the contractions have ceased (i.e., the patient had experienced false labor) or regular, effective contractions that produce cervical change occur. Sedatives should not be used during active labor because they can cause respiratory depression in the neonate (Faucher & Brucker, 2000).

Be sure to— Assess and reassess during the intrapartal period

During the intrapartal period, it is important to assess the laboring patient and her fetus following each intervention to promote comfort. Specifically, nurses should:

- Assess for risk factors: bleeding, infection, ruptured membranes, fetal presentation, prolapsed cord, precipitous labor, meconium-stained amniotic fluid, postmaturity, prematurity, or fetal heart rate irregularities.
- Assess maternal vital signs per facility protocol.
- Assess the patient's anxiety level, coping mechanisms, and labor support.
- Assess the progress of labor.
- Assess the fetal heart rate, lie, and presentation.
- Assess the maternal and fetal response to each comfort measure.
- Carefully document all findings.

Barbiturates

Secobarbital is the most commonly used barbiturate in labor. It is a fast-acting oral agent that produces mild sedation within 15 minutes after administration; its effects last for 3 to 4 hours. Undesirable effects include maternal and neonatal respiratory and vasomotor depression. These effects are intensified if a barbiturate is administered with another central nervous system (CNS) depressant. However, when given without an analgesic to a woman experiencing pain, the pain is increased. For these reasons, barbiturates are rarely used in labor (Faucher & Brucker, 2000; Hawkins, Chestnut, & Gibbs, 2002).

Benzodiazepines

Benzodiazepines are agents primarily used to treat anxiety (e.g., diazepam [Valium]; lorazepam [Ativan]). Their mechanism of action is similar to that of barbiturates. When given with an opioid analgesic, benzodiazepines enhance pain relief and decrease nausea and vomiting, although some have an amnesic effect that may be unacceptable for women in labor (Bricker & Lavender, 2002; Lehne, 2006).

clinical alert

Flumazenil to reverse the effects of benzodiazepine sedatives

Flumazenil (Romazicon) is an agent that reverses the effects of benzodiazepine sedatives. This intravenously administered medication should be readily available in any childbirth setting where benzodiazepines are used.

H₁-Receptor Antagonists

H₁ receptor antagonists are medications that block the action of histamines at the receptor sites. These medications produce sedative, anti-Parkinson, and antiemetic effects. They cause drowsiness and are often used during early labor to promote sleep and decrease anxiety. During labor, the H₁ receptor antagonists commonly used include

promethazine (Phenergan), hydroxyzine (Vistaril), and diphenhydramine (Benadryl) (Hawkins et al., 2002).

Promethazine (Phenergan), a phenothiazine, produces marked sedation and has strong antiemetic effects. It is frequently combined with opiates because it potentiates their effects. Phenothiazines readily cross the placenta, and may produce decreased FHR beat-to-beat variability. They also bind to bilirubin binding sites in the neonate and may cause increased hyperbilirubinemia and jaundice in term infants who were exposed to the drug during the intrapartal period (Hawkins et al., 2002).

Hydroxyzine (Vistaril), a piperazine subtype, is used during early or prodromal labor to decrease nausea and anxiety. It also exerts a sedative effect. Often, women who receive this intramuscular medication awaken to increased contraction intensity that produces cervical changes (i.e., active labor).

Diphenhydramine (Benadryl) is a nonprescription medication with sedative and antiemetic properties that is given during early labor. Because the drug is readily available, nurses can advise women to use it at home although it may cause agitation in some patients. The half-life of diphenhydramine is 1 to 4 hours and its effects may last up to 8 hours.

Nursing Insight— Recognizing the anxiety–tissue anoxia–pain connection

Pain can trigger the body's general stress response, called the “fight or flight” reaction. The release of epinephrine causes peripheral and uterine vasoconstriction, which results in tissue anoxia and increased pain. Decreasing the patient's anxiety through assistance with relaxation techniques or administration of antianxiety medications reduces vasoconstriction and helps to decrease pain.

Now Can You— Discuss informed consent and the use of sedatives and antiemetics during labor?

1. State the three components of an informed consent that must be assured before instituting pharmacological interventions for pain relief during labor?
2. Describe the indications for the use of sedatives and antiemetics during labor and identify two commonly prescribed H₁-receptor antagonists?
3. Explain how diminishing maternal anxiety helps to relieve pain?

DIFFERENTIATING ANALGESIA FROM ANESTHESIA

To enhance understanding of the pharmacological methods of pain relief, it is important to distinguish between the concepts of analgesia and anesthesia. **Analgesia** is relief, to some degree, from pain. Pain may be entirely eliminated or only lessened. Analgesia may be accomplished via many methods, including medications, the application of heat or cold, massage, or electrical stimulation. **Anesthesia** is the partial or complete loss of sensation with or without the loss of consciousness. There are many types of analgesia and anesthesia and a number of

methods for administering it. The analgesic or anesthetic selected is determined, to some degree, by the patient's stage of labor and by the method of birth anticipated (Boxes 13-1 and 13-2). When given too early, analgesia may prolong the labor and cause fetal depression. When administered too late, analgesia provides no benefit to the woman and may cause depression in the neonate.

The nurse's role involves continuous patient assessment to monitor the progress of labor and to identify cues that indicate that the patient would benefit from the administration of analgesic medications prescribed by the physician, certified nurse-midwife (CNM), or certified registered nurse-anesthetist (CRNA). Depending on institutional policy, the CNM or physician may evaluate the woman in the birthing facility or rely on the nurse's assessment and instruct the nurse to administer the ordered medications. In most facilities, the CRNA monitors analgesia-related complications and conducts continuous monitoring for patients who receive epidural anesthesia. In some institutions, an anesthesiologist (physician who specializes in the administration of anesthesia) is available to provide these services.

Box 13-1 Pharmacological Interventions for Intrapartal Pain Control According to Stage of Labor

FIRST STAGE OF LABOR

Systemic Analgesia

Opioid agonists (e.g., hydromorphone hydrochloride [Dilaudid]; meperidine hydrochloride [Demerol]; fentanyl citrate [Sublimaze]; sufentanil citrate [Sufenta])

Opioid agonist-antagonists (e.g., butorphanol [Stadol]; nalbuphine [Nubain])

Nerve Block Analgesia

Epidural

Combined spinal-epidural

SECOND STAGE OF LABOR

Nerve Block Analgesia and Anesthesia

Local infiltration

Pudendal block

Spinal block

Epidural block

Combined spinal-epidural

Box 13-2 Pharmacological Interventions for Intrapartal Pain Control According to Birth Method

VAGINAL BIRTH

- Local infiltration anesthesia
- Pudendal block
- Epidural block analgesia/anesthesia
- Spinal block anesthesia
- Combined spinal-epidural analgesia/anesthesia

CESAREAN BIRTH

- Spinal block anesthesia
- Epidural block anesthesia
- General anesthesia

SYSTEMIC ANALGESIA

Systemic analgesic agents provide central analgesia to the patient and fetus, since they readily cross the placenta. Although this method of pain control during labor has declined, it is still used in facilities where specialists trained in administering regional analgesia (e.g., epidural analgesia) are not available (Bricker & Lavender, 2002; Bucklin, Hawkins, Anderson, & Ulrich, 2005). Fetal-neonatal effects include respiratory depression, decreased alertness, and delayed sucking, depending on the agent used, the dosage given, and the route and timing of administration. Intravenous administration is preferred over intramuscular injection because the onset of action is more rapid and predictable, pain relief is obtained with smaller doses of the drug, and the duration of the effect is more predictable. The medication is administered into the intravenous tubing port nearest the patient while the IV solution is stopped.

Optimizing Outcomes— When administering intravenous medications during labor

Intravenous analgesics are given slowly, in small doses during a contraction. When necessary, the medication may be given over a period of four to five consecutive contractions in order to complete the dose. Administering the medication during a contraction decreases fetal exposure to the drug because uterine blood vessels are constricted during contractions and the medication remains in the maternal vascular system for several seconds before the uterine blood vessels reopen.

In many institutions, patient-controlled analgesia (PCA) is available. The laboring woman self-administers small amounts of an opioid analgesic using a pump previously programmed for dose and frequency. As a result, a smaller amount of medication is required and women are generally pleased with the level of pain control achieved (Bricker & Lavender, 2002). Analgesic agents available for the intrapartum period include opioid (narcotic) agonists and opioid (narcotic) agonist-antagonists.

Nursing Insight— Differentiating between agonist agents and antagonist agents

Analgesic medications used intrapartally include opioid agonists and opioid antagonists.

Agonist agents stimulate receptors to act. Antagonist agents block receptors or medications designed to activate receptors.

Opioid Agonist Analgesics

Opioid agonist analgesics include hydromorphone hydrochloride (Dilaudid), meperidine hydrochloride (Demerol), fentanyl citrate (Sublimaze), and sufentanil citrate (Sufenta) (Table 13-1). These agents work by stimulating the major opioid receptors mu and kappa. They promote feelings of euphoria and exert no amnesic effects. Because they delay gastric emptying time, nausea and vomiting are common side effects; bladder and bowel elimination may also be

diminished. Results from a national survey of women's childbearing experiences revealed that women were not satisfied with the level of pain relief achieved with opioid analgesics given intrapartally. Nearly 40% of women who received parenteral opioids during labor rated them as being not very helpful or not helpful at all. However, intrapartum opioid administration is associated with shorter labors, less use of oxytocin, and fewer instrumented vaginal births (e.g., forceps-assisted, vacuum-assisted) than intrapartum epidural administration (Bricker & Lavender, 2002; Caton et al., 2002; Leighton & Halpern, 2002; Maternity Center Association, 2002). Ideally, opioid agonist analgesics should be given either less than 1 hour or greater than 4 hours before birth to minimize neonatal depression. Fentanyl citrate and sufentanil citrate require more frequent administration because of their relatively short duration of action (30 to 60 minutes, compared with 2 to 4 hours for hydromorphone hydrochloride and meperidine hydrochloride). Consequently, these agents are often administered intrathecally or epidurally, alone or in combination with a local anesthetic medication (Faucher & Brucker, 2000; Florence & Palmer, 2003; Lehne, 2006).

Optimizing Outcomes— Safety measures for women who receive opioid analgesics

Opioid analgesics may cause bradycardia/tachycardia, hypotension, and respiratory depression and should be administered cautiously in women with respiratory or cardiovascular disorders (Lehne, 2006). Because patients may experience sedation and dizziness following administration, nurses should assist with ambulation and observe for adverse effects.

Opioid Agonist–Antagonist Analgesics

Opioid agonist–antagonist agents include butorphanol (Stadol) and nalbuphine (Nubain), which are agonists at kappa opioid receptors and either antagonists or weak

medication: Fentanyl

Fentanyl (**fen**-ta-nil)
Sublimaze

Schedule II Pregnancy Category: C

Indications: Supplement to regional/local anesthesia; often administered epidurally or intrathecally to relieve moderate to severe labor pain and postoperative pain after cesarean birth.

Actions: Binds to opiate receptors in the CNS, alters the response to and perception of pain; produces CNS depression

Therapeutic Effects: Supplement to anesthesia; decreased pain

Contraindications and Precautions:

CONTRAINDICATED IN: Hypersensitivity; known intolerance

Adverse Reactions and Side Effects: Confusion, drowsiness, dizziness, rash, maternal and fetal/neonatal respiratory depression, nausea and vomiting, urinary retention

Route and Dosage: 25–50 mg IV; 1–2 mg with 0.125% bupivacaine at a rate of 8–10 mL/hr epidurally

Nursing Implications:

Assess for respiratory depression; naloxone should be readily available as antidote.

Adapted from Deglin, J.H., and Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

agonists at mu opioid receptors. During labor, these medications provide satisfactory pain control without inducing respiratory depression in the woman or neonate. They are also associated with less nausea and vomiting and are used more often during labor than the opioid agonist analgesics. They may be administered intravenously or intramuscularly; the parenteral route is preferred. Opioid agonist–antagonists should not be given to women with an opioid dependence because the antagonist activity may precipitate maternal/neonatal withdrawal symptoms (Deglin & Vallerand, 2009; Florence & Palmer, 2003; Lehne, 2006).

Table 13-1 Opioid Agonist Analgesics

Opioid–Agonist Analgesic	Route and Dosage	Nursing Considerations
Hydromorphone hydrochloride (Dilaudid)	IV: 1 mg q3h prn IM: 1–2 mg q3–6h prn	Monitor vital signs, FHR pattern and uterine activity prior to and during administration; observe for maternal respiratory depression; encourage voiding q2h, palpate for bladder distention; if birth occurs within 1–4 hours after administration, observe neonate for respiratory depression
Meperidine hydrochloride (Demerol)	IV: 25 mg q1–3h prn IM: 50–100 mg q1–3h prn	
Fentanyl citrate (Sublimaze)	IV: 25–50 mg; 1–2 mg with 0.125% bupivacaine at rate of 8–10 mL/hr epidurally	
Sufentanil citrate (Sufenta)	IV: 1 mg with 0.125% bupivacaine at rate of 10 mL/hr	

 **medication:** Butorphanol
 Butorphanol (byoo-**tor**-fa-nole)
 Stadol

Schedule IV Pregnancy Category: C

Indications: Moderate to severe labor pain; postoperative pain after cesarean birth

Actions: Stimulates kappa opioid receptors and blocks or weakly stimulates mu opioid receptors; alters pain perception, produces generalized CNS depression

Therapeutic Effects: Decreased severity of pain

Contraindications and Precautions:
 CONTRAINDICATED IN: Hypersensitivity; patients dependent on opioids (may precipitate withdrawal)

Adverse Reactions and Side Effects: Confusion, drowsiness, sedation, blurred vision, headache, dysphoria, hallucinations, sweating, maternal palpitations/tachycardia or bradycardia, respiratory depression, transient nonpathologic sinusoidal-like FHR rhythm, urinary retention and urgency

Route and Dosage: 1 mg (range 0.5–2 mg) IV every 3–4 hours as needed; 2 mg (range 1–4 mg) IM every 3–4 hours as needed

Nursing Indications: May precipitate withdrawal symptoms in woman/neonate

Adapted from Deglin, J.H., and Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

critical nursing action When Combining
 Butorphanol with Other
 CNS Depressants

Butorphanol is associated with respiratory depression in both the mother and fetus. When administering butorphanol with other CNS depressants (e.g., hypnotic agents, phenothiazides, sedatives, other tranquilizers, and general anesthetics), the nurse should closely monitor the patient's respiratory and cardiac status for signs of respiratory depression. Ongoing observation of the maternal level of consciousness, vital signs, and pulse oximetry as well as continuous electronic FHR monitoring is recommended. Naloxone (Narcan), the specific antagonist for this medication, should be readily available to reverse the drug effects if needed.

Opioid Antagonists

Opioid antagonists, such as naloxone (Narcan), reverse the CNS depressant effects of opioids. Administered intravenously or intramuscularly, they are of benefit when labor progresses more rapidly than anticipated and birth is expected to occur when the opioid is at its peak effect. Placental transfer of naloxone is variable; the neonate may not require treatment with an opioid antagonist (Lehne, 2006).

 **Now Can You—** Discuss characteristics of systemic analgesia used during labor?

1. Explain how systemic analgesia should be administered during labor?
2. Identify three advantages and one major disadvantage associated with the use of opioid agonist agents during labor?
3. Explain specific precautions that should be taken when administering opioid agonist-antagonists to a woman in labor?

NERVE BLOCK ANALGESIA AND ANESTHESIA

Local anesthetics used in obstetrics may produce regional analgesia, which provides some degree of pain relief and motor block; and anesthesia, which provides complete pain relief and motor block. Regional analgesia may be obtained by the injection of a narcotic agent such as fentanyl along with a small amount of a local anesthetic agent. **Regional anesthesia**, a temporary and reversible loss of sensation, is produced by the injection of an anesthetic agent (a local anesthetic) into an area that brings the medication into direct contact with nervous tissue. Regional anesthetic agents block sodium and potassium transport in the nerve membrane, causing stabilization of the nerve(s) in a polarized resting state, which prevents the initiation and transmission of nerve impulses. Rarely, serious reactions (e.g., respiratory depression, hypotension) to local anesthesia may occur from one or more anesthetic agents. The nurse should ensure that emergency measures, including epinephrine, antihistamines, and oxygen are readily available in all patient areas where these medications are used. When caring for patients receiving analgesia/anesthesia by catheter, nurses must be aware of institutional policy and national standards. The Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN) has developed a clinical position statement (AWHONN, 2002; available at <http://www.awhonn.org/awhonn/content.do?name=05HealthPolicyLegislation/5HPositionStatements.htm>) to guide safe practice.

 **Nursing Insight—** Recognizing local anesthetic agents

Because most local anesthetic agents are chemically related to cocaine, their names end with the suffix “-caine.” Examples of such medications include lidocaine, mepivacaine, bupivacaine, ropivacaine, and chloroprocaine.

The regional anesthetic blocks commonly used in obstetrics include epidural, spinal, or combined epidural–spinal. Epidural blocks may be administered for analgesia during labor and vaginal birth and for anesthesia during cesarean birth. Alternately, a combined epidural–spinal block may be used—the epidural provides analgesia for labor; the spinal provides anesthesia for birth or analgesia after the birth. During the first stage of labor, an epidural relieves pain by blocking the sensory nerves that supply the uterus. Pain experienced during the second stage of labor and with birth can be alleviated with epidural, combined epidural–spinal, and pudendal blocks. A summary of commonly used regional blocks is presented in Table 13-2.

Local Perineal Infiltration Anesthesia

Local perineal infiltration anesthesia is used to provide pain control when an episiotomy is to be performed or when suturing of lacerations is necessary in a patient who does not have regional anesthesia. Epinephrine, which causes vasoconstriction, may be added to the anesthetic agent to intensify the anesthesia effect and to minimize bleeding and prevent systemic absorption (Lehne, 2006).

Table 13-2 Commonly Used Regional Blocks for Labor and Birth

Type of Block; Areas Affected	When Used During Labor and Birth	Nursing Implications
Local Perineal Infiltration <i>Affected area:</i> Perineum	Immediately before birth for episiotomy; after birth for repair of lacerations	Assess patient's knowledge and understanding; provide information as needed. Observe perineum for bruising or discoloration during the recovery period.
Pudendal Nerve Block <i>Affected areas:</i> Perineum and lower vagina	Late in the second stage for episiotomy, forceps, or vacuum extraction; during third stage for repair of episiotomy or lacerations	Assess patient's level of knowledge and understanding; provide additional information as needed.
Spinal Anesthesia Block <i>Affected areas:</i> Uterus, cervix, vagina, and perineum	First stage for both elective and emergent cesarean births; low spinal anesthesia block may be used for vaginal birth—not suitable for labor	Assess patient's level of knowledge and understanding; provide additional information as needed. Monitor maternal vital signs and FHR status.
Lumbar Epidural Block <i>Affected areas:</i> Uterus, cervix, vagina, and perineum	First and second stages	Assess patient's level of knowledge and understanding; provide additional information as needed. Monitor maternal blood pressure—major side effect is hypotension. Provide ongoing support.
Combined Spinal–Epidural <i>Affected areas:</i> Uterus, cervix, vagina, and perineum	Spinal analgesia may be administered during the latent phase for pain relief. Epidural is given when active labor begins	Assess patient's level of knowledge and understanding; provide additional information as needed. Monitor maternal vital signs and FHR status. Provide ongoing support.

Nursing Insight— Recognizing the value of natural pressure anesthesia

Pressure anesthesia is the natural numbing effect caused by pressure of the fetal head against the woman's stretched perineum. For some, pressure anesthesia is adequate enough to allow an episiotomy to be performed without feeling the sensation of the actual surgical cut. Others require additional medication to help reduce the pain associated with childbirth.

Pudendal Nerve Block

A pudendal nerve block provides pain relief in the lower vagina, vulva, and perineum (Fig. 13-6). It should be administered 10 to 20 minutes before perineal anesthesia is needed and may be used late in the second stage of labor

if an episiotomy is to be performed or if forceps or vacuum extraction will be used to facilitate birth. The anesthetic effect diminishes or completely removes the maternal bearing-down reflex. It may also be used during the third stage of labor for laceration repair.

Spinal Anesthesia Block

Spinal anesthesia block involves the injection of a solution containing a single local anesthetic or an anesthetic combined with fentanyl through the third, fourth, or fifth lumbar interspace into the subarachnoid space, where it mixes with cerebrospinal fluid. The subarachnoid space is a fluid filled area located between the dura mater and the spinal cord. At present, the spinal anesthesia block is used more often for elective and emergent cesarean births than epidural

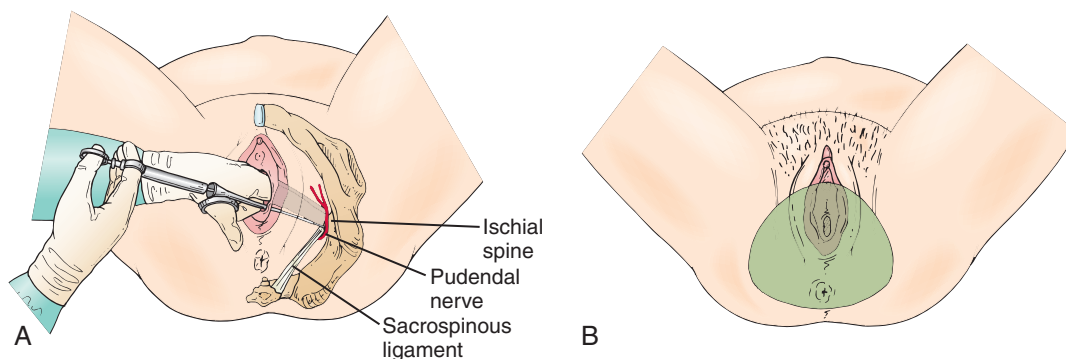

Figure 13-6 A. Administration of a pudendal block. B. The areas of the perineum affected by a pudendal block.

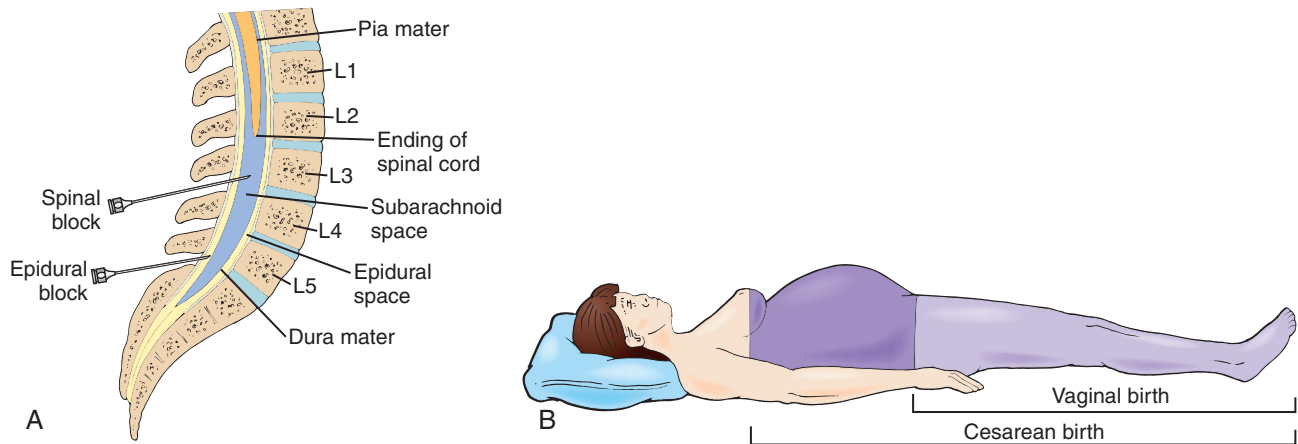

Figure 13-7 A. The spinal column: levels of the sacral, lumbar, and thoracic nerves. B. Levels of anesthesia necessary for vaginal and cesarean births.

anesthesia (Bucklin et al., 2005). The differences in the levels of spinal anesthesia for vaginal and cesarean birth are created by the dosage of the anesthetic agent administered, and the position of the patient after placement of the medication in the dural sac. For vaginal birth, a low spinal anesthesia block provides anesthesia from level T10 (hips) to the feet; patients remain in a sitting position for a brief period of 1 to 2 minutes after administration to facilitate downward migration of the anesthetic solution toward the sacral area. For cesarean birth, the level of anesthesia coverage extends from the nipples (T6) to the feet; after administration of the anesthetic solution, patients are immediately assisted to a supine position with a left lateral tilt to enhance a cephalad spread of the anesthesia (and a higher level of sensory blockade). The anesthetic agent may be “weighted” with glucose to make it heavier than CSF. This prevents the medication from rising too high in the spinal canal and interfering with motor control of the uterus or with the maternal respiratory muscles (Fig. 13-7).

Spinal anesthesia block has several advantages: it is easy to administer; has an immediate onset of anesthesia; requires a smaller volume of medication; produces

excellent muscular relaxation; allows for maintenance of maternal consciousness; and is associated with minimal blood loss. However, because uterine contraction sensation is lost, the patient must be instructed when to bear down during a vaginal birth. Since voluntary maternal expulsive efforts are compromised, there is an increased likelihood of an operative (e.g., episiotomy, forceps-assisted; vacuum-assisted) birth. After childbirth, there is an increased incidence of bladder and uterine atony and postdural puncture headache.

Nursing care during administration of a spinal anesthesia block includes proper positioning of the patient in a lateral or sitting position with the back curved outward to widen the intervertebral space (Fig. 13-8). After injection of the anesthetic solution, the patient is positioned upright to allow downward flow of the solution to provide a lower level of anesthesia suitable for a vaginal birth. For a cesarean birth, the patient is placed in a supine position with the head and shoulders slightly elevated with a wedge placed under one of the hips to displace the uterus (to obtain a higher level of anesthesia coverage). Effects from the anesthesia occur within 1 to 2 minutes after injection and last 1-3 hours, depending on the anesthetic agent used (Hawkins et al., 2002) (Procedure 13-1).

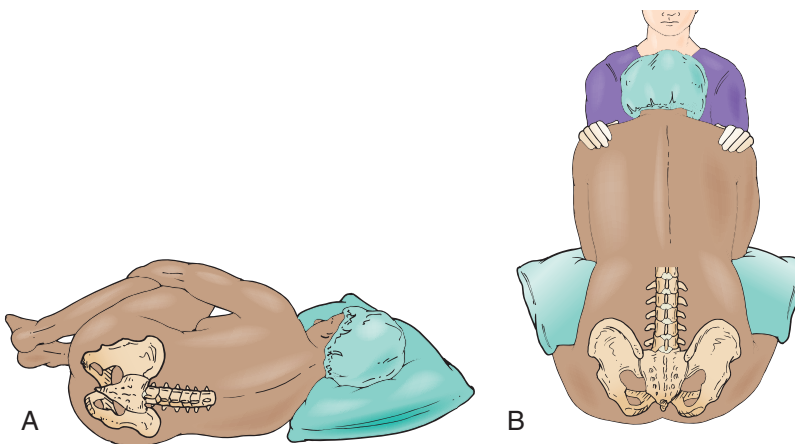

Figure 13-8 A. Lateral position for spinal and epidural block. B. Sitting position for spinal and epidural block.

Procedure 13-1 Assisting with the Administration of Spinal Anesthesia

Purpose

To facilitate administration of a spinal anesthesia block for the relief of pain during labor and birth.

Equipment

- Blood pressure cuff
- Stethoscope
- Fetal monitor

Steps

1. Wash and dry your hands. Explain the procedure and purpose of the examination to the patient.

RATIONALE: Hand washing helps to prevent the spread of microorganisms. Explanations help to decrease anxiety and promote patients understanding and cooperation.

2. Assist the patient to a sitting position on the edge of the bed or operating table (as directed by the nurse anesthetist or anesthesiologist).

3. Provide support, promote comfort, and limit motion during the procedure.

RATIONALE: Proper positioning (e.g., head bowed so that the back arches outward to widen the intervertebral space) and restricted movement are essential to successful anesthesia administration. Support prevents the patient from falling forward (she is “top heavy” from the gravid uterus).

4. Check the intravenous infusion for patency.

RATIONALE: Hypotension from sympathetic blockage in the lower extremities may occur immediately after anesthesia administration. For this reason, IV fluids such as lactated Ringer’s solution (500–1000 mL) are usually given before the injection to ensure maternal hydration; confirming the patency of IV tubing ensures that the fluid is infusing well before the anesthesia is administered and facilitates the rapid infusion of fluids if needed for postadministration hypotension.

5. Assist the patient to lie down on her back after anesthesia administration (as directed by the nurse anesthetist or anesthesiologist)

6. Place a pillow under her head and a wedge under her right hip

RATIONALE: Remaining in an upright position for too long prevents the anesthetic from rising high enough up the spinal canal to achieve pain relief. Conversely, lying down too soon allows the anesthetic to rise too high in the spinal canal. Lying with a pillow under the head helps to ensure that the anesthesia will be confined to the lower spinal canal. A wedge placed under the right hip displaces the uterus and helps to prevent compression of the vena cava.

7. Monitor the pulse, blood pressure, and respirations every 1 to 2 minutes for the first 10 minutes, then every 5 to 10 minutes. Use electronic monitoring to continuously monitor the FHR.

RATIONALE: Frequent assessment of maternal vital signs is essential for recognizing hypotension (from sympathetic blockage in the lower extremities) or an adverse reaction. Ongoing assessment of the fetal heart rate and pattern provides evidence of fetal well-being.

8. Document the procedure on the patient’s chart.

RATIONALE: Documentation provides a record for communication and evaluation of patient care.

Nursing Consideration

The nurse informs the nurse anesthetist or anesthesiologist when a contraction is beginning so that the anesthetic will not be administered during a contraction.

Documentation

8/30/09. 0425: Spinal anesthesia administered by J. Chen, CRNA. 1000 mL lactated Ringers solution infused IV prior to administration per protocol. Procedure tolerated well by patient. Vital signs: Preanesthesia administration, BP: 116/78 mm Hg, Pulse: 84 bpm, Respirations: 14 breaths/min, FHR: 146 bpm and regular; Postanesthesia administration, BP: 110/72 mm Hg, Pulse: 80 bpm, Respirations: 12 breaths/min, FHR: 148 bpm and regular.

–S. Rinaldi, RNC

Complications that may occur with spinal anesthesia block include maternal hypotension, decreased placental perfusion, and an ineffective breathing pattern. Before administration, the patient’s fluid balance is assessed and intravenous fluids are administered to reduce the potential for sympathetic blockade (decreased cardiac output that results from vasodilation with pooling of blood in the lower extremities). After administration of the anesthetic, the patient’s blood pressure, pulse, and respirations and FHR must be taken and documented every 5 to 10 minutes. If indicators of severe maternal hypotension (e.g., a drop in the baseline blood pressure of more than 20%) or fetal compromise (e.g., bradycardia; decreased variability; late decelerations) develop, emergency measures must be instituted.

critical nursing action Severe Maternal Hypotension and Decreased Placental Perfusion

In the event of severe maternal hypotension, the nurse takes the following actions:

- Place the patient in a lateral position or use a wedge under the hip to displace the uterus; elevate the legs.
- Maintain or increase the IV infusion rate, according to institution protocol.
- Administer oxygen by face mask at 10–12 L/min, or according to institution protocol.
- Alert the primary care provider, anesthesiologist, or nurse anesthetist.

- Administer an IV vasopressor (e.g., ephedrine 5–10 mg) according to institutional protocol, if the above measures are ineffective.
- Remain calm, offer reassurance, and continue to assess maternal blood pressure and FHR every 5 minutes until stable or per order from the primary care provider.

Postdural puncture headache, a complication that may develop within 48 hours after the puncture, is believed to occur from leakage of cerebrospinal fluid (CSF) from the puncture site in the dura mater. Typically, the headache is intensified when the patient assumes an upright position and relieved when she assumes a supine position. Accompanying symptoms include auditory (tinnitus) and visual (blurred vision, photophobia) problems. Interventions usually center on oral analgesics, bed rest in a darkened room, caffeine, and hydration. If these measures are not effective, an autologous epidural blood patch may be administered. Approximately 10–20 mL of the patient's blood is slowly injected into the lumbar epidural space. A clot forms in the tear or hole in the dura mater around the spinal cord, effectively sealing the area from further CSF leakage.

Optimizing Outcomes— Discharge instructions after autologous epidural blood patch

Discharge planning after administration of an autologous epidural blood patch includes providing the following instructions:

- Maintain bedrest for 24–48 hours.
- Apply cold packs to the area as needed for pain relief.
- Increase oral fluids.
- Avoid the use of analgesics that affect platelet aggregation (e.g., nonsteroidal anti-inflammatory drugs) for 2 days.
- Observe for signs of infection at the site.
- Observe for signs of neurological complications (pain, numbness, tingling in the legs; difficulty with ambulation).

Now Can You— Discuss local infiltration, pudendal nerve block, and spinal block anesthesia?

1. Discuss the indications for and timing of administration for local infiltration anesthesia and a pudendal nerve block?
2. Name four advantages and two disadvantages associated with spinal block anesthesia?
3. Describe the immediate nursing actions to be taken for severe maternal hypotension with decreased placental perfusion?

Epidural Anesthesia or Analgesia Block

Injection of a local anesthetic such as bupivacaine, an opioid analgesic such as fentanyl or sufentanil, or both into the epidural space (between L4 and L5) provides pain relief from uterine contractions and vaginal or cesarean birth. The degree of analgesic or anesthetic effect obtained is related to the specific medication used. Combining an opioid with a local anesthetic agent reduces the total amount of anesthetic required and helps to preserve a greater amount of maternal motor function (McCool, Packman, & Zwerling, 2004).

Figure 13-9 The epidural space is located between the dura mater and the ligamentum flavum and extends from the base of the skull to the end of the sacral canal.

Figure 13-10 The spinal canal: injection sites for regional anesthesia.

A & P review The Epidural Space

The nerves located in the spinal cord are covered and protected by several tissue layers. The pia mater is the membrane that adheres to the nerve fibers. It is surrounded by CSF. The next layer is the arachnoid membrane; the dura mater is the protective covering that lies outside of this membrane. An anesthetic agent administered into the CSF in the subarachnoid space is called *spinal anesthesia*. The epidural space is a vacant space located

outside the dura mater; beyond the epidural space, the ligamentum flavum, which extends from the base of the skull to the end of the sacral canal, provides another protective layer. With *epidural anesthesia*, an anesthetic agent is placed just inside the ligamentum flavum in the epidural space (Figs. 13-9 and 13-10). ♦

Nursing Insight— *Methods for administering an epidural block*

Epidural blocks, administered by a nurse anesthetist or anesthesiologist, may be given in different ways. For analgesia and anesthesia during labor, the block may be administered as a single dose with an epidural needle. It may also be administered as a single dose through an epidural catheter, with additional doses (“top-offs”) given as needed, or given as a continuous epidural. Patients may be required to remain in bed; other blocks allow ambulation (“walking epidural”) (Mayberry, Clemmens, & De, 2002).

LUMBAR EPIDURAL ANESTHESIA AND ANALGESIA BLOCK. The lumbar epidural anesthesia and analgesia block is the most commonly used method of pain control during labor; nearly two thirds of women in the United States incorporate this intervention for discomfort and pain into their birth plan (Bucklin et al., 2005). Advantages of this method include maternal relaxation, enhanced comfort and pain relief, and an ability to remain alert and participate in the birth. Also, there is little blood loss, the respiratory reflexes remain intact, there is no delay in gastric emptying, and only a partial degree of motor paralysis occurs. Fetal complications are rare and are related to maternal hypotension or effects from the rapid absorption of the medication. Postdural puncture headaches, caused by leakage of CSF, rarely occur because with epidural anesthesia, the CSF space is not entered.

Epidural blocks are advantageous for patients with diabetes, heart disease, pulmonary disease, and, in some cases, pregnancy-induced hypertension because they essentially eliminate the pain associated with labor and thus reduce the maternal stress associated with labor discomfort. The patient’s energy level is preserved because she does not feel the contractions. Epidural blocks may be used with preterm pregnancies because there is minimal effect on the fetus. A gentle, controlled birth is associated with minimal trauma to the immature fetal skull and there are no systemic narcotic analgesics to cause depression in the premature neonate.

Maternal hypotension is the most common complication of epidural anesthesia. Preloading the patient with a rapid infusion of intravenous fluids, which increases the blood volume and cardiac output, can usually prevent this complication. Intravenous fluids are then infused continuously. Most institutions use dextrose-free solutions because dextrose can cause fetal hyperglycemia with rebound hypoglycemia during the first several hours after birth. The nurse should be in continuous attendance after administration of an epidural anesthetic. To detect hypotension, blood pressure should be continuously monitored for at least the first 20 minutes and after each new injection of the anesthetic. Blood pressure should be monitored during the entire time the anesthetic is in effect to ensure that the

systolic pressure does not fall below 100 mm Hg or decrease 20 mm Hg in a hypertensive patient. A drop greater than this may be life-threatening to the fetus unless effective interventions (e.g., maternal position change; administration of antihypotensive agents) are instituted.

Other disadvantages include limited mobility due to medical interventions such as the intravenous infusion and electronic monitoring equipment. Patients may experience orthostatic hypotension, dizziness, sedation, and lower extremity weakness. The accidental injection of a local anesthetic into a blood vessel can cause CNS effects including bizarre behavior, disorientation, excitation, and convulsions. Severe maternal hypotension resulting from sympathetic blockade can cause a significant decrease in uteroplacental perfusion and the delivery of oxygen to the fetus (Anim-Somuah, Smyth, & Howell, 2005).

Nursing Insight— *Shiver response after epidural block administration*

The patient may exhibit a shiver response after administration of epidural block anesthesia. This physiological reaction can result from heat loss related to increased peripheral blood flow. It may also be related to an alteration of thermal input to the CNS when warm but not cold sensations have been suppressed. Essentially, the body believes that the temperature is lower than the true temperature and raises the “thermostat” to generate heat by shivering. The nurse should apply warm blankets for comfort and offer reassurance.

The nurse must perform frequent assessments of the maternal bladder to avoid bladder distention. Although the patient may be unable to void and require catheterization, the bedpan should always be offered initially to minimize the potential for a urinary tract infection. Urinary retention and stress incontinence may also occur immediately postpartum. Intense pruritis is a common side effect of opioid use; this symptom is usually treated with diphenhydramine (Benadryl), 25 mg administered intravenously or 50 mg administered intramuscularly. A temporary elevation in temperature may occur after administration of epidural anesthesia (Hawkins et al., 2002).

Optimizing Outcomes— *During the second stage of labor after administration of an epidural block*

The patient who has received an epidural block may require assistance with pushing because of an inability to feel the contractions or experience the urge to push. She may also need someone to hold or control her legs in order to push. After birth, the nurse must ensure that full sensation has returned and the patient is able to control her legs before ambulation is permitted. Depending on the agent used and the dose administered, this may take several hours.

For relief of labor pain and a vaginal birth, a block from T10 to S5 is performed, usually when the cervix has dilated to 5 to 6 cm. For a cesarean birth, a block from T8 to S1 is required. The patient is positioned on her side

with her legs slightly flexed or she is asked to sit on the edge of the bed. She is instructed to drop her shoulders, round out the small of her back (“arch the back like a cat”), and put her chin into her chest. The medication is injected between contractions to minimize the risk of tachycardia that can occur if the drug is unintentionally injected directly into a vessel. The diffusion of the epidural anesthesia is dependent on the placement of the catheter tip, the dose and volume of medication used, and the patient’s position (e.g., horizontal or upright). Once the epidural has been administered, a side lying position (alternating sides each hour) is maintained to prevent compression of the vena cava. Depending on the degree of motor impairment, ambulation may be encouraged.

Nursing Insight— *Methods for epidural anesthesia block*

Most often, a continuous epidural anesthesia block, a method achieved by the use of a pump to infuse solution into an indwelling catheter, is used. In many areas, patients are allowed to control the dosing with a programmed pump (patient-controlled epidural analgesia [PCEA]). This method empowers the patient to achieve some degree of control over her labor comfort and has been shown to decrease the total amount of medication needed. A lock-out period after each self-administration prevents overdosage. Less commonly, an intermittent block that relies on repeated injections of anesthetic solution is performed.

COMBINED SPINAL–EPIDURAL ANALGESIA. A combination of spinal–epidural analgesia may be used to block pain transmission without interfering with motor ability. Pain relief is immediate, unlike the 20- to 30-minute delay associated with an epidural alone. With the combined approach, an opioid such as fentanyl or sufentanil is injected into the subarachnoid space to rapidly activate the opioid receptors. A catheter inserted in the epidural space extends the duration of the analgesia by using a lower dose of a local anesthetic agent alone or in combination with an opioid agonist analgesic (Hawkins et al., 2002). Although patients may ambulate, they often choose not to do so because of fatigue, sensations of weakness in the legs, and a fear of falling. They should be encouraged to change positions frequently and assisted to an upright position to enhance bearing-down efforts. Because this method is associated with puncture of the dura and placement of a catheter in the epidural space, there is a greater risk for infection and postdural puncture headache (Lieberman & O’Donoghue, 2002; McCool et al., 2004). A combined spinal–epidural block may be used for both labor analgesia and for cesarean birth; the anesthetic and analgesic agents used vary according to the purpose of the procedure. Additional medication may be added to increase its effectiveness or if an instrument-assisted or cesarean birth is needed.

EPIDURAL AND INTRATHECAL OPIOIDS. Another approach for nerve block analgesia/anesthesia involves the use of opioids alone. This method eliminates the effects of a local anesthetic. Advantages of epidural or intrathecal (injected into the subarachnoid space) opioids without local anesthetics include the following: there is no maternal hypotension or alteration in vital signs; the patient is aware of

contractions but does not feel pain—thus she is able to bear down during the second stage of labor; and her motor power remains intact.

Opioids such as fentanyl, sufentanil (short-acting agents—effects last 1.5 to 4 hours) and preservative-free morphine (long-acting—effects last up to 7 hours) may be used. A drawback of this method concerns the potential need for a pudendal nerve block or local perineal infiltration anesthesia since intrathecal opioids do not provide adequate anesthesia for second-stage labor pain, episiotomy, or birth for most women (Cunningham et al., 2005). More often, epidural and intrathecal opioids are used for postoperative pain control. After cesarean birth, women are comfortable enough to freely ambulate and care for their newborns. Early ambulation is associated with enhanced bladder emptying, more rapid return of peristalsis, and a decreased risk of respiratory complications and thrombophlebitis. Side effects are more common when preservative-free morphine is used. These include nausea and vomiting, pruritus, urinary retention, and delayed respiratory depression.

Optimizing Outcomes— *When epidural and intrathecal opioids are administered*

The nurse should monitor and record the patient’s respiratory rate every hour for 24 hours (or per institutional protocol) after administration of epidural or intrathecal opioids. Naloxone (Narcan) should be administered if the maternal respiratory rate decreases to less than 10 breaths per minute or if the maternal oxygen saturation rate decreases to less than 89%. Oxygen may be administered by face mask and the anesthesiologist should be notified.

Now Can You— *Discuss epidural and intrathecal anesthesia?*

1. Name six advantages of epidural anesthesia and identify the most common complication associated with this method?
2. Describe the benefits of combined spinal–epidural anesthesia?
3. Identify an essential component of nursing assessment after the administration of epidural or intrathecal opioids?

GENERAL ANESTHESIA

General anesthesia (induced unconsciousness) may be used for unplanned, rapid (emergency) cesarean birth, when there are contraindications to an epidural or spinal block, or when surgical intervention is required for certain obstetric complications (Box 13-3). The major risks

Box 13-3 Contraindications to Spinal/Epidural Block Anesthesia

- Maternal refusal
- Local or systemic infection
- Coagulation disorders
- Actual or anticipated maternal hemorrhage
- Allergy to specific anesthetic agents
- Lack of trained staff available (Cunningham et al., 2005)

associated with general anesthesia administered for childbirth are hypoxia and the possible inhalation of vomitus during administration. Pregnant women are particularly prone to gastric reflux due to increased stomach pressure from the gravid uterus beneath it. In addition, the gastroesophageal valve may be displaced, allowing the upward passage of stomach contents. The aspiration of stomach contents that have an acid pH may cause chemical pneumonitis and secondary infection of the respiratory tract.

Fetal depression is directly related to the depth and duration of the anesthesia. Most general anesthetic agents reach the fetus in approximately 2 minutes. General anesthesia is not recommended when the fetus is considered to be high risk, especially in preterm birth. Measures to reduce respiratory depression in the neonate include reducing the time from induction of the anesthesia until the umbilical cord is clamped and using a minimum of sedating drugs and anesthetics until after the cord has been clamped.

To prepare the patient for general anesthesia, the nurse ensures that an IV infusion is in place, and if time permits, premedicates her with an oral antacid (e.g., sodium citrate, Bicitra, Alka-Seltzer) to neutralize the acidic contents of the stomach. Some anesthesiologists order ranitidine hydrochloride (Zantac) IV or cimetidine (Tagamet) to decrease the production of stomach acid; metoclopramide (Reglan) may also be prescribed to increase gastric emptying (Hawkins et al., 2002). Before administration of the anesthesia, a wedge is placed under the right hip to displace the uterus (to prevent aortocaval compression and decreased placental perfusion). When possible, the patient is preoxygenated with 3 to 5 minutes of 100% oxygen.

Thiopental sodium (Pentothal), an ultra-short-acting barbiturate, is usually given. This agent causes rapid induction of anesthesia and minimal postpartal bleeding. Succinyl choline (Anectine) is a muscle relaxant used to facilitate passage of the endotracheal tube. To prevent gastric reflux and aspiration before the woman fully loses consciousness, the nurse may be asked to assist with applying cricoid pressure. This maneuver seals off the esophagus by compressing it between the cricoid cartilage and the cervical vertebrae. The cricoid ring, which is the only tracheal cartilage that forms a complete ring, is located immediately below the thyroid bone. The cricoid cartilage is depressed 2 to 3 cm posteriorly and pressure is maintained until the cuffed endotracheal tube is securely in place (Fig. 13-11). While applying pressure, the nurse should use the other hand to support the patient's neck.

After intubation, a 50:50 mixture of oxygen and nitrous oxide is usually administered. Small amounts of a halogenated agent such as isoflurane or methoxyflurane may also be given to enhance pain relief and to reduce maternal awareness and recall (Hawkins et al., 2002). The halogenated agents produce rapid uterine relaxation to facilitate intrauterine manipulation and extraction. However, at high concentrations they readily cross the placenta and can produce fetal narcosis and an increased risk for postpartal maternal hemorrhage due to uterine relaxation.

Recovery room care is focused on maintenance of an open airway, continuous monitoring of cardiopulmonary function, and the prevention of postpartum hemorrhage. Postpartal care should be arranged to facilitate parent–infant bonding as soon as possible. The nurse offers

Figure 13-11 Correct position for applying cricoid pressure until endotracheal tube placement has been completed.

emotional support, answers questions concerning the birth, provides updates regarding maternal/neonatal status, and assesses the patient's readiness to interact with her newborn.

Now Can You— Discuss implications of general anesthesia used during childbirth?

1. Identify two major risks associated with the use of general anesthesia for childbirth?
2. Demonstrate how to apply cricoid pressure and explain the importance of this intervention?
3. Describe two major nursing responsibilities for recovery room patient care following the use of general anesthesia?

Nursing Care for the Patient Receiving Interventions to Promote Comfort During Labor and Birth

The patient's methods of pain relief are influenced by several factors: her wishes and desires; the phase and stage of labor; the availability of the chosen modalities in the birth center; and the knowledge and expertise of the health care team with the various pharmacological and nonpharmacological methods.

NURSING ASSESSMENT AND DIAGNOSES

Assessment during labor is an ongoing process that requires a collaborative approach from the primary care provider, the nurse, the patient, and her labor support person(s). Factors such as maternal/fetal status, the progress of labor, and the patient's level of comfort must be taken into consideration before a decision is made concerning whether nonpharmacological methods, pharmacological methods, or a combined approach will be used. The nurse never assumes that all pain experienced during labor is uterine in origin. Instead, a physical assessment that includes an evaluation of the characteristics of the patient's pain (location, intensity, quality, frequency, duration, and effectiveness of all relief measures) must be performed. The

patient's prenatal record is reviewed to identify pertinent obstetrical information; drug allergies; a history of tobacco, alcohol, or other substance abuse; as well as spinal or neurological disorders.

The patient interview focuses on information concerning the onset of labor; the most recent oral intake (time, amount), present illnesses, allergies, and events that have occurred since her last visit with her primary care provider. She is asked about attendance in childbirth education classes and preferences for intrapartum comfort measures. When available, the birth plan is reviewed and updated or modified as needed.

The physical examination includes assessment of maternal vital signs, fetal heart rate and pattern, uterine contractions, amniotic membranes and fluid, cervical effacement and dilation, and fetal descent. The nurse also evaluates the patient's hydration status and palpates for bladder distention. After the administration of pharmacological agents, the nurse provides ongoing assessment of the patient, fetus, and labor progress according to institutional policy and professional standards (Association of Women's Health, Obstetric and Neonatal Nurses [AWHONN], 2001; Mahlmeister, 2003). Maternal assessment for evidence of allergic reaction to medications includes monitoring vital signs, respiratory status, platelet, and white blood cell count and observing for integumentary changes. Laboratory data are analyzed to identify anemia, coagulopathy or bleeding disorders, or infection. Fetal status is also assessed and non-reassuring changes in heart rate or pattern are promptly reported to the patient's primary health care provider.

A number of nursing diagnoses are relevant to anxiety, discomfort, and pain relief during labor and birth:

- Anxiety related to lack of knowledge about the labor experience
- Ineffective coping related to the combination of uterine contractions and anxiety
- Acute pain related to the processes of labor and birth

Expected outcomes of nursing interventions include:

- The patient verbalizes understanding of what is happening with her labor; she is able to identify the beginning and ending of contractions and demonstrates confidence instead of confusion with the labor process.
- The patient verbalizes confidence in her ability to participate actively in her labor experience, she demonstrates effective breathing techniques, guides her labor support person in providing effective comfort measures, readily engages in position changes and other strategies to enhance comfort and remain in control, and expresses confidence in her labor nurse and other care providers.
- The patient verbalizes that with the methods used, her pain has been relieved to a tolerable level; she is responsive to questions and suggestions and demonstrates an ability to deal with her contractions

A plan of care individualized to each patient is developed and modified as needed. A collaborative approach that includes the patient, her primary care provider, and labor support person is important in ensuring that safe, effective care is provided that promotes a positive childbirth experience for the woman and her family.

summary points

- ◆ Pain during labor is unique in that it is normal, can be anticipated and prepared for, and ends with a birth.
- ◆ Although a universal phenomenon, every individual perceives pain differently.
- ◆ The better prepared a woman is for childbirth, the less likely is the need for analgesia and anesthesia.
- ◆ Relaxation, massage, breathing techniques, and other nonpharmacological strategies should be encouraged in conjunction with prescribed analgesics.
- ◆ The type of analgesic or anesthetic to be used depends, in part, on the stage of labor and the method of birth.
- ◆ Sedatives are used during a prolonged early labor when there is a need to decrease anxiety or promote rest.
- ◆ Regional anesthesia can be extremely effective for pain; the nurse must ensure adequate maternal hydration and normal blood pressure before administration.
- ◆ General anesthesia is rarely used for vaginal birth because of risks for both the woman and her neonate.

review questions

Multiple Choice

1. In the first stage of labor, the perinatal nurse is aware that pain impulses are transmitted via:
 - A. T11, T12 spinal nerve segments
 - B. T9, T10 spinal nerve segments
 - C. L4, L5 spinal nerve segments
 - D. Sacral spinal nerve segments
2. The perinatal nurse is aware that a woman's history of past painful experiences with labor and birth are part of which neural pathway process for pain?
 - A. Transduction
 - B. Transmission
 - C. Perception
 - D. Modulation
3. Marianne, a 29 year old multigravid woman, was given promethazine (Phenergan) and meperidine hydrochloride (Demerol) during labor as part of her pain management. The perinatal nurse is aware that during the first 24 hours after birth, Marianne's infant will have an increased risk for:
 - A. Hyperbilirubinemia
 - B. Tachypnea
 - C. Irritability
 - D. Tremors

Fill-in-the-Blank

4. The perinatal nurse teaches the laboring woman and her partner about the cycle of _____, _____, and _____ that can escalate to decrease labor progress.
5. The perinatal nurse knows that evidence-based care in labor includes providing _____ and a _____ presence.
6. In providing care to the laboring woman, the perinatal nurse must balance the knowledge that the analgesia/

anesthesia chosen is determined by the _____ of _____ and the woman's available _____ at the birth facility.

True or False

7. Childbirth education is encouraged by the perinatal nurse as it increases the information that women and families have about labor, birth, and options for pain relief.

Case Study

8. The perinatal nurse assists Teresa, a laboring woman, and her partner between contractions to increase their knowledge and ability to use breathing methods during the contractions. Teresa's use of breathing techniques during a contraction may decrease pain by:
- Reducing the capacity of nerve pathways to transmit pain
 - Increasing the capacity of nerve pathways to transmit endorphins
 - Decreasing her anxiety about labor
 - Decreasing her distraction during her contractions

Select All that Apply

9. The perinatal nurse is aware that one of the *Healthy People 2010* goals is to:
- Educate women in the use of nonpharmacological pain management in labor.
 - Decrease mortality related to pharmacological methods of pain relief in labor.
 - Increase informed use of pharmacological methods of pain relief in labor.
 - Increase availability of pharmacological pain relief in labor.
10. The perinatal nurse understands that the advantages to a spinal anesthetic for a woman in labor include:
- Easy administration
 - Immediate pain relief
 - Minimal blood loss
 - Good voluntary maternal expulsive efforts

CONCEPT MAP

Caring for the Woman Experiencing Complications During Labor and Birth

And when our baby stirs and struggles to be born it compels humility, what we began is now its own.

—Anne Ridler

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Differentiate critical factors associated with nursing care of women experiencing dysfunctional labor patterns.
- ◆ Discuss pharmacological and nonpharmacological interventions used for the induction and augmentation of labor.
- ◆ Discuss collaborative care of the woman experiencing an induction of labor.
- ◆ Compare and contrast methods of instrumentation assistance of birth.
- ◆ Describe the management of selected maternal complications during the intrapartal period.
- ◆ Discuss how fetal malpresentation and malposition affect labor and birth.
- ◆ Compare and contrast the intrapartal management for placenta previa and abruptio placentae.
- ◆ Describe emergency nursing care for various uterine, placental, umbilical, and amniotic complications during labor and birth.
- ◆ Plan appropriate nursing care for a family experiencing a fetal loss.
- ◆ Discuss maternal and fetal factors associated with cesarean birth.
- ◆ Describe the controversies associated with vaginal birth after cesarean birth.

moving toward evidence-based practice Maternal placental syndrome as it relates to cardiovascular health

Ray, J.G., Vermeulen, M.J., Schull, M.J., & Redelmeier, D.A. (2005). Cardiovascular health after maternal placental syndromes (CHAMPS): Population-based retrospective cohort study. *The Lancet*, 366, 1797–1803.

Research indicates that the presence of maternal placental syndromes, which include hypertensive disorders of pregnancy and abruption or infarction of the placenta, probably originate from diseased placental vessels. These conditions occur more often in women with metabolic risk factors for cardiovascular disease such as obesity, hypertension, diabetes, and hyperlipidemia. The purpose of this study was to assess for the risk of premature vascular disease in women who experienced maternal placental syndrome during pregnancy.

The population-based retrospective cohort study included 1.03 million women who had no evidence of cardiovascular disease before their first documented delivery. The sample, obtained

through multiple databases, consisted of women admitted to the hospital for the first obstetrical delivery of a live or stillborn infant after 20 weeks of gestation. Women younger than age 14, older than age 50, and those with a preexisting diagnosis of cardiovascular disease in the 24 months preceding the birth were excluded.

Maternal placental syndrome included preeclampsia, gestational hypertension, placental abruption, and placental infarction. A history of hospitalization for cardiovascular, coronary artery, or peripheral artery disease a minimum of 90 days after the delivery discharge date was identified as the point for determining the composite for the development of cardiovascular disease.

(continued)

moving toward evidence-based practice (continued)

Data analysis revealed the following findings:

- The mean age of the participants was 28.2 years at the time of the infant's birth.
 - Maternal placental syndrome was diagnosed in 75,380 (7%) of the women.
 - The incidence of cardiovascular disease was 500 per one million person-years in women with a placental syndrome, as compared to 200 per one million-person years in those who did not have a placental syndrome.
 - The risk of cardiovascular disease was higher with the combined presence of maternal placental syndrome and either poor fetal growth or intrauterine fetal death.
 - Of those diagnosed with the maternal placental syndrome, risk factors were more commonly present before delivery than in those participants who were not diagnosed with the maternal placental syndrome.
- The median period for follow-up was 8.7 years. The mean age of the participants at the time of the first cardiovascular event was 38.3 years; the maximum age of the participants was 60.2 years.
 - The risk of cardiovascular disease increased with the number of risk factors present.
 - The risk of premature cardiovascular disease is higher in women who have experienced maternal placental syndrome, especially in the presence of fetal complications.

1. What might be considered as limitations to this study?
2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

The nurse who cares for women and their families experiencing complications during labor and birth is responsible for creating a supportive environment that provides complex nursing care. Under normal circumstances labor and birth places stress on the family unit and when problems are superimposed during this time frame, another layer of complexity is added. The woman often needs to respond rapidly to changing health conditions for which she might not be prepared. The nurse has to be proactive and reassuring in support of the woman and her family unit. It is critical to empower the woman and encourage her to take control as much as possible. The nurse acts as her advocate in collaborative care when the woman is unable to have her voice.

Complications arise from a variety of factors. Women experience problems with uterine dysfunction often referred to as the powers of labor. The presentation and position of the fetus is integral to a positive labor outcome. When the fetus is not in a favorable lie, the labor process may be lengthened, require instrumentation assistance, or necessitate an operative birth. Multiple fetuses are more prone to these issues because of their locations within the uterus. Placenta obstruction or an inadequate bony pelvis may hinder fetal progress through the birth canal and require more extensive medical intervention. Medical emergencies and complications from maternal disease also place the patient at increased risk for a complicated and intervention-driven labor and birth.

Cesarean or operative birth is one of the outcomes associated with a complicated labor. In the United States, the cesarean birth rate has steadily increased. Controversy surrounds this statistic while at the same time more women are requesting an elective cesarean birth. The nurse working in perinatal care has to be concerned with ethical issues and be prepared to foster evidence-based research studies to examine the multiple factors involved with cesarean deliveries.

Perinatal loss necessitates a collaborative response from all professionals involved in the care of the patient. Nurses can lead others in providing support. Spiritual, emotional, psychological, and physical needs are important considerations that need to be met during this time. Although this situation cannot be normalized, the nurse can encourage the woman to hold her infant, give her a baby picture, and provide a memory book to acknowledge the existence of the child.

The nurse serves in many capacities when managing the care of patients experiencing a complicated labor and birth. Use of the nursing process combined with a strong theoretical background provides a foundation for the critical decision making that exists in the clinical unit. Nursing diagnoses specific to the woman experiencing a complication during the intrapartum period refer to specific problems and often relate to the broad concepts of fear, anxiety, coping, and fatigue. Examples of possible nursing diagnoses are presented in Box 14-1. The nurse has the unique opportunity to empower the woman and assist her in taking control as much as possible in these difficult situations. Since patients are unique in their responses, it is incumbent upon the nurse to be sensitive to all individuals and be culturally competent. Finally, the nurse must constantly examine practice and promote research initiatives that give evidence to optimal outcomes in complex perinatal care.

Optimizing Outcomes— Helping to meet *Healthy People 2010* national goals

Nurses who work with birthing mothers can be instrumental in helping the nation to meet *Healthy People 2010* goals that address intrapartum complications:

- Reduce the maternal mortality rate to no more than 3.3 per 100,000 live births from a baseline of 7.1 per 100,000.
- Reduce cesarean births among low-risk women to no more than 15 per 100 deliveries from a baseline of 18 per 100 by carefully monitoring laboring women to

Box 14-1 Possible Nursing Diagnoses for the Woman Experiencing Complications During Labor and Birth

- Fear related to unknown high risk condition of labor
- Anxiety related to loss of control during labor
- Coping, Ineffective, related to inadequate opportunity to prepare for high risk labor
- Fatigue related to increased physical exertion during a long labor
- Powerlessness related to lack of control over decisions in a complicated birth
- Deficient Knowledge related to unknown high risk condition
- Communication, Verbal Impaired, related to cultural differences
- Risk for Spiritual Distress related to emotional response to high risk labor and birth
- Risk for Ineffective Tissue Perfusion related to excessive loss of blood
- Risk for Injury related to damage of tissue during a complicated birth
- Pain, Acute, related to tissue damage
- Fluid Volume, Deficit, related to decreased urinary output
- Fluid Volume, Excess, related to compromise of the cardiovascular system
- Risk for Trauma related to instrumentation-assisted birth
- Anticipatory Grieving related to fetal demise

identify early signs of potentially life-threatening events (i.e., placental abruption, uterine rupture) and by assisting women with fetal malpresentations amenable to rotation with positional changes to help reduce the number of cesarean births.

Dystocia

Dystocia, defined as a long, difficult or abnormal labor, is a term used to identify poor labor progression. Dystocia may arise from any of the three major components of the labor process—the powers (uterine contractions), the passenger (fetus), or the passageway (maternal pelvis). In addition, various medical interventions used during labor and birth may create problems that complicate the birth process.

Dystocia may be related to maternal positioning during labor, as well as fetal malpresentation, anomalies, macrosomia and multiple gestation. Also, maternal psychological responses to the labor, based on past experiences, cultural influences, and the woman's present level of support may play a role in the normal progress of labor.

Nursing Insight— Recognizing indicators of dystocia

Nurses should suspect dystocia when there is a lack of progress in the rate of cervical dilation; fetal descent and expulsion; or an alteration in the pattern of normal uterine contractions.

DYSFUNCTIONAL LABOR PATTERNS

Dysfunctional labor patterns are deviations from the normal pattern of labor as illustrated by a labor curve assessment tool. (See Chapter 12.) Labor alterations occur more

frequently during the first stage of labor (cervical dilation and effacement) than during the second stage (maternal expulsive efforts). Nulliparous women have a higher incidence of abnormalities than do multiparous women. Dysfunctional labor is the fourth most common complication of labor and birth, and several factors may increase a woman's risk for dystocia (Box 14-2). There are two general types of labor dysfunction: hypertonic and hypotonic (Fig. 14-1). These contraction patterns are classified according to when they occur in labor and the nature of the uterine contractions.

HYPERTONIC LABOR

Hypertonic labor contractions are strong and often painful but are ineffective in producing cervical effacement and dilation. An increase in maternal catecholamine release (i.e., epinephrine, norepinephrine) can result in poor uterine contractility (Cunningham et al., 2005). Uterine pacemakers (the energy source of contractions located in the uterine wall) do not initiate a good myometrial response needed for progressive cervical change. Instead, irregular spasmodic episodes occur that do not result in effective contractions or assist in bringing the fetus into a more favorable downward position (Gilbert, 2006).

Maternal anxiety plays a major role in hypertonic labor. Anxiety is known to produce high levels of catecholamines. Many factors contribute to a woman's fear related to labor and birth:

- Primiparous labor
- Loss of control
- Sexual abuse
- Lack of support
- Cultural differences
- Fear of pain

An occiput–posterior malposition of the fetus, which occurs in approximately 15% of labors, also leads to hypertonic labor contractions. In approximately one half of all cases of hypertonic labor patterns, however, there is no apparent cause (Gilbert, 2006).

Although the management of hypertonic labor contractions varies, in general, the emphasis is on establishing a more effective labor pattern. Rest, hydration, and sedation reduce the irritability of the uterus and help to diminish the ineffective contractions. Medications that may be prescribed to induce therapeutic rest include meperidine (Demerol),

Box 14-2 Factors Associated with an Increased Risk for Uterine Dystocia

- Uterine abnormalities, such as congenital malformations and overdistention (e.g., hydramnios, multiple gestation)
- Fetal malpresentation or malposition
- Cephalopelvic disproportion (CPD)
- Maternal body build (>30 lbs. [13.6 kg] overweight, short stature)
- Uterine overstimulation with oxytocin
- Inappropriate timing of administration of analgesic/anesthetic agents
- Maternal fear, fatigue, dehydration, electrolyte imbalance

Source: Gilbert, E.S. (2006). *Manual of high risk pregnancy and delivery*. St. Louis, MO: C.V. Mosby.

hydromorphone (Dilaudid), and morphine (Cunningham et al., 2005). Natural labor with effective contractions often resumes after this simple intervention. Nonpharmacological techniques to reduce anxiety such as relaxation techniques, massage, a warm shower or tub bath, and increased emotional support are also helpful for some women.

For a woman whose fetus is in an occiput–posterior position, the major goal of care is to facilitate rotation of the fetal head into a more favorable position. The nurse can encourage the laboring woman to walk and change positions frequently throughout the course of labor. The descent of the fetus into an anterior lie creates a better environment for normal labor progression.

Nursing care begins with a thorough assessment. It is critical to identify factors that contribute to increased maternal anxiety. Careful monitoring of contractions may provide early information regarding poor labor progression and lead to timely interventions. While frequent checks for cervical dilation are not advisable, this assessment, when performed at proper intervals, provides a strong indicator of labor progression. Along with continued assessment of the contraction pattern, the nurse can use this information to validate the finding of hypertonic labor. Once any intervention has occurred, the nurse evaluates the plan of care and, depending on the results, initiates appropriate measures.

Ethnocultural Considerations— Communication difficulties during labor

Nurses need to be sensitive to cultural differences among women experiencing hypertonic labor—those who are unable to speak or understand the English language may have difficulty communicating their feelings.

HYPOTONIC LABOR

Hypotonic labor is a more common type of uterine dysfunctional pattern that contributes to poor labor progression. With hypotonic dystocia, the uterine contractions decrease in frequency and intensity. A hypotonic labor pattern usually occurs during the active phase of labor. It is defined as fewer than two to three contractions during

a 10-minute period. The uterus can be easily indented, even at the peak of the contraction, and the intrauterine pressure (IUP) is insufficient for the progression of cervical effacement and dilation (Gilbert, 2006).

Hypotonic labor may be associated with a number of maternal and fetal factors that produce excessive uterine stretching and overdistention. For example, fetal macrosomia, multiple gestation, and hydramnios are all risk factors for hypotonic labor. Grand multiparity may also be a contributing cause.

Fetal **macrosomia** occurs in one fourth of all pregnancies and is the leading cause of uterine hypotonia. Macrosomia, defined as a fetus whose birth weight is above the 90th percentile on an intrauterine growth chart for that gestational age, often results from a fetal imbalance between glucose and insulin in women diagnosed with any type of diabetes. Over time, as increased amounts of glucose are absorbed from the mother, the fetus produces pancreatic insulin which results in an increase in fat deposits.

Maternal obesity unaccompanied by diabetes also contributes to a larger fetus. Hall and Neubert (2005) define obesity as a woman who has a body mass index (BMI) of greater than 30 kg/m². In their review of studies that examined obesity and pregnancy, direct links were found between maternal obesity and fetal macrosomia. The study findings are consistent with data from Young's and Woodmansee's (2002) research, which demonstrated a positive relationship between an increased maternal BMI and fetal macrosomia.

Pharmacological agents used to alleviate pain during labor may also contribute to the risk of uterine hypotonia. If a labor pattern is not well established, these medications often halt or significantly slow down the progress of labor. Various studies have produced conflicting data concerning a clear link between the use of analgesia, anesthesia, and the progress of labor. After administration of epidural anesthesia, some women may experience a longer second stage of labor. The effects of the epidural may make it difficult for the patient to identify when to push and how long to push because the contractions are not always detected. However, nulliparous women who experience long and painful labors are more likely to choose epidural anesthesia for pain relief. Often it is difficult to document which factors contribute most significantly to a protracted labor.

Nursing Insight— Recognizing negative maternal effects of hypotonic labor

As an ineffective labor pattern continues, the woman is likely to become fatigued and may be at an increased risk for infection.

Depending on the cause, labor hypotonia is managed in different ways. Careful, ongoing assessments are key. If a diagnostic modality such as ultrasound examination has demonstrated that the woman's pelvis is adequate for vaginal birth, measures to produce effective contractions are implemented. Walking and position changes in labor assist in fetal descent through the maternal pelvis and therefore need to be encouraged. The use of relaxation techniques, massage, and water treatments can decrease the need for pharmacological agents for pain.

Augmentation of labor contractions is considered when either the natural measures are unsuccessful or when it is deemed the best approach. At certain points in the labor, an amniotomy, or artificial rupture of the membranes, may be successful in increasing uterine contractility. Other measures to enhance the progress of labor include membrane stripping, nipple stimulation, and oxytocin infusion. Maternal and fetal assessments including vital signs, contraction patterns, and cervical changes need to be documented on a regular basis.

PRECIPITATE LABOR AND BIRTH

Contrary to both hypertonic and hypotonic labor, **precipitate labor** contractions produce very rapid, intense contractions. By definition, a precipitate labor lasts less than 3 hours from the beginning of contractions to birth. Church and Hodgson (2003) report that multiparous women with little soft tissue resistance are at the greatest risk for this labor pattern. Patients often progress through the first stage of labor with little or no pain and may present to the birth setting already advanced into the second stage. In a nulliparous patient, cervical dilation that occurs faster than 5 cm per hour is defined as precipitous labor. In a multiparous woman, cervical dilation may occur as rapidly as 10 cm in 1 hour. Precipitous labor may result from hypertonic uterine contractions that are tetanic in their intensity (Church & Hodgson, 2003).

Complications from a precipitate labor pattern result from trauma to maternal tissue and to the fetus because of the rapid descent. Hemorrhage may occur from uterine rupture and vaginal lacerations. Most women are ill prepared for the rapid advancement of their labor and become alarmed, highly anxious, and fearful. The fetus may suffer from hypoxia related to the decreased periods of uterine relaxation between the contractions and intracranial hemorrhage related to the rapid birth (Cunningham et al., 2005).

Nursing Considerations

Initial assessments are paramount to establishing the pattern of precipitous labor. A multiparous patient with a previous history of rapid labors needs to alert her physician or certified nurse midwife (CNM) as soon as she recognizes any signs of labor. Her prenatal record should include this information and be readily accessible to nursing personnel managing her care. In a nulliparous patient, careful examination for cervical dilation and effacement is

required. Since a previous labor pattern is an unknown variable in the nulliparous patient, the nurse must be alert in recognizing signs of abnormally rapid cervical dilation (Church & Hodgson, 2003).

The woman and her support person need reassurance throughout the rapidly advancing labor. Breathing and relaxation techniques are helpful tools that the nurse can use to assist the woman to cope with labor. If the patient and her family do not speak or understand the English language, it is incumbent on the nurse to request a translator. Precipitate labor is an anxiety-producing situation that is compounded by the woman's inability to understand what is happening to her body. Although some precipitate labors occur with little or no pain, the patient is nevertheless aware of contractions that are occurring more quickly than normal. This experience can be frightening. The woman may also have concerns regarding a loss of control over her labor. Continuous surveillance, frequent updates on her status, and reassurance about her condition can help to allay the patient's anxiety. Medical management includes readiness on the part of the entire health team for the birth, particularly when the patient has a history of rapid labor. In most circumstances, a planned induction is part of the plan. Small dosages of intravenous analgesics may be used to help decrease pain.

The nurse can assist the woman in breathing through her contractions to avoid pushing and to help prevent tearing. If the nurse is alone with the patient during a precipitous delivery, the nurse follows delivery protocols when assisting in the birth of the infant. At the same time, the nurse uses the call bell to alert others for assistance. The nurse supports the perineum, assists the fetal head as it emerges, and checks for the umbilical cord as the head rotates. The newborn's nose and mouth are suctioned; the shoulders and then the rest of the newborn's body are supported during the birthing process. The nurse assesses the neonate's respiratory and cardiac rates.

After birth, whether assisted by the nurse or physician, the maternal soft tissue and placenta need to be carefully examined. The patient may require suturing of the cervix or vagina for lacerations. During the immediate postpartum period, the woman must be continuously monitored for hemorrhage. Providing ongoing information and support assists the patient and helps her support person cope with this unexpected event (Church & Hodgson, 2003).

critical nursing action Assisting with a Precipitous Birth

The nurse who assists with a precipitous birth should take the following actions:

- Request a translator to interpret for patients unable to speak or understand English.
- Assist the laboring woman to breathe through each contraction to prevent pushing.
- Provide continuous emotional support.
- Provide perineal support with warm cloths.
- Frequently monitor the maternal and fetal vital signs and immediately report any abnormal findings to the physician or certified nurse midwife.
- After birth, carefully monitor the patient for signs of hemorrhage; assess for trauma to the perineum.
- Assess the neonate for evidence of trauma and report and document all findings.

PELVIC STRUCTURE ALTERATIONS

Pelvic Dystocia

Pelvic dystocia occurs when contractures of the pelvic diameters reduce the capacity of the bony pelvis, the midpelvis, the outlet, or any combination of these planes. Contractures of the maternal pelvis may result from malnutrition, neoplasms, congenital abnormalities, traumatic spinal injury, or spinal disorders. In addition, immaturity of the pelvis may predispose some adolescent mothers to pelvic dystocia. During labor, contractures of the inlet, midplane, or outlet can cause interference in engagement and fetal descent, necessitating cesarean birth (Cunningham et al., 2005).

Soft Tissue Dystocia

Soft tissue dystocia occurs when the birth passage is obstructed by an anatomical abnormality other than that involving the bony pelvis. The obstruction, which prevents the fetus from entering the bony pelvis, may be caused by placenta previa, uterine fibroid tumors (leiomyomas), ovarian tumors, or a full bladder or rectum. **Bandl ring** is a pathological retraction ring that develops between the upper and lower uterine segments. It is associated with protracted labor, prolonged rupture of the membranes, and an increased risk of uterine rupture (Cunningham et al., 2005).

TRIAL OF LABOR

A **trial of labor** (TOL) is the surveillance of a woman and her fetus for a set amount of time (usually 4 to 6 hours) during spontaneous active labor to assess the safety of a vaginal birth. Indications for a trial of labor include situations when the maternal pelvis is of questionable size or shape, when the fetus is in an abnormal presentation, and when the woman desires to have a vaginal birth after a previous (low-segment transverse) cesarean birth. Before the TOL, an assessment of the adequacy of the maternal pelvis for vaginal birth (to rule out cephalopelvic disproportion [CPD]) is conducted with sonography or maternal pelvimetry. The cervix must be favorable (soft, dilatable), and throughout the TOL, the woman is assessed for the presence of adequate contractions, engagement and descent of the fetal presenting part and cervical dilation and effacement.

Optimizing Outcomes— Providing support during a trial of labor

Nursing responsibilities during a TOL include assessment of maternal vital signs and FHR and pattern. If complications arise, the nurse notifies the primary health care provider, and evaluates and documents the maternal–fetal responses to the interventions. Offering support and encouragement to the woman and her labor partner and ongoing information about labor progress are essential components of care.

Now Can You— Discuss factors that impede the progress of labor?

1. Describe why maternal anxiety contributes to a lack of labor progression?
2. List three ways the nurse can reduce maternal anxiety?
3. Identify which synthesizing enzymes are significant to the lack of myometrial contractility?

Obstetric Interventions

AMNIOINFUSION

Pregnancy outcome in patients experiencing variable fetal heart rate (FHR) decelerations caused by cord compression is improved through the use of amnioinfusion, which is the instillation of normal saline or lactated Ringer's solution into the uterine cavity. Amnioinfusion is used to supplement the amniotic fluid volume in patients with oligohydramnios due to uteroplacental insufficiency, premature rupture of the membranes, and postmaturity; it may also be done to dilute meconium-stained amniotic fluid (Fraser et al., 2005). Risks of the procedure include infection, overdistention of the uterus, and increased uterine tone.

Nursing Insight— Understanding amnioinfusion as an intervention for meconium-stained amniotic fluid

When there is evidence of moderate to thick meconium in the amniotic fluid, amnioinfusion is used to dilute and help wash out the meconium to avoid neonatal meconium aspiration syndrome (Parer & Nageotte, 2004).

In most circumstances, the fluid is instilled through an intrauterine pressure catheter (IUPC); the amniotic membranes must be ruptured for catheter placement. The fluid may be warmed with a blood warmer before administration and the infusion may be given by bolus or continuous flow. When possible, a double-lumen IUPC is used because the intrauterine pressure can be monitored without stopping the amnioinfusion.

Nursing considerations include careful monitoring of the infusion, the intensity and frequency of uterine contractions, and the maternal vital signs. In some institutions, patients are required to sign an informed consent prior to the intervention. It is important for the nurse to educate the woman and her support person regarding the need for the infusion and its purpose. Nurses must document the amount of the solution infused and the presence of any vaginal discharge (Gilbert, 2006).

critical nursing action When Caring for a Patient Undergoing Amnioinfusion

When caring for a patient undergoing amnioinfusion, the nurse must:

1. Assess the patient's response to the fluid infusion.
2. Continually monitor the frequency and intensity of uterine contractions.
3. Stop the infusion if the following signs and symptoms are noted: maternal shortness of breath, an over distended uterus, hypotension, or tachycardia.

AMNIOTOMY

Amniotomy, or the artificial rupture of membranes (AROM), is a nonpharmacological intervention that may be done to augment or induce labor or to facilitate the placement of internal monitors during labor. The procedure involves the insertion of an Amnihook or other sharp instrument into

the lower segment of the fetal membranes; following rupture, the fluid is allowed to drain slowly (Fig. 14-2). The rupture of the membranes causes a release of arachidonic acid, which converts to prostaglandins, known inducers of labor through the stimulation of oxytocin in the uterus (Gilbert, 2006). Labor usually commences within 12 hours after artificial rupture. However, if labor does not ensue, there is an increased risk of infection; other risks include fetal injury and umbilical cord prolapse. Because of the risk for infection, amniotomy is frequently used in combination with oxytocin induction to facilitate delivery.

The nurse carefully monitors the patient who will undergo an amniotomy. Vital signs, cervical effacement and dilation, station of the presenting part, FHR, and contractions are documented. The presenting part must be engaged and well applied to the cervix to prevent **umbilical cord prolapse** (protrusion of the umbilical cord in advance of the presenting part). There should be no evidence of active infection of the genital tract (e.g., herpes) or human immunodeficiency virus (HIV) infection (Norwitz, Robinson & Repke, 2002).

Optimizing Outcomes—Preparing the Patient for an Amniotomy

The nurse provides information, assesses the woman's understanding of the procedure, and assures her that the membrane rupture will be painless to her and her fetus although she may experience some discomfort when the instrument is inserted through the vagina and cervix. The nurse ensures that the necessary equipment has been assembled: sterile gloves, lubricant, and the Amnihook or Allis clamp. After placing hip pads under the buttocks to absorb the fluid, the nurse positions the woman on a padded bedpan or with rolled up linens to elevate the hips. The nurse assists the health care provider performing the procedure by unwrapping and passing the equipment.

Immediately after the artificial rupture, the nurse notes and records the FHR and pattern. The color, odor, consistency, and clarity (and amount, if unusual) of the amniotic fluid are also documented, along with the time of rupture

Figure 14-2 An Amnihook is used to rupture the membranes.

and the indication for the amniotomy. The patient may request analgesia or epidural anesthesia before the procedure. If she has not requested any medication, the nurse assists her with relaxation and breathing techniques during the contractions following the amniotomy because they are likely to be stronger.

Be sure to— Monitor and document FHR during AROM

The nurse needs to assess the FHR immediately before and after the artificial rupture of membranes. Changes such as transient fetal tachycardia may occur and are common. However, other FHR patterns such as bradycardia and variable decelerations may be indicative of cord compression or prolapse.

Maternal temperature is assessed frequently (at least every 2 hours) after amniotomy to rule out infection. A temperature of 100.4°F (38°C) may be indicative of an infection and the health care provider should be notified. Other signs and symptoms of infection include the presence of chills, uterine tenderness on palpation, foul-smelling vaginal discharge, and fetal tachycardia (Simpson, 2005b).

Pharmacological Induction of Labor

INDICATIONS FOR INDUCTION

Induction of labor describes the use of chemical or mechanical modalities to initiate uterine contractions (before their spontaneous onset) to bring about childbirth. Induction of labor is considered when either a maternal or fetal condition exists that dictates the need for medical intervention in the labor process. According to Simpson and Atterbury (2003), labor induction often leads to an increase in interventionist care including the use of intravenous therapy, amniotomy, internal monitoring, epidural anesthesia, and a longer stay in the labor unit. Martin et al. (2005) reported that since the year 1989, when data were first collected, there has been a 125% increase in labor induction and a 75% increase in labor augmentation. Interestingly, non-Hispanic white women experience the highest rate of inductions. In 2003, the rate was 24.7%, while Asian or Pacific Islanders (14%) and Hispanic women (13.8%) experienced the lowest induction rates.

According to the American College of Obstetricians and Gynecologists (ACOG) the following maternal/fetal conditions serve as some of the indications for induction (ACOG, 1999):

- Postterm pregnancy
- Maternal medical conditions (e.g., diabetes mellitus, renal disease, chronic pulmonary disease, chronic hypertension)
- Pregnancy-induced hypertension (PIH)
- Fetal demise
- Chorioamnionitis
- Premature rupture of membranes
- Fetal compromise (e.g., severe fetal growth restriction, isoimmunization)
- Preeclampsia, eclampsia

Since induction carries certain risks, it is not performed without careful consideration and evaluation of the maternal–fetal status. However, due to the rise in the U.S. cesarean rate over the last two decades, medical management of labor is commonly practiced in many hospitals to prevent the need for surgical delivery. This practice often involves admission of the patient with complete cervical effacement, rupture of the membranes, or expulsion of the mucus plug who is begun on a series of protocols that frequently include amniotomy combined with oxytocin infusion.

Induction of labor is more successful when the cervix is “favorable,” or inducible. The **Bishop score** is a rating system that may be used to determine the level of cervical inducibility. A series of points is awarded to cervical dilation, effacement, station, consistency, and position (Table 14-1). In general, labor induction is more likely to be successful with a higher score (9 or more for nulliparous women; 5 or more for multiparous women) (Cunningham et al., 2005; Gülmezoglu, Crowther, & Middleton, 2006).

Cervical Ripening Agents

If it is determined that the cervix is not favorable for oxytocin induction, a chemical cervical ripening agent using prostaglandin E₁ (PGE₁) (Misoprostol) or prostaglandin E₂ (PGE₂) (Dinoprostone [Prepidil, Cervidil]) may be prescribed (Table 14-2). These agents are most beneficial when the patient’s Bishop score is greater than 6, although they are commonly used when the Bishop score is 4 or less. Before administration, informed consent may be required, according to agency protocol.

Misoprostol (Cytotec) is an analogue of prostaglandin E₁. Available in tablet form, the medication is inserted into the posterior vaginal fornix. Misoprostol ripens the cervix, causing it to begin to dilate and efface. The U.S. Food and Drug Administration (FDA) has not approved the use of misoprostol for cervical ripening. Wing (2002) found misoprostol to be an effective agent for cervical ripening and induction of labor that also decreases the amount of oxytocin required. Culver et al. (2004) concurred that misoprostol is an effective cervical ripening agent but cited higher failure rates in nulliparous women with a low Bishop score and reported an increased incidence of uterine hyperstimulation with the medication. At least 4 hours after the last dose, oxytocin may be initiated for the induction of labor if cervical ripening has occurred and labor has not begun.

Table 14-1 The Bishop Score

	Score			
	0	1	2	3
Dilation (cm)	0	1–2	3–4	>5
Effacement (%)	0–30	40–50	60–70	>80
Station (cm)	–3	–2	–1	+1, +2
Cervical consistency	Firm	Medium	Soft	
Cervix position	Posterior	Midposition	Anterior	

Adapted from Rai, J., & Schreiber, J.R. (2005). Cervical ripening. *EMedicine*. Retrieved from <http://www.emedicine.com>.

Dinoprostone, marketed as Cervidil Insert and Prepidil Gel, is an analogue of (PGE₂). This cervical ripening agent makes the cervix softer, causing it to begin to dilate and efface and stimulate uterine contractions. PGE₂ is used for preinduction cervical ripening when the Bishop score is 4 or less. Cervidil is applied into the posterior vaginal fornix; Prepidil is inserted through a syringe into the cervical canal just below the internal cervical os or into the posterior fornix. Cervidil acts more quickly. Uterine contractions usually begin in 5 to 7 hours after administration. When necessary, induction with oxytocin can be initiated 30 to 60 minutes after removal of the Cervidil insert. When using Prepidil gel, oxytocin induction must be delayed until 6 to 12 hours after the last instillation of the medication. Cervidil has an added advantage—the insert can be removed if uterine hyperstimulation occurs. Dinoprostone is FDA approved for cervical ripening.

Contraindications to the PGE₁ and PGE₂ cervical ripening agents include the presence of a non-reassuring FHR pattern, maternal fever, infection, vaginal bleeding, hypersensitivity, regular, progressive uterine contractions, and a history of cesarean birth or uterine scar. The medications should be cautiously used in women with a history of asthma, glaucoma or renal, hepatic, or cardiovascular disorders. After insertion, the nurse should clearly document all assessment findings and administration procedures.

Mechanical Methods

Mechanical methods provide another approach to cervical ripening. Dilators placed in the cervix cause cervical ripening by stimulating the release of endogenous prostaglandins. Rai and Schreiber (2005) cite the use of a balloon catheter (e.g., Foley catheter) placed into the intracervical canal to increase pressure exerted on the lower uterine segment. Hydroscopic dilators (those that enlarge as they absorb moisture from the surrounding tissue) such as laminaria tents (made from desiccated seaweed) and synthetic dilators containing magnesium sulfate (Lamicel) may be inserted into the endocervix without rupturing the membranes. The dilators remain in place for 6 to 12 hours before removal for assessment of cervical dilation. Fresh dilators may then be inserted if necessary. Amniotomy and membrane stripping (the physician or midwife inserts a gloved finger into the cervical os to gently “strip” the membranes) can be also be used to ripen the cervix.

Oxytocin

Oxytocin, a hormone produced by the pituitary gland, stimulates uterine contractions. (See Chapter 12.) It can be used to induce labor or augment a labor that is progressing slowly due to ineffective uterine contractions. Administration of the medication is closely monitored according to institutional protocols. An intravenous infusion of 0.5 to 2 milliunits per minute of oxytocin is used for labor induction or augmentation. The dose is increased 1 to 2 milliunits per minute at intervals no less than 30 to 60 minutes until adequate labor progress is achieved. The patient should be reevaluated if the dose reaches 20 milliunits per minute (Deglin & Vallerand, 2009).

Table 14-2 Cervical Ripening Agents

Medication	Action	Adverse Effects	Dosage
Prostaglandin E ₁ Misoprostol (Cytotec)	Induces labor contractions	Diarrhea, abdominal pain, headaches, fever, tachysystole, uterine hyperstimulation	Intravaginally: 25 mcg—repeat every 4–6 hours until Bishop score equals 8 or greater.
Prostaglandin E ₂ Dinoprostone (Cervidil Insert, Prepidil Gel)	Promotes initiation of cervical ripening May stimulate labor contractions	Uterine hyperstimulation, fever, back pain, headache, nausea and vomiting, diarrhea, hypotension, tachysystole <i>Adverse effects are more common with intracervical administration.</i>	Cervidil Insert: (10 mg dinoprostone gradually released over 12 hours). Remove after 12 hours or at labor onset. Keep insert frozen until ready to use. Prepidil Gel: (2.5-mL syringe containing 0.5 mg of dinoprostone). Repeat gel insertion in 6 hours as needed (maximum = 1.5 mg or 3 doses/24 hr). Allow gel to reach room temperature before administration; do not heat. Continue administration until maximum dose is reached, or uterine contractions are established (3/10 min) or Bishop score equals 8 or greater or adverse reactions occur.
Teaching: Patient Education			
<ul style="list-style-type: none"> • Assess knowledge of the medication. • Explain purpose of medication and side effects. • Discuss comfort options to offset side effects. • Instruct the patient to void before insertion. • Instruct the patient to maintain a supine position with a lateral tilt or side-lying position for 30–40 minutes after insertion.

Optimizing Outcomes— Through the safe administration of oxytocin

First, the patient's primary health care provider writes an order for oxytocin for labor induction or augmentation. After an explanation and assessment of the patient's level of understanding, the nurse assists the woman to a side-lying or upright position. Assessment of the patient and fetus is conducted and documented. The solution is prepared and administered with a pump delivery system according to the prescribed orders. The piggyback solution is connected to the intravenous infusion at the port nearest the point of venous insertion. The medication is administered as ordered; ongoing assessments are conducted according to institutional protocol. The nurse documents the medication (kind, amount, times of beginning infusion, increasing the dose, maintaining the dose, discontinuing the infusion), maternal–fetal reactions (FHR and pattern, maternal vital signs, pattern and

progress of labor, nursing interventions, and maternal response) and when notification of the primary health care provider takes place.

Oxytocin acts on receptors in the myometrium to create an increase in the strength, duration, and frequency of the contractions. These same receptors are susceptible to uterine hyperstimulation, which constitutes a major risk associated with the medication. Signs of uterine hyperstimulation include the following:

- Uterine contractions that last greater than 90 seconds and occur more frequently than every 2 minutes
- Uterine resting tone greater than 20 mm Hg
- Non-reassuring fetal heart and pattern (baseline less than 100 or greater than 160 beats per minute; Absent variability; Repeated late decelerations or prolonged decelerations)

Higher doses are associated with an increased incidence of hyperstimulation; however, low dosages result in an increased rate of cesarean births due to failure of labor progression (Dudley, 2003). Uterine hyperstimulation causes reduced blood flow through the placenta and results in FHR decelerations, fetal asphyxia, and neonatal hypoxia. Because of the potential for life-threatening adverse complications associated with the use of oxytocin during the intrapartal period, the FDA has issued a number of restrictions to its use.

clinical alert

Contraindications to the use of oxytocin to stimulate labor

Nurses should be aware of contraindications to the use of oxytocin to stimulate labor, which include, but are not limited to (ACOG, 1999):

- Vasa previa or complete placenta previa
- Transverse fetal lie
- Umbilical cord prolapse
- Previous transfundal uterine surgery

Conditions that necessitate special precaution during oxytocin administration include:

- Breech presentation
- Multifetal pregnancy
- Presenting part above the pelvic inlet
- Severe hypertension
- Maternal heart disease
- Polyhydramnios
- One or more previous low-transverse cesarean deliveries
- Abnormal fetal heart rate patterns not necessitating emergent delivery

Augmentation of labor is used to stimulate uterine contractions after labor has begun spontaneously but is not progressing satisfactorily. It is most commonly indicated for the management of hypotonic uterine dysfunction. Labor augmentation may be accomplished with amniotomy, oxytocin infusion, and nipple stimulation. Noninvasive approaches include ambulation, hydration, relaxation, and hydrotherapy and these methods should be attempted before the initiation of invasive measures.

Nipple stimulation has been used for labor augmentation and induction. The action of nipple rolling produces an increase in the release of oxytocin from the anterior pituitary gland. The nurse instructs the woman to roll her nipple through her clothing for ten minutes on one side and then proceed to the other side, resting during a contraction. A breast pump may also be used. Nipple stimulation rarely causes hyperstimulation of the uterus. However, the results of nipple stimulation are less predictable than the administration of specified dosages of oxytocin. Sexual intercourse has also been helpful as a method of induction because semen contains prostaglandins (Gilbert, 2006). Both of these methods require additional evidence-based research before their endorsement as viable alternatives for labor induction.

Complementary Care: Measures for induction of labor

Several nonpharmacological methods or alternative methods have been used to induce labor. Herbal remedies such as black haw, primrose oil, black and blue cohosh, chamomile, and red raspberry leaves are prescribed as labor inducers in some cultures. Technically these substances are medicinal agents with some properties similar to those of oxytocin. Use of these agents creates problems because of the lack of scientific research and validation of their effectiveness. Much of the information about how they work is anecdotal, which also makes it difficult to evaluate the risks and the benefits, critical information for patients and their health care providers (Tenore, 2003). Nonherbal methods include acupuncture, the ingestion of a laxative (e.g., castor oil), and the stripping of membranes.

NURSING CONSIDERATIONS

The nurse's responsibilities during labor induction or augmentation begins with obtaining informed consent for the procedure after physician explanation. Patient education regarding the procedure and its consequences is critical. Monitoring of the labor is essential since hyperstimulation of the uterus may lead to uterine rupture. Oxytocin protocols in many institutions require that the nurse remain at the patient's bedside at all times for careful surveillance. The following data should be placed on a flow sheet in the patient record:

- Patient's vital signs (blood pressure, pulse and respirations every 30 to 60 minutes and with every increment in medication dose)
- FHR (via electronic monitoring)
- Frequency, duration, and strength of contractions (note contraction pattern and uterine resting tone every 15 minutes and with every increment in medication dose during first stage; then monitor every 5 minutes during second stage)
- Cervical effacement and dilatation
- Fetal station and lie
- Rate of oxytocin infusion
- Intake and urine output (limit intravenous fluid intake to 1000 mL/8 hr; output should be 120 mL or more every 4 hours)
- Any untoward effect of the medication administration (nausea, vomiting, headache, hypotension)
- Psychological response of the patient (ACOG, 1999; Gilbert, 2006; Simpson, 2005b).

critical nursing action Recognizing and Responding to Problems During Labor Induction with Oxytocin

During induction of labor with oxytocin, the nurse remains alert to signs indicative of complications such as uterine hyperstimulation, non-reassuring FHR pattern, and suspected uterine rupture. Immediate emergency measures include: discontinuing the oxytocin per institutional protocol; positioning the patient on her side; increasing the

primary IV rate up to 200 mL/hr (unless there is evidence of water intoxication—in this situation, the rate is decreased to one that keeps the vein open); administering oxygen by face mask at 8–10 L/min or per physician order or institutional protocol.

The nurse needs to discuss pain relief options with the patient before oxytocin administration. The information presented should include prescribed medications as well as natural options. If the woman declines pharmacological analgesia or anesthesia, the nurse must work closely with her and her support person in the effective use of relaxation and breathing techniques. The woman placed on bedrest as a result of the induction needs frequent position changes. Massage may enhance her comfort during the procedure. The nurse should keep the patient and her support person informed of her progress as this information reassures the patient and gives her confidence.

Now Can You— Discuss labor induction?

1. Identify eight indicators for labor induction?
2. Explain the relationship between the Bishop score and induction of labor?
3. Identify and discuss the implications of pertinent data recorded on the maternal flow sheet during labor induction with oxytocin?

INSTRUMENTATION ASSISTANCE OF BIRTH

Forceps and vacuum extraction are used to decrease the length of the second stage of labor when indicated because of maternal exhaustion or epidural anesthesia, suspected fetal distress, and the need to rotate the fetal head. In the United States there has been a decrease in the overall use of instrumentation as a birth assist while there has been an increase in operative deliveries. Speculation as to the reason for this trend has been attributed to a fear of malpractice related to complications associated with the methods as well as a lack of physicians' training in the use of delivery instrumentation (Patel & Murphy, 2004).

Forceps-Assisted Birth

A forceps-assisted birth is one in which a steel instrument with two curved blades is used to facilitate the birth of the infant's head. **Forceps** is an instrument consisting of cephalic-curved blades similar to the shape of the fetal head (Fig. 14-3). The two blades slide together at the shaft to form a handle. The first blade is inserted into the maternal vagina next to the fetal head. The second blade is then inserted and applied to the opposite side of the fetal head. The shafts of the forceps are brought together in the midline and secured to form a handle. Forceps prevent pressure from being exerted on the fetal head and facilitate birth.

Maternal indications for a forceps-assisted birth include a need to shorten the second stage of labor for the following reasons: dystocia; an inability to push with contractions (e.g., due to exhaustion, spinal or epidural anesthesia, spinal cord injury); to prevent worsening of serious

medical complications such as cardiac compensation. Fetal indications include an abnormal presentation, arrest of rotation, immaturity, and distress from a complication such as prolapsed cord.

There are various applications and several different types of forceps for forceps-assisted birth. Outlet forceps are used when the fetal scalp is visible on the maternal perineum without manual separation of the labia. Low forceps are used when the fetal head is at a +2 station or more. Midforceps are used when the fetal head is engaged but at less than a +2 station. Because birth trauma has been associated with the use of midforceps, this procedure has been largely replaced by cesarean birth, which poses less risk to the fetus. Forceps are never applied to an unengaged presenting part. Piper forceps are used to facilitate delivery of the head in a breech birth. Some form of anesthesia is administered before forceps application to achieve pelvic relaxation and decrease pain. An episiotomy is usually performed to prevent perineal tearing. Before forceps application, the following criteria must be met:

- The cervix must be fully dilated; bladder empty; presenting part engaged
- The membranes must be ruptured
- Cephalopelvic disproportion must not be present

critical nursing action When Attending a Forceps-Assisted Birth

The FHR and pattern are assessed and recorded before the forceps application. When the forceps are applied, there is a danger of compression of the cord between the fetal head and the forceps blade. Cord compression causes a decrease in FHR. Therefore, assess and record the FHR and pattern again *immediately* after the forceps application.

Perineal trauma is one of the major complications associated with the use of forceps. Since hemorrhage may result from cervical lacerations and vaginal tearing, the woman requires close observation during the postpartum period. To rule out maternal bladder injury, the nurse documents the time and amount of the first postbirth voiding. Some women have reported fecal incontinence following forceps injury. Women who experience forceps-related problems may suffer fear and anxiety regarding the birth experience in subsequent pregnancies (Patel & Murphy, 2004).

Fetal morbidity occurs in direct response to occipital trauma. Superficial scalp and facial markings are the most common complications and are rarely significant. However, it is important for the nurse to clearly discuss this possibility with the family. Once the parents understand that the trauma marks gradually disappear, they are usually more accepting of the baby's (usually) superficial injuries. Other forceps-related complications that rarely occur include facial nerve injury, cephalhematoma, retinal hemorrhage, and ocular trauma. Neonatal intracranial bleeding constitutes a major concern but it is often difficult to ascertain whether the hemorrhage resulted from the forceps or it was related to the difficult birth (Belfort, 2003).

Figure 14-3 Forceps are instruments with curved blades that are used to facilitate the birth of the fetal head.

Now Can You— Discuss issues surrounding the use of forceps?

1. Identify three maternal indications and three fetal indications for a forceps-assisted birth?
2. Describe maternal–fetal complications associated with the use of forceps instrumentation?
3. Discuss key information the nurse provides the parents regarding a forceps-assisted birth?

Vacuum-Assisted Birth

Vacuum-assisted birth, also termed vacuum extraction, is an alternative method used in an assisted vaginal delivery (Fig. 14-4). The vacuum extractor consists of a soft plastic cup that is attached to the fetal head over the posterior fontanel and a suction apparatus that uses negative pressure to facilitate the birth of the head. This modality is used for a patient who is unable to voluntarily push during the second stage of labor (most often due to exhaustion or pharmacological agents), fetal distress or failure to progress. The same conditions apply to the use of the vacuum as for forceps: vertex presentation, ruptured membranes, and absence of CPD. Vacuum-assisted birth has certain advantages over forceps-assisted birth: little anesthesia is required (the fetus is less depressed at birth) and it is associated with fewer lacerations of the maternal birth canal. Vacuum extraction should not be used

following fetal scalp blood sampling. The suction pressure can cause excessive bleeding at the sampling site. It is also not recommended for preterm fetuses whose skulls are extremely soft.

To prepare the patient for a vacuum-assisted birth, the nurse provides education and support and encourages the woman's continued participation in childbirth by pushing during contractions. The FHR is assessed before and throughout the procedure. The nurse assists the woman to a lithotomy position to allow sufficient traction. The primary care provider applies the cup to the fetal head and a caput (swelling of the soft tissue) develops inside the cup as the pressure is initiated. Gentle traction is applied to facilitate descent of the fetal head. An episiotomy may be performed as the head crowns.

Be sure to— Assume nursing responsibilities associated with a vacuum-assisted birth

The nurse is responsible for management of care during a vacuum-assisted procedure. Although the physician applies the vacuum to the infant head, the nurse controls the vacuum gun and the pressure and is responsible for all of the required documentation. The perinatal team must communicate frequently during the procedure as they each assess progress or the lack of progress. The nurse, following protocols, can advocate for cesarean birth if maternal exhaustion and/or failure of descent indicates that the

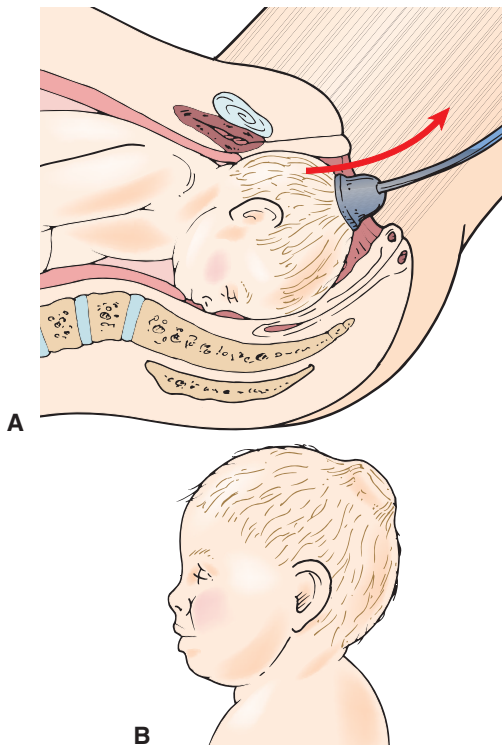

Figure 14-4 Vacuum extraction also facilitates the delivery of the fetal head and is associated with fewer lacerations of the maternal birth canal. A. Vacuum extractor is applied with a downward and outward traction. B. A caput succedaneum, or chignon, is formed from the suction cup.

vacuum assistance is not effective. If the nurse fails to communicate concerns and there is an untoward event, the nurse can be held liable. Liability is also incurred if the nurse fails to document the sequence of events during the vacuum assistance along with the maternal–fetal response. After an assisted birth, the nurse who assesses the neonate is also liable with regard to the documentation of vital signs and the neonatal assessment (Mahlmeister, 2005).

The caput that has formed on the neonate’s scalp begins to disappear in several hours but may persist for up to 7 days after birth. Appropriate education of the parents before the vacuum application helps them to understand that the caput swelling is not harmful to the infant and the markings will decrease rapidly. Neonatal complications include cephalhematoma, scalp lacerations, and subdural hematoma. The infant should be carefully observed for signs of trauma and infection at the application site.

Maternal Conditions that Complicate Childbirth

HYPERTENSIVE DISORDERS

Management of hypertensive disorders during parturition is based on two goals: preventing further deterioration of affected organs and fostering a positive maternal–infant outcome. Women who have been diagnosed with severe

preeclampsia or HELLP syndrome (**H**emolysis, **E**levated **L**iver enzymes, and **L**ow **P**latelets; see Chapter 11) may be placed in an obstetric critical care unit or a medical intensive care unit for hemodynamic monitoring. Maternal vital signs, FHR, urine output, deep tendon reflexes, level of edema, and mental orientation and neurological status are assessed. Fetal–maternal factors that may necessitate immediate interventions to facilitate birth are presented in Box 14-3.

When severe preeclampsia is diagnosed at less than 34 weeks’ gestation, the approach to care may include an observational period and conservative management. If the gestational age is 32 to 35 weeks, induction of labor is usually initiated. Vaginal birth is considered safer than cesarean birth and is attempted if cervical favorability is present. Antenatal glucocorticoids such as betamethasone may be given (12 mg IM 24 hours apart) to promote lung maturity if the gestational age is less than 34 weeks and delivery can be delayed for 48 hours (ACOG, 2002a; Cunningham et al., 2005; Sibai, Dekker, & Kupersminic, 2005). (See Chapter 11.)

Nursing Considerations

The nurse is the manager of care for the woman with preeclampsia during the intrapartal period. Careful assessments are critical. The nurse plans and evaluates all interventions on a continuous basis. The patient with severe preeclampsia is in an extremely fragile condition. Since any change in condition may require an emergency intervention, the nurse must be prepared to provide the necessary care immediately. The nurse is responsible for the continuous monitoring of several key parameters (Box 14-4). Laboratory tests include a complete blood count (CBC) with platelets, coagulation profile to assess for disseminated intravascular coagulation (DIC), metabolic studies for determination of liver enzymes (aspartate aminotransferase [AST], alanine aminotransferase [ALT], lactate dehydrogenase [LDH]) and electrolyte studies to establish renal functioning (ACOG, 2002). (See Chapter 11 for further discussion.)

Box 14-3 Factors that May Necessitate Immediate Intervention to Facilitate Birth in Patients with Hypertensive Disorders

- Uncontrolled severe hypertension
- Eclampsia
- Persistent oliguria (< 500 mL/24 hr)
- Abruption placentae
- Platelet count less than 100,000/mm³
- Elevated liver enzyme levels with epigastric pain or right upper quadrant tenderness
- Pulmonary edema
- Persistent severe headache or visual changes
- Spontaneous labor
- Fetal death
- Rupture of the membranes
- Gestational age less than 34 weeks (an observational period may be initially attempted as a conservative management approach)
- Evidence of fetal compromise

Box 14-4 Intrapartal Nursing Care for Patients with Preeclampsia

BLOOD PRESSURE

The blood pressure is taken every 4 hours or more frequently according to physician orders or institutional protocol. Blood pressure should be taken in the same arm at each assessment. Encourage the patient to assume a side-lying position to enhance uterine perfusion. Record the data. Notify the physician of an increase in blood pressure.

MEDICATION ADMINISTRATION

Administer medication as ordered and evaluate its effect. Adhere to hospital protocol for magnesium sulfate infusion. Monitor maternal vital signs, FHR, urine output, DTRs, IV flow rate and serum magnesium levels to assess for magnesium sulfate toxicity (e.g., depressed respirations, hyporeflexia, sudden onset of hypotension, oliguria, indicators of fetal compromise). Administer calcium gluconate (the antidote for magnesium sulfate toxicity) for respirations below 12 breaths/min and discontinue the magnesium sulfate infusion.

RENAL BALANCE

Edema is rated on scale of 1 to 4. A score of 4 is generalized massive edema that includes the face, abdomen and sacrum. Assess and record urinary output. An indwelling urinary catheter may be inserted to more accurately measure urinary output. A urine output less than 30 mL/hr is indicative of oliguria and the physician must be notified. A dipstick measurement is performed every 4 hours or more frequently to assess urinary protein on a scale of 1–4. A dipstick reading over 2+ is indicative of a worsening condition.

NEUROLOGICAL STATUS

Deep tendon reflexes (DTRs) are assessed every 4 hours (or more frequently) and rated on a scale of 1 to 4. Reflexes greater than 2+ are a sign of worsening status. If dorsiflexion of the foot produces clonus (convulsive spasm), this finding provides an additional indication of a deteriorating maternal condition.

PULMONARY STATUS

Auscultation of the lungs is performed every 4 hours (or more frequently) to assess for dyspnea, crackles and diminished breath sounds, which may be indicative of pulmonary edema. The respiratory rate is assessed every 4 hours (or more frequently). Patients who are receiving magnesium sulfate require more frequent respiratory assessments since a respiratory rate below 12 is an indicator of magnesium toxicity. Hemoglobin oxygen saturation can be assessed with a pulse oximeter.

PSYCHOLOGICAL STATUS

Assess the woman for indicators of anxiety and fear. Provide information to the patient and family about the treatment protocols and status of the maternal condition. Assess their level of understanding and provide updates when indicated.

ADVANCING SYMPTOMS

Headaches, blurred vision, severe right upper quadrant epigastric pain, and restlessness are all indicators of impending eclampsia. Prepare for immediate delivery.

SEIZURES

Protect the patient. Keep the airway patent: turn head to one side and place pillow or folded linen under one shoulder or back. Call for assistance. Ensure that the siderails have been raised. Observe and document all seizure activity. Notify the physician and prepare for delivery. Administer oxygen.

FETAL STATUS

Monitor the fetal heart rate every 4 hours or more frequently as indicated. Assess fetal movements. Notify the physician if indicators of fetal compromise are noted.

The nurse must also monitor the laboratory values for impending HELLP syndrome during labor. The nurse follows the plan of care for the patient with severe preeclampsia.

Special precautions need to be considered to prevent adverse outcomes in a patient with the HELLP syndrome who requires a cesarean birth. The nurse is responsible for administering 5 to 10 units of platelets on the physician's order before the birth to prevent thrombocytopenia. Providing ongoing information to the patient and her family is an essential nursing intervention to help decrease anxiety and fear (Sibai et al., 2005).

DIABETES

Women with the metabolic disorder of diabetes that is under control may safely give birth spontaneously at term provided there are no indications of severe cephalopelvic disproportion (CPD). When a possibility of CPD exists, the diabetic woman may be given a trial of labor. If successful, a cesarean birth, which always presents a higher risk than a vaginal birth for the fetus, has been avoided.

Nursing Insight— Recognizing medical indications for elective preterm birth in women with diabetes

As long as she remains in good metabolic control and all parameters of fetal surveillance are within normal limits, the woman whose pregnancy is complicated by diabetes may safely carry the pregnancy to 38.5–40 weeks of gestation. However, the presence of poor metabolic control, a worsening hypertensive disorder, fetal macrosomia (often defined as weight >4500 g) or fetal growth restriction are all indications for elective preterm birth (ACOG, 2001; Cunningham et al., 2005).

The physician may plan an elective induction of labor between 38 and 40 weeks of gestation. An amniocentesis performed between 37 and 38.5 weeks of gestation is performed to confirm fetal lung maturity. Fetal lung maturation is better predicted by an amniotic fluid phosphatidylglycerol level of greater than 3% than by an amniotic fluid lecithin/sphingomyelin ratio (3:1) in the pregnancy complicated by diabetes. If the fetal lungs are immature, birth may be delayed as long as all parameters of the maternal and fetal assessment remain reassuring (Moore, 2004). (See Chapter 11.)

Intrapartum management for the woman with pregestational diabetes centers on the close surveillance of maternal hydration and blood glucose levels to prevent complications associated with dehydration, hypoglycemia, and hyperglycemia. An intravenous infusion of a maintenance fluid such as lactated Ringer's solution or 5% dextrose in lactated Ringer's solution may be ordered. Insulin is usually administered by continuous infusion; only regular insulin may be administered intravenously. Blood glucose levels are assessed every hour and fluid/insulin adjustments are made as needed to maintain maternal blood glucose levels between 80 and 120 mg/dL (Bernasko, 2004). It is essential that maternal hyperglycemia during the intrapartal period be avoided to prevent neonatal metabolic problems such as hypoglycemia.

The laboring patient is maintained in an upright or side-lying position with continuous FHR monitoring. Nursing care involves close surveillance for indicators of normal labor progression along with a stable maternal-fetal unit. Failure to progress may be related to fetal macrosomia or CPD and necessitate a cesarean birth. Diabetes-related complications such as hyperglycemia, ketosis, and ketoacidosis may develop and must be promptly managed. Shoulder dystocia associated with fetal macrosomia may complicate the second stage of labor. A team that consists of the obstetrician and neonatologist, pediatrician, or neonatal nurse practitioner should attend the birth to provide immediate neonatal assessment and care.

When a cesarean birth has been planned, the surgery is scheduled for the early morning to achieve optimal glycemic control. Depending on physician orders, the nurse may be instructed to withhold the morning insulin. Other protocols allow administration of an intermediate-acting insulin in the morning and every 8 hours until surgery (Chan & Winkle, 2006). The patient is allowed nothing by mouth. Epidural anesthesia is preferred because hypoglycemia can be detected earlier if the woman remains awake. After the surgery, maternal blood glucose levels are assessed at least every 2 hours; target plasma levels are between 80 and 160 mg/dL (Moore, 2004).

The first 24 hours postpartum are remarkable for the dramatic decrease in insulin requirements that occurs after removal of the placenta. Depending on the amount of food consumed, women with type I diabetes may require only one fourth to one third of the prenatal insulin dose (Bernasko, 2004). Some women may not require insulin for 24 to 72 hours postpartum (Chan & Winkle, 2006). Throughout the postpartal period, blood glucose levels continue to be monitored and insulin dosage adjustments are made as needed, often using a sliding scale.

Nursing Insight— Increased risk of postpartal complications in diabetic women

Women whose pregnancies have been complicated by diabetes have an increased risk for complications such as preeclampsia/eclampsia, hemorrhage, and infection (i.e., endometritis) during the postpartal period. Hemorrhage is more likely if the uterus was overdistended due to fetal macrosomia or hydramnios. (See Chapter 16.)

The nurse should encourage mothers with pregestational and gestational diabetes to breastfeed. However, because glucose levels are lower, especially during early postpartum, breastfeeding women are at an increased risk for hypoglycemia. Also, the mother with poor metabolic control may have a delay in lactogenesis that results in decreased milk production (Moore, 2004).

Discharge planning for women with diabetes should include discussion about contraceptive information as appropriate. Because women with gestational diabetes are at increased risk for developing diabetes later in life, the nurse should counsel them about the importance of maintaining a healthy weight and undergoing glucose testing during routine health maintenance visits.

PRETERM LABOR AND BIRTH

Preterm labor that is not arrested leads to preterm birth. In the United States, preterm birth has increased over the last decade despite the use of preventive pharmacological therapies. Martin et al. (2005) reports that in 2002, 12.3% of infants born were preterm. This figure is the highest number recorded since preterm birth data have been collected. Accompanying this dramatic increase in preterm births is a 50% increase in premature infants born with neurological deficits (ACOG, 2003a).

Ethnocultural Considerations— Preterm labor and birth

Race and ethnicity cannot be disregarded in any discussion of preterm labor. Black women are at a higher risk for preterm birth than are Caucasian women. When preterm birth rates of married, educated Black women are compared with those of matched Caucasian women, a disparity continues to be noted in the Black women. The increase in cases of preterm labor results in a greater percentage of infant mortality in the Black population (Moore, 2003).

The causes for preterm birth are often a series of overlapping conditions such as premature rupture of membranes combined with cervical incompetence. Canavan, Simhan, and Cartis (2004) reported that premature rupture of the membranes accounts for approximately 3% of all preterm births. In many cases, patients experience “silent” (asymptomatic) uterine contractions throughout pregnancy that contribute to progressive cervical effacement and dilation. (See Chapter 11.)

Although interventions including bedrest, hydration, and tocolytic therapy are used to inhibit contractions, in many situations the labor cannot be halted. If the woman's membranes have ruptured or if the cervix is greater than 50% effaced and 3 to 4 cm dilated, it is unlikely that the labor can be stopped. If the fetus is very immature and birth is deemed to be inevitable, a cesarean birth may be planned to reduce pressure on the fetal head and decrease the possibility of subdural or intraventricular hemorrhage.

Nursing Considerations

In addition to careful maternal monitoring, FHR monitoring is one of the most important nursing responsibilities when caring for a patient in preterm labor. A number of perinatal complications such as preeclampsia, intra-amniotic infection, oligohydramnios, umbilical cord compression, placental abruption, intrauterine growth restriction, uteroplacental insufficiency, and multiple gestation occur more often with preterm labor. This combination of complications may result in FHR patterns that differ from the norm. Because of the increased incidence of neurological deficits in premature infants, it is essential that the nurse be able to identify and report data suggestive of hypoxia as early as possible (Simpson, 2004).

Best clinical practice for fetal monitoring begins with correct application of the tocodynamometer and the fetal heart monitor. Leopold maneuvers are used to identify the fetal back and presenting part. Since multiple gestations are often associated with preterm labor, it is important to identify and

monitor each fetus. The tocodynamometer needs to be placed at the height of fundus to ensure the best interpretation of the labor contractions (Simpson, 2004).

Optimizing Outcomes— Providing pain relief during preterm labor and birth

The length of the first stage of labor for a woman who is preterm is essentially the same as for a woman with a full term gestation although the second stage may be shorter—the smaller fetal size can be pushed through the dilated cervix more easily. Maternal analgesia is used cautiously due to the immaturity of the fetus, who may have considerable difficulty breathing without the additional burden of sedative effects from maternal analgesic agents. If the patient desires analgesia, the nurse can explain why epidural pain relief is most likely preferable. An episiotomy is often performed at the time of birth to lessen trauma on the fragile fetal head; forceps may also be used.

Because of the patient's medical complications and related fetal issues, she and her support person often experience increased anxiety and fear during the labor and birth. The nurse is there to offer clinical expertise; provide a calming presence; and inform, support, and assist the patient and her partner throughout the birth experience. A careful assessment of the patient's psychological status can help direct the care. Expressions of caring coupled with dialog that includes specific questions help to identify the patient's main concerns.

Optimizing Outcomes— Exploring concerns of the woman experiencing preterm labor

The nurse should use active listening and remain nearby. The patient should be encouraged to participate in decision making as much as possible throughout the labor process. Women who have anticipated an uncomplicated labor and birth experience often feel out of control when events occur that differ from their expectations. The nurse can play a vital role in keeping the patient informed and helping her to remain an active participant throughout the birth process. One approach involves teaching the patient and her partner what to expect during each phase and how they can help one another throughout the process. If the patient so wishes, the nurse involves the support person in the care as much as possible.

Ethnocultural Considerations— Minority women and level of care received

The Institute of Medicine (2003) reported that minorities do not receive the same level of quality care as do white Americans. A nurse working in the birth unit needs to be attentive to this problem. It is incumbent on all nurses to advocate for patients any time there appears to be an ethnic bias in treatment. The nurse also must be aware of any of personal prejudices that could affect care. In institutions that serve minority populations, it is essential that all hospital staff members undergo frequent in-service educational offerings that focus on heightening cultural sensitivity.

Now Can You— Discuss aspects of various maternal conditions that complicate childbirth?

1. Discuss critical aspects of intrapartal care for the woman with diabetes?
2. Describe one critical nursing responsibility in the patient experiencing a nonarrested preterm labor?
3. Identify three teaching needs for the patient experiencing preterm labor and birth?

Complications of Labor and Birth Associated with the Fetus

FETAL MALPRESENTATION

Fetal malpresentation is the second most commonly reported complication of labor and birth. In 2003, it occurred at a rate of 38.5 per 1000 live births (Martin et al., 2005). The fetal occiput is the most favorable presenting part for a vaginal birth. Face, brow, shoulder, compound, and breech constitute malpresentations. A breech presentation, in which the buttocks or legs present first, occurs in approximately 3% of all births and is considered the most common malpresentation. (See Chapter 12.) It is important that these conditions be identified during the antepartum period since a malpresentation may place the woman and fetus at risk for complications during labor and birth. Diagnosis is made by abdominal palpation (i.e., Leopold maneuvers) and vaginal examination and is usually confirmed by ultrasonography.

During labor, descent of the fetus in a breech presentation may be slow. This is because the breech is not as effective as a dilating wedge as the fetal head. There is an increased risk of prolapsed cord if the membranes rupture during early labor (Fig. 14-5).

Nursing Insight— Breech presentation and meconium in the amniotic fluid

When the fetus is in a breech presentation, the presence of meconium in the amniotic fluid may not be indicative of fetal distress. Pressure exerted on the fetal abdomen during the birth process may cause the passage of meconium. It is important to assess the FHR and pattern to ensure there are changes indicative of fetal hypoxia. When the fetus is in a breech position, the FHR is best auscultated at or above the maternal umbilicus.

During the vaginal birth of a fetus in a breech presentation, the physician uses labor mechanisms that manipulate the buttocks and lower extremities. Piper forceps are sometimes applied to facilitate delivery of the head. Before the birth, the physician may attempt an external cephalic version to rotate the fetus to a vertex presentation. (See later discussion.) Cesarean birth is commonly performed when the following circumstances exist: the fetus is estimated to be larger than 3800 g or smaller than 1500 g; the labor is ineffective; this is the woman's first pregnancy; or there are additional maternal–fetal complications.

Face and brow presentations are examples of **asynclitism** (the fetal head is presenting at a different angle than

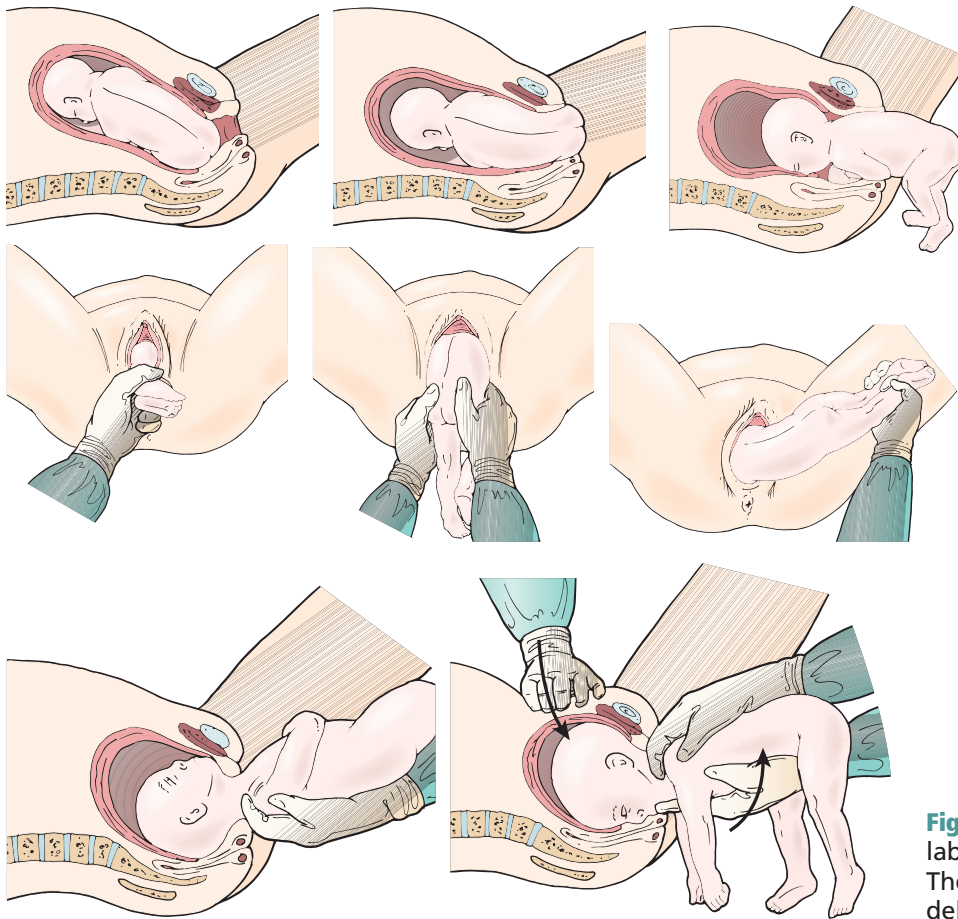

Figure 14-5 The mechanisms of labor in a breech presentation. The aftercoming fetal head delivers last.

expected). Face and brow presentations hyperextend the neck and increase the overall circumference of the presenting part. These presentations are uncommon and are usually associated with fetal anomalies (i.e., anencephaly), macrosomia, CPD, and contractures of the maternal pelvis. Vaginal birth may be accomplished if the fetus flexes to a vertex presentation. Forceps are often used. Cesarean birth is indicated if the presentation persists, if there is evidence of fetal compromise, or if there is an arrest in the progression of labor. Shoulder and compound presentations (e.g., a hand combined with the head) contribute to fetal and vaginal trauma and usually require cesarean birth (Cunningham et al., 2005).

VERSION

Version (turning of a fetus from one presentation to another) may be done either externally or internally by the physician.

External Version

An external cephalic version (ECV) is used as an attempt to turn the fetus from a breech presentation to a vertex presentation to allow a vaginal birth (Fig. 14-6). Since cesarean birth is a major surgical procedure associated with numerous maternal and fetal risks, ECV may offer an alternative to surgery. The procedure, performed in a birth unit, may be attempted after 37 weeks' gestation. Contraindications to ECV include previous cesarean birth,

uterine anomalies, CPD, placenta previa, multifetal gestation, and oligohydramnios (Cunningham et al., 2005).

Before the version, ultrasonography is obtained to confirm the fetal position, locate the umbilical cord; rule out placenta previa; assess the maternal pelvic dimensions and the amniotic fluid volume, fetal size and gestational age, and the presence of anomalies. Before the version, a non-stress test (NST) is performed to confirm fetal well-being, or the FHR may be electronically monitored for a brief period (e.g., 10 to 20 minutes).

Ultrasound guidance is used as the physician slowly applies gentle, steady pressure over the fetal head and buttocks to rotate the position. Complications associated with version include umbilical cord compression, placental abruption, maternal hemorrhage, and fetal bradycardia (Vadhera & Locksmith, 2004).

The procedure of rotating the fetus (version) requires uterine relaxation. Tocolytic agents such as magnesium sulfate or terbutaline are used to facilitate this process. Acoustic stimulation of the fetus has also resulted in successful versions (Vadhera & Locksmith, 2004).

Optimizing Outcomes—Assisting with ECV

The nurse is responsible for obtaining written informed consent from the patient after physician explanation, providing teaching regarding the procedure, administering medications as ordered, and conducting constant surveillance of the maternal–infant dyad. The patient

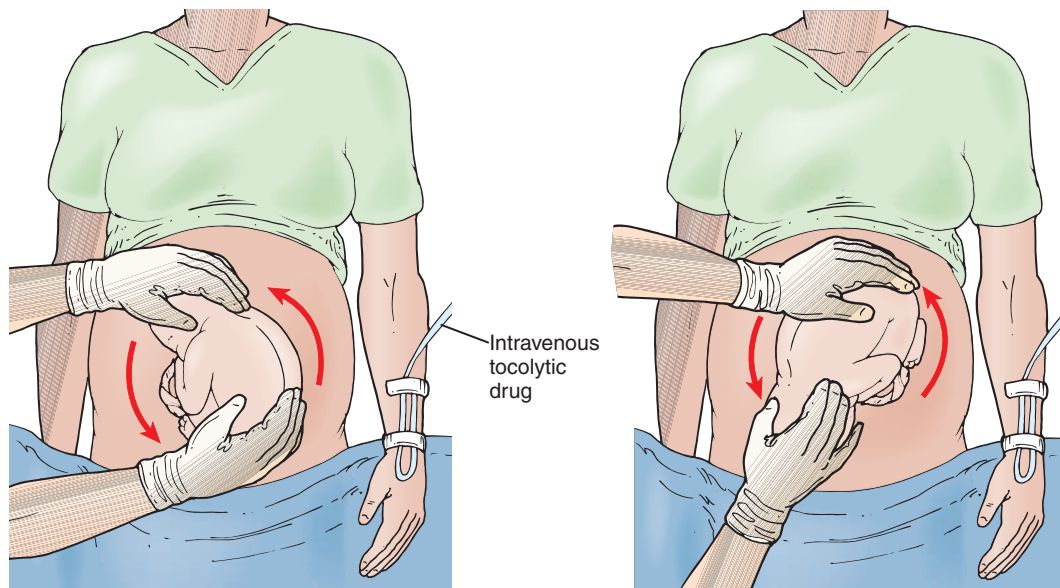

Figure 14-6 External cephalic version is a maneuver performed through the maternal abdominal wall in an attempt to change the fetal position from a breech to a cephalic presentation.

needs to know not only that the version attempt might not be successful; she must also be aware of the associated complications that may occur such as rupture of the membranes, fetal bradycardia, and discomfort. During the version, if there is any indication of significant fetal or maternal compromise, the nurse prepares the woman for a cesarean birth. Women who are Rh-negative are given Rh immune globulin because the manipulation may cause fetomaternal bleeding (Bowes & Thorp, 2004; Vadhera & Locksmith, 2004).

Internal Version

With internal version, the physician rotates the fetus by inserting a hand into the uterus and changes the fetal presentation to cephalic (head) or podalic (foot). Internal version is used with multifetal gestations to deliver the second fetus. However, the safety of this procedure has not been documented. Cesarean birth is usually performed for malpresentation in multiple gestations. Nursing responsibilities center on maternal–fetal monitoring and providing support to the woman.

SHOULDER DYSTOCIA

Shoulder dystocia is an uncommon obstetric emergency that occurs in 0.5% to 1.5% of all births (Jevitt, 2005). In this type of dystocia, the head is born but the anterior shoulder cannot pass under the maternal pubic arch. The problem is often not identified until the head is born. Risk factors for shoulder dystocia include maternal pelvic abnormalities, a history of shoulder dystocia in a previous pregnancy, obesity, diabetes, prolonged labor, postdate pregnancy, and fetal macrosomia (greater than 4000 g) (Gherman, 2005).

Although there are no methods to predict or prevent shoulder dystocia, the nurse should be alert to clinical

indicators: slowed labor progression and formation of a caput succedaneum that increases in size. When the fetal head emerges on the perineum (crowning), it retracts instead of protruding with subsequent contractions (termed the “turtle sign”), and external rotation does not occur (ACOG, 2002b; Bowes & Thorp, 2004; Jevitt, 2005). Fetal/neonatal injuries are related to birth asphyxia; damage to the brachial plexus; and fractures, usually of the humerus or clavicle. Maternal injury is most commonly associated with excessive blood loss that results from uterine atony or rupture; other risks include lacerations, extension of the episiotomy, and postpartum endometritis.

A number of maneuvers have been attempted to free up the anterior shoulder and facilitate delivery. The McRoberts maneuver is one approach. The woman is placed in a dorsal lithotomy position, and her thighs are sharply flexed on her abdomen. This position increases the angle between the symphysis pubis and the sacral promontory, allowing for greater room in fetal descent. Suprapubic pressure applied immediately above the symphysis pubis may be needed along with the McRoberts maneuver to loosen the trapped shoulders (Baxley & Gobbo, 2004; Camune & Brucker, 2007) (Fig. 14-7).

Other methods of delivery assistance for shoulder dystocia center on maternal positional changes: a hands-and-knees position, a squatting position, or a lateral recumbent position (Bowes & Thorp, 2004; Camune & Brucker, 2007; Jevitt, 2005).

Optimizing Outcomes— When birth is complicated by shoulder dystocia

When childbirth is complicated by shoulder dystocia, the nurse’s role is to assist the woman in assuming the positions, assist the physician with the maneuvers, and to document all procedures. The nurse also provides careful

Figure 14-7 Methods to relieve shoulder dystocia. **A.** Pressure is applied immediately above the maternal symphysis pubis to push the fetal anterior shoulder downward. **B.** McRoberts maneuver. The woman's thighs are sharply flexed on her abdomen to straighten the pelvic curve. **C.** Angle of pelvis before maneuver. **D.** Angle of pelvis after maneuver.

instruction to the patient to facilitate cooperation and understanding (Jevitt, 2005). After birth, the woman is closely observed for signs of hemorrhage and soft tissue trauma of the birth canal; the neonate is assessed for fracture of the clavicle or humerus, brachial plexus injuries, and asphyxia (Bowes & Thorp, 2004).

CEPHALOPELVIC DISPROPORTION

Although there are true problems that create issues between the head of the fetus and the pelvis of the mother, in the United States, **cephalopelvic disproportion** (CPD) is often used to describe unsuccessful attempts at vaginal birth. When CPD is present, the fetus cannot fit through the maternal pelvis to allow a vaginal birth. Often related to excessive fetal size (macrosomia), CPD occurred at a rate of 14.6 per 1000 live births in 2003 (Martin et al., 2005). A macrosomic infant (birth weight greater than 4000 grams) is likely to have a large head that can prevent descent into the mother's pelvis.

Despite ultrasound evaluation, it is difficult to predict the safest mode of birth for the macrosomic infant. A trial of

labor is suggested if the woman is nulliparous. Women with a previous history of cesarean birth for CPD may also be offered a trial of labor although a prompt cesarean birth is recommended at the earliest sign of maternal or fetal compromise.

The maternal pelvis is assessed before the onset of labor to determine type and size. A gynecoid pelvis is considered to be the most common female pelvic type and most amenable to vaginal birth although markedly small dimensions may preclude a vaginal birth. Other pelvic types are the android, anthropoid, and platypelloid. (See Chapter 5 for further discussion.) Although the other types of pelvises may not contraindicate a trial of labor, vaginal birth may not be possible for the woman with a platypelloid pelvis because its markedly shortened anterior–posterior diameter prevents fetal descent (Cunningham et al., 2005).

Nursing Care

A thorough nursing assessment including a review of present and past pregnancies is important in guiding care. Women with a history of cephalopelvic disproportion are at increased risk during the present labor. Slow progression of effacement and dilation, lack of fetal descent, and excessive pain are all possible indicators of CPD. Nursing interventions such as maternal position changes, particularly to an upright posture (e.g., sitting or squatting) to widen the pelvic girdle, relaxation, and water therapy are strategies to facilitate labor progression. The use of analgesic agents may alleviate pain-creating tension that is interfering with fetal descent. Supportive care includes information related to labor status and encouragement when progress has been made.

MULTIPLE GESTATION

Managing the births of more than one fetus is complex and requires the expert collaboration of medical and nursing personnel. The gestational age, number, health and presentation of the fetuses determine the mode of birth, whether vaginal or cesarean.

Nursing Insight—Fetal presentations with multiple gestations

Both fetuses present in the vertex position (most favorable for vaginal birth) in only one half of all twin pregnancies. In one third of multifetal pregnancies, one twin may present in the vertex position and one in the breech position (Cunningham et al., 2005).

Multiple births are associated with more complications than singleton births. The woman's health status may be compromised by problems such as hypertension of pregnancy, anemia, or gestational diabetes. She is also at increased risk for hemorrhage related to atony from uterine overdistention, abruptio placentae, and multiple or adherent placentas. Because of the multiple fetuses, abnormal fetal presentation may occur. Increased fetal/newborn complications are related primarily to problems associated with low-birth-weight infants due to preterm birth and intrauterine growth restriction. Intrapartum fetal distress may result from cord prolapse and the onset of placental

separation after the birth of the first fetus. Because of these problems, the risk for long-term disabilities such as cerebral palsy is greater among multiple births.

Women who present at 38 weeks with a twin pregnancy are less likely to experience fetal morbidity and mortality and may be appropriate candidates for a vaginal birth. It is recommended, although it is not always possible, that women with a multiple gestation, particularly triplets or higher-order multiples, deliver at a tertiary care center where facilities are available in the event of an emergency. Birthing centers must have transport ready for infant transfer to neonatal intensive care units. Patients who will undergo labor or a trial of labor require careful monitoring. Ultrasound is used to determine position and presentation of the fetal parts. Electronic fetal monitoring (EFM) is applied. It is important to identify each of the individual FHRs and the use of a separate monitor for each fetus is preferable. Interventions, such as analgesia, anesthesia, and intravenous infusions are determined on a case-by-case basis. The stimulation of labor with oxytocin, and epidural anesthesia, forceps, and vacuum assistance and fetal version may all be used to facilitate the vaginal birth of twins. Women in good health and with no evidence of fetal distress should be given the opportunity to participate in medical decision management.

When the woman is fully dilated and ready to push, she is moved to the birthing suite, where personnel, equipment, and supplies are readily available in the event there is a need for a cesarean birth. The woman may safely give birth in a labor, delivery, recovery, postpartum (LDRP) suite provided there is quick access to the surgical area. The nurse prepares the woman and her support for the possibility that she may experience both a vaginal and a cesarean birth depending on the fetal presentation. The nurse also explains the external version procedure in case this intervention is necessary. Patient education is carried out in a timely manner when the patient is capable of participation.

The majority (approximately 80%) of vertex, vertex twins are delivered with success vaginally. The first infant born is identified as “A” and neonatal care is initiated. Oxytocin, usually given to halt contractions and minimize bleeding, is withheld to avoid compromising circulation to the unborn fetus. In the vertex, breech presentation, an external version of the second twin is attempted provided that the conditions are favorable. If the second fetus is a footling breech, has a hyperextended head, or exhibits signs of compromise, a cesarean birth is considered the better option. The birth of the second twin normally occurs within 15 minutes of the birth of the first twin. Although there has been concern over complications associated with a longer time period between births, studies have shown that with proper fetal monitoring and maternal surveillance, a safe vaginal birth can take place in an indefinite amount of time (Cunningham et al., 2005; Vadhera & Locksmith, 2004). The nurse documents the time of birth for the first infant and all subsequent infants who are born.

Across Care Settings: Planning the multiple gestation birth

Together, the obstetrician, anesthesiologist, and patient discuss the anesthetic options available for childbirth. This collaborative meeting is best done in an office visit before the

onset of labor. Epidural anesthesia is considered a safe method for providing relief of pain and it allows prompt intervention in case the second twin requires an external version or a cesarean birth (Vadhera & Locksmith, 2004). The woman may experience an unmedicated birth provided she understands that if it is necessary to proceed to a cesarean birth she will receive a general anesthetic to facilitate uterine relaxation.

There is controversy over the medical management in twin births where the second twin is not in a vertex position. Data from a retrospective cohort study with 15,185 participants that studied twin births of vertex, nonvertex pairs showed that there is a higher risk of neonatal mortality and morbidity with vaginal birth of the nonvertex twin (Yang et al., 2005). The acknowledged limitations of large cohort studies lies in the fact that they are chart reviews and therefore do not examine complications associated with the birth of the second twin (Wen et al., 2004).

Triplets and higher order multiples generally require a cesarean birth. This mode of birth decreases the risk that the second fetus will experience anoxia as well as other complications such as cord entanglement and premature placental separation. While there are reports of triplet vaginal births, these successes are tempered with the strong possibility that both the second and the third neonates may be in breech presentations and require operative interventions. If it is deemed possible for the woman to give birth to triplets vaginally, the medical team must be on ready standby for an immediate cesarean surgery (Cunningham et al., 2005).

Now Can You— Discuss birth options for a woman with a multiple gestation?

1. Identify what factors determine whether a woman with multiple gestation may be allowed to attempt a vaginal birth?
2. Describe the primary recommendations concerning the childbirth options available for a woman with a multiple gestation?
3. Discuss controversies that surround the medical management of twin births?

NON-REASSURING FHR PATTERNS

Fetal heart monitoring is one type of assessment that provides the nurse, the patient, and her support(s) feedback concerning the well-being of the fetus. Families often request to increase the volume of the fetal monitor so that they hear the reassurance of a strong heartbeat. It is essential that the nurse understand actions that should be taken when decelerations or other ominous FHR patterns are detected. (See Chapter 12.)

Optimizing Outcomes— Responding to a non-reassuring FHR pattern

- Provide information to the woman; assist her to a lateral position.
- Encourage relaxation and mental imagery to reduce anxiety.

- Assess for and correct maternal hypotension by elevating the legs.
- Increase the rate of the maintenance IV fluids.
- Assess for hyperstimulation by palpating the uterus.
- Discontinue oxytocin if infusing.
- Administer oxygen at 8-10 L/min by mask.
- Consider internal monitoring to obtain more accurate fetal/uterine assessments.
- Apply fetal scalp or acoustic stimulation.
- Assist with fetal oxygen saturation monitoring if ordered.
- Assist with birth (cesarean or vaginal-assisted) if a non-reassuring FHR pattern cannot be corrected.

It is important that the nurse immediately notifies the physician or certified nurse midwife and initiate appropriate interventions for non-reassuring FHR patterns. (See Chapter 12.) A **prolonged deceleration** is the presence of a decrease in the FHR below the baseline 15 beats per minute or more that lasts more than 2 minutes, but less than 10 minutes. A deceleration that lasts more than 10 minutes is considered a baseline change (National Institute of Child Health and Human Development [NICHD], 1997). Benign causes of prolonged FHR decelerations include pelvic examination, application of a fetal spiral electrode, rapid fetal descent, and prolonged maternal Valsalva maneuver. Less benign causes include progressive severe variable decelerations, umbilical cord prolapse, hypotension associated with spinal or epidural analgesia/anesthesia, paracervical anesthesia, tetanic uterine contractions, placental hemorrhage, uterine rupture, and maternal hypoxia. A prolonged FHR deceleration that occurs late in the course of severe variable decelerations or a series of prolonged decelerations may occur immediately before fetal death.

critical nursing action Assisting with Intrauterine Resuscitation

Intrauterine resuscitation, a term used to describe interventions initiated when a non-reassuring FHR pattern is detected, centers on improving uterine and intervillous space blood flow and cardiac output (Simpson & James, 2005). When intrauterine resuscitation is underway, nursing priorities are: (1) to open the maternal and fetal vascular systems; (2) to increase the blood volume; and (3) to optimize oxygenation of the circulating blood volume. These interventions are accomplished by maternal positional changes, increasing the rate of the primary IV, and providing oxygen by face mask.

When non-reassuring FHR patterns are detected by EFM, other methods of assessment may be initiated:

- Fetal scalp and vibroacoustic stimulation
- Fetal oxygen saturation monitoring
- Fetal scalp blood sampling

Fetal Scalp and Vibroacoustic Stimulation

Fetal stimulation is done to elicit an acceleration of the FHR (15 beats per minute for at least 15 seconds) that occurs in response to a tactile stimulus (Tucker, 2004). Acceleration of the FHR will not occur in the presence of fetal distress and acidosis; thus, fetal stimulation is an assessment of the fetal acid-base balance. Scalp stimulation is conducted by

applying pressure with the fingers to the fetal scalp during a vaginal examination. Vibroacoustic stimulation is accomplished by placing an artificial larynx or fetal acoustic stimulation device on the maternal abdomen directly over the fetal head for 1 to 2 seconds. Acceleration of the FHR in response to the stimulation is usually indicative of fetal well-being; lack of a FHR acceleration does not necessarily indicate fetal compromise but warrants further evaluation.

Fetal Oxygen Saturation Monitoring

Fetal pulse oximetry (FPO), or continuous monitoring of fetal oxygen saturation, is similar to pulse oximetry used in children and adults. A small sensor designed to assess oxygen saturation is inserted next to the fetal cheek or temple area. The sensor is connected to a monitor; incoming data are continuously displayed on the uterine activity panel of the fetal monitor tracing. The normal range for oxygen saturation in the healthy fetus is 30% to 70%. Before this modality can be used, certain criteria (e.g., 36 weeks' gestation or greater; singleton fetus; vertex presentation; non-reassuring FHR pattern; ruptured membranes; fetal station less than or equal to -2) must be met. The American College of Obstetricians and Gynecologists (ACOG) has not endorsed FPO in clinical practice and recommends further clinical research for this assessment modality (ACOG, 2005).

Fetal Scalp Blood Sampling

Fetal scalp blood sampling is conducted to assess the fetal pH, PO₂ and PCO₂. A small sample of capillary blood is taken from the fetal scalp as it presents at the dilated cervix. If the fetus is hypoxic, there is a drop in the pH (acidosis). A scalp blood pH greater than 7.25 is considered normal for a fetus during labor; a scalp blood pH below 7.20 is acidotic and is recognized as an indicator of fetal distress. However, because of the frequent variations in fetal blood gas values associated with transient circulatory changes, fetal blood sampling is rarely performed except in tertiary centers that have a capability for repetitive sampling and the rapid report of results.

Depending on the situation, watchful waiting with continuous monitoring conducted by the nurse may provide the best option for assessment of fetal well-being. Since non-reassuring FHR patterns constitute a risk indicator for cesarean birth, the nurse and all members of the health care team must be ready for this outcome at all times. It is important to provide ongoing support for the laboring woman and keep her informed of her labor progress and fetal status.

“What to say” — When a non-reassuring FHR pattern is detected via electronic monitoring

When electronic monitoring reveals a non-reassuring FHR pattern, the nurse needs to maintain a calming presence and offer factual, simple explanations for all actions. For example, the nurse may say:

“We are concerned about your baby’s heart rate pattern.”

“I am going to change your position to your side to increase oxygen flow to your baby.”

“I am also going to place this oxygen mask on your face to increase the oxygen flow to you and to your baby, and increase your IV rate.”

“Do you have any questions?”

“I am here to help in any way and I will stay here with you. Please let me know what concerns you have.”

Amniotic Fluid Complications

Oligohydramnios (less than 300 mL of amniotic fluid), **hydramnios** (polyhydramnios) (greater than 2 L of amniotic fluid), and the presence of **meconium** (the first stools of the infant) in the amniotic fluid complicate labor and birth.

OLIGOHYDRAMNIOS

Oligohydramnios may result from fetal renal abnormalities, poor placental perfusion, or premature rupture of the membranes. During labor, the absence of the amniotic fluid buffer may lead to cord compression during contractions and decreased fetal blood flow as evidenced by variable heart rate decelerations. Women with pregnancies complicated by oligohydramnios require careful nursing and medical surveillance; amnioinfusion may be indicated to replace the cushion of fluid for the cord and relieve the frequency and intensity of variable decelerations. (See Chapter 12.)

HYDRAMNIOS

Hydramnios occurs in multiple gestations, fetal anomalies, and as a complication of maternal disease such as diabetes. During labor, the nurse needs to be aware that the excessive volume of fluid may obscure the fetal heart tracings. Hydramnios can cause fetal malpresentation because of the extra uterine space for the fetus to turn that it provides. The mother is also at risk for prolapse of the umbilical cord because the increased amount of fluid pushes the fetus high into the uterine cavity. Preterm rupture of the membranes, another complication associated with hydramnios, increases the risks of both infection and prolapsed cord.

MECONIUM

Meconium-stained amniotic fluid during intrapartum is an indication for careful fetal surveillance by EFM and possibly fetal scalp blood sampling. Although not always a sign of fetal distress, its presence, which occurs during fetal loss of sphincter control, is highly correlated with its occurrence. Reasons for the passage of meconium during labor include:

- Hypoxia-related peristalsis and sphincter relaxation
- Breech presentation or normal physiological function that occurs with fetal maturity
- Following umbilical cord compression-induced vagal stimulation in the mature fetus

Meconium staining, which occurs in approximately 20% of births, is observed more frequently in prolonged pregnancies. A decrease in amniotic fluid (oligohydramnios) increases the viscosity of the meconium and the risk of neonatal aspiration during delivery. The nurse must carefully document the presence of meconium stained fluid at the time of rupture of the membranes. In addition, the nurse should note the occurrence of variable decelerations and immediately notify the physician or certified nurse midwife regardless of whether or not meconium is present. Amnioinfusion has been shown to be effective in decreasing the fetal mortality associated with variable FHR decelerations.

Optimizing Outcomes— Intrapartal neonatal suctioning and meconium-stained amniotic fluid

The nasopharynx and oropharynx of the neonate born in the presence of meconium-stained amniotic fluid are often suctioned before the first breath to reduce the incidence and severity of meconium aspiration syndrome (MAS). However, because research does not support the efficacy of routine intrapartum suctioning to prevent MAS, this practice is no longer recommended (Vain et al., 2004).

NUCHAL CORD

Nuchal cord (a cord that is wrapped around the infant's neck) and cords with true knots are observed in approximately 1% of all births. Nuchal cord, which rarely causes hypoxia, occurs most often in fetuses with long umbilical cords. When a tight knot is present in the cord, variable heart rate decelerations associated with fetal asphyxia may be noted on EFM. Nursing interventions follow protocols used for other abnormal variations of the fetal heart tracing.

Once the head is born, gentle palpation is used to feel for the cord. If the cord is present, it is loosened and carefully slipped over the head. If it is too tightly coiled to allow this intervention, the cord is clamped twice, cut between the clamps, and unwound from around the neck before the shoulders are delivered. Otherwise, the cord could tear and interfere with the fetal oxygen supply.

Complications Associated with the Placenta

Critical nursing actions are required when the woman's intrapartum course is complicated by bleeding related to placenta previa (a low implantation of the placenta) or abruptio placentae (a premature separation of the placenta). (See Chapter 11.) Either condition places the woman at risk for hemorrhage and shock. A deteriorating physiological status of the mother impacts the fetus and often results in hypoxia. The nurse faces the challenge of helping to manage this intrapartum emergency. Guidelines for nursing care of the patient experiencing an intrapartum hemorrhage are presented in Table 14-3.

PLACENTA PREVIA

With placenta previa, bleeding occurs when the lower uterine segment begins to differentiate from the upper segment late in pregnancy and the cervix begins to dilate. If the bleeding has stopped, the maternal vital signs are stable, the fetal heart sounds are of good quality, and the fetus has not yet reached 36 weeks, the woman is usually managed by expectant watching. If the woman is at term (greater than 37 weeks of gestation) and in labor or bleeding persistently, immediate birth by cesarean is almost always indicated. Women diagnosed with partial or marginal placenta previa who have no bleeding or minimal bleeding may be allowed to attempt a vaginal birth.

When cesarean birth is planned, nursing responsibilities include continuous maternal–fetal assessment while preparing the woman for surgery. Maternal vital signs are

Table 14-3 Care of the Patient Experiencing an Intrapartal Hemorrhage

Assessment	Plan	Intervention	Evaluation
Vital Signs	Establish maternal stability.	Take every 5 minutes if unstable, or every 15 minutes if stable.	Vital signs are within normal range.
		Use pulse oximetry.	Pulse is between 60 and 120 beats/min.
		Auscultate respirations.	Respirations are between 14 and 26 breaths/min.
			Temperature is less than 100.4°F (38.0°C).
			Blood pressure is greater than 90/60.
Bleeding	Resolve hemorrhage.	Start two large-bore IV sites.	Bleeding is minimized.
	Prevent shock.	Infuse normal saline and lactated Ringer's solution.	Homeostasis is established.
		Estimate blood loss	
		(1 g = 1 mL) for replacement.	
		Infuse blood products as necessary.	
		Monitor circulatory volume using CVP/ Swan-Ganz catheter as needed for extreme bleeding.	
		Send blood sample to lab for analysis of gases.	
Document blood loss.			
Intake/Output	Prevent volume depletion.	Insert indwelling urinary catheter.	Urine output will be greater than 30 mL/hr.
		Measure and record output every hour.	
		Measure and record input every hour.	
Fetal Status	Prevent fetal injury.	Continuous electronic fetal monitoring	Fetal heart rate tracings remain between 120 and 160 beats/min. No evidence of abnormal tracings.
Emotional Response	Assist patient to cope with condition.	Educate the patient regarding all procedures.	Patient verbalizes an understanding of her condition.
		Inform the patient of her status throughout the bleeding crisis.	Face displays no grimace.
		Provide relaxation and breathing techniques.	Muscles remain relaxed.
		Provide spiritual support as necessary.	
Pain	Reduce pain.	Provide relaxation and breathing techniques.	Patient reports pain on a scale of 1–10 as between 3 and 5.
		Use guided imagery.	
		Offer massage.	
		Monitor contractions.	
		Offer limited pain medication as ordered.	

Adapted from MacMullen et al. (2005); Curran (2003); and Mandeville & Troiano (1999).

assessed for indicators of hemorrhage (decreasing blood pressure, tachycardia, changes in the level of consciousness (LOC), and oliguria). Continuous EFM is used to assess the fetus for signs of hypoxia.

There is an increased risk for postpartal hemorrhage because the placental site is in the lower uterine segment, which does not contract as efficiently as the upper segment. Also, because the uterine blood supply is less in the lower uterine segment, the placenta tends to grow larger than when implanted in the upper segment. Thus, a larger denuded surface area is exposed after removal of the placenta. Nursing care throughout the intrapartal course centers on providing emotional support for the woman and her family and collaborating with and supporting medical management.

PLACENTAL ABRUPTION

Placental abruption (*abruptio placentae*), which tends to occur in late pregnancy, may occur as late as the first or second stage of labor. Although the primary cause of premature placental separation is unknown, predisposing factors include maternal hypertension, cocaine use (associated with vasoconstriction), direct trauma, and a history or previous placental abruption (Ananth, Oyelese, Yeo, Pradhan, & Vintzileos, 2005).

Treatment for *abruptio placentae* depends on the severity of maternal blood loss and the fetal maturity and status. If the abruption is mild and the fetus is less than 36 weeks and not in distress, expectant management may be implemented. (See Chapter 11.) When the fetus is at term gestation or if the bleeding is moderate to severe and the woman or fetus is in jeopardy, delivery is facilitated. Nursing care includes continuous maternal-fetal monitoring and emotional support. The patient is maintained in a lateral position to prevent pressure on the vena cava and to facilitate placental blood flow. To avoid further damage to the injured placenta, no vaginal or pelvic examinations are performed and no enemas are administered.

Blood and fluid volume replacement are implemented to maintain the urine output (assessed by indwelling Foley catheter) at 30 mL/hr or more and the hematocrit at 30% or more. Hemodynamic monitoring may be necessary. If the premature placental separation occurs during active labor, the physician may elect to rupture the membranes or augment the labor with intravenous oxytocin to hasten birth. Rupturing the membranes prevents large amounts of blood from collecting in the myometrium, which can interfere with uterine contractions. Artificial rupture of the membranes allows a slow, steady escape of amniotic fluid, preventing a sudden change in intrauterine pressure that may encourage further placental separation. Vaginal birth is desirable, especially in cases of fetal death. If birth does not appear to be imminent, a cesarean birth is the delivery method of choice. However, cesarean birth should be reserved for cases of fetal distress or other obstetric indications and should not be attempted if the woman has severe and uncorrected coagulopathy (i.e., disseminated intravascular coagulation [DIC]).

The patient with unresolved bleeding from a placental abruption is most vulnerable to severe complications. Maternal problems resulting from *abruptio placentae* include a **Couvellaire** uterus (the accumulation of blood between the

separated placenta and the uterine wall) and DIC. Although a **Couvellaire** uterus is rare, its implications are severe. The uterus takes on a bluish tinge as blood extravasates from the clot into the myometrium. Contractility is lost. The condition is so severe that a hysterectomy may be necessary to control the bleeding (Cunningham et al., 2006).

If DIC has developed, surgery poses a major maternal risk due to the possibility of hemorrhage during surgery and later from the incisional site. The administration of intravenous fibrinogen or cryoprecipitate (which contains fibrinogen) may be given to increase the maternal fibrinogen level.

The maternal prognosis depends on how quickly interventions are initiated and how effective they are in halting the hemorrhage. Death can occur from massive hemorrhage that leads to shock or renal failure from circulatory collapse. The fetal prognosis depends on the extent of the abruption and the severity of the accompanying hypoxia.

case study A Pregnant Adolescent in the Emergency Department

Maria Selles is a 14-year-old girl who arrives in the emergency department (ED) complaining of severe abdominal pain. She is pale and diaphoretic. A small amount of bright red blood is slowly trickling from her vagina. On assessment, her blood pressure is 120/70; pulse, 100; respirations 22 breaths/minute; temperature 99°F (37.2°C). Her physical examination reveals an enlarged abdomen, which is rigid and board-like with extreme tenderness. Maria is known to the ED because of a history of repeated drug abuse including cocaine. She has been living on the street since she was kicked out of her house several months ago.

critical thinking questions

1. Based on this initial information, what is the nurse's assessment of the possible problem?
2. Since Maria is in such extreme distress, the nurse is aware of a need to limit the number of questions asked. What critical questions should be asked at this point?
3. What laboratory tests would be important to check?

◆ See Suggested Answers to Case Studies in the text on the Electronic Study Guide or DavisPlus.

The nurse's further assessment reveals dark red vaginal bleeding and clinical signs consistent with pregnancy (the presence of abdominal enlargement, deeply pigmented areolae, *linea nigra*, and *striae gravidarum*). The young patient has said very little in response to the questions but Maria does admit to sexual intercourse and no recent periods.

Given this information, the nurse formulates the care priorities for Maria. Although her physical condition and that of the fetus warrant immediate priority, the nurse needs to support this young girl psychologically in order to proceed with any plan. Any support people who have come with her to the ED should be identified. If there is no one with her, the nurse explains the plan of care and describes what she should expect. The nurse places Maria on the electronic fetal monitor and immediately notifies the physician of her condition. Because cocaine is associated with placental abruption, the nurse must identify any recent drug use. The care plan should be developmentally oriented. The nurse implements strategies to keep Maria warm, provides emotional support and a calming presence, and continues to monitor her vital signs and her vaginal flow until the physician arrives.

DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation (DIC) is an acquired disorder of blood clotting. Affected individuals can experience widespread internal and external bleeding and clotting. Clinical symptoms may include easy bruising, the appearance of multiple petechiae, and bleeding from intravenous sites. DIC is most often triggered by the release of large amounts of tissue thromboplastin, which occurs in abruptio placentae, and in retained dead fetus (the fetus has died and is retained in the uterus for 6 or more weeks) and amniotic fluid syndromes (Cunningham et al., 2005).

Optimizing Outcomes— Prompt identification of clinical signs that may indicate DIC

When conducting a physical assessment of the pregnant woman at risk for DIC, the nurse must be alert to the following clinical signs:

- Bleeding from multiple sites: intravenous access site, venipuncture site, site of urinary catheter insertion
- Spontaneous bleeding from the gums and nose
- Widespread petechiae and bruising
- Gastrointestinal bleeding
- Tachycardia
- Diaphoresis

With DIC, the anticoagulation and procoagulation factors are activated simultaneously. Thromboplastin (a clotting factor) is released into the maternal circulation as a result of placental bleeding and the consequent clot formation. Circulating levels of thromboplastin activate widespread clotting throughout the microcirculation. This process consumes or “uses up” other clotting factors such as fibrinogen and platelets. The condition is complicated further by the activation of the fibrinolytic system to lyse (destroy) the clots. As a result, there is a simultaneous decrease in clotting factors and an increase in circulating anticoagulants, leaving the circulating blood unable to clot. Laboratory results reveal low hemoglobin, hematocrit, platelets, and fibrinogen and elevated fibrin split/degradation products.

The priority in treatment of DIC is to correct the underlying cause and replace fluids and essential clotting factors. When premature placental separation has triggered the coagulopathy, delivery of the fetus and placenta must be accomplished so that the production of thromboplastin, which is driving the process, is halted. This is accomplished with intravenous administration of heparin to stop the clotting cascade. Heparin is cautiously given close to the time of birth to decrease the likelihood of postpartum hemorrhage after the delivery of the placenta. The administration of blood and platelets is usually delayed until after completion of the heparin therapy so that the newly infused blood factors are not consumed by the widespread coagulation process. Depending on the clinical setting, antithrombin III factor, fibrinogen, or cryoprecipitate may also be used to restore blood clotting (Labelle & Kitchens, 2005).

Nursing care includes continuous maternal–fetal assessment, administering the prescribed fluids, blood, and blood products; and assessing for signs of complications from the replacement products. The woman is positioned in a side-lying tilt to maximize placental perfusion, and oxygen may be administered via rebreathing mask at 8 to 10 L/min or according to physician or institutional protocol. Because renal failure may result from DIC, urinary output is closely monitored; it should be maintained at more than 30 mL/hr. The patient and her family should be provided with ongoing information and emotional support (Labelle & Kitchens, 2005). (See Chapters 11, 16, and 33 for further discussion on DIC.)

RUPTURE OF THE UTERUS

Rupture of the uterus during labor is a rare but life-threatening obstetric complication that occurs in 1 to 1500 to 2000 births (Fig. 14-8). It is most often associated with the tearing of a uterine scar (usually from a previous classic cesarean birth), uterine trauma (e.g., accidents, surgery), and a congenital uterine anomaly. Rupture of the uterus occurs more often in multigravidas than in primigravidas. Intraparturine uterine rupture may result from overdistention (e.g., multiple gestation), hyperstimulation (e.g., oxytocin, prostaglandin), external or internal version, malpresentation, or a difficult forceps-assisted birth (Cunningham et al., 2005).

Nursing Insight— Understanding types of uterine rupture

Uterine rupture may be classified as complete or incomplete. A complete rupture extends through the endometrium, myometrium, and peritoneum. When this occurs, uterine contractions stop. The woman complains of sudden, severe abdominal pain during a strong contraction followed by cessation of the pain. There is bleeding into the abdominal cavity and possibly into the vagina. An incomplete rupture extends into the peritoneum but not into the peritoneal cavity or broad ligament. Bleeding is usually internal and the woman may be asymptomatic (a “silent” rupture) or complain of localized tenderness and aching pain over the lower uterine segment.

Changes in fetal heart tracings such as late decelerations, decreased variability, and increased or decreased heart rate may or may not be present. Maternal signs and symptoms may include faintness, vomiting, abdominal tenderness, hypotonic uterine contractions, and lack of labor progress. As blood loss continues, the woman may exhibit signs of hypovolemic shock (hypotension; tachypnea; pallor; and cool, clammy skin). Fetal parts may be readily palpable through the abdomen.

Rupture of the uterus constitutes an obstetric emergency; the type of medical management depends on the severity. A small rupture may be safely managed with a laparotomy and birth of the infant, repair of the tear, and volume replacement with fluids and blood transfusions if needed. A complete uterine rupture requires hysterectomy and blood replacement.

Nursing Care Plan The Patient with Abruption Placentae

Nursing Diagnosis: Deficient Fluid Volume related to active losses from premature separation of the placenta.

Measurable Short-term Goal: The patient and her fetus will maintain fluid balance during the intrapartum period.

Measurable Long-term Goal: The patient and newborn will have stable homeostatic conditions upon discharge.

NOC Outcomes:

- Fluid Balance (0601) Water balance in the intracellular and extracellular compartments of the body
- Blood Loss Severity (0413) Severity of internal or external bleeding/hemorrhage
- Fetal Status Antepartum (0111) Extent to which fetal signs are within normal limits from conception to the onset of labor

NIC Interventions:

- Fluid Management (4120)
- Bleeding Reduction: Antepartum Uterus (4021)
- Electronic Fetal Monitoring: Intrapartum (6772)

Nursing Interventions:

1. Monitor vital signs every 5–15 minutes with active bleeding or if the vital signs are not stable.

RATIONALE: The vital signs provide important information about the response of the cardiac system to active bleeding and possible development of shock.
2. Provide continuous monitoring of the FHR and pattern.

RATIONALE: The fetus reacts directly to an assault on the mother's system. Bleeding from the placenta places the fetus in distress, which is manifested by changes in the FHR.
3. Observe the perineum and behind the patient's back at least every hour for signs of active bleeding. Weigh pads as needed to estimate losses.

RATIONALE: Observation of active bleeding may indicate the need for an emergency cesarean delivery. One gram of weight can be estimated to equal 1 mL of blood lost.
4. Assess for abdominal pain, palpate fundal tone, and measure abdominal girth at the umbilicus at least each hour.

RATIONALE: Concealed bleeding into the myometrium may result in a painful, rigid, board-like uterus that becomes enlarged over time.
5. Review baseline and ongoing laboratory data including: complete blood count (CBC), clotting studies, serum electrolytes, and renal function tests.

RATIONALE: Baseline information is used to alert the care providers to changes in the patient's condition as additional lab tests are obtained.
6. Maintain intravenous access with a large-bore catheter and administer intravenous fluids as directed.

RATIONALE: Intravenous access is required to maintain and replace fluid volume. Large catheters facilitate the infusion of large volumes of fluid quickly.
7. Administer blood replacement products in a timely manner as directed.

RATIONALE: The hematocrit level should be 30% or greater to prevent severe shock.
8. Assess hourly intake and output with an indwelling urinary catheter.

RATIONALE: A decrease in urine output below 30 mL/hr indicates that the patient may be developing shock.
9. Monitor for development of abnormal clotting studies, bleeding from gums, oozing from injection sites, bruising, or petechiae and notify caregiver.

RATIONALE: The patient is at risk for developing DIC because of excessive bleeding. Fibrinogen levels should be greater than 150 mg/dL.
10. Facilitate delivery as necessary to prevent maternal–fetal injury.

RATIONALE: If the patient is actively bleeding, or there is any indication that she has concealed bleeding, she must be delivered to prevent hemorrhage, shock, and death.

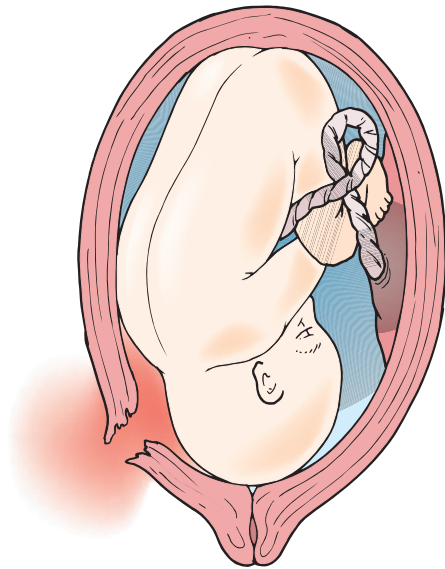

Figure 14-8 Rupture of the uterus in the lower uterine segment.

Nursing responsibilities include administering intravenous fluids, blood products, and oxygen and helping to prepare the woman for immediate surgery. Since the patient is anxious and fearful, it is important for the nurse to attempt to provide emotional support for the woman and her support person throughout the process. The nurse must maintain a calm demeanor while organizing critical care for the patient. As much as possible, the patient and her support person should be involved in decision making and informed of all procedures. Depending on the circumstances, it may be appropriate to provide information about chaplain support services. The associated fetal mortality rate ranges from 50% to 75% and the maternal mortality rate may be high if treatment is not initiated immediately (Cunningham et al., 2005).

UTERINE INVERSION

Uterine inversion (uterus is turned inside out) is a rare but potentially life-threatening complication that most often results from excessive pulling on the umbilical cord in an attempt to hasten the third stage of delivery. Other contributing factors include fundal implantation of the placenta, vigorous fundal pressure, uterine atony,

and abnormally adherent placental tissue (Bowes & Thorp, 2004). When complete inversion occurs, a large, red, globular mass (that may contain the still-attached placenta) protrudes 20 to 30 cm outside the vaginal introitus. A partial or incomplete inversion is not visible; instead, a smooth mass is palpated through the dilated cervix. Maternal symptoms include pain, hemorrhage, and shock. Management involves manual replacement of the fundus (under general anesthesia) by the physician, followed by oxytocin to facilitate uterine contractions and antibiotic therapy to prevent infection. Prevention (by not pulling strongly on the cord until the placenta has fully separated) is the safest and most effective therapy (Cunningham et al., 2005).

UMBILICAL CORD PROLAPSE

Umbilical cord prolapse occurs when a loop of the umbilical cord slips down below the presenting part of the fetus (Fig. 14-9). Prolapse of the umbilical cord may be *occult* (hidden; not visible) at any time during labor whether or not the membranes have ruptured—the cord lies beside the presenting part in the pelvic inlet. With a *complete* cord prolapse, the cord descends into the vagina, where it is felt as a pulsating mass on vaginal examination. It may or may not be seen. *Frank* (visible) prolapse most commonly occurs immediately after rupture of membranes as gravity washes the cord in front of the presenting part. Risk factors associated with cord prolapse include a long (greater than 100 cm) cord, malpresentation (e.g., breech), transverse lie, hydramnios, preterm or low-birth-weight infant, multiple gestation, and unengaged presenting part (Cunningham et al., 2005). If the presenting part does not fit snugly into the lower uterine segment, the sudden gush of amniotic fluid that accompanies rupture of the membranes may cause the cord to be displaced downward.

Optimizing Outcomes— Actions to reduce the risk of umbilical cord prolapse

If SROM has occurred, the woman should be kept on bed rest until the fetal presenting part is engaged. AROM should not be attempted until engagement has occurred. To rule out umbilical cord prolapse, the nurse should assess the fetal heart sounds immediately after spontaneous or artificial rupture of the membranes.

Figure 14-9 Umbilical cord prolapse. **A.** Occult. The cord cannot be seen or felt during a vaginal examination. **B.** Complete. During a vaginal examination, the cord is felt as a pulsating mass. **C.** Frank. The cord precedes the fetal head or feet and can be seen protruding from the vagina.

It is imperative that the nurse recognizes indicators of umbilical cord prolapse: fetal bradycardia with variable decelerations during contractions; observing or palpating the cord in the vagina; woman's statement that she "feels the cord" after membrane rupture. Prolonged cord compression causes fetal hypoxia; occlusion of blood flow to and from the fetus for greater than 5 minutes is likely to result in central nervous system damage or fetal death.

To relieve pressure on the cord, the examiner places a sterile gloved hand into the vagina and manually lifts the presenting part off of the umbilical cord. The patient is assisted into a position such as a modified Sims, extreme Trendelenburg, or knee–chest position, which uses gravity to cause the presenting part to fall back from the cord (Fig. 14-10). The nurse administers oxygen at 10 L/min by face mask to improve oxygenation to the fetus; the physician may order administration of a tocolytic agent to reduce uterine activity and relieve pressure on the fetus. If the cord is protruding from the vagina, the exposure to room air will cause drying, which leads to atrophy of the umbilical vessels. No attempts should be made to place the cord back into the vagina. Instead, the nurse should cover the exposed segment of umbilical cord with warm, sterile saline compresses to prevent drying. Prompt delivery, often with forceps assistance, is facilitated if the cervix is fully dilated. Otherwise, the

nurse or other care provider continues to manually maintain upward pressure on the presenting part (using a hand in the vagina) until a cesarean birth can be accomplished.

critical nursing action After Prolapse of the Umbilical Cord

After prolapse of the umbilical cord, immediate nursing interventions are essential:

- Call for assistance; notify the primary health care provider.
- Using the gloved examining hand, insert two fingers into the vagina to the cervix. Place one finger on either side of the cord or both fingers to one side and quickly exert upward pressure against the presenting part to relieve compression of the cord.
- Assist the woman into an extreme Trendelenburg, modified Sims, or knee–chest position.
- If the cord is protruding from the vagina, wrap it loosely in a sterile towel saturated with a warmed, sterile normal saline solution.
- Administer oxygen at 10 L/min by face mask.
- Increase the IV fluids; administer a tocolytic agent as ordered.
- Continuously monitor the FHR by internal fetal scalp electrode if possible.
- Provide information and support to the woman and her birth partner.
- Prepare for an immediate vaginal birth if the cervix is fully dilated or for cesarean birth if it is not.

Figure 14-10 Interventions to relieve pressure on a prolapsed umbilical cord until birth can be effected. *A.* A gloved hand is placed in the vagina to lift the presenting part off the cord. *B.* The maternal hips are elevated with two pillows; this intervention is often combined with a Trendelenburg position. *C.* The knee–chest position uses gravity to shift the fetus out of the maternal pelvis.

VARIATIONS RELATED TO UMBILICAL CORD INSERTION AND THE PLACENTA

Velamentous Cord Insertion/Vasa Previa

A *velamentous* insertion of the umbilical cord occurs when the fetal vessels separate at the distal end of the cord and insert into the placenta at a distance away from the margin (Fig. 14-11). The vessels are not protected by Wharton's jelly and are subject to compression, rupture, and thrombosis, major complications that may lead to severe fetal distress and death. This form of cord insertion most frequently occurs with placenta previa and multiple pregnancies; it may also be associated with fetal anomalies. Rupture of the membranes or traction on the umbilical cord may tear the fetal vessels. This event produces rapid, usually fatal, fetal hemorrhage. **Vasa previa** occurs when the unprotected fetal vessels cover the cervical os and precede the fetus. It is usually seen with a velamentous insertion of the umbilical cord. Because the vessels are not covered with Wharton's jelly, the examiner may be able to feel pulsations of the umbilical cord. Lacerations of the vessels, which can occur at any time, cause sudden fetal blood loss. The onset of sudden, painless bleeding at the beginning of cervical dilation or during rupture of membranes (ROM) may signal the presence of vasa previa; diagnosis may be confirmed by sonogram (Clark, 2004; Cunningham, 2005).

Without ultrasound assessment, velamentous cord insertion is not easily detectable. The nurse may note a drop in FHR during a vaginal exam. A ready FHR return to the baseline after the exam may be indicative of a velamentous cord insertion. With any episode of vaginal bleeding, the alum-precipitated toxoid (APT) test may be used to determine the presence of fetal blood cells. After the rupture of blood vessels, fetal blood leaks into the vagina and can be readily sampled for examination. Despite the rarity of this condition, velamentous cord insertion should always be suspected and ruled out via a careful vaginal exam with cervical palpation for detection of exposed vessels. Immediate action by the medical team, prompted by the nurse's critical assessments, can result in an emergency cesarean birth; best outcomes occur with early prenatal diagnosis and cesarean birth at 35 weeks or earlier (Oyelese et al., 2004).

Circumvallate, Succenturiate, and Battledore Placenta

Other placental variations and problems related to the umbilical cord insertion site include **circumvallate** placenta (placenta circumvallata), **succenturiate** placenta (placenta succenturiata), and **battledore** placenta. These conditions are associated with variations that occurred during placentation (formation and attachment of the placenta). The circumvallate placenta is one in which a ring composed of a double fold of amnion and chorion has formed near the fetal surface. This placental aberration has been reported to be associated with antepartum hemorrhage, preterm delivery, and fetal malformations. The succenturiate placenta contains one or two separate lobes, each with its own circulation. After childbirth, one of the separate lobes may be retained in the uterus and impede contractions, resulting in severe maternal hemorrhage. The remaining lobes must be manually removed from the uterus to prevent hemorrhage. Battledore insertion of the cord describes a condition in which the umbilical cord is implanted near the margin of the placenta. Battledore placenta may be associated with fetal hemorrhage, especially after marginal separation of the placenta (Cunningham et al., 2005).

Placenta Accreta, Placenta Increta, Placenta Percreta

Abnormal adherence of the placenta is rare and its causes are unknown. After birth, the usual maneuvers to remove the placenta are unsuccessful and laceration or perforation of the uterine wall may result. When this occurs, the woman is at high risk for hemorrhage and infection. The placental adherence may be partial or complete. **Placenta accreta** describes a slight penetration of the myometrium by the trophoblast. **Placenta increta** describes a deep placental penetration of the myometrium and **placenta percreta** describes placental perforation of the uterus. Depending on the degree of placental adherence (and the severity of the hemorrhage), the patient will require blood replacement and a vaginal hysterectomy may be indicated (Clark, 2004; Cunningham et al., 2005).

AMNIOTIC FLUID EMBOLISM

Amniotic fluid embolism (AFE) (obstruction of a blood vessel by amniotic fluid) is a rare complication of the intra- and postpartum periods that is associated with a high incidence of maternal and fetal death. For mothers, the mortality rate is as high as 80%; approximately 50% of neonates who survive this event have neurological impairment (Schoening, 2006). The origins of the problem are not clear, but it is hypothesized that amniotic fluid containing particles of fetal debris (meconium, hair, vernix, skin cells) escapes into the maternal circulation and causes the release of endogenous mediators such as histamine, prostaglandins, and thromboxane. Obstruction of the pulmonary vessels leads to respiratory distress and circulatory collapse. Hemorrhage, disseminated intravascular coagulation, and pulmonary edema are present to some extent in women who experience an amniotic fluid embolism. AFE is not preventable because it cannot be predicted although maternal factors (including multiparity, abruptio placentae, tumultuous labor) and fetal problems (including macrosomia, meconium passage, death) have been associated with an increased risk for development (Cunningham, 2005).

The nurse must recognize the rapidly deteriorating maternal condition and seek immediate help. Frequently, the first symptom is acute dyspnea, followed by severe hypotension. Other symptoms include restlessness, cyanosis, tachycardia, respiratory arrest, shock, and cardiac arrest (Schoening, 2006).

critical nursing action When Amniotic Fluid Embolism Develops

The immediate management includes the administration of oxygen by face mask or cannula at a rate of 8–10 L/min; or resuscitation bag to deliver 100% oxygen. Nursing interventions center on support of resuscitation efforts:

- Prepare for intubation and mechanical ventilation.
- Initiate or assist with cardiopulmonary resuscitation (CPR). Position the pregnant woman in a 30-degree lateral tilt to displace the uterus.
- Administer intravenous fluids and blood (e.g., packed cells; fresh frozen plasma).
- Insert indwelling urinary catheter; measure hourly urine output.
- Continuously monitor maternal–fetal status.
- Prepare for emergency birth once the woman is stable.
- Provide ongoing information and emotional support to the woman and her family.

The maternal prognosis depends on the size of the embolism and speed and skill of the responding perinatal team. If the woman survives, she will most likely be transferred to a critical care unit for hemodynamic monitoring, blood replacement, and coagulopathy treatment. Although rapid delivery is paramount to save the fetus, a delay in delivery usually occurs to stabilize the mother. In the event of maternal cardiopulmonary arrest, for optimal fetal survival, a perimortem cesarean delivery should occur within 5 minutes (Curran, 2003).

This type of a situation is very difficult for all health professionals involved in the care of the patient. An ethical conflict may arise when the health of the mother is

given consideration over the fetus. While there are no easy answers to these dilemmas, the nurse can serve as a leader by organizing regular meetings during which issues of this nature can be discussed in a calm, open manner. The nurse is in a key position to help create an environment where health professionals can resolve or work through difficult dilemmas.

Collaboration in Perinatal Emergencies

Approximately 1% to 2% of pregnancies are complicated by an obstetrical emergency and require a multidisciplinary approach to provide an effective, rapid response. Communication is an essential component in all patient environments but it is critical in emergency obstetrical nursing. Team members need to collaborate to provide timely interventions that promote patient safety. Learning how to present information in a way that is non-threatening but effective is key to promoting positive communication patterns (Clements, Flohr-Rincon, Bombard, & Catanzarite, 2007).

Miller (2005) identifies the hierarchical communication that often exists between physicians and nurses as detrimental to good perinatal outcomes. The need to employ healthy communication patterns to effect safe and healthy outcomes for the patient is tantamount. Effective communication does not mean that there are no followers of orders or directives. Instead, it is important for both the leaders and the followers to employ critical thinking skills. Use of the word “we” promotes collaboration and underscores the nurse’s role as a patient advocate in this effective communication style.

“What to say” — Communicating concerns with members of the health care team

Simpson (2005a) emphasizes the critical need for effective communication among the health care team. Problems in care are encountered when people fail to collaborate or communicate. Teamwork is enhanced when everyone knows the expectations of their role in the obstetric emergency (Box 14-5). Standardization of protocols allows everyone to function more effectively and prevent poor outcomes.

Box 14-5 Collaborative Care Principles in Perinatal Nursing

To facilitate the team process when providing care in emergency situations, the perinatal nurse should:

- Employ effective communication techniques.
- Advocate for the patient through assertive statements.
- Conduct interdisciplinary reviews of all cases to identify risks.
- Promote team collaboration by rotating leadership roles in the case reviews.
- Assist in the evaluation process of all emergency cases.
- Use outcome measurements to evaluate safe and effective care.

Perinatal Fetal Loss

The World Health Organization definition of **perinatal death** is death of the offspring “occurring during late pregnancy (at 22 completed weeks gestation and greater), during childbirth and up to seven completed days of life” (Smith, 2005, p. 17). Perinatal deaths can occur during the antepartum, intrapartum, or postpartum periods. A variety of causes may lead to the death of the fetus or the newborn and these are often related to obstetric complications such as placental abruption or neonatal prematurity related to genetic disorders or congenital malformations (Smith, 2005). Perinatal death is rare because the majority of the childbearing population consists of young healthy women who expect to give birth to healthy babies. This prevailing expectation among the general population constitutes a major reason why it is so difficult for all involved when a perinatal death occurs.

Nursing practice has changed over the years in regard to caring for families who are dealing with a perinatal loss. During the 1960s through the 1980s, women who experienced a perinatal loss were often placed on a medical–surgical unit to prevent them from hearing the sounds of infants crying. One problem with this approach lies in the fact that the most experienced professionals in perinatal nursing are not located in the medical–surgical areas. The patient who has suffered a loss still requires all assessments and interventions involved in normal postpartum care. A nurse in the perinatal practice area can better focus on therapeutic interventions to assist the woman and her family in the grieving process.

The nurse organizes and coordinates a team approach to bereavement. Different members may participate but there should be key individuals such as spiritual or religious representatives, social workers, and physicians, in addition to the nurse. It is important to identify which hospital routines associated with perinatal death might interfere with allowing the family to have options concerning decisions made regarding their infant. As an example, in some cases, the infant’s body might be moved to the funeral home before the family has had the opportunity to hold him or her. Many parents wish to hold their child prior to an autopsy, and they should be encouraged to do so. Before presenting the parents with their infant, the nurse should make certain the infant has been cleaned and is wrapped in a soft blanket. Depending on the cause of death, it may also be prudent to give the parents an idea of their infant’s appearance. Usually, parents’ preconceived perceptions concerning how their infant will look is much worse than the reality. Individuals from the hospital morgue or a funeral home who are involved with regular bereavement team meetings can be instrumental in developing a perinatal bereavement plan that is grounded in compassion and sensitivity.

When healthy infants are discharged, it is common practice to take their picture. Photographs should also be taken when an infant has died. Parents should always be encouraged to view, touch, and hold the deceased infant. However, if they do not wish to see the infant while in the hospital, the picture provides a way for them to see their infant at a future time when they are ready. Photographs can be stored in a file and given to the parents upon their request. Use of an experienced photographer is preferred, since the

infant may not always be in the most favorable condition. The maternity unit should always have a supply of clothing and new blankets available for these infants.

To provide the family as much privacy as possible from hospital workers who might not know that the family has experienced a loss it is best to have some sort of indicator outside of the room. One hospital unit places a single red rose across the door. Another places a special “remembrance card” outside the doorframe. Both provide an immediate identification to any hospital worker entering the room that the patient and her family have experienced a loss.

All of these practices stem from the development of hospital protocols regarding bereavement. The team develops a list of critical actions and specific plans to respond to each point. There is flexibility to allow the parents to be active participants in the decision making but it is also organized so that as nursing and hospital personnel change, there is consistency in the approach.

Communication is another critical factor in providing care for the family who has experienced a fetal or neonatal loss. Parents report that comforting words, touch, and directed speech are helpful to them. Nurses need to avoid using phrases such as:

- “It’s God’s will.”
- “You can always have another.”
- “There was a problem with this baby.”
- “There’s always next time.”

Parents respond better to acknowledgment of the infant’s death than to avoidance. A simple “I’m sorry” and a touch of the hand can convey the nurse’s care and concern when the right words are hard to find. It is also important for the nurse to sit and listen. Parents often have multiple feelings, which they need to share. The nurse, as the objective individual, can help interpret feelings and recommend resources to assist the family as they deal with their grief. It is essential that the perinatal care team remain sensitive to the cultural and spiritual beliefs and practices of the bereaved parents and families. (See Chapter 11 for further discussion.)

“What to say” — *To the mother whose newborn has died*

When caring for the mother whose infant has died, the nurse conveys compassion by simply being available. Often, the mother finds comfort in talking about the birth experience, her infant, and how she will cope with her loss. The nurse can gain insights into the mother’s support systems by asking the following questions:

- “What are you most worried or fearful about?”
 - “How supportive is the baby’s father and your family or friends?”
 - “What coping techniques have been helpful for you in the past?”
- (Gilbert, 2006)
-

A perinatal loss might be the first experience a family has with death. It is a confusing, anxiety-provoking time that often creates a fear that it will happen again. Death of a child of any age is also viewed as unnatural. Parents expect

their children to die after them—not before them. Dreams and expectations for the lost child will now never be realized. A resource guide given to the family on discharge is an important tool to help them cope with their loss. Since much of the grieving work is done after the hospitalization, family members need to know where to call for help.

A support group that includes someone from the bereavement team can offer the parents a connection to the hospital. Some parents find this helpful in acknowledging the existence of their child while others feel more comfortable with the support of a close family network. The key is that the family is supported through their loss and is able to move through the grief process toward resolution. It is important to understand that many families will never totally come to terms with the untimely death of a child, regardless of the age of the infant or fetus.

CULTURAL ASPECTS OF LOSS

In a cultural context, death has many views. There are different ways of grieving. Tears and emotional outbursts are common to some cultures while others are quiet and introspective. The nurse needs to have an awareness and understanding of how different cultural groups interpret the meaning of death and the factors that govern their response to death. The Hispanic culture that includes Mexicans, Puerto Ricans, and Cubans views children as their future. The loss of a child denies that future. They welcome touch from others and expect health care professionals to respect their need for extended family during this time frame. All cultures should be treated with sensitivity, respect and caring (Gilbert, 2006).

Now Can You— Discuss Issues Concerning Perinatal Death?

1. Identify significant members of the bereavement team?
2. Discuss interventions for families experiencing a perinatal loss?
3. Voice some comments that would be helpful for a grieving family?

Cesarean Birth

DEFINITION AND INCIDENCE

Cesarean birth is the birth of a fetus through an abdominal incision into the uterus; it is performed to preserve the life of the mother and her fetus. In 1965, the rate of cesarean births in the United States was less than 5% (Hamilton et al., 2005). Preliminary data for 2005 indicate that 30.2% of all live births in this country were cesarean births, marking the highest U.S. total cesarean rate ever reported. Since 1996, the number of cesarean births has increased by 46%, driven by both an increase in the percentage of all women having a first cesarean and a decline in the percentage of women who gave birth vaginally after a previous cesarean birth (CDC, 2007). Modern surgical advances and the use of antibiotics have resulted in a decrease in maternal and fetal morbidity and mortality. However, despite these advances, cesarean birth is a major surgical procedure that poses threats to the health of the mother and her infant.

INDICATIONS

Cesarean birth is performed when the health of the mother or her fetus is jeopardized. Maternal medical risk factors most closely associated with cesarean birth include hypertensive disorders, active genital herpes, positive HIV status, and diabetes. Fetal complications most closely associated with cesarean birth include CPD, malpresentations (i.e., breech, shoulder), placental abnormalities (e.g., abruptio, previa), dysfunctional labor patterns, fetal distress, multiple gestation, and umbilical cord prolapse. In actuality, few absolute indications exist for cesarean birth and most are primarily performed for the benefit of the fetus (Martin et al., 2005).

Elective cesarean births have been on the rise since 1985. In contemporary society, women are requesting cesarean births for reasons other than medical, obstetric, or fetal complications. One reason is related to a fear of vaginal birth, or tocophobia. Others are concerned about the potential for future problems with pelvic support or sexual dysfunction related to perineal or rectal injury. Some women view cesarean birth to be an empowering experience and wish to choose the birth method and date rather than have it selected for them (Tillett, 2005; Williams, 2005). At issue is the question of whether or not an elective cesarean birth is more beneficial or harmful to a woman and her baby than a vaginal birth (Hannah, 2004). The Association of Women's Health, Obstetric and Gynecologic and Neonatal Nurses (AWHONN) supports the need to learn more about the nature of elective cesarean birth. AWHONN calls for continued research into strategies to decrease traumas associated with vaginal birth and subsequently decrease the need for elective cesarean birth due to maternal fear (Simpson & Thorman, 2005; Wax, Cartin, Pinette, & Blackstone, 2004; Williams, 2005).

Cesarean birth is a major surgical procedure that carries risks and complications. It is associated with a host of potential postoperative problems such as hemorrhage, thromboembolism, and infection during the postpartum period. The surgery can result in adhesions, dehiscence of the wound, and problems with the placenta in subsequent pregnancies (Porter & Scott, 2003). Zelop and Heffner (2004) report that women face a higher incidence of death during a surgical procedure with the use of general anesthesia. Women are also at greater risk for intraoperative surgical complications such as lacerations of the uterus and bladder. In addition, there is a greater likelihood for hysterectomy associated with cesarean birth than with vaginal birth.

ETHICAL CONSIDERATIONS OF ELECTIVE CESAREAN BIRTH

If it is more dangerous to have an elective cesarean birth than a vaginal birth, is it ethical to allow the woman to select this as her birth method of choice? Wax (2004) discusses the contrast between beneficence (the principle of doing good) and the physician's responsibility to do no harm and the patient's right to autonomy. The American College of Obstetricians and Gynecologists (ACOG) Committee on Ethics maintains that if a patient requests a cesarean birth, and the physician believes that the overall health of the mother and fetus will benefit, then the elective cesarean delivery has merit (ACOG, 2003b). If the physician does not think a cesarean method of birth is in

the best interest of the patient, the patient should be informed and given the right to select another physician. However, the issue is far more complex than this simple example.

Williams and Shah (2003) plead for a return to common sense. Birth is a normal and natural event. These authors raise the following questions: “Have we become a nation so obsessed with expediency and control that we are willing to relinquish our humanity to technology? Are we truly willing to sacrifice our health and future childbearing for the lure of ‘birth by appointment’? Are our demands for perfection or compensation unnecessary interventions (p. 284)?” All women are entitled to unbiased information and a safe, supportive environment. Continued studies that examine the myriad issues concerning aspects of benefit versus harm including the economic ramifications of elective cesarean birth are in order.

SURGICAL PROCEDURES

There are two main types of cesarean operations: the classic (vertical) incision and the lower-segment transverse (LST) incision (Fig. 14-12). The surgeon chooses the incision type based on the patient’s condition and the fetal status. Rarely used today, the classic cesarean incision is reserved for some cases of shoulder presentation, placenta previa, and when birth must take place immediately. Since this type of uterine incision is associated with complications including considerable blood loss, infection, and uterine rupture with subsequent pregnancies, women who undergo classic cesarean births may not attempt future vaginal births.

The lower segment cesarean (preferred by women for cosmetic reasons) may involve either a vertical or a transverse uterine incision. The transverse incision, more commonly performed, is associated with less blood loss, fewer postoperative infections, and a decreased likelihood of uterine rupture during subsequent pregnancies (Bowes & Thorp, 2004; Cunningham et al., 2005). The skin incision made into the abdomen is either transverse (sometimes called a “Pfannenstiel” or “bikini” incision) or vertical

Figure 14-12 Abdominal wall and uterine incisions for cesarean births. *A.* Skin (abdominal wall) incisions. Vertical and transverse (Pfannenstiel). *B.* Uterine wall incisions. Low transverse, low vertical, classic.

(sometimes called a “midline” incision). The skin incision may or may not be the same type of incision that is made into the abdomen. After the skin incision, the surgeon carefully moves through the tissue layers to the uterus. An incision is made into the uterus and the fetal head is gently elevated through the opening. A patent airway is established and the rest of the fetus is delivered. The cord is clamped and the newborn is placed, depending on the circumstances, either in the arms of the parent or in the neonatal warmer. After removal of the placenta, the incision is sutured at each layer and a sterile bandage is placed over it (Cunningham et al., 2005; Porter & Scott, 2003).

The nurse documents all components of patient care including the time of birth and offers ongoing encouragement and support to the mother. Once the birth has taken place, the nurse facilitates attachment with the new family. When complications are present, the nurse provides information including a description of the newborn to the family. If the newborn requires resuscitation or a transfer to the neonatal intensive care unit, the family is allowed to view the neonate in the isolette before transport. When the newborn’s condition is satisfactory, the newborn is presented to the parent or support person to hold. Although the mother is restrained by surgical equipment, the parent or support person can hold the baby close to the mother’s face so that she can see her child. This initial bonding experience can usually take place while the surgeon completes the suturing process. The family is then moved to the recovery room for post-surgical care.

NURSING CARE

In most instances, the patient scheduled for a planned cesarean birth is admitted on the day of surgery. When the need for an emergency or unplanned cesarean arises, the patient undergoes the same procedures but in a more timely manner. Blood work, including type and cross match and a complete blood count, is obtained before admission and the results are entered in the chart. The woman has been instructed to remain NPO since midnight before admission. The nurse orients the patient to the unit, reviews the prenatal history, and responds to any questions or concerns. An informed consent is signed. A fetal monitor is placed on the patient’s abdomen for a 20- to 30-minute baseline assessment. Vital signs are taken and charted. In preparation for the surgery, the abdomen is cleaned and shaved, an intravenous line is placed, and an indwelling urinary catheter is inserted to keep the bladder empty during the operation. Medications are administered according to the physician’s orders. If an epidural anesthetic is to be used, the nurse properly positions the patient and supports her during its administration. If a general anesthetic is to be used, an oral antacid may be prescribed to neutralize gastric secretions in the event of aspiration. The woman is then transported to the operative suite (Simpson & Creehan, 2001).

Optimizing Outcomes—Enhancing maternal anesthesia knowledge and choice

Spinal, epidural, and general anesthesia are used for cesarean births. Although epidural anesthesia is a popular choice because the woman may remain awake during the birth

experience, the type of anesthesia used depends on factors such as the maternal medical history and current status, and how quickly the birth needs to take place. In addition, the woman is a factor—she may harbor fears about having an anesthetic injected into her back. Patients should be given information including the risks and benefits associated with the different types of anesthesia to empower them to make an informed decision whenever there is a choice.

SURGICAL CARE

The nurse's role varies during the surgical procedure. Depending on the hospital setting and protocols, one nurse assists the physician during the procedure while another nurse circulates. A team consisting of a neonatal nurse and a neonatologist or nurse skilled in neonatal resuscitation is in attendance to provide care for the infant. The patient is placed on the surgical table with a hip wedge to slightly elevate the hips. The fetal heart rate is continuously monitored until the patient's abdomen is ready for surgical preparation according to hospital protocol. The support person, dressed in appropriate surgical attire, may be present at any point in the process but is usually asked to wait until the surgical drapes are in place before being seated by the patient's head. The anesthesiologist monitors the maternal vital signs and the intravenous solutions.

When the woman remains awake during the procedure, the nurse and other members of the care team provide information about the events taking place and sensations that the woman may be experiencing. Continued support and explanations help to decrease anxiety, enhance feelings of comfort, and help the woman to maintain a sense of control in the unfamiliar and perhaps frightening, environment.

POSTOPERATIVE CARE

After the completion of the surgery, the woman is transferred to a recovery room or to her labor room. According to agency protocol, the nurse assesses various aspects of the recovery progress, including effects from the anesthesia, the status of the postoperative/postbirth uterus, and the degree of pain. If a general anesthetic was used, special attention is given to maintenance of a patent airway. The patient is positioned to prevent aspiration and vital signs are assessed every 15 minutes for the first 2 hours, or until stable. The nurse frequently inspects the incisional dressing and assesses the fundus, the amount of lochia, the intravenous infusion, and the urinary output. The woman is assisted to turn, cough, deep breathe, and perform leg exercises. Pain medications are administered as needed.

If the neonate is with the mother and her labor support, time is provided to facilitate family bonding and attachment. If the woman wishes to breastfeed, she is encouraged to do so. Patients generally remain in the recovery area for 1 to 2 hours before transfer to the postpartum unit for continued care. (See Chapter 15.)

VAGINAL BIRTH AFTER CESAREAN

There is an old adage, “once a cesarean, always a cesarean.” During the 1970s and 1980s, women challenged this rule and fought for the opportunity to attempt a **vaginal birth after a cesarean birth** (VBAC). Dauphinee (2004)

reported that research conducted during that time provided evidence that a VBAC was safe and a more cost-effective birth alternative. This movement also coincided with the growing concern in the United States over the dramatic increase in cesarean birth rates, especially among women requiring a repeat cesarean birth.

In 1988, the American College of Obstetricians and Gynecologists (ACOG), having concluded that women with a low transverse incision could safely be allowed a trial of labor and possible vaginal birth, released a statement in support of VBAC. ACOG endorsed the practice of oxytocin administration, epidural anesthesia, and early ambulation for women with previous cesarean births who met certain criteria. A standby team prepared to perform a cesarean birth in the event of an emergency was to be available at all times (Dauphinee, 2004). Numerous studies supported the success of VBAC. During the 1990s, approximately 60% to 80% of women who underwent a trial of labor following a previous cesarean were able to give birth vaginally with minimal complications (Porter & Scott, 2003). Safety concerns arose although data showed that uterine rupture, the most serious of complications, was a rare event. In response to these concerns, physicians began to more closely restrict the types of patients allowed to attempt a trial of labor. Criteria for the selection of candidates for a trial of labor have been developed (Box 14-6). A critical point confirmed by the studies was that VBACs needed to be performed in large hospitals or tertiary level centers since these institutions offer continued 24-hour anesthesia coverage necessary to prevent perinatal mortality and morbidity if uterine rupture occurs (Porter & Scott, 2003).

NURSING IMPLICATIONS

To provide safe, effective care, it is essential that nurses who care for patients in the labor and birth suite have received extensive training in fetal monitoring interpretation. At the first sign of any abnormality in the fetal heart rate tracing, the nurse must alert the physician or certified nurse midwife. Meticulous documentation is critical, as it provides essential information to other members of the health care team. For the elective cesarean birth, informed consent is obtained in the physician's office before admission and the nurse confirms this with the patient. Once patients actually experience labor, it is possible for them

Box 14-6 Selection Criteria for Vaginal Birth After Cesarean Birth (VBAC)

- One previous low-transverse cesarean birth (If two prior cesarean births, only those who have also had a vaginal birth as well should be considered candidates for a spontaneous labor)
- Clinically adequate pelvis in relation to fetal size
- No other uterine scars, anomalies, or previous rupture
- Physician immediately available throughout active labor capable of monitoring labor and performing an emergency cesarean birth
- Availability of anesthesia and personnel for emergency cesarean birth

Source: American College of Obstetricians and Gynecologists (ACOG). (2004a). *Vaginal birth after previous cesarean delivery* (Practice Bulletin No. 54). Washington, DC: Author.

to change their minds and, depending upon the circumstances, they may choose not to have a vaginal birth. As in other situations, the nurse responds to questions and concerns and ascertains the patient's understanding of the associated benefits and risks (Dauphinee, 2004).

During the entire labor process the nurse is alert for any changes in the maternal–fetal condition. The FHR pattern and uterine activity are usually monitored electronically during the active phase of labor. Non-reassuring FHR patterns such as prolonged decelerations, late decelerations, and variable decelerations, may precede uterine rupture or herald its occurrence. The nurse continuously evaluates the woman's level of pain. Uterine rupture may be accompanied by abdominal, shoulder, or back pain even when epidural anesthesia has been administered. However, the nurse should frequently palpate the uterus for signs of rigidity since the patient may report no pain. Since there is always the possibility of an emergency at any time, the nurse must be prepared to react in a calm manner. As the labor progresses, the patient and her support(s) should receive reassurance and information regarding any change in the plan of care (Dauphinee, 2004).

Now Can You— Discuss VBAC?

1. Name five criteria for a patient to be allowed to attempt a vaginal birth after a previous cesarean birth?
2. Discuss possible patient concerns regarding VBAC and how the nurse should appropriately respond to them?
3. List three specific nursing implications associated with the care of the woman who is experiencing a VBAC?

RESEARCH FINDINGS AND IMPLICATIONS

The rising rate of cesarean births and the decrease in the number of vaginal births after cesarean births (VBAC) are related. The higher the number of first-time mothers who experience a cesarean delivery, the higher the number of women who may not have a choice for a vaginal delivery the next time if their physician is reluctant to attempt a VBAC. Medical studies currently question the rising cesarean birth rate. Kabir and colleagues (2004) evaluated a large database of U.S. patients and concluded that a high proportion of unnecessary cesarean births occur. For study purposes, an “unnecessary cesarean birth” was defined as one that occurred when there were no identified medical risks or adverse circumstances. The adverse consequences of higher cesarean birth rates contribute to an increase in maternal morbidity and mortality. In addition, there are significant economic costs related to the prolonged hospital stays and the increased need for expensive surgery-related technologies. Although the greatest concern centers on the health and safety of the mother and her fetus, burgeoning health care costs cannot be discounted as a problem (Kabir et al., 2004).

Nurse researchers should continue to examine evidence to provide a better understanding of the factors that impact the cesarean birth rate. A few of the modifiable variables include maternal obesity, fear of labor and delivery, physiological pushing techniques, fear of injury, and convenience in planning a birth. Nurses need to engage in clinical research designed to offer evidence identifying the myriad

of factors that contribute to the rise in cesarean births. The results of such studies may lead to a decrease in the overall cesarean birth rate, which has risen steadily throughout the last decade. Nurse educators in the community can provide supportive interventions for all of these issues. Counseling during the prenatal period to allay anxieties and fears is critical. Families also need realistic plans for the childbirth along with thorough explanations of procedures and what they should expect (Tillett, 2005).

Prepared childbirth classes have increased in numbers and variety in the United States. Although many health educators serve an important role, the nurse with a clinical practice in obstetrics and women's health is in an ideal position to offer constructive guidance to families. Families need to learn to advocate for themselves through increased knowledge and understanding of the issues surrounding operative deliveries. If women's fears concerning childbirth are lessened, they become more open to teaching and can begin to function as collaborators in their own care. For example, perinatal education and selective tension-reducing labor techniques may reduce the woman's fear of labor and birth. Perhaps women who are able to overcome their fear of labor will choose to attempt vaginal birth instead of an elective cesarean birth. Nurses who serve as childbirth educators have a unique opportunity to empower women and their families through education and this new knowledge and self confidence may translate into a reduction in the rate of cesarean births.

Postterm Pregnancy/Prolonged Pregnancy

A **postterm pregnancy** is defined as one that extends beyond 294 days or 42 weeks past the first day of the last normal menstrual period. Stated another way, a postterm pregnancy has gone at least 1 day past 42 completed weeks (gestational age 42+1). A similar term, **postdate**, identifies a pregnancy that has gone past the estimated date of birth. It is estimated that postterm pregnancies occur in approximately 3% to 12% of all pregnancies.

Prolonged pregnancies are at risk for a number of problems including fetal macrosomia associated with shoulder dystocia and fetal injury, oligohydramnios, meconium aspiration, intrapartum fetal distress, and stillbirth. Neonatal problems may include asphyxia, meconium aspiration syndrome, hypoglycemia, polycythemia, respiratory distress, and dysmaturity syndrome (Gilbert, 2006).

Maternal risks such as trauma, hemorrhage, infection, and labor abnormalities are also associated with postterm pregnancy. Labor interventions including induction with prostaglandins or oxytocin, forceps- or vacuum-assisted birth and cesarean birth are more likely to be needed. In addition, the woman may experience fatigue and psychological responses such as depression, frustration, loss of control, and feelings of inadequacy as the pregnancy extends beyond the estimated date of birth (ACOG, 2004b; Moore & Martin, 2003).

The exact cause of postterm pregnancy is unknown. However, a possible cause may be related to a deficiency of placental estrogen and the continued secretion of progesterone. Low levels of estrogen may result in a decrease

in prostaglandin precursors and the reduced formation of myometrial oxytocin receptors (Gilbert, 2006). A woman with a history of one postterm pregnancy is more likely to experience another with subsequent pregnancies (Divon, 2002).

Because the placenta ages rapidly past the fortieth week of gestation, it becomes inefficient and cannot adequately support the fetus. A decrease in oxygen and nutrients results in fetal hypoxic episodes. Hypoxic events that occur on a regular basis stress the fetus. When labor commences, the postterm compromised fetus is at a greater risk for severe distress than the nonstressed term infant (Gilbert, 2006).

Antenatal testing combined with careful expectant management is used to monitor fetal status beyond the fortieth week of gestation. Antenatal testing is not viewed as a predictor of an untoward event but as a way to identify the fetus that demonstrates signs of compromise. The antenatal assessments most often obtained include non-stress tests (NST), biophysical profiles (BPP), amniotic fluid volume (AFV) measurements and maternal daily fetal movement counts. Other tests include the contraction stress test (CST), which relies on oxytocin-stimulated contractions to identify FHR decelerations associated with fetal hypoxia and Doppler flow measurements. The tests are usually performed on a weekly or twice-weekly basis (Cunningham et al., 2005; Divon, 2002). (See Chapter 11 for further discussion.)

MEDICAL MANAGEMENT

If a woman does not experience spontaneous labor by the 42nd week (sometimes earlier), induction is considered the primary medical management choice. Expectant management, including daily kick counts, weekly monitoring of the amniotic fluid index, and non-stress testing provide information regarding fetal well-being but are not always conclusive. If the gestational age is documented by ultrasound to be beyond 42 weeks and the cervix is favorable, most physicians proceed with labor induction. A cervix that is favorable (i.e., one that has begun to efface and dilate) is more conducive to the induction. If the cervix is not favorable, a cervical ripening agent (e.g., prostaglandin insert or gel) may be administered, followed by oxytocin induction (ACOG, 2004b; Resnik & Resnik, 2004). Some women with an unfavorable cervix may choose to continue with careful daily monitoring instead of the induction. As long as the physician considers the surveillance to be a safe option, the patient may be allowed to continue with the process of expectant management. However, if spontaneous labor does not begin by the 42nd or 43rd week, most physicians proceed with induction (Beckman et al., 2002).

NURSING IMPLICATIONS

The nurse conducts the non-stress and nipple stimulation contraction stress tests in the antepartum clinical setting, interprets information for the patient and provides reassurance. The nurse must be cautious in providing only the factual information. Since there is a possibility of false readings, the nurse must avoid offering unfounded reassurances and immediately notify the physician if test results are not normal. Understandably, patients often experience

increased anxiety when their due date has passed and they are still pregnant. The nurse is in a position to provide a consistent presence and respond to any questions or concerns. If induction is decided as the treatment option, the nurse explains the procedure to the patient and again responds to questions and concerns.

Intrapartal nursing care centers on close maternal–fetal surveillance and continued emotional support. During labor, the fetus should be monitored electronically to obtain an accurate assessment of the FHR and pattern. Umbilical cord compression, which is more likely to occur in the presence of decreased amniotic fluid, results in fetal hypoxia. Variable or prolonged deceleration patterns and the passage of meconium are reflective of fetal hypoxia. If oligohydramnios is present, amnioinfusion may be performed to restore the amniotic fluid volume to provide a fluid cushion for the umbilical cord (Cunningham et al., 2005).

summary points

- ◆ The nurse serves in many capacities when managing the care of women experiencing a complicated labor and birth; a strong theoretical background provides a foundation for the necessary critical decision-making
- ◆ Dystocia, a long, difficult or abnormal labor, may arise from any of the three major components of the labor process: the powers, passenger or passageway
- ◆ During a trial of labor, nursing responsibilities center on assessment of maternal vital signs and fetal heart rate and pattern
- ◆ Oxytocin used during labor induction and augmentation should always be administered as a “piggyback” solution, and a uterine and FHR monitor should be used continuously during the infusion
- ◆ Forceps and vacuum extraction are methods to assist birth; the mother and the infant require special observation during and after these procedures
- ◆ The management of hypertensive disorders during intrapartum is focused on preventing further deterioration of affected organs and fostering a positive maternal–fetal outcome
- ◆ Cesarean birth, which may be a scheduled or emergency procedure, is associated with increased risk for the mother and her infant and should be undertaken only when medically necessary
- ◆ Perinatal loss necessitates a collaborative response from all professionals involved in the care of the patient

review questions

Multiple Choice

1. When reviewing hypotonic labor, the perinatal nurse explains to a student nurse that the leading cause of this dysfunctional labor pattern is:
 - A. Fetal macrosomia
 - B. Maternal android pelvis
 - C. Inadequate uterine pacemakers
 - D. Fetal occiput posterior position

2. The perinatal nurse is aware that the minimal amount of fluid that would be infused for an amnioinfusion is:
 - A. 500 mL
 - B. 300 mL
 - C. 250 mL
 - D. 800 mL
3. The perinatal nurse understands that one of the risks of oxytocin infusion includes fetal heart rate changes related to:
 - A. Decreased placental perfusion
 - B. Oligohydramnios
 - C. Maternal hypotonic contractions
 - D. Maternal hypotension

True or False

4. The perinatal nurse understands the definition of hypotonic labor to be one that has fewer than five contractions in a 10-minute period.
5. The perinatal nurse is aware that clinical signs that require discontinuation of an amnioinfusion include maternal shortness of breath or tachycardia.
6. The perinatal nurse recognizes that the presence of hydramnios, which occurs when there is an excessive amount of amniotic fluid, may increase the risk of prolapsed umbilical cord following rupture of membranes.

Fill-in-the-Blank

7. The perinatal nurse knows that fetal macrosomia is significantly related to maternal _____ measurement and _____.
8. After a precipitous birth, the perinatal nurse carefully assesses the mother and her neonate for signs or symptoms of _____.
9. In providing information to a woman in labor who is to have an amniotomy, the perinatal nurse identifies _____ to be one of the procedure's risks, which means that there will be a commitment to have this birth occur in a timely manner.

Case Study

10. The perinatal nurse is caring for Christy, a 22-year-old G3 TPAL 1011, who is 9 cm. dilated and contracting every 2 to 3 minutes. Her labor has been rapid and she has been admitted in the last 30 minutes. Christy's membranes rupture spontaneously and the perinatal nurse is not able to auscultate the fetal heart. The most immediate nursing action is to:
 - A. Check the perineum for the possibility of a prolapsed umbilical cord.
 - B. Reposition the Doppler to attempt to auscultate the fetal heart rate.
 - C. Reposition Christy to a left lateral position.
 - D. Reassure Christy that her labor is progressing well.

CONCEPT MAP

Across Care Settings:

- Collaborative care for multiple gestation birth

Critical Nursing Actions:

- Assisting with precipitous birth
- Caring for the patient undergoing amnioinfusion
- Responding to umbilical cord prolapse

Ethnocultural Considerations:

- Level of quality of care differs between white and non-white populations

What To Say:

- For preterm labor: active listening, explore concerns
- Calm, factual explanation during fetal distress
- Effective team communication during obstetric emergencies
- Conveying compassion in fetal loss

Now Can You:

- Identify factors that impede labor progression
- Explain the difference between labor induction and augmentation
- Explain correct procedure for application of the fetal monitor
- Discuss care and medical management of twin births
- Discuss issues and appropriate communication concerning perinatal death

two
three
four
five

Care of the New Family

Caring for the Postpartal Woman and Her Family

chapter 15

Within a period of one day, most of what has been carefully accumulated over nine months is eliminated as no longer necessary by the body.

—Rubin, 1984, p. 753

LEARNING TARGETS *At the completion of this chapter the student will be able to:*

- ◆ Discuss the physiological and psychological changes that occur in the postpartal woman.
- ◆ Assess the physiological and psychosocial status of the postpartal woman.
- ◆ Plan holistic nursing care for the postpartal woman and her family that includes strategies for home follow-up.
- ◆ Implement nursing interventions to promote positive breast and formula feeding outcomes for the mother and her infant.
- ◆ Describe effective maternal self-care measures to be implemented during the puerperium.
- ◆ Discuss methods for assessing and treating pain in the postpartal period.
- ◆ Conduct appropriate nursing assessments and plan interventions for the patient who has experienced a cesarean birth.
- ◆ Discuss dimensions of postpartal care for the multicultural family.
- ◆ Plan postpartal nursing care with interventions to assess and foster maternal/infant/family bonding.

moving toward evidence-based practice The Influence of Norms on Breastfeeding Decisions

Swanson, V., & Power, K.G. (2005). Initiation and continuation of breastfeeding: theory of planned behavior. *Journal of Advanced Nursing*, (50)3, 272–282.

Rimal, R.N., & Real, K. (2003). Understanding the influence of perceived norms on behaviors. *Communication Theory* 13(2), 184–203.

The purpose of this study was to investigate the subjective norms of new mothers in relation to the decision to breast or bottle feed. Norms were defined as “group identity-based codes of conduct that are understood and disseminated through group interaction” (Rimal & Real, 2003). The Theory of Planned Behavior (TPB), a social cognition model, was used as a framework for the study, which explored how attitudes, norms, and perceived behavior control (PBC) predicted mothers’ feeding behaviors at birth.

Specifically, the research was designed to measure changes in norms and attitudes on the selected infant feeding method from birth to 6 weeks postpartum. Follow-up for both breast- and bottle-fed infants and a decision to discontinue breastfeed-

ing during this period was examined. The researchers also explored the views held by significant persons in the women’s environment (partner, own mother, and nurses) in relation to the mother’s decision about a method of feeding.

An initial interview and self-administered questionnaire were completed by 203 new mothers after childbirth. At 6 weeks postpartum, 118 of the participants completed a follow-up questionnaire. The sample included primiparous and multiparous women who experienced a vaginal or cesarean birth. At the time of delivery, 103 participants planned to breastfeed; 100 planned to bottle feed.

(continued)

moving toward evidence based practice (continued)

Data analysis revealed the following findings:

- One half of the sample were multiparas; the majority of these mothers chose to use the same feeding method used with their previous children.
- Eight mothers who had breast fed their first child chose to bottle feed the newborn; 11 mothers who had bottle fed their first child chose to breastfeed the newborn.
- Mothers who bottle fed their children tended to be younger, single, less educated, of lower socioeconomic status, and more likely to live in a rental unit.
- At the 6-week follow-up, 48% who initially planned to breastfeed continued to do so; 47% continued to bottle feed; and 12% combined breast and bottle feeding methods.
- Mothers who were breastfeeding reported positive beliefs toward breastfeeding. In addition, mothers who were bottle-feeding also reported positive beliefs.
- No significant differences were found in the mothers' perceived level of control over their choice of infant feeding methods.

- Both breast-feeding and bottle-feeding mothers were in agreement with social norms as expressed by their partner, mother, close female friends, and nurses or midwives.
- At 6 weeks postpartum, the breastfeeding mothers indicated that significant persons were more in favor of bottle feeding than breastfeeding. Ratings of the bottle-feeding mothers did not change.
- The partners, nurses, and nurse midwives were considered to have the most influence in relation to the mother's decision about a method of feeding.
- Mothers who discontinued breastfeeding by 6 weeks perceived more overall social pressure to bottle feed.

The researchers concluded that nurses and midwives have a crucial role in communicating positive views on breastfeeding to new mothers.

1. What might be considered as limitations to this study?
2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

Postpartum care begins immediately after childbirth. During this time, the nurse assists the new mother in learning how to care for herself and her baby. This 6-week period of time, also known as the **puerperium**, is filled with a myriad of changes that require careful nursing assessments for the mother, the newborn, and the family. The nurse's knowledge and care provided during this "**fourth trimester**" of pregnancy can have a life-long impact in shaping the future plans and choices for the new family.

The *Healthy People 2010* national initiative includes several goals that encompass the time period of the early puerperium:

- Reduce the maternal mortality rate to no more than 3.3/100,000 live births from a baseline of 7.1/100,000.
- Reduce the proportion of births occurring within 24 months of a previous birth to 6% from a baseline of 11%.
- Increase to at least 75% the proportion of mothers who breastfeed their babies in the early postpartum period from a baseline of 64% (DHHS, 2000).

Nursing actions to help the nation achieve these goals center on close observation to identify hemorrhage and related complications during the critical first hour after childbirth and ongoing education and support for women and families. Teaching about normal physiological changes during the puerperium, signs of danger, contraceptive methods, and benefits of breastfeeding empowers them to make informed decisions and choices.

Current trends reflect a shortened hospital stay for the new mother and her infant. However, there are several drawbacks to this approach. A longer (greater than 24 hours) hospital stay provides more rest and recuperation

time for the mother; a greater opportunity for postpartal education about self and infant care; and time for infant observation and assessment for anomalies, defects, or other problems, and improved maternal outcomes. Early hospital discharge has advantages as well. These include a decreased risk of nosocomial infections for the mother and infant, reduced medical expenses, and an opportunity for enhanced infant—family bonding.

Providing care during this period requires knowledge of the physiological and psychosocial aspects of the puerperium. The transitions that occur as the changes of pregnancy are reversed are considered to be a normal, but distinct, process. Protecting this process requires the nurse who cares for the postpartum patient to be equipped with special knowledge and skills. This chapter will discuss the physiological and psychosocial adaptations that occur during the postpartum period and the nursing assessments and interventions required to promote positive, healthy outcomes.

Ensuring Safety for the Mother and Infant

Early newborn discharge began as a consumer-initiated movement and as an alternative to home births in the 1980s. In the 1990s, third-party payers began to refuse reimbursement for hospital stays that extended beyond 24 hours, particularly after an uncomplicated vaginal birth. Congress responded to the growing concern over the safety of this practice by signing into law the Newborns' and Mothers' Health Protection Act of 1996. This legislation prohibits third-party payers from restricting benefits for hospital stays of less than 48 hours after a vaginal birth or less than 96 hours after a cesarean birth. Forty-eight hours is an incredibly short amount of time to

assess, assist, and educate new mothers about matters concerning personal, newborn, and family health. Information provided by the postpartum nurse can protect the newborn and his family from unnecessary morbidity and mortality.

Fears surrounding infant abductions have long been a common concern among hospital staff and families. These concerns have created the need for the electronic tracking of infants. The growing need for fail-proof mechanisms to ensure infant safety has prompted the development of a variety of systems designed to foil infant abduction attempts. In response to increased litigation and pressure from The Joint Commission, it has become mandatory for hospitals to offer state-of-the-art security protection for their patients, mother/baby units, and visitors.

To meet The Joint Commission mandatory infant safety requirements, hospitals have instituted policies and procedures that nurses and mothers must follow to ensure their newborn's safety. Infant security experts agree that an informed mother is the baby's first line of defense while in the hospital as well as after returning home. It is essential that nurses educate new mothers about measures designed to protect their newborns from potential abductors.

Be sure to— Check identification bracelets

The safety and security of the infant must be maintained at all times during hospitalization. This process involves the placement of identification bands on both the mother and infant shortly after birth. On bringing the infant to the mother, it is essential for the nurse to verify that the bracelets match. At discharge, it may be necessary for the nurse to retain both the infant's and parent's identification bracelets as part of the permanent record. This safety measure serves a twofold purpose: to prevent the unauthorized removal of the infant from the hospital unit and to prevent the inadvertent mix-up or switching of newborns.

Be sure to— Protect the infant from abduction

Protecting the infant from abduction is an extremely important consideration during hospitalization. Personnel, parents, and significant others must be educated regarding the various measures implemented to protect the safety of the infant. Any time the infant is transported from the nursery to the mother's room, it is essential for staff to follow the hospital's protocol. In most facilities, infants may be transported only in a bassinet and parents are prohibited from carrying the infant in the halls. When identification bracelets are used, they are matched before giving the infant to the mother. Mothers should be instructed to release the infant only to properly identified hospital personnel. After birth, admission photographs and footprints are most likely taken and affixed to the permanent record. When two or more infants have a similar or same last name, it is common practice for the infants' cribs and charts to indicate the mother's first name, and bear a label that designates a "NAME ALERT." When there are multiple births, the infants' cribs may be labeled with the infant's name followed by a letter of the alphabet (i.e., A, B, C, or D).

Hospital personnel are typically required to wear visible photo identification when working in the maternal child unit. All employee photo badges should be similar in appearance to facilitate the ready identification of individuals posing as hospital employees. Visitors may be required to wear identification badges while on the unit. Hospital staff should be empowered to question any suspicious activity or individuals who are present on the maternal child unit.

Now Can You— Discuss strategies to ensure maternal-infant safety?

1. Identify three measures the hospital nurse can implement to ensure the safety of both the infant and the mother?
2. Suggest a strategy to decrease the potential for confusing infants whose last names are similar or identical?
3. Describe two actions that hospital personnel can take to help prevent infant abduction?

Early Maternal Assessment

VITAL SIGNS

During the postpartum period, vital signs are a reflection of the body's attempts to return to a pre-pregnant state. Vital signs can alert the nurse to the presence of hemorrhage or infection and should be monitored according to hospital policy. After a vaginal birth, vital signs are typically monitored every 15 minutes during the first hour after childbirth, then every 30 minutes during the second hour, once during the third hour, and then every 8 hours until discharge or until they are stable. A different protocol is followed for vital sign assessment after a cesarean birth (e.g., q30min \times 4 hours; then q1h \times 3; then q4–8h).

Temperature

During the first 24 hours postpartum, some women experience an increase in body temperature up to 100.4°F (38°C). The exertion and dehydration that accompany labor are the primary causes for the temperature elevation, and increased fluids usually return the temperature to a normal range. Increased breast vascularity may also cause a transient increase in temperature. After the first 24 postpartal hours have passed, however, the patient should be afebrile. A temperature above 100.4°F (38°C) at this time may be indicative of infection. (See Chapter 16 for further discussion).

Pulse

Heart rates of 50 to 70 beats per minute (bradycardia) commonly occur during the first 6 to 10 days of the postpartum period. During pregnancy, the weight of the gravid uterus causes a decreased flow of venous blood to the heart. After childbirth, there is an increase in intravascular volume. The elevated stroke volume leads to a decreased heart rate. Postpartal tachycardia may result from a complication, prolonged labor, blood loss, temperature elevation, or infection.

Blood Pressure

Postpartal blood pressure values should be compared with blood pressure values obtained during the first trimester. Decreased blood pressure may result from the physiological changes associated with the decrease in intrapelvic pressure, or it may be indicative of uterine hemorrhage. An increase in the systolic blood pressure of 30 mm Hg or 15 mm Hg in the diastolic blood pressure, especially when associated with headaches or visual changes, may be a sign of gestational hypertension. Further assessment is indicated.

In the puerperium, plasma renin and angiotensin II levels return to normal, nonpregnant levels. These physiological changes produce a decrease in vascular resistance. Orthostatic hypotension may occur when the patient moves from a supine to a sitting position. Otherwise, maternal blood pressure should remain stable (Cunningham et al., 2005).

Respirations

The respiratory rate should remain within the normal range of 12 to 20 respirations per minute. However, slightly elevated respirations may occur due to pain, fear, excitement, exertion, or excessive blood loss. Careful nursing assessment for causes of an elevated respiratory rate is indicated, along with appropriate interventions. Tachypnea, abnormal lung sounds, shortness of breath, chest pain, anxiety, or restlessness are abnormal findings that must be reported immediately. These signs and symptoms may be indicative of pulmonary edema or emboli. (See Chapter 16 for further discussion.)

Nursing Insight— Promoting comfort during the immediate postpartum period

It is not unusual for women to experience shaking chills during the time immediately after childbirth. This physiological response results from: (1) pressure changes in the abdomen after the reduction in the bulk of the uterus and (2) temperature readjustments after the diaphoresis of labor. Feelings of excitement and exhaustion may also play a role. Nurses should reassure patients of the normalcy of this temporary reaction and offer warm blankets and beverages as comfort measures.

FUNDUS, LOCHIA, PERINEUM

Within a few minutes after birth, the firmly contracted uterine fundus should be palpable through the abdominal wall halfway between the umbilicus and the symphysis pubis. Approximately 1 hour later, the fundus should have risen to the level of the umbilicus, where it remains for the following 24 hours.

Optimizing Outcomes— Uterine assessment crucial during the first hour postpartum

Because the first postpartal hour represents the most dangerous time for the patient, it is essential that the nurse conduct frequent uterine assessments during this time. Relaxation of the uterus (atony) results in rapid, life-threatening blood loss because no permanent thrombi have yet formed at the placental site.

The fundus then descends one fingerbreadth (1 cm) per day in size. The fundus, **lochia** (puerperal discharge of blood, mucus, and tissue), and perineum need to be assessed every 15 minutes during the immediate postpartum period. To facilitate the perineal assessment, the nurse assists the patient into a Sim's (side-lying) position with her back facing the nurse.

Nursing Insight— Perineal assessment

Protecting the patient's privacy and ensuring adequate lighting are essential components of the perineal assessment. Although some edema of the vulva and perineum is a common finding during the first few postpartum days, excessive swelling, discoloration, incisional separation, or discharge other than lochia should be reported, along with the patient's complaints of pain or discomfort.

With adequate lighting in place, the nurse gently lifts the buttock cheeks to visualize the perineum. Use of the acronym REEDA guides the nurse to assess for **R**edness, **E**dema, **E**cchymosis, **D**rainage or discharge, and **A**pproximation of the episiotomy if present (Table 15-1). The episiotomy and/or laceration repairs should appear intact with the tissue edges closely approximated. Hemorrhoids

Table 15-1 The REEDA Acronym to Guide the Perineal Assessment

Points	Redness	Edema	Ecchymosis	Discharge	Approximation
0	None	None	None	None	Closed
1	Within 0.25 cm of incision bilaterally	Less than 1 cm from incision	1–2 cm from incision	Serum	Skin separation 3 mm or less
2	Within 0.5 cm of incision bilaterally	1–2 cm from incision	0.25–1 cm bilaterally or 0.5–2 cm unilaterally	Serosanguineous	Skin and subcutaneous fat separated
3	Beyond 0.5 cm of incision bilaterally	Greater than 2 cm from incision	Greater than 1 cm bilaterally or 2 cm unilaterally	Bloody, purulent	Skin, subcutaneous fat and fascial separation

may also be present. The nurse should note and document the number, appearance, and size (in centimeters) of the hemorrhoids.

HEMORRHOIDS

Hemorrhoids that may be present before pregnancy or develop during pregnancy can become enlarged due to pressure on the lower bowel during the second stage of labor. The application of ice packs and/or pharmaceutical preparations such as topical anesthetic ointments or witch hazel pads helps to relieve discomfort. Frozen tea peripads may also be used as a comfort measure for hemorrhoids and labial swelling. The tannic acid decreases edema and is soothing. Other actions to minimize hemorrhoidal discomfort include assisting the patient to a side-lying position in bed and teaching her to sit on flat, hard surfaces and to tighten her buttocks before sitting. Soft surfaces and pillows such as donut rings should be avoided because they separate the buttocks and decrease venous flow, intensifying the pain. If the hemorrhoids are severe, the patient can be taught how to manually reposition the hemorrhoids back into the rectum. Hemorrhoids that developed during pregnancy generally disappear within a few weeks after childbirth.

Now Can You— Discuss postpartum vital signs and perineal assessment?

1. Describe the expected vital sign findings during the postpartum period?
2. Identify potential causes for increased blood pressure, pulse, and respirations during the postpartum period?
3. Explain what is meant by the REEDA acronym to facilitate the perineal assessment?

A Concise Postpartum Assessment Guide to Facilitate Nursing Care

THE BUBBLE-HE MNEMONIC

Use of a systematic assessment process helps the nurse ensure that the special needs of postpartum patients are met. As with all nursing care, a complete head-to-toe assessment must be completed for the postpartum patient who has unique needs not found in any other nursing environment. To assist with the postpartum assessment, the mnemonic BUBBLE-HE is commonly used to guide nursing practice. BUBBLE-HE reminds the nurse to assess the breasts, uterus, bladder, bowel, lochia, and episiotomy. Assessment of maternal pain, Homans' sign, the patient's emotional status and initiation of infant bonding are other important components to be included in the postpartum evaluation (Table 15-2). Medications commonly prescribed during the puerperium are presented in Table 15-3.

Breasts

A number of physiological changes occur during pregnancy to prepare the breasts for the process of lactation. The mammary glands, or milk producing system, are unlike any other organ system. Throughout the woman's growth and development, no other human organ under-

Table 15-2 BUBBLE-HE: Components of a Postpartum Assessment

Letter	Assess	Assessment Includes
B	Breasts	Inspection of nipples: everted, flat, inverted? Breast tissue: soft, filling, firm? Temperature and color: warm, pink, cool, red streaked?
U	Uterus	Location (midline or deviated to right or left side) and tone (firm, firm with massage, boggy)
B	Bladder	Last time the patient emptied her bladder (spontaneously or via catheter)? Palpable or nonpalpable? Color, odor, and amount of urine?
B	Bowels	Date/time of last BM; presence of flatus and hunger (unless the colon was manipulated, do not need to auscultate for bowel sounds)
L	Lochia	Color, amount, presence of clots, any free flow?
(I) E	(Incision) Episiotomy	Type as well as other tissue trauma (lacerations, etc.) Assess using REEDA
L/H	Legs (Homans' sign)	Pain, varicosities, warmth or discoloration in calves; presence of pedal pulses; sensation and movement (after cesarean birth)
E	Emotions	Affect, patient-family interaction, effects of exhaustion
(B)	Bonding	Interaction with infant—"taking in" phase—presence of finger tipping, gazing, enfolding, calling infant by name, identifying unique characteristics

goes the dramatic changes in size, shape, and function that take place in the breasts (Riordan, 2005). Essentially, the breasts serve no function other than to nourish the child. Breast size has no bearing on the woman's ability or capacity to nourish her infant. Instead, the infant's appetite and frequent emptying of the breasts dictate the quantity of milk produced.

A & P review Hormonal Changes to Prepare the Breasts for Lactation

Up until the onset of puberty, the breasts are much the same in males and females and their internal structure is similar: they consist of a collection of ducts that empty into the nipple. In the female, breast tissue responds to the release of the female sex hormones estrogen and progesterone during puberty. Estrogen stimulates the formation of additional ducts, the elongation of existing ducts and the formation of a system of milk secreting glands. These changes are associated with an increase in volume and elasticity of connective tissue, deposition of adipose tissue and increased vascularity. Progesterone stimulates the formation of lobules, the glands in the breast which produce milk.

Table 15-3 Commonly Used Medications in the Postpartum Period

Classification	Medication	Dose Safety of Use in Breastfeeding	Indication for Use in Postpartum Phase
Stool softener	Docusate sodium (Colace)	50 mg to 500 mg by mouth daily until bowel movements are normal. Not contraindicated in breastfeeding mother.	Used in the treatment of constipation
Stool softener	Bisacodyl (Dulcolax)	10 mg to 30 mg by mouth until bowel movements are normal. Not contraindicated in breastfeeding mother.	Used in the treatment of constipation
Topical anesthetic	Lidocaine spray	Spray to perineal area after sitz bath or perineum care. Not contraindicated in breastfeeding mother.	Used on the skin to relieve pain and itching
Hemorrhoid care	Witch hazel (Tucks)	Apply to perineal area after sitz bath or perineum care. Not contraindicated in breastfeeding mother.	Used on the skin to relieve the itching, burning, and irritation associated with hemorrhoids
Nonsteroidal anti-inflammatory drugs	Ibuprofen (Motrin)	400 mg by mouth every 4–6 hours as needed for pain. Not contraindicated in breastfeeding mother.	Used for the treatment of mild to moderate pain
Opioid analgesics	Darvocet (propoxyphene and acetaminophen)	Take one tablet by mouth every four hours as needed for pain. Not contraindicated in breastfeeding mother.	Used for the treatment of moderate to severe pain
Opioid analgesics	Percocet (oxycodone and acetaminophen)	Take one to two tablets every 4-6 hours as needed for pain. Not contraindicated in breastfeeding mother.	Used for the treatment of moderate to severe pain

Source: Deglin, J.H., & Vallerand, A.H. (2009). *Davis's Drug Guide for Nurses* (11th ed.). Philadelphia: F.A. Davis.

By the time the breasts are fully formed, typically by the age of 15, breast tissue extends medially from the second or third rib to the sixth or seventh rib, and laterally from the breastbone to the edge of the axillae. Although genetic factors, body size and ethnicity account for some variations, on average, the breasts weigh approximately 200 grams. During pregnancy, each breast increases in size and weight to reach approximately 600 grams and 600 to 800 grams during lactation (Lawrence & Lawrence, 2005).

Until menopause, when menstrual periods cease, the woman's breast tissue continues to respond to the changing hormonal environment that accompanies each menstrual cycle. Throughout the majority of the woman's life, the breasts remain in a resting state except for the time during pregnancy and lactation. ♦

Regardless of whether the woman plans to breast or bottle feed, the breasts require careful assessment. After ensuring privacy, the nurse asks the patient to remove her bra. The chest area is covered with a sheet or towel and the woman is instructed to raise her arms and rest her hands on her head. The nurse inspects and palpates each breast for size, shape, tenderness, and color. During the first 2 postpartal days, the breast tissue should feel soft to the touch. By the third day, the breasts should begin to feel firm and warm. This change is described as "filling." On the fourth and fifth days postpartum, breastfeeding mothers' breasts should feel firm before infant feeding, then become soft once the baby is satiated. The noticeable changes in breast firmness are indicative of milk transfer.

The process of lactation is established in all postpartum women, regardless of their intention to breast or formula

feed. Tense, painful breasts in a breastfeeding mother are indicative of poor transfer of milk to the infant. This finding should prompt a breastfeeding assessment and, when appropriate, referral to an international board-certified lactation consultant. (See discussion later in this chapter.)

Occasionally, small, firm nodules can be palpated in the filling breasts. The nodules result from incomplete emptying of the breasts during the previous feeding. Usually, a nodule arises from a blocked milk duct or from milk contained in a gland that is not flowing forward to the nipple. Although the nodules typically disappear after a satisfactory feeding, their location should be noted and monitored. Persistence of any breast mass may be indicative of fibrocystic disease or malignant growths unrelated to the pregnancy. The nurse also documents the appearance of the nipples, noting the presence of fissures, cracks, blood, or dried milk, and whether they are erect or inverted.

Uterus

Involution is a term that describes the process whereby the uterus returns to the nonpregnant state. The uterus undergoes a dramatic reduction in size although it will remain slightly larger than its size before the first pregnancy. Immediately after expulsion of the placenta, the uterus rapidly contracts to prevent hemorrhage. The uterus weighs approximately 1000 g in the immediate postpartal period and by the end of the first week, its weight has diminished to 500 g. Uterine size and weight continue to decrease and on average, the uterus weighs 300 g by the end of the second week and thereafter the weight is 100 g or less (Cunningham et al., 2005).

After the birth of the infant, placental expulsion spontaneously occurs within 15 minutes in approximately 90% of women. To prevent hemorrhage, rapid uterine contractions seal off the placental site, effectively pinching off the massive network of maternal blood vessels that were attached to the placenta (Cunningham et al., 2005).

The original site of placental implantation covers a surface area that is approximately 8 to 10 cm in size. By the end of the second postpartal week, the site has shrunk to about 3 to 4 cm; complete healing takes approximately 6 to 7 weeks. The uterus is predominantly composed of a muscle layer, the myometrium. The myometrium is covered by serosa and lined by the decidua basalis. The process of uterine involution results from a decrease in the size of the myometrial cells rather than from a decrease in the number of myometrial cells. The decrease in cell size results in myometrial thickening and ischemia from reduced blood flow to the contracted uterus.

Phagocytosis (the engulfment and destruction of cells) contributes to the process of uterine involution by removing elastic and fibrous tissue from the uterus. The process is further hastened by autolysis (self-digestion) that results from migration of macrophages to the uterus.

Subinvolution is the failure of the uterus to return to the nonpregnant state. Uterine involution may be inhibited by multiple births, hydramnios, prolonged labor or difficult birth, infection, grand multiparity, or excessive maternal analgesia. In addition, a full bladder or retained placental tissue may prevent the uterus from sustaining the contractions needed to prevent hemorrhage or to facilitate involution. (See Chapter 16 for further discussion.)

The placental site heals by a process called exfoliation. Exfoliation is the scaling off of dead tissue. New endometrial tissue is generated at the site from the glands and tissue that remain in the lower layer of the decidua after separation of the placenta. This physiological process results in a uterine lining that contains no scar tissue, which could impede implantation in future pregnancies. Regeneration of the endometrium is complete by the 16th postpartum day, except at the placental site, where regeneration is usually not complete until approximately 6 weeks after childbirth.

Figure 15-1 To palpate the uterus, the upper hand is cupped over the fundus; the lower hand stabilizes the uterus at the symphysis pubis.

To perform the uterine assessment, the nurse assists the patient to a supine position so that the height of the uterus is not influenced by an elevated position. The patient's abdomen is observed for contour to detect distention and the presence of striae or a diastasis (separation), which appears as a slightly indented groove in the midline. When present, the width and length of a diastasis are recorded in fingerbreadths. The uterine fundus is palpated by placing one hand immediately above the symphysis pubis to stabilize the uterus and the other hand at the level of the umbilicus (Fig. 15-1). The nurse presses inward and downward with the hand positioned on the umbilicus until the fundus is located. It should feel like a firm, globular mass located at or slightly above the umbilicus during the first hour after birth.

clinical alert

Proper technique for uterine palpation

The uterus should never be palpated without supporting the lower uterine segment. Failure to do so may result in uterine inversion and hemorrhage.

FUNDUS. Immediately after childbirth, the uterus rapidly contracts to facilitate compression of the intra myometrial blood vessels. The uterine fundus can be palpated midline, midway between the umbilicus and symphysis pubis. Within an hour, the uterus settles in the midline at the level of the umbilicus. Over the course of days, the uterus descends into the pelvis at a rate of about 1 cm/day (one fingerbreadth) (Fig. 15-2). After 10 days, the uterus has descended into the pelvis and is no longer palpable.

The fundus is assessed for consistency (firm, soft, or boggy), location (should be midline), and height (measured in finger breadths). During the fundal assessment, the nurse notes whether it is located midline or deviated to one side. On occasion, the fundus can be palpated slightly to the right because of displacement from the sigmoid colon during pregnancy. Assessment of the fundus should be made shortly after the patient has emptied her bladder. A full bladder prevents the uterus from contract-

Figure 15-2 Fundal heights postpartum.

Table 15-4 Assessment and Documentation of Uterine Involution

Time	Location of Fundus	Documentation
Immediately after birth	Midline, midway between umbilicus and symphysis pubis	
1–2 hours	At the level of the umbilicus	at U (umbilicus)
12 hours	1 cm above umbilicus (1 fingerbreadth)	U + 1
24 hours	1 cm below umbilicus	U – 1
2 days	2 cm below umbilicus (2 fingerbreadths)	U – 2
3 days	3 cm below umbilicus (3 fingerbreadths)	U – 3
7 days	Palpable at the symphysis pubis	
10 days	Not palpable	

ing and instead pushes the uterus upward and may deviate it from the midline, due to laxness of the uterine ligaments. A flabby, noncontracted, boggy uterus is associated with increased bleeding. A well-contracted fundus is firm, round, and midline. The nurse documents the location of the fundus according to fingerbreadths above or below the umbilicus (Table 15-4).

Afterpains (afterbirth pains) are intermittent uterine contractions that occur during the process of involution. Patients often describe the sensation as a discomfort similar to menstrual cramps. The primiparous woman typically has mild afterpains, if she notices them at all, because her uterus is able to maintain a contracted state. Multiparas and patients with uterine overdistention (e.g., large baby, multifetal gestation, hydramnios) are more likely to experience afterpains, due to the continuous pattern of uterine relaxation and vigorous contractions. When the uterus maintains a constant contraction, the afterpains cease. Breastfeeding and the administration of exogenous oxytocin usually produce pronounced afterpains because both cause powerful uterine contractions. Afterbirth pain is often severe for 2 to 3 days after childbirth. Nursing interventions for discomfort include assisting the patient into a prone position with a small pillow placed under her abdomen, initiating sitz baths (for warmth), encouraging ambulation, and administering mild analgesics.

Optimizing Outcomes—Breastfeeding and afterpains

Analgesics such as ibuprofen (Advil, Motrin) or naproxen (Aleve, Anaprox) are frequently administered to lessen the discomforts of afterpains. Breastfeeding women should take pain medication approximately 30 minutes before nursing the baby to achieve maximum pain relief and to minimize the amount of medication that is transferred in the breast milk.

Now Can You—Discuss changes in the breasts and uterus during the postpartum period?

1. Name each component of the BUBBLE-HE mnemonic for the postpartum assessment?
2. Explain normal breast changes that occur during the first few postpartal days?
3. Explain what is meant by “involution”?

Bladder

After childbirth, spontaneous voiding should occur within 6 to 8 hours and the first few voiding amounts should be monitored. Urinary output of at least 150 mL/hr is necessary to avoid urinary retention or stasis. Generalized edema is often present in the early puerperium. It is related to the fluid accumulation that normally occurs during pregnancy combined with intravenous fluids frequently administered during labor and birth. Maternal diuresis occurs almost immediately after birth and urinary output reaches up to 3000 mL each day by the second to fifth postpartum days.

Decreased bladder tone is normal during pregnancy, and results from the effects of progesterone on the smooth muscle, edema from pressure of the presenting part, and mucosal hyperemia from the increase in blood vessel size. Prolonged labor, the use of forceps, analgesia, and anesthesia may intensify the changes in the immediate postpartum period. Pressure caused by the fetal head pressing on the bladder during labor can result in trauma and a transient loss of bladder sensation during the first few postpartal days or weeks. These changes can result in incomplete bladder emptying and overdistention.

Bladder and urethral trauma is not uncommon during the intrapartum period and may be associated with a decreased flow of urine immediately after a vaginal birth. An increase in the voided volume, the total flow time (how long it takes to empty the bladder) and the time to peak urine flow (the maximum urinary flow rate) begins to occur during the first postpartum day. Urine volume and flow time should return to pre-pregnant levels by 2 to 3 days after childbirth. Epidural anesthesia, catheterization before birth, and an instrument-facilitated birth are associated with an increased risk of postpartum urinary retention. Urethral and bladder trauma and lacerations may accompany vaginal or cesarean birth.

Urinary retention can also result from bladder hypotonia after childbirth since the weight of the gravid uterus no longer limits bladder capacity. Assessment of the maternal bladder is an extremely important component of the nursing evaluation (Table 15-5). An overdistended bladder, which displaces the uterus above and to the right of the umbilicus, can cause uterine atony and lead to hemorrhage. Other assessment findings may include presence of the bladder palpated as a hard or firm area just above the symphysis pubis and a urinary output that is disproportionate to the fluid intake. Bladder percussion enhances the assessment. To percuss the bladder, the nurse places one finger flat on the patient's abdomen over the bladder and taps it with the finger of the other hand. A full bladder produces a resonant sound. An empty bladder has a dull, thudding sound. Patients may express an urge to void but be unable to void. Fortunately, spontaneous voiding typi-

Table 15-5 Nursing Assessment and Interventions for the Urinary System

Patient's Signs and Symptoms	Nursing Interventions
<ul style="list-style-type: none"> • Location of fundus above baseline level • Fundus displaced from midline • Excessive lochia • Bladder discomfort • Bulge of bladder above symphysis pubis • Frequent voiding of less than 150 mL of urine; urinary output disproportionate to fluid intake 	<ul style="list-style-type: none"> • Promote hydration • Promote ambulation • Administer an analgesic before voiding, as prescribed • Place ice on perineum to reduce swelling and pain • Encourage the use of a sitz bath • Provide privacy • Turn on the bathroom faucet

cally returns within 6 to 8 hours after childbirth. Until this time, the nurse should support and enhance the woman's attempts to void. Nursing interventions may include assisting the patient to the toilet, providing privacy and a unhurried environment, turning on the lavatory faucet, and assisting the patient into a sitz bath.

Bowel

The gastrointestinal system becomes more active soon after childbirth. The patient often feels hungry and thirsty after the food and fluid restrictions that usually accompany the intrapartal experience. The peptide hormone relaxin, which reaches high circulating levels during pregnancy, depresses bowel motility (Cunningham et al., 2005). The relaxed condition of the intestinal and abdominal muscles, combined with the continued effects of progesterone on the smooth muscles, diminishes bowel motility. These factors commonly result in constipation during the early puerperium. After childbirth, bowel movements are typically delayed until the second or third puerperal day and hemorrhoids (distended rectal veins), perineal trauma, and the presence of an episiotomy may be associated with painful defecation. Early ambulation, abundant fluids, and a high-fiber diet are a few strategies to help prevent constipation (Box 15-1).

Lochia

Separation of the placenta and membranes occurs in the spongy or outer layer of the decidua basalis. The uterine decidua basalis reorganizes into the basal and superficial layers. The inner basal layer becomes the foundation from which new layers of endometrium will form. The superficial layer becomes necrotic and sloughs off in the uterine discharge, called lochia. Lochia is composed of erythrocytes; epithelial cells; blood; and fragments of decidua, mucus, and bacteria (Cunningham et al., 2005). The characteristics of the lochia are indicative of the woman's status in the process of involution.

During the first few days postpartum, the lochia consists mostly of blood, which gives it a characteristic red color known as **lochia rubra**. Lochia rubra also contains elements of amnion, chorion, decidua, vernix, lanugo,

Box 15-1 Nursing Interventions to Facilitate Normal Bowel Function During the Puerperium

To facilitate the return of normal bowel function in the puerperium, the nurse should:

- Encourage the patient to drink at least six to eight 8-oz. glasses of water every day to help keep the stool soft.
- Encourage the patient to eat a high-fiber diet that includes an abundance of fruits and vegetables, oat and bran cereal, whole-grain bread, and brown rice.
- Encourage the patient to avoid ignoring the urge to defecate.
- Encourage the patient to avoid straining to have a bowel movement.
- Encourage the patient to initiate early ambulation.
- Administer stool softeners and/or laxatives as ordered.
- Explain that after hospital discharge, over-the-counter medications may be helpful for hemorrhoidal symptoms of pain, itching, or swelling but encourage the patient to consult with her caregiver before using such medications.

and meconium if the fetus had passed any stool in utero. These components cause the fleshy odor associated with lochia rubra.

After 3 to 4 days, the lochia becomes the pinkish-brownish **lochia serosa**. Lochia serosa contains blood, wound exudates, erythrocytes, leukocytes, and cervical mucosa. After approximately 10 to 14 days, the uterine discharge has a reduced fluid content and is largely composed of leukocytes. This combination produces a white or yellow-white thick discharge known as **lochia alba**. Lochia alba also contains decidual cells, mucus, bacteria, and epithelial cells. It is present until about the third week after childbirth but may persist for 6 weeks.

The pattern of lochia flow, from lochia rubra to serosa to alba, should not reverse. A return of lochia rubra after it has turned pink or white may indicate retained placental fragments or decreased uterine contractions and new bleeding. Lochia should contain no large clots, which may indicate the presence of retained placental fragments that are preventing closure of maternal uterine blood sinuses. The odor of lochia is similar to that of menstrual blood. An offensive odor is indicative of infection.

After assessment of the lochia, the nurse may find it difficult to document the findings correctly. Lochia is typically documented in amounts described as *scant*, *small*, *moderate*, or *heavy*. The amount of vaginal discharge is not a true indicator of the lochia flow unless the time factor is also considered. For example, a perineal pad (peripad) that accumulates less than 1 cm of lochia in 1 hour is associated with scant flow (Fig. 15-3). Nurses must also be certain to take into account the specific type of peripad used, since some are more absorbent than others. At times, visually assessing the amount of lochia flow can be difficult and inaccurate.

Optimizing Outcomes—Abnormal findings in a postpartal patient

During a routine postpartal assessment conducted 2 hours after childbirth, the nurse records the following vital signs: pulse = 102 beats/minute; blood pressure = 130/86 mm Hg;

Figure 15-3 Assessment of lochia flow in one hour.

respirations = 21 breaths/minute; temperature = 98.9°F (37.1°C). The nurse's first action is to assess the fundus. With the cupped palm placed directly over the uterine fundus, the nurse uses palpation to assess for the state of contraction (e.g., soft, boggy, or firmly contracted), along with the location and height of the fundus. If soft, the fundus is massaged in a circular motion with the cupped palm until the uterus is well contracted. The nurse inspects the peripad for the lochia amount and color, and the presence of odor. The physician or nurse midwife is notified of the findings. If excessive blood loss has occurred or if the uterus is not well contracted, the nurse administers appropriate prn medication(s) (e.g., Methylergonovine [Methergine]) as ordered.

Episiotomy

An episiotomy is a 1- to 2-inch surgical incision made in the muscular area between the vagina and the anus (the perineum) to enlarge the vaginal opening before birth. The midline episiotomy is a straight incision extending toward the anus. A mediolateral episiotomy extends downward and to the side. (See Chapter 12.) Typically, the episiotomy edges have become fused (the edges have sealed) by the first 24 hours after birth. Although the patient's perineal folds may interfere with full visualization of a midline episiotomy, it is important for the nurse to carefully assess the episiotomy for redness, edema, ecchymosis, discharge, and approximation (REEDA) and then document all findings.

clinical alert

Hematoma after an episiotomy

Severe hemorrhage after an episiotomy is possible. Maternal complaints of excessive perineal pain should alert the nurse to the possibility of a perineal, vulvar, vaginal, or ischiorectal **hematoma** (a blood-filled swelling that occurs from damage to a blood vessel).

medication: Methylergonovine

Methylergonovine (meth-ill-er-goe-noe-veen)

Methergine

Pregnancy Category: C

Indications: Prevention and treatment of postpartum and postabortion hemorrhage caused by uterine atony or subinvolution

Actions: Directly stimulates uterine and vascular smooth muscle.

Therapeutic Effects: Uterine contraction

Pharmacokinetics:

ABSORPTION: Well absorbed after oral or IM administration

ONSET OF ACTION: Oral: 5–10 minutes; IM: 2–5 minutes; IV: Immediately

DISTRIBUTION: Oral: 3 hours; IM: 3 hours; IV: 45 minutes. Enters breast milk in small quantities.

METABOLISM AND EXCRETION: Probably metabolized by the liver

HALF-LIFE: 30–120 minutes

Contraindications and Precautions

CONTRAINDICATED IN: Hypersensitivity. Should not be used to induce labor.

USE CAUTIOUSLY IN: Hypertensive or eclamptic patients (more susceptible to hypertensive and arrhythmogenic side effects); severe hepatic or renal disease; sepsis

EXERCISE EXTREME CAUTION IN: Third stage of labor

Adverse Reactions and Side Effects:

CENTRAL NERVOUS SYSTEM: Dizziness, headache

EYES, EARS, NOSE, THROAT: Tinnitus

RESPIRATORY: Dyspnea

CARDIOVASCULAR: Hypotension, arrhythmias, chest pain, hypertension, palpitations

GASTROINTESTINAL: Nausea, vomiting

GENITOURINARY: Cramps

DERMATOLOGICAL: Diaphoresis

Route and Dosage:

PO: 200–400 mcg (0.4–0.6 mg) q6–12h for 2–7 days

IM, IV: 200 mcg (0.2 mg) after delivery of fetal anterior shoulder, after delivery of the placenta, or during the puerperium; may be repeated as required at intervals of 2–4 hours up to five doses.

Nursing Implications:

1. Physical assessment: Monitor blood pressure, heart rate and uterine response frequently during medication administration. Notify the primary health care provider if uterine relaxation becomes prolonged or if character of vaginal bleeding changes.
2. Assess for signs of ergotism (cold, numb fingers and toes, chest pain, nausea, vomiting, headache, muscle pain, weakness)

Data from Deglin, J.H., and Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

To assess for perineal hematoma, the nurse should:

1. Look for discoloration of the perineum.
2. Listen for the patient's complaints or expression of severe perineal pain.
3. Observe for edema of the area.
4. Listen for the patient's expression of a need to defecate (the hematoma may cause rectal pressure).
5. Don sterile gloves, gently palpate the area, and observe for the patient's degree of sensitivity to the area by touch.
6. Call the physician or nurse-midwife to report the findings immediately. The bleeding that has produced the hematoma must be promptly identified and halted.

Optimizing Outcomes— Early episiotomy care

The nurse should apply an ice bag or commercial cold pack to the perineum during the first 24 hours after childbirth. The ice bag should be wrapped in a towel or disposable paper cover to prevent a thermal injury. Application of cold provides local anesthesia and promotes vasoconstriction while reducing edema and the incidence of peripheral bleeding. Later (after 24 hours), the nurse encourages the use of moist heat (sitz bath) between 100° and 105°F (37.8–40.5°C) for 20 minutes three to four times per day. The sitz bath increases circulation to the perineum, enhances blood flow to the tissues, reduces edema, and promotes healing. Dry heat, in the form of a commercial perineal “hot pack,” may also be used. The packs are “cracked” to generate heat. Women should be cautioned to apply a washcloth or gauze square between the hot pack and their skin to prevent a potential burn.

ASSESSMENT OF PAIN. Pain, sometimes considered the fifth “vital sign,” must be recognized as an important assessment focus throughout the postpartum period. Nurses play an important role in assessing, planning, and implementing interventions to manage maternal pain effectively. Pain should be recognized and treated in a timely manner. The failure to manage pain effectively has been associated with numerous complications, including prolonged recovery, increased length of hospital stay, depression, anxiety, poor coping, and altered sleep patterns.

Discomfort and pain may occur from several sources. Afterpains, which most commonly occur in the multiparous patient, can be quite intense, especially after breastfeeding. Analgesics such as acetaminophen (e.g., Tylenol) or nonsteroidal anti-inflammatory agents (NSAIDs) such as ibuprofen (e.g., Motrin, Advil) are effective and safe for use. Heat is not applied to the abdomen because of the potential for uterine relaxation and bleeding.

Muscular aches and cramps related to the physical exertion expended during labor and birth may be relieved with back rubs and massage. When necessary, acetaminophen (e.g., Tylenol) may be used to alleviate the discomfort. Pain occurring in the calf of the leg must be carefully evaluated for thromboembolic disease. Episiotomy pain and discomfort may be associated with sitting, walking, bending, urinating, and defecating. It may interfere with the woman’s ability to comfortably hold and feed her infant. Interventions to decrease discomfort from the episiotomy include the application of cold (first 24 hours) and heat, and the use of topical anesthetic creams, sprays, and sitz baths. The **sitz bath** is a portable unit with a reservoir that fits on the toilet. When filled with warm water, the swirling action of the fluid soothes the tissue, reduces inflammation by promoting vasodilation to the area, and provides comfort and healing. The nurse prepares and assists the patient to the sitz bath, which should be used for 20 minutes three to four times a day (Procedure 15-1).

Optimizing Outcomes— Enhancing comfort and healing with a sitz bath

A sitz bath is a warm-water bath taken in the sitting position that covers only the perineum and buttocks. It can be placed in the toilet, with the seat raised. Other mechanisms

for taking a sitz bath include sitting in a tub filled with 4–6 inches of warm water or the use of a nonportable sitz bath unit (similar to a toilet that fills up with warm water). A sitz bath may be used for either healing or hygiene purposes. The water may contain medication. Sitz baths are used to relieve pain, itching, or muscle spasms.

The patient likely has expectations regarding pain management during the postpartum phase. She should be encouraged to express her requests or concerns regarding pain control. Education regarding the available modalities is essential and will likely enhance the patient’s perception of control, as well as her level of satisfaction with the nursing care received. The nurse should regularly assess for pain and medication side effects and actively involve the patient in her pain management regimen. Use of a standardized pain rating scale enhances the assessment by allowing the patient to select the pain intensity level being experienced.

The nurse assesses and documents the patient’s pain behavior regarding the:

- Location of the pain
- Type of pain: stabbing, burning, throbbing, aching
- Duration of pain: intermittent or continuous

Nursing interventions include the administration of analgesics and patient education about other measures to promote comfort.

- Suggest nonpharmacological methods for pain relief such as imagery, therapeutic touch, relaxation, distraction, and interaction with the infant.
- Provide pain relief by administering prescribed agents such as ibuprofen, propoxyphene napsylate/acetaminophen (Darvocet-N), or oxycodone/acetaminophen (Percocet).
- Suggest over-the-counter medications and alternative therapies such as tea tree oil for self-care after hospital discharge. Teach the patient that medications such as acetaminophen or ibuprofen may be equally as effective as narcotic analgesics.
- Reassure the patient that the pain and discomfort should not persist beyond 5 to 7 days and that since the episiotomy sutures are made of an absorbable material, they will not need to be removed.

Complementary Care: Tea tree oil to facilitate episiotomy healing

Tea tree (*Melaleuca alternifolia*) oil applied to the perineum is believed to be beneficial in facilitating healing of the episiotomy site. *Melaleuca alternifolia* oil has been in use as a botanical medicine in various forms for centuries. For hundreds of years, the Australian aboriginal people have used tea tree oil as an antiseptic, antimicrobial, and anti-inflammatory agent. The anti-inflammatory properties are believed to be particularly helpful in promoting incisional healing (Halon & Milkus, 2004) although allergic contact dermatitis may occasionally occur (Stonehouse & Studdiford, 2007).

Postpartum women with episiotomies may be taught to fill an applicator with tea tree oil and then apply the oil directly to the wound. A few drops of the oil provide cooling to the wound, relieve pain, enhance comfort, and promote healing.

Procedure 15-1 Preparing a Sitz Bath

Purpose

To facilitate healing through the application of moist heat.

Equipment

- Sitz bath tub/toilet insert with water receptacle
- Medications to be added to water or saline, as ordered
- Towels for drying the perineal area after the treatment
- Clean perineal pad to be applied after the treatment

Steps

1. Wash your hands, identify the patient, and explain the procedure.

RATIONALE: Hand washing helps to prevent infection. Patient identification ensures that the procedure is performed on the correct patient. Providing an explanation educates the patient and helps to alleviate anxiety.

2. Assess the patient to confirm that she is able to ambulate to the bathroom.

RATIONALE: A sitz bath can cause dizziness and increase the potential for injury. It is important to ascertain that the patient can safely ambulate to the bathroom before initiating the procedure.

3. Assemble equipment and ensure that all equipment is clean.

RATIONALE: Gathering all equipment before the procedure enhances efficiency.

4. Raise the toilet seat in the patient's bathroom.

5. Insert the sitz bath apparatus into the toilet. The overflow opening should be directed toward the back of the toilet.

6. Fill the collecting bag with water or saline, as directed, at the appropriate temperature (105°F [41°C]).

7. Test the water temperature. It should feel comfortably warm on the wrist.

RATIONALE: Ensuring a correct water temperature reduces the chance of thermal injury. The flow of warm water to the perineum promotes healing by increasing circulation and reducing inflammation.

8. If prescribed, add medications to the solution.

9. Hang the bag overhead to allow a steady stream of water to flow from the bag, through the tubing, and into the reservoir.

10. Assist the ambulating patient to the bathroom. Help with removal of the perineal pad from front to back. Assist the patient to sit in the basin.

RATIONALE: Assistance with ambulation reduces the chance for patient injury. Removal of the pad from front to back decreases the risk for infection transmission. Proper placement on the seat ensures comfort and effectiveness of the treatment.

11. Instruct the patient to use the tubing clamp to regulate the flow of water. Ensure that the patient is adequately covered with a robe or blankets to prevent chilling.

RATIONALE: The swirling warm water helps to reduce edema and promote comfort. Clothing and extra blankets for warmth prevent chilling and enhance patient comfort.

12. Verify that the call bell is within reach and provide for privacy.

RATIONALE: Easy access to the call bell reassures the patient that prompt assistance is readily available when needed.

13. Encourage the patient to remain in the sitz bath for approximately 20 minutes.

RATIONALE: After 20 minutes, vasoconstriction occurs and heat is no longer therapeutic.

14. Provide assistance with drying the perineal area and applying a clean perineal pad by grasping the pad by the ends or bottom side.

RATIONALE: Holding the pad correctly decreases the risk for contamination and subsequent infection.

15. Assist the patient back to the room.

RATIONALE: After the procedure, the patient may be fatigued or light headed from the warm water; assistance minimizes the risk of injury.

16. Assess the patient's response to the procedure. Reinforce teaching about continued perineal care at home.

RATIONALE: Assessment helps to determine the effectiveness of the procedure; teaching enhances understanding and promotes continuity of care after discharge.

17. Record completion of the procedure, the condition of the perineum, and the patient's tolerance.

RATIONALE: Documentation provides evidence of the intervention and an additional opportunity for evaluation of care and the patient's tolerance of the procedure.

Clinical Alert The warm environment associated with a sitz bath may cause the patient to feel light-headed or dizzy. It is important to monitor the patient frequently throughout the intervention to ensure safety and tolerance.

(continued)

Procedure 15-1 Preparing a Sitz Bath (continued)

Teach the Patient

1. The benefits of using the sitz bath, which include enhanced hygiene, comfort, and improved circulation
2. To use the sitz bath as often as recommended—usually three to four times per day or as needed for discomfort
3. To contact the nursing staff immediately if she becomes light-headed or dizzy
4. To check the temperature of the solution before use. Applying water or solution that is too warm may result in local trauma or burns to the area

Note

If the patient prefers to prepare a sitz bath in the tub at home, she should be instructed not to use the same water for bathing. Instead, fresh water should be drawn for washing to diminish the potential for infection.

Caution: The nurse must check the temperature of the water before administration of the sitz bath to ensure that it is not too warm.

Documentation

6/29/09 1500 Patient reported perineal discomfort. Mild perineal edema noted. Patient assisted into bathroom for sitz bath. Tolerated sitz bath with warm water for 20 minutes. She denied any discomfort or syncope throughout treatment. Perineal care was provided and a new peripad was applied. The patient was assisted back into bed. She denies perineal pain at present.

-Olga Sanchez, RN

Homans' Sign

Homans' sign is often used in the assessment for deep venous thrombosis (DVT) in the leg. To assess for Homans' sign, the patient's legs should be extended and relaxed with the knees flexed. The examiner grasps the foot and sharply dorsiflexes it (Fig. 15-4). No pain or discomfort should be present. The other leg is assessed in the same manner. If calf pain is elicited, a positive Homans' sign is present. The pain occurs from inflammation of the blood vessel and is believed to be associated with the presence of a thrombosis. Pain on dorsiflexion is indicative of DVT in approximately 50% of patients. Thus, a negative Homans' sign does not rule out DVT. A diagnosis based solely on the evaluation of clinical signs that include pain in the calf, erythema, warmth greater in one calf than the other, and unequal calf circumference has proven to be unreliable. Instead, specific diagnostic procedures (e.g., venography, real-time and color Doppler ultrasound) should be performed when DVT is suspected. (See Chapter 16 for further discussion.)

Figure 15-4 Assessing for Homans' sign.

Emotional Status

The birth of a child is associated with a range of emotional experiences in the new mother. During the early puerperium, it is not unusual for patients to have periods of happiness that are intermingled with sadness, insecurity, and depression. Continued assessment of the woman's emotional status is an important nursing action that begins immediately after childbirth and continues throughout the hospital stay. The nurse should offer support to the new mother, which may include listening to her share her labor experience or reassuring her about her ability to effectively care for the newborn. The nurse should also provide information regarding the "baby blues," and emphasize that these feelings are common and temporary (Horowitz & Goodman, 2005).

Now Can You— Discuss essential components of postpartum nursing care?

1. Identify three types of lochia and explain the characteristics and duration of each?
2. Describe nursing interventions to promote healing, enhance comfort, and prevent infection in the patient with an episiotomy?
3. Discuss the nurse's role in pain assessment of the postpartal patient?

Maternal Physiological Adaptations and Continued Assessment of the Patient

HEMATOLOGICAL AND METABOLIC SYSTEMS

During the immediate postpartum period, a decrease in blood volume correlates with the blood loss experienced during delivery. During the next few days after childbirth, the maternal plasma volume decreases even further as a

Nursing Care Plan Acute Pain/Discomfort in the Postpartal Patient

Nursing Diagnosis: Acute Pain related to tissue damage secondary to childbirth

Measurable Short-term Goal: The patient will report decreased pain to a level that is acceptable to her.

Measurable Long-term Goal: The patient will report minimal or no pain upon discharge from the hospital.

NOC Outcomes:

- Pain Level (2102) Severity of observed or reported pain
- Pain Control (1605) Personal actions to control pain

NIC Interventions:

- Pain Management (1400)
- Analgesic Administration (2210)
- Heat/Cold Application (1380)

Nursing Interventions:

1. Perform routine, comprehensive pain assessments to include: onset, location, intensity, quality, characteristics, and aggravating and alleviating factors of the discomfort. Note verbal and nonverbal indications of discomfort.

RATIONALE: Routine, comprehensive pain assessments enable the nurse to provide interventions in a timely manner to enhance effectiveness of medications and ensures early identification of complications resulting in painful stimuli.
2. Ask the patient to rate her pain on a standard 0 to 10 pain scale before and after interventions and to identify her own acceptable comfort level on the scale.

RATIONALE: Use of a consistent pain scale provides objective measurement of the patient's perception of pain, the effectiveness of interventions, and the acceptable comfort level for the individual.
3. Identify cultural or personal beliefs about the experience of pain and the use of pain interventions, including prescribed medications.

RATIONALE: Expression of pain and use of pain relief interventions may vary according to culture and personal beliefs. Patients may prefer a stoic response to pain or fear becoming addicted to narcotics.
4. Provide factual, nonjudgmental information regarding pain interventions that are available to the patient. Encourage use of culturally based comfort measures when appropriate.

RATIONALE: Accurate information and respect for the individual's experience and preferences empowers the patient and reduces psychic discomfort.
5. Offer an ice pack to the perineum if the patient experienced perineal trauma or episiotomy. Apply for 20 minutes followed by removal for 10 minutes.

RATIONALE: Cold therapy causes vasoconstriction and reduces edema resulting in decreased pain. Periodic removal avoids thermal injury.
6. Assist the patient with a sitz bath as ordered if the patient experiences perineal discomfort.

RATIONALE: Cool water in the sitz bath decreases pain associated with edema while warm water promotes vasodilation and increased circulation to promote healing and provide comfort.
7. Teach the patient to apply topical medications for perineal or hemorrhoid pain as ordered.

RATIONALE: Topical anesthetics, such as Dermoplast spray, produce localized pain relief by inhibiting conduction of sensory nerve impulses. Tucks pads contain witch hazel, which has astringent properties to shrink hemorrhoids and reduce perineal edema.
8. Teach the patient about the sources of pain and the effects of prescribed medications and interventions. Encourage her participation in developing a pain management plan.

RATIONALE: Information and involvement increases the patient's perception of control and increases her personal satisfaction with postpartum pain management.

result of diuresis. The 500-mL blood loss that typically accompanies a vaginal birth (1000 mL for a cesarean birth) usually results in a 1 gram (2 grams for a cesarean birth) drop in hemoglobin. It is important for the nurse to remember that as the body's excess fluid is excreted, the hematocrit may rise due to hemoconcentration. However, the hematocrit should have returned to pre-pregnancy levels by 4 to 6 weeks postpartum.

The white blood cell (WBC) count, which increases during labor and in the immediate postpartum period,

returns to normal values within 6 days. Levels of plasma fibrinogen tend to remain elevated during the first few postpartal weeks. Although this alteration exerts a protective effect against hemorrhage, it increases the patient's risk of thrombus formation. Overall, the hematologic system has usually returned to a nonpregnant status by the third to fourth postpartal week.

Circulating levels of estrogen and progesterone decrease dramatically after delivery of the placenta. The decline in these two hormones signals the anterior pituitary gland to

produce prolactin in readiness for lactation. In nonlactating (formula feeding) women, prolactin levels return to normal by the third to fourth postpartal week.

After childbirth and expulsion of the placenta, circulating levels of other hormones, including placental lactogen, cortisol, growth hormone, and insulinase, also fall. During the early postpartum period, the decline in the serum levels of these substances reduces the anti-insulin effects that occur during pregnancy. Hence, insulin requirements are reduced for insulin dependent women during this time, sometimes termed a “honeymoon phase.” For many insulin-dependent diabetics, glucose levels remain in a normal range (without intervention) during the first few days after childbirth (Chan & Winkle, 2006).

NEUROLOGICAL SYSTEM

Fatigue and discomfort are common complaints after childbirth. The demands of the newborn frequently create altered sleep patterns that contribute to increased maternal fatigue. Anesthesia and analgesia received during labor and birth may cause transient maternal neurological changes such as numbness in the legs or dizziness. When these changes are present, the nursing priority is to safeguard the patient and her infant and prevent injury from falls.

Complaints of headaches require further nursing assessment. Patients who received epidural or spinal anesthesia may experience headaches, especially when they assume an upright position. After spinal or epidural anesthesia, headaches may result from the leakage of cerebrospinal fluid into the extradural space. Labor-induced stress or gestational hypertension may also cause headaches. It is essential that the nurse assess the quality and location of the headache and carefully monitor maternal vital signs. Headaches that are accompanied by double or blurred vision, photophobia, epigastric or abdominal pain, and proteinuria may be signs of a developing or worsening preeclampsia. Report these findings immediately to the primary health care provider. Implement environmental interventions such as reducing the room lighting and noise levels and limiting visitors. The physiological edema of pregnancy is dramatically reversed during postpartum diuresis. Patients who experienced medial nerve compression and carpal tunnel syndrome during pregnancy often obtain relief of symptoms.

RENAL SYSTEM, FLUID, AND ELECTROLYTES

The renal plasma flow, glomerular filtration rate (GFR), plasma creatinine and blood urea nitrogen (BUN) return to pre-pregnant levels by the second to third month after childbirth. Urinary glucose excretion increases in pregnancy by 100-fold over nonpregnant values. These values return to nonpregnant levels after the first postpartal week. Pregnancy-associated proteinuria (up to 1+ on a urine dipstick or less than 300 mg in 24 hours) is common during pregnancy and generally returns to pre-pregnancy values by 6 weeks postpartum (Cunningham et al., 2005).

During the postpartum period, there is a rapid, sustained natriuresis (excessively large amount of sodium in the urine) and diuresis as the sodium and water retention of pregnancy is reversed. The physiological reversal is particularly pronounced during the second to fifth puerperal days. In most women, the body's fluid and electro-

lyte balance has been restored to a nonpregnant homeostatic state by the third postpartal week.

After childbirth, a decrease in levels of oxytocin and estrogen naturally occurs and contributes to diuresis. As the serum levels decline, the diuresis becomes more pronounced. Nurses often note a maternal urinary output that reaches 3000 mL excreted in a 24-hour period. For the postpartum patient, a single voiding may contain 500 to 1000 mL of urine.

Now Can You—Describe early postpartal physiological adaptations in the metabolic, neurological, and renal systems?

1. Explain what is meant by the “honeymoon phase” and why this may occur?
2. Identify possible causes and describe appropriate nursing assessments for patients who complain of headache?
3. Discuss physiological adaptations in the renal system and identify one patient teaching need related to these adaptations?

RESPIRATORY SYSTEM

Respiratory alkalosis and compensated metabolic acidosis occur during labor and may persist into the postpartum period. In most situations, however, after delivery of the placenta and the decline in levels of progesterone, the respiratory system quickly returns to a pre-pregnant state. In addition, the immediate decrease in intra-abdominal pressure associated with the birth of the baby allows for increased expansion of the diaphragm and relief from the dyspnea usually associated with pregnancy. By the third postpartal week, the respiratory system has returned to a pre-pregnant state.

INTEGUMENTARY SYSTEM

Changes in the skin during pregnancy and in the postpartum period are related to the major alterations in hormones. Women may experience alterations in pigmentation, connective and cutaneous tissue, hair, nails, secretory glands, and pruritus. Most pregnancy-related skin changes disappear completely during the postpartum period although some, such as striae gravidarum (stretch marks) fade but may remain permanently.

Ethnocultural Considerations—Pregnancy-related skin changes in the puerperium

Although abdominal stretch marks (striae gravidarum) appear more pronounced immediately after childbirth, they tend to fade over the following 6 months. In Caucasian women, striae become pale and white in color; in African American women, they will appear as a slightly darker pigment.

CARDIOVASCULAR SYSTEM

During pregnancy, the heart is displaced slightly upward and to the left. As involution of the uterus occurs, the heart returns to its normal position. Dramatic changes in the maternal hemodynamic system result from birth of the baby, expulsion of the placenta, and loss of the amniotic

fluid. These abrupt alterations can create cardiovascular instability during the immediate postpartum period. Despite the usual blood loss (500 mL with a vaginal birth; 1000 mL with a cesarean birth), the maternal cardiac output is significantly elevated above prelabor levels for 1 to 2 hours postpartum and remains high for 48 hours postpartum. The cardiac output returns to pre-pregnant levels within 2 to 4 weeks after childbirth.

On average, a 3-kg weight loss occurs during the first postpartal week. Diuresis takes place between the second and fifth day. A major fluid shift involves the movement of extracellular fluid back into the venous system for excretion through urine and perspiration. If the physiologic diuresis does not occur, there is an increased risk of pulmonary edema. The cardiac output and stroke volume remain elevated for at least 48 hours after childbirth. Within 2 weeks, the cardiac output has decreased by 30% and then reaches pre-pregnant values by 6 to 12 weeks postpartum in most women (Cunningham et al., 2005).

IMMUNE SYSTEM

The WBC count is increased during labor and birth and remains elevated during the early postpartum period, gradually returning to normal values within 4 to 7 days after childbirth. Depending on the patient's blood type and immune status, administration of RhoGAM (see below) may be indicated. Women who are rubella susceptible during pregnancy should receive the MMR (measles–mumps–rubella) vaccine at the time of hospital discharge; varicella vaccine should also be encouraged (American College of Obstetricians and Gynecologists [ACOG], 2003).

Rh_o(D) Immune Globulin

Nonsensitized women who are Rh_o(D)-negative and have given birth to an Rh(D)-positive infant should receive 300 mcg of Rh_o(D) immune globulin (RhoGAM) within 72 hours after giving birth. RhoGAM should be given whether or not the mother received RhoGAM during the antepartum period. In some situations, depending on the extent of hemorrhage and exchange of maternal–fetal blood, a larger dose of RhoGAM may be indicated. (See Chapter 11 for further discussion.)

Rubella Vaccine

Before discharge, the patient needs to be assessed for rubella immunity. If nonimmune (rubella titer less than 1:8, or antibody negative on the enzyme-linked immunosorbent assay [ELISA]), the MMR vaccine should be administered. The nurse should counsel the patient about the need to avoid pregnancy for 1 month after receiving the vaccine (due to the teratogenic effects associated with congenital rubella syndrome) and advise her that she may briefly experience rubella-type symptoms such as lymphadenopathy, arthralgia, and a low-grade fever. The vaccine may be safely given to breastfeeding mothers. A signed consent form must be obtained before administration of the vaccine (ACOG, 2003).

REPRODUCTIVE SYSTEM

The uterus undergoes a rapid reduction in size (involution) and returns to its pre-pregnant state in about 3 weeks. The former site of the placenta heals by the process of exfolia-

tion, which ensures that the placental site heals without leaving a fibrous scar. Formation of scar tissue would limit areas for future implantation and adversely affect the potential for future pregnancies. After a vaginal birth, the vagina often appears edematous or bruised and superficial lacerations may be present. Although swelling is resolved during the healing process, the vagina does not return to its nulliparous size and the labia majora and labia minora remain more flaccid in the multiparous woman (Cunningham et al., 2005).

During the postpartum phase, the return of ovulation and menstruation varies according to the individual. Menstruation usually resumes within 6 to 8 weeks after childbirth in women who are not breastfeeding. Seventy-five percent menstruate by the twelfth postpartal week. The first cycle is often anovulatory. The return of ovulation and menstruation is typically prolonged in lactating women. Those who exclusively breastfeed may not ovulate or menstruate for 3 or more months. It is important to educate patients that since ovulation can precede menstruation, breastfeeding is not a reliable method of contraception.

GASTROINTESTINAL SYSTEM

Owing to hormonal effects, gastric motility is decreased during pregnancy. It is further decreased during labor and in the first few postpartal days due to decreased abdominal wall tone. Abdominal discomfort results from gaseous distention related to decreased motility and abdominal muscle relaxation. Constipation, a common nursing diagnosis for the postpartal patient, is associated with abdominal discomfort and decreased hunger. Straining to pass hard stool can cause hemorrhoids and tear episiotomy sutures. Although spontaneous bowel movements usually resume by the second or third day after childbirth, it is important to educate the patient about strategies to prevent constipation. Stool softeners may be necessary. Additional nursing diagnoses for the postpartal patient focus on a variety of other problems such as pain, fatigue, and sleep disturbances, infant feeding difficulties and knowledge deficit (Box 15-2).

Box 15-2 Common Nursing Diagnoses During the Puerperium

- Breastfeeding, ineffective/effective
- Risk for constipation
- Sleep-pattern disturbed
- Fatigue
- Pain, acute
- Activity intolerance
- Skin integrity, risk for impaired
- Knowledge, deficient regarding self-care or care of infant
- Risk for infection
- Family processes parenting impaired
- Risk for situational low self-esteem related to body image changes
- Risk for urinary retention

MUSCULOSKELETAL SYSTEM

During pregnancy, the pelvic joints and ligaments have increased laxity. The hormones relaxin and progesterone are believed to contribute to the relaxation of the soft tissues (muscles, ligaments, and connective tissue) in the maternal pelvis to create room for the birthing process. In some women, the loosening of the pelvic joints causes pain and functional limitations.

During the first few days after childbirth, the woman may experience muscle fatigue and general body aches from the exertion of labor and delivery of the baby. Muscle fatigue can be exacerbated by the extended lack of nutrition and fluids throughout the course of labor. The maternal expenditure of glucose during **parturition** (the act of giving birth) can also add to muscle fatigue and may interfere with the patient's ability to ambulate and initiate postpartum exercises. The nurse needs to assure the patient that the muscular discomforts are temporary and not indicative of a serious medical problem.

During pregnancy, the abdominal walls are stretched to accommodate the growing fetus. The progressive stretching causes a decrease in the muscle tone of the rectus muscles of the abdomen and results in the soft, flabby, and weak muscles experienced after birth. Rectus abdominis diastasis is a conventional term used to define the split between the two rectus abdominis muscles that can occur from pregnancy. Women should be aware that during the early postpartal period, the abdominal wall may not be sufficiently protected to withstand additional stress from increased activities. Nurses should teach them to maintain correct posture when performing activities such as lifting, carrying, and bathing the baby for at least 12 weeks after birth. Performing modified sit-ups during this time is beneficial in helping to strengthen the abdominal muscles.

 **Now Can You—** Describe postpartal physiological adaptations in the respiratory, cardiovascular, and reproductive systems?

1. Explain why pregnancy-related dyspnea is relieved in the early postpartal period?
2. Describe three intra-postpartal events that cause dramatic changes in the maternal hemodynamic system?
3. Identify when ovulation and menstruation usually occur in the postpartal woman and explain specific information that should be given to lactating mothers?

Care for the Multicultural Family

ENHANCING CULTURAL SENSITIVITY

According to the United States Census Bureau (2001), ethnic and racial diversity in the U.S. population has reached new levels. At present, the population includes 77.1% Caucasians, 12.9% African Americans, 12% Hispanics, 4.2% Asians, 1.5% Native Americans/Alaska Natives, 0.3% Native Hawaiian/other Pacific Islanders, and 2.4% as persons who describe themselves as members of other races. Diversity in the population reaches into the health care sector and has prompted emphasis on cultural awareness in nursing education curricula and mandatory in-service offerings for hospital staff.

Culturally competent care involves knowledge of the various dimensions of care, including moving beyond the biomedical needs of the patient. Rather, a holistic approach is one that expands knowledge, changes attitudes, and enhances clinical skills. To provide optimal care in a variety of clinical settings, it is important for health care professionals to conduct cultural assessments and expand their knowledge and understanding of culturally influenced beliefs, common health care practices, customs, and rituals (Taylor, 2005). In preparation for the cultural assessment, health care providers should:

- Assess their own cultural beliefs, identifying personal biases, stereotypes, and prejudices.
- Make a conscious commitment to respect and value the beliefs of others.
- Learn the customs and rituals of the common cultural groups within the community.
- Seek input from patients regarding health-related traditions and practices.
- Evaluate if what is about to be taught is really better than what the patient is already doing for herself.
- Adapt care to meet the special needs of the patient and her family, as long as standards of health and safety are not compromised.
- Include cultural assessment as a routine part of perinatal health care.

CULTURAL INFLUENCES ON THE PUERPERIUM

In certain multicultural populations such as India, Thailand, and China, the woman's postpartum confinement lasts for 40 days. During this time, prolonged rest with restricted activity is believed to be essential. The postpartum period is an important time for ensuring future good health; thus great emphasis is placed on allowing the mother's body to regain balance after the birth of a child.

During the 40-day confinement, support for the mother is provided by the female family members, usually the woman's mother, sister(s), and mother-in-law, who perform household chores such as cooking and caring for the siblings and new baby. The woman's mother or older female relative often prescribes cultural remedies to aid in recovery and promote good health in the future. The female family members also provide the new mother with information on caring for herself and activities to avoid. Lack of adequate rest and poor diet are believed to result in poor eyesight, varicose veins, digestive disorders, headache, and backache (Davis, 2001).

Certain beliefs regarding hot and cold exist among several multicultural groups. Blood is considered "hot," and because the postpartum woman loses blood, she is considered to be in a "cold" state. To avoid illness, the mother must restore her health status by moving from a cold to hot state. The mother accomplishes this by:

- Adopting a diet that includes drinking/eating hot foods (foods such as black pepper, ginger, and garlic are believed to improve blood circulation). Sour foods such as lemons, grapefruits, and oranges are discouraged because they are thought to cause urinary incontinence later in life if eaten too early during the puerperium.

- Avoiding the consumption of ice water or cold water. These cold beverages are believed to cause weakness and delay healing.
- Avoiding cold temperatures, which are thought to be detrimental to the mother's recovery. To maintain warmth, the mother dresses warmly and stays in bed for several days. Bathing, showering, and washing the hair is delayed for 40 days because water cools the body.
- Avoiding drafts by keeping doors and windows closed and avoiding fans and air-conditioning.

CLINICAL IMPLICATIONS OF CULTURALLY APPROPRIATE CARE

To provide sensitive, appropriate care, nurses need to adopt a flexible approach when caring for women who embrace non-Western health beliefs and practices. Inquiring about cultural beliefs, and, when possible, incorporating the beliefs into the plan of care are important strategies to help achieve this goal. For example, to demonstrate sensitivity to beliefs regarding hot and cold, the nurse may offer a warm sponge bath instead of a shower, adjust the thermostat in the room and provide extra blankets for warmth; offer warm drinks instead of cold beverages; and allow female family members as much access to the mother as possible.

Now Can You— Provide culturally sensitive postpartal care?

1. Identify at least five ways that health care providers can enhance cultural sensitivity before conducting a cultural assessment?
2. Describe several cultural beliefs concerning “hot” and “cold” and identify specific nursing interventions that allow women to adhere to these beliefs?

Promoting Recovery and Self-Care in the Puerperium

ACTIVITY AND REST

In the postpartum period, it is important for the new mother to begin ambulating as soon as her condition permits. Despite recent advances in diagnosis and treatment, deep vein thrombosis after birth continues to constitute a leading cause of maternal morbidity and mortality. Venous stasis and hypercoagulation, conditions that exist in pregnancy, are continued into the postpartum period. Early postpartum ambulation is key in preventing maternal thromboembolic events.

The type of birth and overall health status determines how soon the patient is allowed to resume exercise. The woman should be taught to begin with mild exercises, such as Kegel exercises, to strengthen the pelvic floor muscles. Nonambulating patients may begin with leg exercises. All exercise methods should be increased gradually.

Many women enter labor fatigued from the discomforts of pregnancy and lack of satisfying sleep associated with the third trimester. The length of labor and demands of the new mothering role further increase the feelings of exhaustion. During the hospital stay and later at home, all

patients should be encouraged to obtain adequate sleep and frequent rest periods to help facilitate an optimal recovery.

NOURISHMENT

A weight loss of approximately 10 to 12 lbs. (4.5 to 5.5 kg) occurs immediately after childbirth, and this amount is directly related to the collective weights of the baby, placenta, and amniotic fluid. An additional 5 lbs. (2.3 kg) is lost over the following week as a result of puerperal diuresis and uterine involution. How quickly the woman returns to her pre-pregnancy weight depends on her physical activity level, eating habits, and lifestyle. Olson, Strawderman, Hinton, and Pearson (2003) noted that women whose weight increase was within the recommended limit of 25 to 30 lbs. (11.4 to 13.6 kg) during pregnancy could anticipate a return to the pre-pregnancy weight by 6 to 8 weeks postpartum. Factors associated with weight changes during the postpartum period include gestational weight gain, frequency of exercise, dietary intake, and breastfeeding for longer than 1 year.

Because of the restriction of food during labor, most patients demonstrate a hearty appetite after childbirth. All parturient women should be encouraged to eat a balanced, nutritious diet with multivitamin supplements. Iron is recommended only if the patient's hemoglobin is low.

ELIMINATION

Voiding should occur within 4 hours of childbirth. Patients should be encouraged to empty the bladder every 4 to 6 hours and to expect to excrete large volumes of urine. In addition to the extra- to intravascular fluid shift that follows childbirth, there is a decrease in the production of the adrenal hormone aldosterone. Declining levels of aldosterone are associated with a decrease in sodium retention and an increase in urinary output.

An intake and output record should be maintained to monitor the volume of urine passed during the first 24 hours. The woman who has recently given birth is prone to urinary stasis and retention. Incomplete bladder emptying or urinary retention may result from trauma to urethral tissue sustained during the “pushing phase” of a vaginal birth. Also, patients who were catheterized or who received regional anesthesia during childbirth sometimes experience an absence of the sensation to void. Bladder hypotonia during labor may also lead to postpartal urinary retention or stasis, factors that increase the risk of infection.

Incomplete emptying of the bladder is suspected when the patient experiences urinary frequency and passes 100 to 150 mL of urine with each voiding. The nurse's assessment includes careful palpation of the lower abdomen to identify a distended or displaced uterus. The uterine fundus is felt above the symphysis pubis with a lateral displacement of the uterus. The nurse also notes an increase in the amount of lochia since the uterus is unable to contract effectively. The bladder is displaced, bulges above the symphysis pubis, and feels “boggy” on palpation. Patients experiencing urinary retention due to absence of the urge to void can be helped by assisted early ambulation to the toilet and other measures such as running the water from the lavatory faucet. If ambulation is

not possible, the nurse can pour warm water over the vulva and perineal area to help relax the urethral sphincter. Owing to the risk of urinary infection associated with urinary stasis, catheterization may be necessary if the patient is unable to void.

Constipation commonly occurs because of slowed peristalsis associated with pregnancy hormones and childbirth anesthesia. In addition, perineal discomfort, fear of suture separation at the episiotomy site, and incisional pain (after a cesarean birth) may contribute to decreased frequency in bowel movements. To prevent constipation, nurses should encourage patients to consume foods high in fiber and roughage. Adequate fluid intake that includes drinking at least six to eight glasses of water or juice daily is another important strategy to prevent constipation. Early ambulation is also encouraged to improve peristalsis and relieve abdominal gas pain. If these measures are not effective, the primary care provider may prescribe a stool softener, suppository, or enema to alleviate the symptoms.

PERINEAL CARE

The perineum is susceptible to infection because of impaired tissue integrity resulting from bruising, laceration, or an episiotomy. The proximity of the perineum to the anus increases the risk of the incision becoming contaminated with fecal material; continuous drainage of blood creates a favorable medium for the proliferation of bacteria. To minimize infection, patients should be taught about perineal hygiene. A teaching approach that incorporates a return demonstration, encouragement, and positive reinforcement is most likely to be successful. Instructions should be given about properly cleansing the perineal area and the value of sitz baths, which not only cleanse but also provide relief from discomfort during the first 24 to 48 hours postpartum.

Patients should be educated about the importance of cleansing the perineum after each voiding and bowel movement. Hand washing before and after perineal care (“pericare”) is essential for the prevention of infection. The nurse instructs the patient to gently rinse her perineum with fresh warm water after use of the toilet and before a new perineal pad is applied. The patient is taught to fill the peri-bottle (hand-held squirt bottle) with warm tap water and gently squirt the water toward the front of the perineum and allow the water to flow from front to back. Consistent use of the peri-bottle is soothing, cleansing, and helps to relieve discomfort. Peri-pads should be changed often and secured in the underwear to allow for free drainage of the lochia. Tampons are contraindicated due to the risk of infection.

The nurse provides pericare for patients recovering from cesarean births until they are ambulatory and able to perform personal self-care. To provide pericare for the bed-bound patient, a plastic-covered pad is placed under the patient’s buttocks to protect the bed during the procedure. With the woman in a supine position, the nurse carefully removes the perineal pad in a front-to-back direction. This prevents the portion of the pad that touched the rectal area from sliding forward and contaminating the vagina. Next, a bedpan is positioned under the buttocks. The movement associated with lifting the buttocks helps to expel clots and/or pooled blood in the vaginal canal. This also serves as a good time to assess the fundus for tone. Uterine palpation

may be beneficial in helping the patient expel additional blood or clots. The nurse uses a peri-bottle filled with warm water (or other solution used according to hospital policy) and gently squirts the perineum from front to back while allowing the water to collect in the bedpan. The labia are not separated because they prevent the solution from entering the vagina. The perineal area is then gently dried and a clean peripad is applied from front to back.

Optimizing Outcomes— Teaching about perineal care

To enhance the patient’s understanding about proper perineal care, the nurse provides the following instructions:

1. Fill the squeeze/peri bottle with tap water. The water should feel comfortably warm on your wrist.
2. Sit on the toilet with the bottle positioned between your legs so that water can be squirted directly on the perineum. Aim the bottle opening at your perineum and spray so that the water moves from front to back. Do not separate the labia and do not spray the water into your vagina. Empty the entire bottle over the perineum— this should take approximately 2 minutes.
3. Gently pat the area dry with toilet paper or cotton wipes. Move from front to back, use each wipe once, then drop it in the toilet.
4. Grasping the bottom side or ends of a clean perineal pad, apply it from front to back.
5. Stand before flushing the toilet to prevent the water from the toilet from spraying onto your perineum.

Ice Packs

To reduce perineal swelling and pain that result from bruising, ice packs may be applied every 2 to 4 hours. Application of cold is beneficial because of its vasoconstriction and numbing effects. The ice pack should always be covered and applied from front to back. It should be left in place for no longer than 20 minutes to minimize the complications associated with prolonged vasoconstriction. Patients obtain the most relief when ice packs are applied within the first 24 hours after childbirth.

DISCOMFORT RELATED TO ATERPAINS

Afterbirth pains describe intermittent uterine contractions that occur during the process of involution. In general, the pains are more pronounced in patients with decreased uterine tone due to overdistention. Uterine overdistention is associated with multiple gestation, multiparity, macrosomia, and hydramnios. Afterpains also tend to be more intense in breastfeeding women because infant suckling and/or pumping the breasts triggers an endogenous release of oxytocin, the hormone that initiates the milk-ejection reflex. Oxytocin causes powerful uterine contractions. Afterbirth pain maybe severe for 2 to 3 days after childbirth. Mild analgesics should provide relief.

SPECIAL CONSIDERATIONS FOR WOMEN WITH HIV/AIDS

Women who have the human immunodeficiency virus (HIV) or acquired immunodeficiency syndrome (AIDS) require special precautionary care during the puerperium.

All personnel who come in close contact with the patient should wear latex gloves (unless the patient has a latex allergy). In that situation, nonlatex gloves are used, as well as safety glasses to prevent the transmission of blood and body fluids. Patients need to be taught to avoid contact of personal body fluids with the infant's mucous membranes and open skin lesions. Breastfeeding is not advised due to the risk of transmission of HIV to the infant. (See Chapter 11 for further information.)

Now Can You—Promote recovery and self-care in the puerperium?

1. Identify factors that determine how quickly patients should return to the pre-pregnant weight?
2. Describe the essential components of patient teaching about perineal care?
3. Describe special precautions that should be taken for postpartal HIV-positive women?

Care of the Postpartal Surgical Patient

PERMANENT STERILIZATION (TUBAL LIGATION)

A postpartum tubal ligation is a procedure that blocks the fallopian tubes to prevent the woman from becoming pregnant. When requested, the procedure, called a mini-laparotomy, is performed after childbirth while the mother is still hospitalized. The size and position of the uterus during the early puerperium facilitates the surgical procedure. When a cesarean birth has been performed, the tubal ligation may be done at the same time. Patients need to be informed that while it is typically considered to be a permanent form of fertility control, there is a small chance that a future pregnancy may occur. (See Chapter 6 for further discussion.)

Patients scheduled for a tubal ligation are NPO before the surgical procedure. If epidural anesthesia was used for childbirth, the catheter is often left in place so that the patient can be re-anesthetized easily. When no epidural was previously placed, general anesthesia will most likely be used during surgery.

CARE OF THE PATIENT AFTER A CESAREAN BIRTH

Nursing care of the postoperative postpartum patient is similar to the care provided to all postoperative patients. The nurse must complete the BUBBLE-HE assessment previously discussed. Because the woman is confined to bed until full sensation has returned to the lower extremities, interventions for the prevention of deep vein thrombosis (DVTs) must be implemented. Preventive strategies include leg exercises (flexion and extension of the knee) and application of compression boots as ordered by the physician.

How the patient reacts to her surgery is often tied to the circumstances surrounding the birth—that is, whether the cesarean section (“c-section”) was a planned procedure or an emergency event. Women who experience an emergency or unplanned cesarean birth may suffer from

extreme disappointment, feelings of inadequacy, guilt, and personal failure. They may also harbor hostilities directed toward the medical and nursing staff. (See Chapter 16 for further discussion.)

After a cesarean birth, especially when unplanned, nurses must be aware of the myriad of potential psychological issues that may arise. Research suggests that women may perceive cesarean birth to be a less positive experience than a vaginal birth. Vaginal birth has been shown to be associated with enhanced maternal satisfaction and perceptions of greater personal control over the birth. Women who experience vaginal birth describe feelings of empowerment, elation, and achievement (Lavender, Hofmeyr, Nielson, Kingdon, & Gyte, 2007). Particularly for unplanned or emergent cesarean deliveries, the experience of cesarean birth may be associated with more negative perceptions of the birthing experience. However, research regarding the psychological outcomes associated with cesarean birth remains mixed (Patel, Murphy, & Peters, 2005).

The benefits of maternal–child interaction during the early postpartal hours are well documented. The first few hours after childbirth constitute a critical time for the initiation of a healthy maternal–infant interaction. For most mothers, a successful vaginal birth is psychologically better tolerated and avoids the need for additional recovery time that is necessary after a cesarean birth. In addition, early breast feeding (for those who wish to breast feed) is more easily implemented after a vaginal birth.

Additional challenges faced by patients during recovery from a cesarean birth include recovery from the anesthesia, a need to cope with incisional and gas pain, and slow ambulation. Mother–infant bonding may be delayed and patients are at an increased risk for hemorrhage, surgical wound infection, urinary tract infections, and DVT. (See Chapter 16 for additional information.)

CARE OF THE INCISIONAL WOUND

The surgical incision requires ongoing nursing assessment after a cesarean birth. The nurse should assess for approximation of the wound edges, and make note of any redness, discoloration, warmth, edema, unusual tenderness, or drainage. If a dry sterile dressing has been applied, the surrounding tissue should be carefully evaluated for evidence of a reaction to the tape used to secure the dressing. Assessing for and effectively treating incisional pain is also of paramount importance.

RECOVERY FROM ANESTHESIA

Ambulation is encouraged as soon as the patient's vital signs are stable. If a spinal or epidural anesthesia was used, ambulation is delayed until full sensation has returned to the lower extremities. Common side effects of anesthesia include paresthesias (sensation of pins and needles in the legs) and headache. Assistance is required when the patient gets out of bed for the first time. Nurses should administer pain medication 30 minutes before the patient attempts ambulation. To minimize dizziness from orthostatic hypotension, the nurse should instruct the patient to sit on the side of her bed for several minutes before moving into a standing position.

Respiratory Care

Incisional pain and abdominal distension often cause patients to adopt shallow breathing patterns that can lead to decreased gas exchange and a reduced tidal volume. To facilitate adequate lung functions, patients should be taught how to perform pulmonary exercises. After being placed in a high Fowler's position, the patient is shown to use a pillow to support her incision and instructed to take a deep breath and cough. Respiratory therapists are often included in the team approach to care for postoperative patients. Expectoration of secretions and deep breathing help prevent common complications including atelectasis and pneumonia. The nurse should administer pain medication 15 to 30 minutes before the patient begins her respiratory exercises.

Abdominal distension and gas pains are common after abdominal surgery and result from delayed peristalsis. Breakdown of digested food in the colon produces a buildup of gas that results in distension and discomfort. Anesthesia also causes a delay in the return of peristalsis and it usually takes several days for the intestinal function to return.

Until bowel sounds are present, the nurse should offer the patient ice chips and small sips of water only. The diet is slowly advanced as tolerated. To minimize gas pains and stimulate the return of peristalsis, frequent ambulation is encouraged.

An indwelling Foley catheter connected to a closed drainage system remains in place for approximately 24 hours after a cesarean birth. While the catheter is in place, the nurse must assess for urine output of at least 150 mL/hr and maintain appropriate perineal care to reduce the risk of urinary tract infection. Once the catheter has been removed, the patient is at risk for urinary retention and her output must be closely monitored. The nurse can help facilitate the return of normal voiding patterns by encouraging early ambulation to the toilet, ensuring privacy, allowing water to run in the lavatory, and pouring warm water on the perineum. If the patient is unable to void within 6 hours, a diagnosis of urinary retention should be considered and catheterization may be necessary.

Now Can You— Provide nursing care for the surgical postpartal patient?

1. Identify nursing assessments appropriate for the postoperative postpartum patient?
2. Describe maternal psychological issues that may accompany a cesarean birth?
3. Discuss nursing interventions to facilitate ambulation and lung expansion?

Facilitating Infant Nourishment: Educating Parents to Make Informed Choices

Holistic care during the puerperium includes educating women and their partners about infant nutrition and providing support to facilitate success with the feeding method chosen. By the time they enter the postpartum phase of childbearing, most women have already made a

decision about infant feeding. Providing current, evidence-based information, offering clinical guidance, and identifying appropriate resources when needed empowers patients to achieve success in nourishing and nurturing their newborn.

Breastfeeding has long been established as the optimal method of infant feeding and current trends are reflective of the public's awareness of its value. Today, more women in the United States are breastfeeding their babies than at any time in modern history. While the rate of breastfeeding has increased in all demographic groups, certain populations of women are less likely to breastfeed. These include women younger than 25 years of age; those with a lower income; primiparas; African Americans; those who participate in the special Supplemental Nutrition Program for Women, Infants, and Children (WIC); those with a high school education or less; and those who are employed full time outside of the home (Johnston & Esposito, 2007).

Human breast milk is the ideal infant food choice. It is bacteriologically safe, fresh, readily available and balanced to meet the infant's needs. According to the American Academy of Pediatrics, "human milk is species-specific, and all substitute feeding preparations differ markedly from it, making human milk uniquely superior for infant feeding" (Gartner et al., 2005). When discussing infant feeding options with parents, nurses can share factual information about the physiological and psychological benefits of breastfeeding (Box 15-3). There are economic benefits as well: breastfeeding reduces the cost of feeding and preparation time. Providing such information may reinforce the mother's decision to breastfeed or help women and their partners in the decision-making process. The partner's level of support with the infant feeding method is an important factor in the woman's decision and success. There are only a few situations in which breast feeding is contraindicated:

- Infants with galactosemia (due to an inability to digest the lactose in the milk)

Box 15-3 Selected Breastfeeding Benefits

FOR MOTHERS

- Decreased risk of breast cancer
- Lactational amenorrhea (LAM) (although breastfeeding is not considered an effective form of contraception)
- Enhanced involution (due to uterine contractions triggered by the release of oxytocin) and decreased risk of postpartum hemorrhage
- Enhanced postpartum weight loss
- Increased bone density
- Enhanced bonding with infant

FOR INFANTS

- Enhanced immunity through the transfer of maternal antibodies; decreased incidence of infections including otitis media, pneumonia, urinary tract infections, bacteremia and bacterial meningitis
- Enhanced maturation of the gastrointestinal tract
- Decreased likelihood of developing insulin-dependent (type 1) diabetes
- Decreased risk of childhood obesity
- Enhanced jaw development
- Protective effects against certain childhood cancers

- Mothers with active tuberculosis or HIV infection
- Mothers with active herpes lesions on the nipples
- Mothers who are receiving certain medications, such as lithium or methotrexate
- Mothers who are exposed to radioactive isotopes (e.g., during diagnostic testing)

Despite knowledge of the benefits of breastfeeding some women choose to formula feed. Concerns about convenience, opportunity to involve the father in the baby's care, and modesty and embarrassment may be factors that influence the mother's decision. An unsuccessful breastfeeding experience during a previous pregnancy may also play a role. Some women anticipate that breastfeeding will interfere with plans to return to work. Whatever the reasons, the nurse must provide information and support in a caring, nonjudgmental manner. Postpartal women who planned to bottle feed may still benefit from education about the benefits of breast milk over formula (Miller, Cook, Brooks, Heine, & Curtis, 2007). The nurse's offer of breastfeeding support and assistance may encourage some women to change their chosen feeding method. The importance of the nurse's role in the promotion of breastfeeding has been underscored in an AWHONN clinical position statement (1999; available at <http://www.awhonn.org/awhonn/content.do?name=05HealthPolicyLegislation/5HPositionStatements.htm>).

Optimizing Outcomes— Supporting women in their infant feeding choice

Although breast milk provides the best nutrition choice for infants, the decision to breastfeed is always one that must be made by the woman. She should make the choice based on what pleases her and makes her feel most comfortable. If the woman is pleased and comfortable with her choice, the infant will also be pleased and comfortable and both will benefit from the experience.

ENHANCING UNDERSTANDING OF THE PROCESS OF LACTATION

Normal Structure of the Breast

The breast is composed of glandular, connective, and fatty tissue. The lactating breast contains lobes that house the milk production cells called aveoli (alveolus), fatty tissue, and a series of small and main ducts. The ducts converge into 9 to 10 duct openings in the nipple (Fig. 15-5). According to most published literature, each breast contains 15 to 20 lobes although recent ultrasound studies have demonstrated variations that range from 4 to 18 lobes per breast (Ramsay, Kent, Hartmann, & Hartmann, 2005). Each lobe has a small duct that unites with others to form a main duct. The lobes are connected by areolar tissue and blood vessels. The ducts function to collect milk from the alveolus and transport it toward the nipple. The Cooper's ligaments, along with the fatty adipose tissue, give shape to the breasts and provide support to the ductal system (Fig. 15-6).

The areola, a 15- to 16-mm circular pigmented structure, darkens and enlarges with pregnancy. The Montgomery tubercles are small sebaceous glands in the areola that enlarge during pregnancy. They secrete a waxy substance

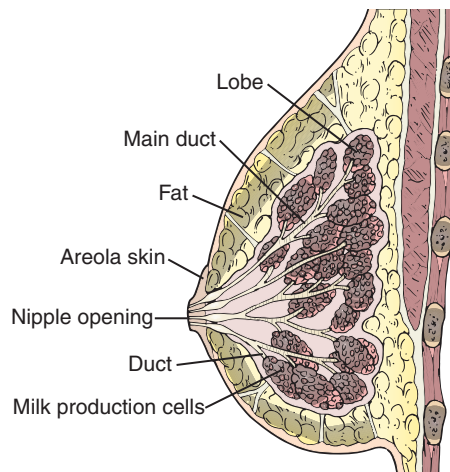

Figure 15-5 Cross section of a lactating breast.

that acts as a lubricant and contains anti-infective properties that protect the nipples. The nipple, a mass of conical erectile tissue, is located in the center of the areola and projects a few millimeters from the center of the breast. Circular smooth muscles surround the areola and cause the nipple to become erect with stimulation. The main ducts converge and open into the nipple (Riordan, 2005).

Blood and Nerve Supply and Lymphatic Drainage

There is an abundant vascular supply to the breasts. Approximately 60% of the blood supply to the breasts comes from the internal mammary artery. The remainder is supplied by branches of the intercostal, subclavian, and axillary arteries (Lawrence & Lawrence, 2005). Branches from the mammary arteries anastomose around the nipples and areolae and provide blood to those structures.

The fourth, fifth, and sixth intercostal nerves provide innervation to the breasts. The fourth nerve enters into the posterior aspect of the breast (anatomically, in the position of 4 o'clock on the left breast; 8 o'clock on the right breast) and provides maximum sensation to the nipple and the areola. The areola is the most sensitive area of the breast; the nipple itself is the least sensitive area. Damage to the intercostal nerves can result in some loss of sensation to the breast (Riordan, 2005). Loss of sensation may prevent the nipple from protruding and becoming erect in preparation for a baby's latching-on to breastfeed.

The breasts contain an extensive lymphatic network. The skin covering the breasts houses superficial lymph

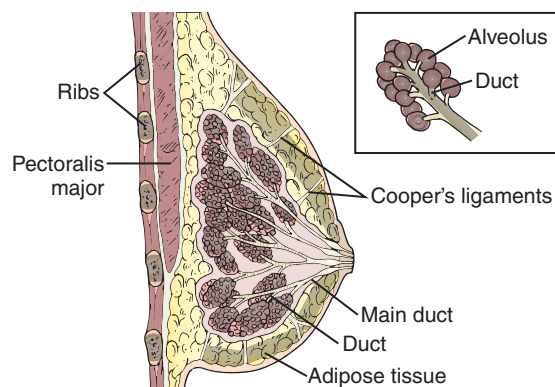

Figure 15-6 The ductal system of the breast.

channels that serve the chest wall and are continuous with the superficial lymphatics of the neck and abdomen. A rich network of lymphatics is also present deep in the breasts. The primary deep lymphatics drain laterally toward the axillae.

The Physiology of Lactation

MILK PRODUCTION AND LET-DOWN. **Lactogenesis**, the process by which the breasts secrete milk, is dependent on the release of the hormones prolactin and oxytocin. The process of milk synthesis begins after the delivery of the placenta. This event results in a dramatic decrease in plasma progesterone and estrogen and an increase in the secretion of prolactin from the anterior lobe of the pituitary gland. Prolactin stimulates the alveoli, or milk-producing cells, to secrete milk. Stimulation from infant suckling or pumping the breasts triggers the release of oxytocin from the posterior lobe of the pituitary gland. Oxytocin prompts contraction of the smooth muscle myoepithelial cells surrounding the alveoli to eject milk from the alveoli into the lactiferous (main) ducts (Fig. 15-7). Movement of milk into the large lactiferous ducts for removal is called the “**milk ejection reflex**” or the “**let-down**” reflex. Lactating mothers describe “let-down” as a tingling or pins and needles sensation that occurs immediately before or during breastfeeding. Frequent stimulation and release of milk from the breasts are necessary for the continued release of prolactin.

The initiation of milk production is divided into three stages. Stage 1 occurs in late pregnancy and is characterized by the maturation of the alveoli, the proliferation of the secretory alveoli ductal system, and the increase in size and weight of the breast. Stage 2 begins during the postpartum period. Reduced plasma progesterone levels lead to an increase in prolactin levels that cause a copious milk production by the fourth to fifth postpartal day. Stage 3, the establishment and maintenance of the milk supply, is governed by a principle of “supply and demand”

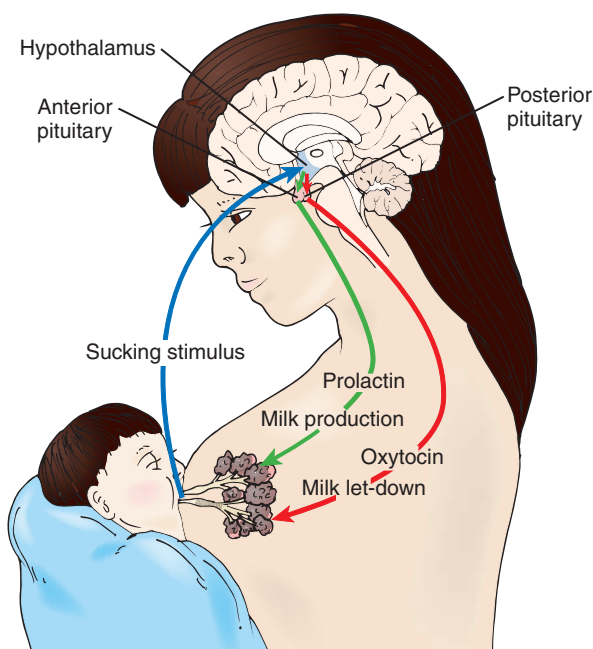

Figure 15-7 Mechanism for milk production.

and continues until breastfeeding ceases. The “weaning” stage, sometimes referred to as “Stage 4,” begins when breast stimulation ceases. This stage is characterized by a significant reduction in milk volume.

A lack of breastfeeding (in breastfeeding or non breastfeeding mothers), or a failure to empty the breasts by pumping, results in an accumulation of inhibiting peptides, or hormones released from the hypothalamus. Inhibiting peptides act on the breast secretory cells, causing a gradual decrease in milk volume and the eventual death of the epithelial cells.

ASSISTING THE MOTHER WHO CHOOSES TO BREASTFEED: STRATEGIES FOR BREASTFEEDING SUCCESS

The most important information that the nurse can give to a mother is that breastfeeding should not be painful. When the baby is feeding at the breast, the woman should experience a strong tugging sensation and occasional mild discomfort. However, pain associated with breastfeeding is not a normal finding. The nurse should refer women who experience breastfeeding pain or other difficulties to a board-certified lactation consultant (IBCLC) for help and assistance. Although the pediatrician is responsible for the health care of the infant, the IBCLC is a lactation expert who offers the most current, up-to-date, accurate information on breastfeeding using a “hands-on” approach. Mothers should be encouraged to consult with an IBCLC when they have any questions, are having difficulty with the latch-on process, or express concerns about their milk production. Ideally, all breastfeeding mothers should be discharged with an appointment to an IBCLC.

Collaboration in Caring—Partnering with an IBCLC and other community resources

An IBCLC is a health care professional who specializes in the clinical management of breastfeeding. IBCLCs are certified by the International Board of Lactation Consultant Examiners Inc. under the direction of the US National Commission for Certifying Agencies. IBCLCs work in a variety of health care settings including hospitals, pediatric offices, public health clinics, and private practice. The IBCLC credential is primarily an add-on qualification that brings together health professionals from different disciplines who share a common knowledge base in human lactation. Among those who become IBCLCs are midwives, nurses, family practitioners, pediatricians, obstetricians, educators, dietitians, and occupational, speech, and physical therapists. Most of these health care professionals have spent at least 4 years acquiring the experience and education required for certification.

Costs for services provided by IBCLCs depend upon the environments in which they work. Charges for inpatients are typically incorporated into the hospital stay. Follow-up visits in a hospital-based lactation department may or may not be included as a benefit for giving birth at that facility. Other consultations are fee-for-service. Most insurance companies do not pay for lactation services unless the service is provided within a physician’s office under the supervision of the physician. Under these circumstances, the office visit charges may apply.

Many government sponsored health programs such as the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) provide breastfeeding support services that are staffed by breastfeeding peer counselors. A mother who indicates that she is breastfeeding and is part of the WIC program will be provided with a special food package for herself and for her newborn. The La Leche League, an international support organization for breastfeeding mothers, is another resource that may be available in the community.

Optimizing Outcomes— Care of the breasts during lactation

The nurse should teach breastfeeding mothers to wash the nipples with warm water. Soap, which can have a drying effect and cause cracked nipples, should be avoided. Breast creams are also to be avoided. They may block the natural oil secreted by the Montgomery tubercles on the areolae; others contain alcohol, a drying agent. Creams or oils that contain vitamin E should also be avoided because the infant may absorb toxic amounts of the fat-soluble vitamin.

Initiating the Feeding

The optimal time to breastfeed is when the baby is in a quiet alert state. Crying is usually a late sign of hunger and achieving satisfactory latch-on at this time is difficult.

Latch-on is proper attachment of the infant to the breast for feeding. The neonate is most alert during the first 1 to 2 hours after an unmedicated birth, and this is the ideal time to put the infant to the breast. Bathing the neonate before the first breastfeeding should be avoided. The smell of the amniotic fluid on the infant matches the smells of the mother and serves as a “homing device” for the baby. Cesarean deliveries and medicated births, including those with epidural anesthesia, may require more mother–infant skin to skin contact before a successful latch-on occurs.

To assist the breastfeeding mother, the nurse must understand that a baby latched on to the breast is not necessarily transferring milk. A baby that breastfeeds effectively cues (shows readiness) for feedings, is in a good feeding position, latches-on (attaches) deeply at the breast, and moves milk forward from the breast and into the mouth. When the infant is properly latched-on to the breast, the tip of his nose, cheeks and chin should all be touching the breast (Fig. 15-8).

To feed effectively, the infant must awaken and let his mother know that he wants to eat. When possible, mother-baby rooming-in creates an optimal situation for breastfeeding. When the infant is in the mother’s room at all times, she is able to observe “feeding-readiness cues” that signal the infant’s readiness to feed (Box 15-4).

“What to say” — *To assist the mother whose infant won’t awaken to breastfeed*

During hospitalization, nurses provide much information and coaching regarding breastfeeding. One new mother expresses her concern that her infant is too sleepy to breastfeed.

Figure 15-8 When properly latched-on, the tip of the infant’s nose, cheeks and chin should all be touching the breast.

The nurse may ask:

- Have you tried to unwrap the baby’s swaddling? Doing this will increase skin-to-skin contact and help to awaken the infant and promote feeding.
- Have you tried to rest with the baby by your breast? Doing this may allow the infant to feel and/or smell the breast, which may promote feeding.
- Are you familiar with feeding cues? Watching for feeding cues may help you to recognize when your baby is ready to breastfeed. Examples of infant feeding cues are vocalizations, movements of the mouth, and moving the hand toward the mouth. Hunger-related crying is a late sign of hunger and should not be used as the cue for feeding.

An optimal breastfeeding experience begins with the mother’s prompt response to her infant’s feeding readiness cues (Cadwell et al., 2006). The mother should hold the baby so that his nose is aligned with the nipple and watch

Box 15-4 Infant Feeding-Readiness Cues

The infant demonstrates readiness for feeding when she:

- Begins to stir.
- Bobs the head against the mattress or mother’s neck/shoulder.
- Makes hand-to-mouth or hand-to-hand movements.
- Exhibits sucking or licking.
- Exhibits rooting.
- Demonstrates increased activity; arms and legs flexed; hands in a fist.

for an open mouth gape. At the height of the gape, when the mouth is open widest, the mother should aim the bottom lip as far away as possible from the base of the nipple. With this action, the infant's chin and the lower jaw meet the breast first and the nipple is pointed to the roof of the mouth. To facilitate a proper latch-on, it is desirable that the nipple be aligned with the baby's nose. This position allows the baby to tilt his head upward slightly so that the chin and lower jaw drops, creating the wide open gape desired. Next, the infant's mouth should be placed 1 to 2 inches beyond the base of the nipple. Depending on the areola size, most of the areola should be visible from the infant's top lip but not from the bottom lip. The top and bottom lips should be flanged outward. When properly positioned, there should be no slurping or clicking sounds or dimpling of the cheeks. Also, the mother should report a tugging sensation but no pain or pinching. If any of these are present, the infant should be removed from the breast by instructing the mother to insert her finger into the corner of the baby's mouth to break the seal. As an alternative, the mother can gently lift up and push back on the baby's upper lip (Fig. 15-9).

Optimizing Outcomes— Assessing for milk let-down

The nurse assesses for cues that indicate that the milk let-down reflex has occurred:

- The mother reports a tingling sensation in the nipples (not always present).
- The infant's quick, shallow sucking pattern transitions to a slower, more drawing pattern.
- The infant exhibits audible swallowing.
- The mother reports uterine cramping; increased lochia may be present.
- The mother states she feels extremely relaxed during the feeding.
- The opposite breast may leak milk.

Once the baby is latched on correctly, he must suckle and transfer milk. There should be a 2:1 or 1:1 suck/swallow ratio with audible swallowing to indicate that milk transfer is occurring. A 5:1 or higher suck/swallow ratio is indicative of non-nutritive suckling. Non-nutritive suckling can result in poor milk supply and lead to poor infant weight gain.

Figure 15-9 Infant latch-on. *A.* Nipple is aligned with the baby's nose. *B, C.* As the baby latches to the nipple, the baby's mouth is placed one to two inches beyond the base of the nipple. *D.* To remove the baby from the breast, the mother inserts her finger into the corner of the baby's mouth to break the seal.

Feedings that last less than 10 minutes or continue for longer than 40 minutes are not satisfactory and require consultation and assessment by a lactation consultant.

Optimal feeding results in the infant coming off the breast without assistance. Once the feeding has ended, the infant should be in a relaxed state with hands open; he may or may not be asleep. After a successful breastfeeding experience, mothers often describe their baby as having a “drunken stupor” look. The nipple should be everted and round, never flat or pinched on any side. The mother should report no pain and the infant should appear satiated.

EVALUATION OF NOURISHMENT: INFANT WEIGHT GAIN

All newborns are expected to lose weight during the early days of life. A newborn who is feeding frequently and effectively, in general, may lose an average of 5% of his birth weight (American Academy of Pediatrics [AAP], 2004). Any infant who loses more than 7% of his birth weight should be carefully evaluated to make sure that he is being fed frequently enough and that the feeding technique is effective in transferring milk from the mother's breast.

An infant weight loss of greater than 7% is not an “automatic” reason to supplement breast feedings with formula. The administration of formula may interfere with the baby's interest in feeding at the breast and his ability to learn appropriate breastfeeding techniques.

Nursing Insight— Preventing nipple confusion

Nipple confusion may result when breast fed infants receive supplemental feedings. Essentially, the infant exhibits difficulty in knowing how to latch-on to the breast. Nipple confusion occurs because breastfeeding and bottle feeding require different skills. Sucking and swallowing patterns as well as the way the tongue, cheeks, and lips are used vary considerably between breast and bottle feeding. The infant's tongue is pulled backward when sucking from the breast; it is thrust forward when sucking from a rubber nipple. Parents should be taught to avoid bottles until breast feeding is well established (usually 3 to 4 weeks).

Once the mother's milk production increases and the volume of milk consumed increases, most infants begin to gain 15 to 30 g or 1/2 to 1 oz. per day (AAP, 2004). This rate of gain continues for the first several months of life. Loss of excessive weight or failure to begin a steady pattern of weight gain indicates that the mother is not producing adequate milk, or the infant is not ingesting adequate milk, or, much less commonly, the infant has other organic problems. In most instances, correcting latch-on difficulties and proper positioning improves milk transfer from the breast to the baby. As long as the baby continues to feed well and is gaining weight the mother can be reassured not to worry.

POSITIONS FOR BREASTFEEDING

Common positions for nursing a baby include cradle hold, cross-cradle hold, football, and side-lying (Fig. 15-10). In the cradle hold position, the infant is cradled

in the arm, close to the maternal breast. The infant's abdomen is placed against the mother's abdomen with the mother's other hand supporting the breast. The cross cradle hold is similar to the cradle hold, although in this hold, the infant is laying in the opposite direction. In the

Figure 15-10 Common positions for breastfeeding. A. Cradle hold position. B. Football hold position. C. Side-lying position.

football hold, the infant's back and shoulders are held in the palm of the mother's hand. The infant is tucked up under the mother's arm, keeping the infant's hip, shoulder, and ear in alignment. The mother supports the breast to touch the infant's lips. Once the infant's mouth is open, the mother pulls the infant toward the breast. In the side-lying position, both the mother and the infant lay on their sides. Facing one another, the mother should place a pillow behind the infant's back for support. The nipple should be placed within easy reach for the infant with the mother guiding the nipple into the infant's mouth (Lawrence & Lawrence, 2005).

Now Can You— Discuss the physiology of lactation and assist the breastfeeding mother?

1. Describe the four stages involved in the process of lactation?
2. Discuss techniques the breastfeeding mother can use to promote proper "latch-on"?
3. Explain what the mother should be taught regarding the infant's weight?
4. Demonstrate four common breastfeeding positions?

PROBLEMS THAT RESULT IN INEFFECTIVE BREASTFEEDING

Sore nipples are related to an incorrect latch-on and positioning of the infant at the breast. If a mother complains of pain when the infant is nursing, it is important to observe the baby for correct latch-on during feeding. The nurse can assess for proper latching by making the following observations when the infant is at the breast: maternal–infant positioning is optimal for feeding; the infant exhibits a flanged lower lip, there is a good seal between the mouth and nipple, and an audible swallow. Successful latch-on is essential to prevent trauma to the nipple. The shape of the nipple at the conclusion of the feeding also provides a good indicator for correct latching. If the nipple shape has changed at the end of the feeding, the nurse should troubleshoot for specific problems and teach the mother about correct latch and positioning techniques.

Optimizing Outcomes— Breast shells for flat, inverted, or sore nipples

Breast shells, which are plastic "nipple cups," or inserts that fit into the bra, are useful for women with flat or inverted nipples because they help the nipples to become more protruberant. They may also be used to prevent sore nipples from making contact with the woman's clothing or bra.

Breast **engorgement** is described as excessive swelling and overfilling of the breast and areola and is a physiological response to an increase in blood flow and an increase in milk production. Engorgement, which may occur from infrequent feeding or ineffective emptying of the breasts, results in congestion and overdilation of the collecting ductal system and obstruction of lymphatic drainage. It typically lasts about 24 hours. Symptoms of engorgement usually occur between the third and fifth day after childbirth (when the milk "comes in")

and vary from minimally engorged (patients complain of breast fullness and discomfort) to severe engorgement, characterized by symptoms of pain, tenderness, hardness and warmth to the touch. With severe engorgement, swelling of the breasts is profuse and extends from the clavicle to the tail of Spence and the lower rib cage. The breasts may have a shiny, taut appearance. The areolae become very firm and the nipples may flatten, making it difficult for the infant to latch-on. Back pressure exerted on full milk glands inhibits milk production. Thus, if milk is not removed from the breasts, the milk supply may decrease. Treatment involves relieving the patient's discomfort by removal of the milk (via breast feeding or pumping) to decrease stasis, which reduces the swelling and discomfort.

Because the infant is very efficient in the removal of milk, frequent feeding (at least every 2 to 3 hours) is advised to minimize the stasis of milk. The infant should feed at each breast at least 15 to 20 minutes until at least one breast softens after the feeding. To help reduce the swelling and enhance milk flow, the nurse should instruct the mother to use warm compresses and perform hand expression before nursing. This action softens the areola, initiates the let-down reflex, and allows the infant to more easily grasp the areola. Massaging the breasts during feedings is also beneficial. Other methods to enhance milk flow and help facilitate infant latch-on include taking a warm shower or leaning over a bowl of warm water and hand-expressing some milk before nursing. Since breast swelling is related to increased blood flow, cold ice packs may be used after breastfeeding or pumping to constrict blood flow and reduce the edema.

Complementary Care— Cabbage leaves to diminish breast swelling

Patients can be taught to place raw cabbage leaves over their breasts between feedings to help reduce swelling. First, several large cabbage leaves are washed, then stored in the refrigerator until they become cool. The leaves are then crushed and placed directly on the breasts for 15 to 20 minutes. This process may be repeated two to three times only; frequent application of the cabbage leaves may decrease the milk supply. Women who are allergic to cabbage, sulfa drugs, or who develop a skin rash should not use cabbage leaves (Lactation Education Resources, 2004).

A nonprescription anti-inflammatory medication such as ibuprofen (e.g., Motrin, Advil) may be taken for the pain and swelling related to engorgement. It may be particularly helpful for the mother to take the medication before breastfeeding in anticipation of postfeeding discomfort. Because of the significant increase in breast size during lactation, patients should be advised to wear well-fitting supportive bras with no underwire for comfort. Bras that are too small may compress the ducts and obstruct milk flow. If the infant is unable to breastfeed, warm soaks, breast massage and the use of a manual or electric pump for the expression of milk help to reduce milk stasis and swelling.

Ethnocultural Considerations— Cultural influences and interventions for breastfeeding discomfort

When educating mothers regarding management of breastfeeding-related discomfort, the nurse must consider the cultural background of the patient. Many non-Western cultures such as Asian, Latin, and African cultures embrace a hot and cold “humoral theory.” Breastfeeding mothers from these cultures may choose not to utilize a cold modality for the relief of breast engorgement or discomfort. Although the nurse may explain the clinical rationale for applying ice packs to the breasts, the patient is culturally bound to adhere to her beliefs. Nurses must remain sensitive to culturally influenced customs and allow patients to use relief measures that do not conflict with their personal beliefs.

COLLECTING AND STORING BREAST MILK

Collecting and storing breast milk is a necessity for mothers who are separated from their infants due to problems such as prematurity or illness. In other situations, women may elect to return to school or work and wish to have breast milk available for feeding by another individual. Freshly pumped breast milk can be safely stored at room temperature for four hours or refrigerated at 34 to 39°F (0°C) for 5 to 7 days after collection. Milk kept in a deep freezer at 0°F (−19°C) can be stored for 6 to 12 months (Lawrence & Lawrence, 2005).

The oldest milk should be used first, unless the pediatrician recommends the use of recently expressed milk. Women should be taught to thaw breast milk by placing the collection container in the refrigerator. The thawing process may be accelerated by holding the collection container under warm running water or by placing it in a cup, pot, bowl, or basin of warm water. Breast milk should not be allowed to thaw at room temperature, in very hot water, or in the microwave oven. Microwaving the breast milk container can create “hot spots” and use of the microwave oven or heating the container in very hot water may decrease the milk’s anti-infective properties. Breast milk separates during storage. The cream rises to the top, because breast milk is not homogenized. To mix the milk after storage, the collection container should be gently swirled, or rotated; vigorous shaking should be avoided. After the feeding, any milk that remains in the feeding container should be discarded and not saved for a later feeding. Thawed milk should never be refrozen.

Optimizing Outcomes— With manual (hand) and electric expression of breast milk

Performing manual or electric expression of breast milk is sometimes necessary because of medical complications or for occupational reasons. During the early postpartum period, the woman should be encouraged to frequently express her breast milk. This action helps to establish and increase the milk supply for later breastfeeding needs. Once lactation has been established, the mother should be encouraged to express milk, either manually or with an

electric breast pump, whichever method is most convenient or effective for her (Miller et al., 2007).

Electric Expression of Breast Milk

Women should be encouraged to avoid pumping the breasts until the infant is breastfeeding comfortably. Although the mother can help her baby learn to take a bottle once breastfeeding has been well established, it is best to wait for 3 to 4 weeks before introducing bottle feeding. The American Academy of Pediatrics (2004) recommends exclusive breastfeeding with no supplements, for the first 6 months of life.

The nurse teaches the woman to use hot, soapy water to wash her hands, all components of the breast pump that will touch her breasts and all collecting bottles before proceeding. Most equipment may also be safely cleaned in an automatic dishwasher. If soap and water are not available, many “quick clean” products may be safely used instead. Collecting bottles should be allowed to air dry on a clean towel.

The woman is encouraged to carefully read the instruction manual and practice pumping when she is rested, relaxed, and when her breasts feel full. The nurse can teach employed mothers to begin to pump and store breast milk 2 to 3 weeks before returning to work. The breasts should be pumped once a day, every day, 7 days a week. The first morning pumping usually produces the largest quantity of milk. If possible, the woman should nurse the baby on one breast while pumping the other breast. The breast milk may be stored in the refrigerator or freezer. The 7-day-a-week pumping schedule should continue even after the woman has returned to work (Tully, 2005).

Many employed mothers use the fresh breast milk they pump while at work for infant feedings the following day. For example, the breast milk pumped at work on Monday should be refrigerated and used on Tuesday. Mothers should be counseled to breastfeed the infant before leaving for work and then adhere to a set schedule of pumping and feeding each day. Breast milk collected (by pumping) on Friday and Saturday can be frozen for future use. Ideally, mothers should pump the breasts for each missed feeding, but two pumpings per work day during an 8-hour work shift is realistic for most women. The breasts should be pumped for 15 to 20 minutes or until the milk flow stops. Breastfeeding should be resumed during the evening and throughout weekends (Johnston & Esposito, 2007).

Types of Breast Pumps

A variety of manual and electric breast pumps are available, and, for most women, the choice is made according to needs, preferences, and financial resources. Hospital-grade electric breast pumps are designed for complete mother–baby separation. In these situations, the infant will not be able to breastfeed for an indeterminate period of time due to problems such as prematurity, surgery, or illness. Hospital-grade electric pumps are typically considered to be multiple-user rental equipment. Retail or “personal use” electric breast pumps are excellent alternatives to the rented hospital-grade pump (Fig. 15-11). These single-user electric breast pumps usually work well for the

Figure 15-11 Personal use electric breast pump.

working mother or in situations in which consistent pumping is needed. Occasional use battery powered or manual breast pumps are designed for the mother who needs to have extra milk only once in a while.

INFANT WEANING

When a mother decides to wean the baby from the breast, it is recommended that she begin by eliminating one feeding at a time. Usually the least favorite nursing time is the first one that is discontinued (Cadwell et al., 2006). After waiting for a few days, an alternate feeding time (not the one immediately before or after the one already discontinued) may be eliminated. Mothers should be advised to carefully observe the baby for signs of emotional or physical reactions (i.e., cow's milk allergy if formula is introduced). Babies sometimes choose to stop nursing although this does not usually occur with infants younger than 1 year of age. The American Academy of Pediatrics (2004) currently recommends breastfeeding for the first 12 months of life.

ASSISTING THE MOTHER WHO CHOOSES TO FORMULA-FEED HER INFANT

Information regarding formula choices should be offered to mothers who choose not to breastfeed. Formula preparations come in ready-to-feed cans that can be poured directly into a bottle, liquid concentrates that require dilution before feeding and powder formulas that are mixed with water.

A variety of bottles and nipples are also available, and selection is usually based on the parent's preference. For example, the mother may choose from glass bottles or plastic bottles with angled or straight nipples or convenience bottles with disposable liners. The nurse should remind the parents to periodically check the nipple integrity to ensure that the formula flows freely one drop at a

time. If the formula flows too quickly, the nipple should be discarded because it poses a risk for infant choking and aspiration.

Parents should also be advised to read and follow the manufacturer's instructions explicitly when preparing the formula. For example, no water should be added to the ready-to-feed preparations and care should be taken to correctly dilute the concentrate and powder preparations. Poorly prepared formula that is too concentrated (from adding an incorrect amount of water) may result in infant hypernatremia and dehydration. Formula that is too dilute may cause the infant to demonstrate symptoms of undernourishment and water intoxication.

Bottles and nipples must be thoroughly washed in hot soapy water with dishwashing detergent and then rinsed in hot clean water. They may also be cleaned in an automatic dishwasher. Some parents prefer to sterilize their equipment and a variety of commercial sterilizers that can be placed in a microwave oven are available for purchase at most baby stores. If boiling is the preferred cleaning method, parents should be instructed to wash the bottles, nipples, rings, discs and all other equipment used to prepare the formula in hot soapy water. The items are then well rinsed in hot, clean water, placed in a pot filled with enough water to cover the equipment and boiled for 5 to 10 minutes.

Although formula can be fed to the baby at room temperature, if warmed formula is preferred, the parents are instructed to place the prepared bottle of formula in a bowl of hot (not boiling) water for a few minutes. Alternatively, the prepared bottle of formula can be warmed in an electric bottle warmer available at most baby stores. It is important to emphasize to parents the need for testing the temperature of warmed formula before feeding. Parents are instructed to shake a few drops of formula on the inside of the wrist. The liquid should feel warm, but not hot.

When feeding the baby, parents should choose a comfortable chair, and hold the baby in their arms close to them with the baby's head higher than the rest of the body to prevent aspiration and minimize ear infection. Holding the baby skin-to-skin and maintaining full eye contact throughout the feeding helps to facilitate the bonding process. To prevent the baby from swallowing too much air, the bottle should be kept in an angled position with the nipple continuously filled with formula. Burping is usually performed midway and at the end of the feeding to remove excess air from the infant's stomach. To burp the baby properly, parents are taught to either hold the baby over their shoulder or on their lap with the baby's head supported. The baby's back is gently rubbed until air is expelled (Fig. 15-12).

Parents should be advised that babies usually spit up during burping and that this is normal. However, the pediatrician must be consulted if the baby vomits large amount of formula with burping or after feeding. Since babies eat more efficiently and take in the desired amount of formula when they are hungry, a "baby-driven" demand feeding schedule rather than a regimented feeding schedule is desirable. The pediatrician can provide guidelines regarding the volume of formula the baby needs.

Safe Practices for Bottle Feeding

When informing parents about the safety of formula, it is important for health care professionals to be aware that

Figure 15-12 One infant burping technique.

liquid formulas have been subjected to high temperatures to make the product sterile. Powdered formulas are not sterile because high temperatures destroy vital nutrients. The microorganism *Enterobacter sakazakii*, known to cause meningitis, has been identified in powdered formula. To minimize the risk of infection, health care professionals must provide accurate instructions to parents regarding the correct procedure for formula preparation, storage and reconstitution. Instructions given should emphasize the importance of good handwashing techniques before handling the equipment that is to be used to reconstitute the powder. The formula should never be mixed in a blender or stored in large amounts for longer than 24 hours. Cold water should be used to mix the powder, only the amount to be used for each feeding should be prepared, and any unused formula should be discarded. Parents should be cautioned not to use a microwave oven to prepare or warm the formula due to the potential for “hot spots” that can burn the infant’s mouth. They should also be taught to never prop the bottle to allow the infant to feed alone or put the infant to bed with a bottle. These practices may result in choking, ear infections, and tooth decay.

Optimizing Outcomes— Safely preparing infant formula

Nurses can provide the following safety instructions to parents who plan to formula feed their infant:

- Wash hands before beginning to prepare formula and after any interruptions.
- Always shake and wash tops of liquid formula cans before opening.
- Reconstitute the formula according to the manufacturer’s recommendations.
- Store the ready-to-feed formula according to the manufacturer’s recommendations.

- Shake the bottle well before feeding.
- Discard any formula that the infant does not drink.
- Wash thoroughly/sterilize all equipment used to prepare the infant formula and use a bottle and nipple brush to remove milk residue.
- Replace the nipples regularly.

Now Can You— Discuss breast milk storage and assist the mother who is bottle feeding her infant?

1. Explain what the breastfeeding mother should be taught about pumping and storing breast milk?
2. Discuss appropriate cleaning techniques for bottles and nipples?
3. Describe special precautions to be used with powdered formulas?

Promoting Family and Infant Bonding

FACILITATING THE TRANSITION TO PARENTHOOD

The transition to parenthood can be an especially difficult and challenging time for primiparous mothers with limited experience in infant care and for new parents who are experiencing social isolation from family or friends. Feelings of anxiety and inadequacy regarding parenting skills, lack of knowledge and confidence about providing baby care, emotional concerns, depression, and detachment toward the infant are all symptoms not infrequently expressed by first-time mothers. This information underscores the importance patients place on nurses and other health care professionals to provide emotional support and accurate information about self care and baby care.

An essential goal of nursing care at this time is to create a supportive teaching environment that increases the parents’ knowledge and confidence in caring for themselves and their infants. Using the principles of Family-Centered Care as a guideline, nurses can help parents cope with the emotional and physical changes that accompany the child-bearing year. To create a supportive teaching environment, the nurse can:

- Perform a needs assessment to identify the parents’ knowledge/skill deficits.
- Utilize good communication and listening skills to provide support.
- Empower the parents by assisting them in recognizing their own strengths.
- Facilitate parents’ actions to participate in the decision making process.
- Provide learning opportunities that move the parents from dependence to independence and self-reliance.

ASSUMING THE MOTHERING ROLE

Rubin (1975) described three distinct phases that are associated with the woman’s assuming the mothering role. She labeled these phases “Taking-in,” “Taking-hold,” and “Letting-go” (Table 15-6). At the time of Rubin’s work, women were traditionally hospitalized for 5-7 days after childbirth and nurses could readily observe their patients’

Table 15-6 Phases Associated with the Mothering Role

Phase 1: Taking-In	Phase 2: Taking-Hold	Phase 3: Letting-Go
<p>First 1–2 days</p> <p>The mother is recovering from the immediate exhaustion of labor.</p> <p>She is relatively dependent on others to meet her physical needs.</p> <p>Characteristics of her behavior include:</p> <ul style="list-style-type: none"> a) Physical exhaustion b) Elation, excitement, and/or anxiety and confusion. c) Reliving, verbally and mentally, the events of her labor and birth. 	<p>Second and/or third day</p> <p>The mother starts to initiate action and to begin some of the tasks of motherhood.</p> <p>She may:</p> <ul style="list-style-type: none"> a) Ask for help with self-care b) Begin caring for the baby c) Be anxious about her mothering abilities. 	<p>First 2–6 weeks postpartum</p> <p>This is the time during which the mother redefines her new role.</p> <p>She:</p> <ul style="list-style-type: none"> a) Moves beyond the mother–infant symbiosis of pregnancy and early postpartum and begins to see her infant as an emerging individual. b) Starts to focus on issues larger than those associated directly with herself and her newborn. (She begins to focus on her partner, other children, and family issues.)

Adapted from Rubin R. (1975). Maternal tasks in pregnancy. *MCN: The American Journal of Maternal-Child Nursing*, 4(3), 143–153.

transitions through each phase. Today, however, with shortened hospital stays, women seem to move through the transitions much more rapidly and often there is overlapping of the phases.

In the first day or two after birth, the mother is exhausted and should be encouraged to rest. During this time she is reflecting and clarifying, or “*taking-in*” her birth experience. Many mothers want to talk about their labor, discuss with family members the detailed events of the labor, seek clarification if unexpected events occurred, and share joys or disappointments associated with the birth. Mothers who hold specific expectations for their birth experience and are unable to follow a birth plan or who are required to transfer from a birth center to a hospital setting may experience feelings of loss and mourn for the hoped for birth experience.

As the mother’s physical condition improves, she begins to take charge, and enters the *taking-hold* phase where she assumes care for herself and her infant. At this time, the mother eagerly wants information about infant care and shows signs of bonding with her infant. During this phase, the nurse should closely observe mother–infant interactions for signs of poor bonding and if present, implement actions to facilitate attachment.

critical nursing action Assessing for Maternal–Infant Attachment

When observing the mother with her newborn, the nurse should look for clues that indicate successful bonding. The nurse should assess for the following indicators:

Does the mother show eagerness to care for her infant?

What is her response when the baby cries?

Does she make eye contact when holding and feeding her baby?

In the *letting-go phase*, seen later in the mother’s recovery, the woman begins to see the infant as an individual separate from herself. At this point, she can leave the baby with a sitter, set aside more time for herself, become more involved with her partner, and begin adapting to the reali-

ties of parenthood. Maladjustment during this phase may occur with an overprotective mother who has difficulty accepting help with infant care from others and who excludes the partner from her affections.

Across Care Settings: Successful maternal transition into the letting-go phase

During the letting-go phase, the mother may have difficulty with the tasks associated with viewing the infant as a separate individual. This phase occurs after the mother has been discharged from the hospital or birthing center. Postpartum and community health nurses who suspect that patients may have difficulty making a successful transition into this phase must communicate their concerns with the infant’s pediatric care team so that appropriate assessments and interventions can be carried out.

Bonding and Attachment

Bonding is described by Klaus (1982) as the promotion of a unique and powerful relationship between the parent and the infant. **Attachment** refers to the tie that exists between the parent and infant and is recognized as a feeling that binds one person to another.

MATERNAL

Bonding begins at the moment the pregnancy is confirmed and continues through the birth experience, during the postpartal period and throughout the early years of the child’s life. Bonding is critical for the infant’s survival and development. Providing parents with a model of caring during labor, birth, and in the early postpartum period enhances the bonding process and helps to lay the foundation for the nurturing care that the child will later receive.

Touch is recognized as an important communication tool between humans. Touch is an essential element in the creation of a loving relationship and lasting attachment between the parents and their child. Nurses can be

Figure 15-13 Bonding is enhanced with mother-infant eye-to-eye contact.

instrumental in enhancing the bonding process by minimizing the time that the infant is separated from the mother. Fostering a positive mother–child relationship begins in the delivery/birthing room when the infant is placed directly on the mother’s chest and is held skin-to-skin. The nurse should encourage the mother to initiate early eye contact during the first 30 minutes after childbirth when both the mother and her baby are alert (Fig. 15-13). This special quiet time provides an opportunity for connecting and communicating with one another. Early initiation of breastfeeding for mothers who wish to breastfeed and utilizing a rooming-in protocol are important nursing interventions that contribute to a positive maternal-child relationship (Dabrowski, 2007).

Optimizing Outcomes— Providing couplet care as an alternative to rooming-in

Rooming-in is a common strategy to enhance bonding. With this arrangement, the mother and her infant share a room and the mother and her nurse share the care of the infant. Some facilities offer a variation termed **couplet care**. In these settings, the nurse has been educated in both mother and infant care and serves as the primary nurse for the mother and the infant, even when the infant is kept in the nursery.

PATERNAL

Historically, mothers have been considered to be the major nurturer of children. By tradition, the mother took care of the child’s needs while the father, in the “breadwinner” role, worked and formed little attachment during the infant’s early years. Changes in women’s roles, couples’ participation in childbirth preparation classes, allowing fathers in the delivery room and encouraging early contact with the infant have all been instrumental in promoting and fostering early paternal–infant bonding. Other researchers (St. John, Cameron, & McVeigh, 2005) have documented the benefits of early and ongoing contact between fathers and infants (Fig. 15-14). When the primary caregiver is able to touch, hold, and attach with the newborn infant, this special interaction helps to build the

Figure 15-14 The father gets acquainted with his newborn.

foundation for a nurturing and protective relationship. Fathers should be encouraged to assume an active role in infant bonding by participating in the care giving activities. For example, fathers can change diapers, engage in skin-to-skin holding and infant massage, and feed the bottle-fed infant.

FACTORS THAT MAY INTERRUPT THE BONDING PROCESS

Stress associated with insufficient finances to purchase infant supplies, a chaotic home life, concerns about child care if the mother must return to work, lack of family support, and substance abuse may negatively interfere with the bonding process. An essential nursing role involves identifying obstacles to optimal bonding and coordinating with appropriate community resources such as social services to explore the mother’s eligibility for Medicaid, the Women’s Infants and Children’s (WIC) program, and Healthy Start. Other resources may include counseling and support services, financial aid, and pastoral care.

Adolescent mothers may not demonstrate attachment behaviors because they have unrealistic expectations of the infant’s level of functioning and may not be aware of the infant’s vulnerability. It is important for nurses to create a supportive environment that allows the young mother close and frequent interaction with her infant. The nurse must also provide anticipatory guidance and education about infant care that includes how to recognize and respond appropriately to infant cues. With today’s shortened hospital stays, it becomes imperative that appropriate home follow-up and social work referrals are established before discharge for this vulnerable population.

case study Adolescent Primipara with a Possible Bonding Difficulty

Sarah, a 17-year-old primipara, gave birth to a healthy 7 lb., 8 oz. (3.4 kg) baby boy yesterday. Although Sarah has been pleasant during her hospitalization, she has expressed little interest in her infant. When the nurses offer to bring the infant to the room, Sarah typically asks them to keep the infant in the nursery so that she can “relax and sleep.” She plans to bottle feed her son but has repeatedly found excuses not to feed the baby. The nursery personnel have been feeding the infant instead. The nurses are becoming very concerned because Sarah is to be discharged home with the infant tomorrow.

1. How would you initially respond to the situation? Based on your understanding of the developmental tasks of adolescence, how will you initiate dialog with Sarah?
 2. How can the nurse help Sarah begin to feel comfortable holding her baby and also promote maternal–infant bonding?
 3. What other nursing actions are indicated?
- ◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

Women from diverse cultural groups who reside in extended families may be comfortable enlisting the help of their mother, mother-in-law, or a female relative in caring for the infant while they recuperate from childbirth. It is important for the nurse to explore the mother’s cultural values and mores before reporting a lack of bonding and attachment between the mother and her infant.

An interruption in the bonding process may occur when infants must be separated from their parents for medical or surgical interventions. To promote optimal bonding in these special circumstances, it is important to allow the parents early and frequent access to the infant. The staff in the neonatal intensive care unit (NICU) can enhance parental attachment and bonding by encouraging the parents to touch, speak to and hold their neonate skin-to-skin as soon as is medically safe. If the mother is unable to visit, photographs of the infant should be sent to her as soon as possible and frequent telephone calls made to keep her advised of the infant’s status. The mother must be reassured that the bonding process is ongoing and that lack of early contact will not interfere with the development of a positive relationship with her infant.

ADJUSTMENT OF SIBLINGS TO THE NEWBORN

The arrival of a new baby into the family results in many emotional changes for the siblings. Feelings of hurt and jealousy, sibling rivalry, and behavioral regression are all common among younger siblings. For example, a toilet trained toddler may once again require diapers or a 2-year-old who has been weaned may now wish to breastfeed.

Parents should be prepared for these common emotional upheavals and formulate strategies that will help the sibling(s) adjust and accept the baby. Many hospitals offer sibling classes for young (ages 2 to 8) children that introduces the concept of having a new addition to the family and provides parents with specific information about how to make the transition easier.

Family Teaching Guidelines... Helping Older Siblings Adjust to the New Baby

Nurses can be instrumental in arming parents with strategies to help their children accept and adjust to a new infant. The following tips may be useful:

- ◆ Talk with the child(ren) about their feelings regarding the new baby. Listen and validate their feelings.
- ◆ Teach the older sibling how to play with the new baby; encourage gentleness.
- ◆ Help develop the child’s self-esteem by giving him/her special jobs, for example, bringing the diaper when you are changing the baby. Praise each contribution.
- ◆ Praise age-appropriate behaviors and do not criticize regressive behaviors.
- ◆ Set aside a special time each day for you to be alone with the older child; remind the child that he/she is loved very much.

TOPIC: Warning signs indicative of poor sibling adjustment

Professional help may be needed when the child:

- ◆ Continually avoids or ignores the baby
- ◆ Shows the baby no affection
- ◆ Is consistently angry, taunting or demonstrating aggressive behavior towards the baby or other family members
- ◆ Experiences nightmares and sleeping difficulties

Adapted from International Childbirth Education Association (2003).

ADJUSTMENT OF GRANDPARENTS TO THE NEWBORN

Grandparents can provide much support to the new family and the degree of their involvement is often linked to cultural expectations. Many cultures (i.e., Hispanics, Asians, and Caribbeans) strongly value the extended family. In these settings, the grandparents are intimately involved in the fabric of family dynamics and frequently exert a strong influence on child-rearing practices. Grandparents’ classes, offered by most hospitals, usually focus on defining grandparenting roles such as helping with sibling care during the mother’s hospitalization and providing assistance with household activities and cooking and shopping during the first few postpartal weeks. Other class themes include current recommendations concerning infant positioning, feeding and clothing, responding to behavior cues, and positive strategies for assuming a supportive, rather than a parenting role.

Now Can You— Facilitate family bonding with the newborn?

1. Identify and describe Rubin’s three phases associated with assuming the mothering role?

2. Describe strategies to facilitate maternal and paternal bonding?
3. Discuss five specific activities that parents can use to help older siblings adjust to the newborn?

Emotional and Physiological Adjustments During the Puerperium

EMOTIONAL EVENTS

Many mothers experience a roller coaster of emotions after childbirth. These feelings stem from a number of influences and are often linked to perceptions concerning the fulfillment of expectations surrounding the childbirth experience. A complicated birth, a premature birth or a sick infant, as well as the woman's parity, age, marital status and stability of family finances are some of the many factors known to shape emotions experienced during the postpartum period.

The first 3 months after birth are recognized as the most vulnerable emotional period for mothers. Insecurity about infant care, the constant demands associated with caring for the baby, sleep deprivation, and minimal social support create the potential for frequent and dramatic mood changes. Rapid hormonal changes during the first few postpartal days and weeks may give rise to mood disorders. The most common of these is often termed "the blues." Other less common puerperal mood disorders include post partum depression and post partum psychosis. (See Chapter 16 for further discussion.)

Maternity Blues/Baby Blues/Postpartum Blues

The "maternity blues" are considered to be a normal reaction to the dramatic changes that occur after childbirth including abrupt withdrawal of the hormones estrogen, progesterone and cortisol. Women experience a range of symptoms that include tearfulness, mood swings, insomnia, fatigue, anxiety, difficulty concentrating, irritability and poor appetite. The symptoms usually begin during the first few postpartal days, peak on the fifth day, and then subside over the next several days. Blues do not affect the woman's ability to care for herself or her newborn and family.

The "blues" are treated with support and reassurance (Beck, Records, & Rice, 2006). Proactive education to prepare the woman and her family for the possibility of postpartum blues is important. The nurse needs to explore what resources the new mother will have available when she goes home. The discussion should focus on whether the patient has adequate food, clothing, shelter, and transportation, and whether there are relational concerns that need to be addressed before discharge. Incorporating community resources such as the woman's church, a Mother's Day Out group, a hobby club, or La Leche League can help the new mother realize she is not alone in the experience of nurturing a newborn, while also caring for herself and her family. Referral to a health care provider is appropriate for women whose symptoms persist for more than ten days, as this pattern is suggestive of postpartum depression.

Postpartum Depression

Postpartum depression, which affects 10% to 13% of women, usually appears around two weeks after child-

birth. The symptoms associated with this condition are often insidious and include sleep disturbances, guilt, fatigue, and feelings of hopelessness and worthlessness. In severe instances, suicidal ideation may occur. Patients who demonstrate symptoms of post partum depression must be promptly referred for evaluation and intervention. (See Chapter 16 for further discussion.)

Postpartum Psychosis

Postpartum psychosis develops in approximately one or two women for every 1000 births and is unlikely to manifest itself during the early postpartum period. Symptoms include delusions; hallucinations; agitation; inability to sleep; and bizarre, irrational behavior. Before hospital discharge, patients with a history of mood disorders or depression should be referred to appropriate resources for community support and follow-up. (See Chapter 16 for further discussion.)

PHYSIOLOGICAL RESPONSES TO EMOTIONAL EVENTS

Tiredness and Fatigue

Postpartum tiredness and fatigue have long been considered a natural physiological and psychological response to the stresses of labor and childbirth coupled with the additional responsibilities of motherhood. Although new mothers are often confident that tiredness will improve upon returning home, this phenomenon is not supported by the nursing literature. Rather, the multiplicity of demands associated with motherhood augments the experience of physical and mental exhaustion. While changes in societal trends in the care of children suggest that fathers are taking a more active role, mothers continue to hold the main responsibility for care. Thus, it is essential for the nurse to encourage new mothers to enlist the support and assistance of family and friends in an effort to promote time for rest and recovery (Runquist, 2007).

Nursing Insight— Persistent fatigue during the puerperium

Feelings of fatigue that extend beyond the 6-week postpartal period may be indicative of a more serious condition. Persistent, pervasive fatigue may be indicative of postpartum depression (Troy, 2003). The woman and her family should be provided with guidelines about normal feelings and reactions during the puerperium and encouraged to report excessive tiredness or fatigue to the health care provider.

Contributors to fatigue and tiredness in the postpartum period include physical, psychological, and situational variables. Physical contributors include the length of labor, maternal hormone shifts, maternal anemia, episiotomy or surgical incision healing, breast feeding, and pain. Psychological contributors include difficulty sleeping, depression, and a non supportive partner. The challenge of managing multiple roles, cultural influences and expectations, a lack of assistance with housework or childcare, having more than one child under the age of 5 in the home, and returning to outside employment are situational variables that can readily lead to fatigue. Insights into the multiple

contexts that shape the patient's environment allow nurses to provide anticipatory guidance regarding fatigue and its relationship with diminished quality of life in the postpartum period (Runquist, 2007).

Postpartal Discharge Planning and Teaching

PROMOTING MATERNAL SELF CARE

Because of early postnatal discharge, all postpartal women must be taught strategies for self-care. A self-assessment sheet completed before discharge helps to identify areas of deficits. When possible, parents are encouraged to attend a discharge teaching class. Topics reviewed usually include infant bathing, breastfeeding, perineal hygiene, physical activity, rest and expected emotional changes. This information is useful because it empowers the family to identify normal events and to promptly recognize complications that should be reported to the health care provider. Many institutions also distribute home care booklets that provide written information about maternal and newborn care and available community resources. Often, home visitation by a community health nurse is arranged before the patient's discharge. The community health nurse visit typically includes an examination of the mother and infant, an opportunity for discussion about problems or concerns and breastfeeding or formula feeding support. Additional areas of focus during the postpartal visit include education regarding basic maternal and infant care, plans for follow up visits and contraception counseling (Fig. 15-15).

Optimizing Outcomes— When early postpartum discharge is planned

Women and their families may have the option of early discharge with postpartum home care. Maternal criteria for early discharge includes an uncomplicated perinatal course, no evidence of PROM, no difficulties with voiding or ambulation, normal vital signs, hemoglobin > 10 g and no sig-

Figure 15-15 The postpartum home visit usually involves an examination of the mother and baby. It provides an opportunity for teaching and promotes continuity of care.

nificant vaginal bleeding. The infant must also meet certain criteria (i.e., full term, normal vs and physical examination, feeding, urinating, stooling, laboratory/screening tests completed). Early follow-up visits are an essential component of safe care for mothers and their infants (AAP Committee on Fetus and Newborn, 2004; Meara, Kotagal, Atherton, & Lieu, 2004).

COMPONENTS OF MATERNAL SELF-ASSESSMENT

Fundus

The woman is taught how to locate and palpate the fundus and how to determine the progression of the fundal height as it involutes into the pelvis. After months of abdominal enlargement, many women are delighted to be able to rest in a prone position. Nurses can explain that lying on the abdomen is beneficial because this position supports the abdominal muscles and aids involution because the uterus is tipped into its natural forward position.

clinical alert

Avoiding the knee-chest position

The nurse teaches the patient to avoid a knee-chest position until at least the third postpartal week. This position causes the vagina to open. Since the cervical os is still open to some extent, there is a danger that air can enter the vagina, pass into the cervix and enter the open blood sinuses inside the uterus. Entry of air into the circulatory system can cause an air embolus.

Lochia

The nurse reinforces to the patient that the lochia (vaginal discharge) may continue for 3 to 6 weeks after birth. During this time, it is important for her to examine the peripads for color, amount and odor each time she visits the toilet. The woman should be provided with guidelines concerning the anticipated color and amount of the lochia and reminded to promptly report abnormal findings such as heavy bleeding, the passing of large clots and foul smelling odor.

Hygiene

The patient is advised to continue to use her perineal squeeze bottle until the bleeding stops and to use the prescribed medications and/or sitz bath for episiotomy discomfort. After each visit to the toilet she is reminded to carefully wipe from front to back and thoroughly wash her hands before and after changing the peri pads.

Abdominal Incision

Nurses should instruct the post operative patient to shower as normal and to carefully pat the incision dry. If staples were applied at the incision site, the obstetrician will inform her when to come into the office for removal. Steri-strips used for incision closure should remain undisturbed until they eventually fall off. The woman is advised to avoid the application of cream or powder to the incision site and to notify her obstetrician if she experiences fever or develops signs of incisional infection such as redness, offensive odor or discharge.

Body Temperature

Some women experience a transient increase in body temperature along with breast heaviness on the third to fourth postpartum day when the milk supply is established. They should be reminded that temperatures above 100.4°F (38.0°C) and flu-like symptoms (e.g., chills, body aches, severe pain) may indicate infection and should be promptly reported to the health care provider.

Urination

Before discharge, all patients should be able to pass urine without difficulty. Women should be taught the signs and symptoms of a urinary tract infection (UTI). Specifically, burning on urination (dysuria), frequent voiding with only a small amount of urine passed, the presence of a “fishy” odor to the urine and lower abdominal or flank pain are symptoms that must be reported to the health care provider. To reduce the likelihood of a urinary tract infection, patients are advised to drink at least eight 8-oz. glasses of water each day, avoid delays in emptying the bladder, wipe the perineum from front-to-back after each use of the toilet, change peripads after toileting, and to wash their hands frequently.

Bowel Function

The nurse teaches about the importance of maintaining good hydration and consuming a healthy diet abundant in fiber and roughage. An exploration of the woman’s dietary preferences facilitates discussion about specific types of foods (e.g., fruits, vegetables, whole-grain cereals) that promote bowel regularity. The patient should consult with her obstetrician or certified nurse midwife if laxatives or other medications become necessary. Stool softeners are usually prescribed for women with third or fourth degree episiotomies or vaginal lacerations.

Nutrition

Most women are concerned about weight increase during the pregnancy and how quickly they can expect to return to their pre-pregnancy weight. A well-balanced diet that includes high-energy foods is essential to recovery in the puerperium. Patients should be counseled about the need for adequate protein to promote tissue repair and healing and encouraged to select a healthy, low-fat diet that contains protein along with carbohydrates, fruits, and vegetables.

Fatigue

Patients should be reminded that since the first six postpartal weeks are devoted to infant care and recovery from childbirth, energy depletion, usually manifested as extreme tiredness and fatigue, often occurs. They should be encouraged to limit visitors and whenever possible to rest when the baby sleeps. Patients may wish to cook easily prepared meals in advance and freeze foods for later use. When possible, the new mother should solicit help from her partner, family members and friends to assist with the household chores, shopping and child care.

Weight Loss

Weight loss at the time of childbirth is precipitous. Within minutes after birth, the parturient woman loses

half of the weight gained during the previous nine months. On average, the weight loss amounts to 10 to 12 lbs. (4.5 to 5.5 kg). This loss comes from the infant, the placenta, amniotic fluid, and blood. Rapid diuresis and diaphoresis occur during the second to fifth postpartum days and result in an additional weight loss of about 5 lbs. (2.3 kg). By the sixth to eighth postpartal week, many women will have returned to their pre-pregnant weight. The amount of weight lost during the puerperium is primarily related to the amount of weight gained during pregnancy and the woman’s level of physical activity.

Exercise

The patient is advised to resume activities gradually, beginning with Kegel exercises to strengthen the pelvic-floor muscles. After a vaginal birth, patients may begin modified sit-ups to strengthen the abdominal muscles and perform knee and leg roll exercises to firm the waist. Modified sit-ups are especially beneficial for women with diastasis recti.

Optimizing Outcomes— Postnatal exercises to promote physical fitness

Teaching patients about exercises to help return the body to its pre-pregnant state is an important component of postpartal care. Exercises to strengthen the back, abdominal muscles, thighs, and shoulders are particularly beneficial at this time.

Supple Spine

Begin on all fours. Inhale. Lift your head, keeping your back straight or arching slightly (avoid strain). Then exhale, round your back, tighten abdominals, tuck in tail and head. Repeat the sequence eight times. This exercise strengthens the back and abdominals.

Tighter Abdominals

Lie on your back in a straight line. Then exhale, lowering the back, vertebra by vertebra. Repeat sequence five times. This exercise helps develop a strong back and abdominals.

Stronger Back

Sit upright, knees bent, feet flat on the floor, back straight, arms forward at shoulder level. Inhale, then exhale and lean back halfway. Inhale again and sit up slowly. Repeat five times. This exercise strengthens the back and abdominals.

Flexible Body

Stand upright with arms raised, elbows slightly relaxed. Inhale, then exhale and bend forward, keeping back straight and swinging arms down and back. Then relax your head and stretch your arms up behind you. Inhale as you swing arms and body up again, returning to your original position. Repeat eight times. Go carefully and do not strain. This exercise is good for thighs, hips, back, arms, shoulders, and neck.

Pain Management

Medications for pain relief (nonsteroidal antiinflammatory medications or analgesics) may be prescribed, especially for postoperative patients. The nurse should ensure that medications prescribed for breastfeeding patients are not contraindicated. Information regarding therapeutic modalities such as ice packs, sitz baths, or topical anesthetics may be helpful for the relief of perineal discomfort from hemorrhoids or the episiotomy incision. Patients are instructed to notify their health care provider if pain persists or increases in intensity, and the nurse also reviews other danger signs and symptoms that must be promptly reported (Box 15-5).

Mood

The nurse should provide support and empower the family by discussing the often overwhelming responsibilities associated with newborn care. Information shared with the mother and her partner includes the emotional changes such as feelings of sadness and weepiness that often appear on the second or third postpartal day. Patients can

Box 15-5 Postpartum Discharge Teaching: Danger Signs to Be Reported

An important component of discharge teaching focuses on alerting patients to signs and symptoms that must be reported to the health care provider. The nurse should ensure that the patient is given written information and knows how to reach her care provider. The patient should immediately report:

- Temperature greater than 100.4°F (38.0°C), chills, or flu-like symptoms
- Abdominal incision that is red, tender to touch, or painful, or if edges of the incision have separated.
- Difficulty initiating urination, urinary frequency or painful urination
- Increased vaginal bleeding with or without clots, or foul-smelling vaginal discharge
- Persistent pain or marked swelling at the site of a perineal laceration or episiotomy
- Swelling or masses in the breasts, red streaks, shooting pain in the breasts, or cracked, bleeding nipples.
- Swelling, warmth, tenderness or painful areas in the legs
- Blurred vision or persistent headache that is not relieved by pain medication
- Overwhelming feelings of sadness or an inability to care for self or the baby

be assured that “mood swings” and periods of unexpected crying, moodiness or anxiety are common and occur in 70% to 80% of women. If the following symptoms persist for more than 2 weeks after childbirth, the woman, her partner, a family member or a support person should contact the health care provider for assistance:

- Crying excessively
- Significant changes in appetite
- Feeling helpless
- Experiencing extreme worry, concern
- Unable to sleep/wanting to sleep all the time
- Unable to care for herself or the baby
- Panic attack
- Fear of harming self or the baby

Sexual Activity and Contraception

To maximize healing and prevent infection, patients are discouraged from resuming sexual activity until after the six week postpartum check-up with the obstetrician or midwife. It is important for the nurse to inform the woman and her partner that since ovulation may resume as early as two weeks after childbirth, pregnancy can occur if no contraceptive is used.

Although advised to abstain from sexual intercourse until the postpartum examination, many couples wish to resume intimate relations before this time. Coitus is safe once the woman’s lochia has transitioned to alba and the episiotomy (if present) has healed. This usually occurs after the first week after childbirth. The patient should be warned that she may experience vaginal discomfort because the cells lining the vagina may not be as thick as before, due to a hormone imbalance. A contraceptive foam or lubricating jelly may be used to enhance comfort.

Exploring previously used methods of contraception may be helpful in identifying a starting place for the discussion. The couple's religion and cultural background often dictates their contraceptive choice. Discussing contraception options with the patient and her partner (if present) before discharge allows the couple time to make informed decisions before resuming sexual intercourse. The breastfeeding mother should be warned that she can become pregnant during lactation and that breastfeeding is not a substitute for birth control. If the breastfeeding patient wishes to use an oral contraceptive the nurse must inform the healthcare provider so that a progesterone-only pill can be prescribed. (See Chapter 6 for further information.)

PLANNING FOR THE FOLLOW-UP EXAMINATION

Most health care providers schedule a 6-week follow-up appointment ("postpartal check"). Women who have had cesarean births are often scheduled for a return visit to the physician's office 2 weeks after hospital discharge. It is helpful to indicate the date and time of the return appointment in the patient's discharge instructions.

The nurse can explain that during the 6-week follow-up visit, fundal palpation and a vaginal examination will be performed to evaluate the size of the uterus. The episiotomy or abdominal incision site will be evaluated for healing and a breast examination will be performed. If desired, a contraceptive method or prescription will also be given. The nurse should encourage the patient to discuss any concerns during this visit.

The parents should also schedule a newborn follow-up appointment before hospital discharge. Most physicians and clinics wish to see the infant within the first week or by age 2 weeks.

Now Can You— Promote self-care for the puerperium?

1. Outline postpartal teaching guidelines that include information about self-assessment of the fundus, lochia, hygiene, incisional site, body temperature, and elimination?
2. Demonstrate appropriate exercises for the postpartal patient?
3. Identify at least six symptoms indicative of poor emotional adjustment that, if present for more than 2 weeks, should be reported to the healthcare provider?

Patients with Special Needs During the Puerperium

CARE OF THE ADOLESCENT

The period of adolescence is a time to form important relationships with peers—these close connections help to facilitate self-growth and development. Adolescents who are thrust into an untimely motherhood role must also deal with their own personal and social development. Adjusting to pregnancy and impending motherhood can be emotionally and physically challenging for a mature woman; the adolescent requires special assistance from the nurse.

Many adolescents enter motherhood with unrealistic expectations. They lack mothering and child care skills.

Fatigue and sleep deprivation, common in all new mothers, coupled with the responsibility of caring for an infant who requires constant attention often results in limited time for social activities and subsequent social isolation from their peers.

Nurses who care for the adolescent mother must be cognizant of personal prejudices or feelings of disapproval and avoid expressing negative feelings toward the teen mother. It is important for the nurse to provide emotional support for the postpartum adolescent that will help her adjust to role changes, foster feelings of positive self-esteem and assist her in developing a new identity and sense of self (Logsdon & Koniak-Griffin, 2005). The nurse must create a supportive environment by recognizing the adolescent as the infant's primary caregiver, irrespective of her age. The nurse models and facilitates infant caring behaviors that will promote bonding and teaches about infant care and child safety. Before discharge, arrangements should be made for a community health nurse follow-up visit within a week.

“What to say” — When planning the adolescent mother's hospital discharge

The adolescent mother has unique needs for discharge planning. The nurse can best explore the young patient's immediate plans for herself and the baby by initiating dialog in a supportive, nonthreatening environment. Examples of appropriate questions that the nurse may ask include the following:

“Do you have someone available to offer you help and/or support?”

“Do you feel a sense of closeness or attachment to your baby?”

“After you leave the hospital, will anyone be helping you to care for your baby?”

“Will anyone be taking care of the baby so that you can go back to school?”

“Where will you take the baby for follow-up care?”

To facilitate a supportive home and family environment, the community health nurse will conduct a social support assessment to identify the significant family member or other person who will be assisting with parenting responsibilities and financial support. If the adolescent's mother is identified as the primary support person, the nurse explores the mother's and grandmother's expectations in caring for the newborn in order to provide anticipatory guidance regarding each person's new role before discharge.

A supportive family environment is the single most important element in facilitating the adolescent mother's successful transition to motherhood. When appropriate, referrals should be made for social services and other community resources such as home health nursing care, pastoral care, teen parent support groups, and economic assistance. Guidance and support provided by these professionals help to reinforce infant care skills and identify additional resources to enable the young mother to complete her education. Professional and family support has proven to be effective in helping adolescents delay a sub-

sequent pregnancy, stay enrolled in school, find work and complete the developmental tasks of adolescence (Logsdon & Koniak-Griffin, 2005; Secco et al., 2007).

THE WOMAN WHO IS PLACING HER INFANT FOR ADOPTION

The relinquishment of an infant triggers a host of emotions for the woman and her family. Nurses must be sensitive to the myriad of psychological stressors and social stigmas associated with placing a child for adoption. Depending on hospital policy, the patient may be admitted to the postpartum unit where she can be attended to by nurses who are experienced in perinatal care. The nurse should offer support, a “listening ear,” and a compassionate environment where the patient feels safe in expressing her feelings. The woman will likely experience a range of emotions such as grief, loneliness, and guilt. After birth, the patient should have access to her newborn if she so desires. The opportunity to see, hold, and feed the infant may help her to accept the reality that she has given birth to a healthy child. This affirmation may foster feelings of self-esteem and provide a foundation for emotional healing. Postpartum care may continue well beyond hospital discharge for women who choose to give up the infant. Referrals to various community resources may be appropriate (Cunningham et al., 2005). In some cases, the adoptive couple may come into the hospital to meet the new infant. The new parents will need the same instruction in infant care and safety as the biological parents.

THE OLDER WOMAN

Today, it is not uncommon for women over age 35 to experience their first pregnancy, and when pregnancy occurs among this population, it is deemed “advanced maternal age”.

The older patient may have preexisting medical conditions (e.g., hypertension, diabetes) and experience greater health risks and pregnancy complications such as gestational diabetes and preeclampsia. In these situations, pregnancy and puerperal care involve a collaborative approach that includes a physician with special training in high-risk obstetrics (perinatologist) and medical specialists (e.g., endocrinologist, rheumatologist, cardiologist).

Women experience pregnancy after the age of 35 for a number of reasons. Some postpone pregnancy in order to make advancements in careers; others have struggled with infertility and become pregnant following advanced reproductive techniques while others report contraceptive failure. There is a wide range of attitudes and emotions that accompany parenthood during midlife. Some women believe that delaying motherhood enhances the adaptation to the parental role. They cite qualities such as maturity, patience, and understanding and greater life experiences as positive influences for assuming the parental role. For others, parenthood at an older age can be disruptive to intimate relationships, interfere with career goals, and create a perception of loss of control. Reassurance, support, and referral, when appropriate, help to facilitate transitions during the puerperium for the older couple.

Community Resources for the New Family

SUPPORT GROUPS

The birth of a newborn constitutes a major life transition. For the new parent, attending a support group can provide a venue for sharing experiences and challenges with other new parents. Information about “essential” parenting topics, such as infant feeding and nutrition, behavior, sleeping patterns, and strategies for fostering family relationships is readily available during the meetings. Specific support groups may also be available for unique populations, such as single parents, working mothers and parents of infants with special needs. Parents who participated in childbirth education classes together often reunite to form a support group after childbirth.

HOME VISITS

Some facilities routinely schedule home visits for maternal and baby assessment. This visit provides the nurse with an opportunity to assess bonding, conduct patient teaching, answer questions, correct learning deficits, reinforce hospital discharge instructions and make appropriate community referrals.

TELEPHONE FOLLOW-UP

Facilities that offer home follow-up services usually call parents approximately two to three days after discharge. Making personal contact with the family provides early support and reassurance, allows for questions to be answered and discharge instructions to be reviewed and clarified.

OUTPATIENT CLINICS

Outpatient clinics provide another option for facilities that do not offer home visitation. The clinics are often nurse-managed and allow the mother and her baby to receive further information about maternal-infant care. The patient’s additional questions or concerns can also be dealt with at this time.

A list of community resources and phone numbers is often provided to the couple before discharge. These services may include professional lactation services, nursing mother’s support groups, “Mommy and Me” classes, postnatal exercise classes, parenting education and support groups, medical care, crisis lines/counseling, emergency and financial assistance, and bereavement support.

Now Can You— Care for postpartal patients with special needs and identify community resources for the postpartal family?

1. Identify nursing interventions that foster the postpartal adolescent’s self-esteem and empower her to bond with and care for her infant?
2. Describe nursing interventions to provide appropriate emotional support for the woman who chooses to place her infant for adoption?
3. Identify at least three sources of community support for the postpartal family and discuss the benefits of each?

summary points

- ◆ During the postpartum period, the nurse assumes the responsibility of facilitating the integration of the newborn into the family unit.
- ◆ The postpartum patient has unique assessment needs that include physical and psychosocial considerations.
- ◆ The new mother should be given the opportunity to discuss her birth experience.
- ◆ The postpartum woman who has experienced a cesarean birth is also considered to be a surgical patient who has special needs for additional nursing care.
- ◆ Effective pain management should be an integral component of the postpartal nursing assessment.
- ◆ The breastfeeding mother should be provided with sufficient support to facilitate success.
- ◆ The nurse should provide anticipatory guidance that includes family members whenever possible.

review questions

Multiple Choice

1. In the preadmission clinic, the perinatal nurse describes the advantages to a short hospital stay as including:
 - A. Decreased risk of nosocomial infection
 - B. Increased rest and recuperation
 - C. Increased opportunity to initiate successful breastfeeding
 - D. Increased teaching about infant care
2. In the immediate postpartum period, the perinatal nurse knows that the postpartum woman most often has a:
 - A. Bradycardia
 - B. Tachycardia
 - C. Pulse within the normal adult range
 - D. Tachycardia then a pulse rate that returns to normal in 4 hours
3. The postpartum nurse expects a postpartum woman's bladder function to return to normal within which length of time:
 - A. 4–6 hours
 - B. 6–8 hours
 - C. 2–4 hours
 - D. 8–12 hours

Fill-in-the-Blank

4. The perinatal nurse knows that the first 6 weeks after birth is described as the _____.
5. The perinatal nurse works with the healthcare facility's unit council to develop policies to promote patient safety. The policy on infant safety particularly focuses on the challenge of two infants/families with the same _____ to ensure that there are specific strategies to protect each family.
6. The perinatal nurse recognizes that it is common for women using insulin to have _____ insulin requirements postpartum. This finding is due to a _____ in levels of placental lactogen and insulinase.

True or False

7. The perinatal nurse teaches the student nurse about the use of the acronym REEDA for wound assessment. The "R" stands for Redness and the "A" stands for Approximation of the wound edges.

Select All that Apply

8. The perinatal nurse teaches a new nurse about the *Healthy People 2010* initiative, which includes postpartum teaching that focuses on:
 - A. Warning signs during the postpartum period
 - B. Benefits of breastfeeding
 - C. Use of infant soothers
 - D. Contraceptive methods
9. The postpartum nurse recognizes that after birth, the patient is at risk for decreased bladder tone and function if her labor/birth included:
 - A. Forceps
 - B. Vacuum extraction
 - C. Prodromal labor
 - D. Prolonged second stage

Case Study

10. The perinatal nurse is assessing Ruth, who has given birth 2 hours ago. The nurse notes a discoloration of the perineum and Ruth complains of pain and rectal pressure. The most appropriate action for the nurse is to:
 - A. Call the health care provider to assess immediately.
 - B. Increase IV fluids and request an order for ergonovine (Ergotrate).
 - C. Reassure Ruth and her family that postpartum pain is normal and medication is available.
 - D. Apply ice packs to the perineum as quickly as possible.

CONCEPT MAP

Caring for the Woman Experiencing Complications During the Postpartal Period

Do all the good you can. By all the means you can.
In all the ways you can. In all the places you can.
At all the times you can. To all the people you can.
For long as ever you can.

—John Wesley

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Describe the causes and collaborative management of postpartum hemorrhage.
- ◆ Discuss the signs and symptoms of postpartum hematoma; describe nursing care for a patient experiencing a postpartum hematoma.
- ◆ Describe the collaborative management for infections during the puerperium.
- ◆ Discuss the collaborative management of thrombophlebitis and thrombosis in postpartum women.
- ◆ Describe the signs, symptoms, and management of a pulmonary embolism.
- ◆ Summarize important interventions in meeting psychosocial needs of postpartum women and their families.
- ◆ Describe current community and governmental services that are available to vulnerable postpartum women and their families.

moving toward evidence-based practice Postpartum Depression

Dennis, C.L., & Ross, L. (2005). Relationship among infant sleep patterns, maternal fatigue, and development of depressive symptomatology. *Birth, 32*(3), 187–193.

Through the replication of a previous study, the purpose of this longitudinal study was to examine the relationship among infant sleep patterns, maternal fatigue, and the development of postpartum depression in women with no major depressive symptomatology.

Depression was defined in the previous study as either meeting the criteria for the diagnosis of a major depression or scoring above 15 on the Edinburgh Postnatal Depression Scale. Variables in the original study and considered to be predictive of depression included maternal age, depression during pregnancy, thoughts of death and dying at 1 month postpartum, and difficulty falling asleep at 1 month postpartum. Prenatal participants in the study were recruited through family physician, obstetrician, and nurse midwife offices. Postnatal participants were

obtained through the input of public health nurses during the standard 48-hour discharge telephone call to new mothers. Participation was voluntary and included mothers who were at least 18 years of age and at more than 32 weeks of gestation. Data was obtained through an initial questionnaire and follow-up questionnaires at 4 and 8 weeks postpartum. From a potential population of 857 candidates, 667 agreed to participate. Of that total, 585 returned the questionnaire at 1 week, with 505 (86.3%) scoring less than 13 on the Edinburgh Postnatal Depression Scale (EPDS), qualifying them to participate in this study.

The EPDS assessed symptoms of depression through ratings of 10 items on a four-point scale; a high score indicated a more depressed mood. Depressive symptomatology was defined as a score >12.

(continued)

moving toward evidence-based practice (continued)

Sleep outcomes were assessed based on the infant's sleep patterns and their impact on the mother. Examples of those questions included: how well the baby slept; how many times the baby usually awoke during the night; and how many hours of sleep the mother usually had in a 24-hour period. High ratings indicated an increased likelihood of depressive symptoms.

Data analysis revealed the following findings about the mothers and their scores on the EPDS:

- Ages of the mothers ranged from 18 to 43; the mean age was 29 years.
- Ninety-three percent of the mothers were Caucasian; 92% were married; 42% were primiparous; 77% experienced a vaginal birth.
- Twenty-two percent of the mothers had a university degree or higher; 39% graduated from a technical school or college; 34% graduated from high school; and 4% did not have a high school diploma.
- Thirty-six percent of the mothers reported an annual household income greater than \$60,000; 26% between \$40,000 and 60,000; 37% less than \$40,000.
- Scores on the EPDS were as follows: 21 (4.6%) scored >12 at 4 weeks postpartum, 20 (4.7%) scored >12 at 8 weeks. These findings were consistent with the previous study's meta-analysis.

Results at 4 weeks: Mothers who reported that their baby cried often and woke up three times or more during the night, and who slept less than 6 hours in a 24-hour period were more likely to exhibit EPDS scores of >12.

Results at 8 weeks: Mothers who reported that their baby cried often, woke up three times or more during the night, and slept less than six hours in a 24-hour period were more likely to exhibit EPDS scores of >12. These mothers were also three times more likely to report that their baby did not sleep well and six times more likely to report that their baby's sleep pattern did not allow them to obtain a reasonable amount of sleep in a 24-hour period.

Mothers with scores of >12 were more likely to report feeling tired at 4 weeks and at 8 weeks.

The researchers concluded that mothers who demonstrated depression symptoms on the EPDS at 4 and 8 weeks were more likely to report that their baby cried often and woke up three times or more during the night. Mothers who demonstrated depression symptoms were also more likely to sleep less than 6 hours in a 24-hour period and indicated that their baby did not sleep well, a factor that prevented them from getting more sleep. Mothers who scored >12 on the EPDS were also more likely to report feeling tired.

The researchers stated that their findings suggest that infant sleep patterns and maternal fatigue are strongly associated with the onset of depressive symptoms during the postpartum period.

Introduction

Most childbearing women have healthy babies and recover from the physiological and psychological adaptations to pregnancy without difficulty. Physiological complications and psychosocial complications are rare, especially in industrialized nations such as the United States, Japan, Australia, and in European countries. Because perinatal care focuses on wellness, health promotion-maintenance, and education for healthy women in multiple settings across the childbearing cycle, the danger of minimizing or misinterpreting pathological signs and symptoms is ever present. Delayed or absent communication between care provider call groups combined with this wellness focus can lead to suboptimal outcomes for women and their families.

When prenatal care begins, whether in a private practice or clinic setting, nurses can serve as liaisons between patients, families, care providers, and community agencies. In this role, the nurse is often the first health care provider to identify physiological signs and symptoms or recognize psychosocial concerns that need to be addressed by the health care team. Synthesizing knowledge with clinical data and thinking critically about the meaning of these data are vitally important.

This chapter describes postpartum physiological and psychosocial complications and concerns from a nursing

process perspective. The nurse's role in the collaborative treatment of patients and their families who experience these complications is multifaceted and cannot be overly emphasized. More than any other health care team member, the nurse uses vigilance to apply nursing knowledge and implement informed nursing actions. Vigilance involves combining careful observation, knowledge, and expectations with cues from the patient and her family (Meyer & Lavin, 2005) and is a critical component of nursing care, particularly in the perinatal area where patients are assumed to be healthy. Whether functioning as an independent practitioner or as a member of the health care team, the nurse's judgments and actions affect both present and future generations for years to come.

Postpartum Hemorrhage

INCIDENCE AND DEFINITION

Postpartum hemorrhage (PPH) is a leading cause of maternal morbidity and mortality in the United States and around the world. Approximately 5% of all women who give birth vaginally experience a postpartum hemorrhage. Internationally, postpartum hemorrhage accounts for one of the three major causes of maternal mortality. According to The World Health Organization, 25% of all pregnancy related deaths

result from postpartum hemorrhage (Cunningham et al., 2005; Magann, Hutchinson, Collins, Howard, & Morrison, 2005). Historically, practitioners have defined postpartum hemorrhage as a blood loss greater than 500 mL after a vaginal birth and 1000 mL or more after a cesarean birth (MacMullen, Dulski, & Meagher, 2005). Hematocrit levels that decrease 10% from pre- to postbirth measurements are also included in the definition (Cunningham et al., 2005), along with a need for a red blood cell transfusion due to anemia or hemodynamic instability (Magann et al., 2005). Cunningham and colleagues (2005) emphasize that postpartum hemorrhage is a description “of an event, not a diagnosis” (p. 635).

As is often the case with other clinical events, most definitions of postpartum hemorrhage contain a subjective component. Caregivers rarely measure actual blood loss after childbirth. Instead, the physician, nurse midwife, or nurse attendant estimates the amount of blood soaked on the bedding and pads or collected in the placenta basin and suction canister. This nonscientific method is frequently inaccurate and may lead to an underestimation of actual blood loss by as much as 40% to 50% (Cunningham et al., 2005). Accuracy in determining true blood loss is possible if a member of the health care team carefully weighs the placenta basin and all bloody items such as pads, linens, and clothing with a gram scale (1 mL = 1 gram). If in doubt, the nurse should err on the side of safety until objective data can be obtained and confirmed.

critical nursing action Accurately Determining Blood Loss

After childbirth, the nurse carefully weighs all pads, linens, clothing, and clots in the placenta basin on a gram scale to accurately determine the patient's blood loss.

EARLY VERSUS LATE HEMORRHAGE

Although the criteria for a diagnosis of postpartum hemorrhage may vary from practitioner to practitioner, the definition of an early and a late postpartum hemorrhage is straightforward. An early hemorrhage occurs within the first 24 hours after birth. A late hemorrhage occurs more than 24 hours but less than 6 weeks postpartum. The greatest likelihood for occurrence of an early hemorrhage is within the first 4 postpartum hours. During this time, the blood flow to the uterus is between 500 and 800 mL/minute, and the placental site contains multiple exposed venous areas and low resistance (Smith & Brennan, 2006). One researcher suggests the use of the acronym “LARRY” to serve as a memory prompt for the common causes of early PPH (Flamm, 2003): **L**acerations, **A**tony, **R**etained placental tissue, **R**uptured uterus, and “**Y**ou pulled too hard on the cord (thereby creating an inversion of the uterus).” More commonly, the 4 “T’s” serve as a reminder of factors associated with PPH: **t**one, **t**rauma, **t**issue, and **t**hrombin (Cunningham et al., 2005; Smith & Brennan, 2006). A lack of uterine tone (**atony**) and genital tract trauma are the most common conditions that cause postpartum hemorrhage.

Nursing Insight— Using a standardized assessment for blood loss after childbirth

According to Luegenbiehl, Brophy, Artigue, Phillips, and Flack (1990), nurses may use the following definitions to accurately describe the amount of blood saturation on a perineal pad:

Scant: Peripad blood stain <2 inches (<10 mL) within 1 hour

Small: Peripad blood stain >2 inches, <4 inches (10–25 mL) within 1 hour

Moderate: Peripad blood stain >4 inches but <6 inches (25–50 mL) within 1 hour

Large: Peripad blood stain >6 inches to saturated peripad (50–80 mL) within 1 hour

UTERINE ATONY

Uterine atony is a failure of the uterine myometrium to contract and retract following birth. Normally, the uterine muscle fibers contract firmly around the blood vessels during placental separation. A lack of contraction and retraction results in noncompression of the uterine arteries and veins at the placental implantation site, thereby preventing hemostasis. The hallmark of uterine atony is a soft uterus filled with clots and blood. Multiple factors place the childbearing woman at risk for hemorrhage from uterine atony. An understanding of the factors that increase the risk of uterine atony allows the nurse to anticipate hemorrhage and intervene to prevent excessive blood loss (Box 16-1).

TRAUMA

During the second stage of labor, soft tissue trauma from a number of causes (e.g., rapid labor, operative delivery, episiotomy) can result in genital tract lacerations (Box 16-2). While PPH from uterine atony is evident from a soft,

Box 16-1 Risk Factors for Uterine Atony

- Uterine overdistention
- Large baby
- Multiple gestation
- Hydramnios
- Bladder distention
- Prolonged first and/or second stage labor
- Precipitous labor
- Labor induction/augmentation with Pitocin
- Tocolytic therapy (especially with magnesium sulfate)
- High parity*
- Retained placental fragments
- Halogenated anesthetic agents
- Prolonged/mismanaged third stage of labor**

*Magann et al. (2005) found no correlation between PPH from uterine atony and maternal parity in their large study (18,735 women).

**In his review of PPH risk factors, Hobbins (2005) determined that a third stage >18 minutes increased the risk of PPH and that there is a six time greater risk of PPH if the third stage is >30 minutes.

Box 16-2 Risk Factors for Postpartum Hemorrhage from Tissue Trauma

- Rapid second stage labor
- Rapid/precipitous labor (< 3 hours from onset to delivery)
- Operative vaginal deliveries (forceps, vacuum extraction)
- Fetal manipulation (extrauterine or intrauterine version, corkscrew maneuver for shoulder dystocia [corkscrew maneuver: a progressive 180 degree manual rotation of the baby's posterior shoulder to release the impacted anterior shoulder]) (Cunningham et al., 2005, p. 512)
- Large episiotomies, including extensions
- Large baby
- Cesarean birth
- Uterine rupture (increased incidence with previous uterine surgery, tetanic contractions, labor stimulation, versions, placental attachment abnormalities)

blood-filled uterus, if the source of hemorrhage is genital tract lacerations, the uterus remains firm. One large or several small lacerations can adversely affect hemodynamic stability.

clinical alert

Postpartal blood loss

The nurse and other practitioners must remember that in the presence of a firm uterus, continual vaginal bleeding in a slow but steady trickle, with or without clots, can result in significant blood loss (MacMullen et al., 2005; Smith & Brennan, 2006).

Lacerations are usually internal and are not visible when the nurse examines the perineum. Identifying either a vaginal wall or cervical laceration usually requires that the physician or midwife examine the patient while she is in the lithotomy position. Not infrequently, the doctor locates and repairs a laceration before the patient's transfer to the postpartum unit.

TISSUE

Careful examination of the placenta after delivery is a component of standard care. Hence, retained placental tissue is an uncommon cause of early PPH. If the pregnancy included problems with placental implantation (e.g., previa, accreta), the primary care provider is aware of these risks before the birth takes place. Should the practitioner note that lobes of the placenta are missing during the placental examination, the physician or certified nurse midwife explores the patient's uterus to remove them. More often, a soft uterus with bright red bleeding later in the postpartum course identifies the source of a late postpartum hemorrhage (Cunningham et al., 2005; MacMullen et al., 2005).

THROMBIN

Thrombin refers to problems with maternal coagulation. Disorders of the coagulation system and platelets do not usually result in excessive bleeding during the immediate postpartum period. Preexistent maternal factors such as low fibrinogen levels and idiopathic thrombocytopenia

(ITP) and acquired pathology such as HELLP syndrome (condition characterized by **H**emolysis, **E**levated **L**iver enzymes, and **L**ow **P**latelet count) disseminated intravascular coagulation (DIC), sepsis, and abruptio placentae require vigilant care and anticipation of possible hemorrhage after birth (Smith & Brennan, 2006).

LATE POSTPARTUM HEMORRHAGE

Late postpartum hemorrhage occurs in only 1% to 2% of all childbearing women, usually within the first 2 weeks after birth (Franzblau & Witt, 2006). Retained placental fragments are the most common cause of late PPH. Other causes include subinvolution (failure of the uterus to return to its pre-pregnant size) and uterine infection. Regardless of the cause, treatment usually includes ergonovine medication (Ergotrate or Methergine 0.2 mg orally every 4 hours for 48 hours), antibiotics, and, if necessary, dilation and curettage to remove placental fragments. Since *Chlamydia trachomatis* is a common organism for postpartum uterine infection that causes subinvolution (Cunningham et al., 2005), tetracycline anti-infective agents such as Tetracap, Tetracylin and Sumycin are often prescribed. After birth and before discharge, the nurse is responsible for educating the patient and her family about the signs and symptoms of subinvolution. Signs and symptoms of subinvolution include lower abdominal (uterine) tenderness with or without fever, continuation of red vaginal drainage beyond 1 week, and foul smelling vaginal drainage, regardless of color.

Nursing Insight— Recognizing characteristics that point to the source of postpartal bleeding

The color and character of the blood and the consistency of the uterus can often identify the source of postpartal bleeding. When bleeding is associated with uterine atony or retained placental fragments, the blood is dark red with clots and the uterus is soft and boggy. When bleeding is associated with lacerations from the perineum, cervix, or vagina, the blood is bright red and the uterus remains firmly contracted.

HYPOVOLEMIC SHOCK

Hypovolemic (hemorrhagic) shock can result if PPH is not managed aggressively. Most women can tolerate a 1000 mL blood loss because they are healthy, have a 35% to 45% increase in the plasma and red blood cell (RBC) volume (2 pints of blood), and give birth in positions that “pool blood” in the pelvis (Cunningham et al., 2005).

clinical alert

Blood loss and vital signs

Normal physiological adaptations in pregnancy mean that a large loss of blood can occur before changes in vital signs (decreased blood pressure and increased pulse) are evident. The lack of objective signs and symptoms may lead to a delay in treatment.

The nurse, physician, or midwife may not see the usual signs of shock—restlessness, anxiety, pallor, cool, clammy

skin, increased pulse, tachypnea, shaking, decreased blood pressure—until 30% to 40% of the patient's total circulating blood volume has been lost.

COLLABORATIVE MANAGEMENT OF PPH

After birth, standard care requires frequent measurement of vital signs and fundal massage to check the location and condition of the uterine fundus. Most hospitals and birthing centers require that the registered nurse perform these checks at least every 15 minutes for the first postpartal hour. Thereafter, the frequency of assessment varies from one institution to another. As the primary caregiver and the one completing these assessments, the registered nurse may be the first person to identify excessive blood loss. When identified, immediate actions are necessary. While another member of the team calls the physician or nurse midwife, the nurse can obtain some important assessment data. The nurse must be cognizant of risk factors in the patient's history. After locating the uterine fundus and initiating fundal massage, the nurse can also begin frequent vital sign measurements with an automatic device. The nurse should also palpate the bladder for distention. The length of time it takes for blood loss to saturate a perineal pad is an important parameter to record, as is a measurement of total intake and output up to that point. Keeping in mind that the pulse and blood pressure may remain unchanged until a large volume of blood has been lost, the nurse must pay particular attention to the mean arterial pressure (MAP). A decrease in this measurement may be the first indicator of hypovolemia (Cunningham et al., 2005). Of importance, also, is to note the patient's behavior, in particular her level of consciousness, the presence of restlessness, vague complaints, and her pain level. Possible nursing diagnoses and goals for postpartum hemorrhage are listed in Boxes 16-3 and 16-4.

Box 16-3 Possible Nursing Diagnoses for Postpartum Hemorrhage

Fluid volume deficit related to decreased circulating blood volume secondary to uterine atony (genital tract trauma, uterine rupture, retained placental fragments, inversion of the uterus)

- Altered tissue perfusion related to hypovolemia
- Fear related to threat to health and powerlessness
- Pain related to uterine massage and invasive procedures
- Risk for infection related to invasive procedures

Box 16-4 Possible Goals for the Patient Experiencing a Postpartum Hemorrhage

- The patient's circulating blood volume will be maintained and/or the blood volume will be restored to a physiologically adequate level.
- Peripheral pulses and oxygenation will be maintained.
- The patient/family will express their fears.
- The patient's pain will be managed at a level acceptable to her.
- The patient will maintain normal vital signs and laboratory values.

Adapted from Wilkinson, J.M. (2005). *Nursing diagnosis handbook*. Upper Saddle River, NJ: Pearson Education.

Optimizing Outcomes— Using time intervals and weight to improve accuracy of the estimate of perineal pad saturation

It is difficult to estimate the amount of blood required to saturate a perineal pad. When fully saturated, a perineal pad can hold between 50 and 80 mL. The nurse can use distinct time intervals for measurement, such as every 15 or 30 minutes, to increase the accuracy of the estimated blood loss. For example, six pads saturated in 30 minutes is much more alarming than six pads saturated in 6 hours. It is also essential to differentiate between the terms “saturated” and “used” when performing a pad count. An accurate way to measure vaginal blood loss is to weigh the perineal pad before and after use and subtract the difference. One gram (1 g) in weight equals one milliliter (1 mL) in volume of blood because grams and milliliters are comparable measures. The woman should be positioned on her side when observing for blood loss. Otherwise, large amounts of pooled blood under her buttocks may go undetected.

Once the physician or nurse identifies a postpartum hemorrhage, interventions quickly follow. If the cause of the hemorrhage is uterine atony, continual fundal massage with lower uterine segment support is mandatory (Procedure 16-1). While one member of the team massages the fundus, another nurse establishes intravenous access with a large-bore needle (usually an 18-gauge or larger) and administers oxytocic drugs. The usual order of oxytocic drug administration is oxytocin (Pitocin), followed by methylergonovine (Methergine) or ergonovine (Ergotrate), carboprost (Hemabate), and recently, misoprostol (Cytotec). See Table 16-1 for further information and nursing implications concerning these medications.

clinical alert

Off-label use of misoprostol for postpartum hemorrhage

Misoprostol (Cytotec), a prostaglandin E₁ analogue, is neither marketed by its maker (Pfizer) for obstetrical use nor approved by the FDA for obstetrical use. However, its effectiveness in abating postpartum hemorrhage (and ripening of the cervix for the induction of labor) is now generally accepted. Since first introduced in 1985, it has been approved for use in the prevention and treatment of PPH in more than 85 countries. Misoprostol may be administered orally, sublingually, and intravenously. Maternal pyrexia and shivering are the most common side effects; nausea, vomiting, and diarrhea may also occur (Walters & Wing, 2007).

critical nursing action Immediate Intervention for Uterine Atony

As soon as excessive blood loss is noted, the nurse's most important intervention is to begin fundal massage. Support the lower uterine segment by placing a hand in a slight “C” position just above the symphysis pubis. *Do not* express clots if the uterus does not become firm with massage. The clots may protect the patient from an even greater blood loss.

Procedure 16-1 Performing Fundal Massage

Purpose

Fundal massage is used as an emergency measure to contract the uterus that is soft and boggy due to atony. It is performed to promote uterine tone and consistency and minimize the risk of hemorrhage. Uterine atony may result from prolonged labor, rapid or precipitous labor and birth, high parity, medications during labor (e.g., oxytocin, magnesium sulfate, inhalation anesthesia), intra-amniotic infection, operative delivery and uterine overdistention from multiple gestation, hydramnios, or macrosomia.

Equipment

- Clean examination gloves
- Disposable cleansing wipes
- Two clean peripads

Preexamination Preparation

1. Wash and dry hands, explain the procedure and its purpose to the patient; ensure privacy.

RATIONALE: Hand washing helps to prevent the spread of microorganisms. Explanations help to decrease anxiety; providing privacy helps to promote the patient's comfort and self-esteem.

2. Assemble necessary equipment, including clean examination gloves, disposable cleansing wipes, clean peripads.
3. Ask the patient to void, unless fundal massage must be performed immediately due to excessive bleeding.

RATIONALE: An empty bladder prevents uterine displacement and facilitates an accurate assessment of uterine tone.

4. Assist the woman to a supine position with the knees flexed and the feet placed together.

RATIONALE: Proper positioning facilitates easy visualization and enhances the effectiveness of the procedure.

Steps

1. Don gloves, remove the peripad, and inspect the perineum. Observe the character and amount of drainage on the pad and the presence of clots. Apply a clean peripad.

RATIONALE: Gloves serve as a barrier against possible infection from the vaginal drainage. Obtaining a baseline assessment provides information for future assessments; it also provides a means for evaluating the effectiveness of the procedure.

2. Place one hand on the abdomen, just above the symphysis pubis.

RATIONALE: This location provides support for the lower uterine segment.

3. Place the other hand around the top of the fundus.

RATIONALE: This location helps to locate and assess the fundus and the fundal height.

4. With the lower hand maintained in a stable position, rotate the upper hand and massage the uterus until it is firm. Avoid overmassaging the uterus.

RATIONALE: The uterus should be massaged only when it is not firm. Massaging a firm uterus may result in muscle fatigue and uterine relaxation. Overly aggressive fundal massage may result in uterine prolapse.

5. Once the uterus has become firm, gently press the fundus between the hands. Apply a slight downward pressure against the lower hand.

RATIONALE: Gentle squeezing with downward pressure assists in the expulsion of blood or clots that have collected in the uterine cavity.

6. Observe the perineum for the passage of clots and the amount of bleeding.

RATIONALE: This action helps to assess the presence of clots and the degree of bleeding.

7. Once the uterus remains firm, cleanse the perineum and apply a clean peripad. Dispose of the soiled gloves and pads according to institutional policy.

RATIONALE: This action promotes maternal comfort and hygiene and reduces the risk for infection.

8. Document the findings. Continue to assess the fundus and vaginal drainage according to institutional protocol. Alert the physician or nurse midwife if the fundus does not remain contracted or if bleeding persists.

RATIONALE: Documentation serves as a means for evaluation. Continued assessment allows for the early identification of problems and facilitates timely intervention with additional measures such as medications (i.e., oxytocin) to prevent hemorrhage.

Documentation

7/27/10 0550: Fundal massage performed with a moderate amount of bright red lochia and small clots expressed. Uterus remained firm and contracted below the umbilicus. Procedure tolerated well by the patient.

-Sejal Patel, RNC

Table 16-1 Medications and Nursing Considerations for Postpartum Hemorrhage

Name	Action	Dosage/Route	Contraindications	Nursing Considerations
Oxytocin (Pitocin)	Stimulates uterine smooth muscle and produces contractions similar to those that occur during spontaneous labor	10 units IM if no IV access; 10–40 units in 1000 cc crystalloid IV fluid (lactated Ringer's or normal saline)	Hypersensitivity	Monitor uterine response. DO NOT administer a bolus of undiluted oxytocin, as it can cause hypotension and cardiac arrhythmias. Consider administration of pain medication for uterine cramping.
Methylergonovine (Methergine)	Causes uterine contractions by stimulating uterine and vascular smooth muscles.	0.1–0.2 mg IM followed by 0.2 mg PO q4–6h × 24 hours	Hypersensitivity History of, or current elevation of blood pressure	Keep refrigerated. DO NOT add it to IV solutions or mix in a syringe with other medications.
Carboprost* (Hemabate)	Stimulates contractions of the myometrium	250 mcg IM or directly into the uterus (by MD or CNM) may repeat dosage	Asthma or glaucoma	Do not administer if patient demonstrates shock, as it will not be well absorbed. Keep refrigerated. This medication is VERY expensive.
Misoprostol (Cytotec)	Acts as a prostaglandin analogue; stimulates powerful contractions of the myometrium	400–1000 mcg rectally	Hypersensitivity to prostaglandins	Stable at room temperature. Rectal absorption is likely slower than IV medication. Monitor uterine response.

*Eighty to ninety percent effective in stopping postpartum hemorrhage when patient is unresponsive to Pitocin or Methergine (Smith & Brennen, 2006).

Data from Adams et al. (2005); Cunningham et al. (2005); Smith & Brennan (2006); and Tucker (2004).

If the patient has a distended bladder, an indwelling urinary catheter needs to be inserted and all intake and output carefully recorded. The nurse also needs to weigh pads, linens, and other bloody items on a gram scale to obtain an accurate picture of blood loss. It may be necessary to administer oxygen at 10 to 12 L/min to treat compromised tissue perfusion. Additional baseline information that should be obtained includes a complete blood count (CBC) and coagulation studies (PT [prothrombin time] partial thromboplastin time [PTT], fibrinogen, and fibrin degradation products). The physician or nurse midwife orders the blood tests, along with a type and cross match for replacement blood as an anticipatory measure in the event a transfusion is necessary. The patient is carefully assessed for indicators of disseminated intravascular coagulation (DIC).

DIC is a diffuse clotting pathology that involves the consumption of large amounts of clotting factors including platelets, fibrinogen, prothrombin, and factors V and VII. The pathological process may cause both internal and external bleeding. Vascular occlusion of small vessels occurs as small clots form in the microcirculation. Although DIC may occur during the postpartum period, it is most likely to be associated with abruptio placentae, severe preeclampsia, amniotic fluid embolism, septicemia, cardiopulmonary arrest, hemorrhage, and dead fetus syndrome (a complication that may occur when the fetus has died and is retained in the uterus for 6 or more weeks). Diagnosis is made according to clinical findings and laboratory results. (See Chapters 11, 14, and 33 for further discussion.)

Labs: Findings with DIC	
Low hemoglobin	Low fibrinogen
Low hematocrit	Elevated fibrin split/degradation products
Low platelets	

The physician or midwife may also perform bimanual compression in an effort to empty the uterus of clots and restore its tone. To perform this procedure, the physician inserts one hand in the vagina while pushing against the fundus through the abdominal wall with the other hand (Fig. 16-1). If these interventions fail to stabilize the patient by restoring tone to the uterus and decreasing the blood loss, an invasive procedure performed in the operating room will be necessary. Invasive procedures include the placement of uterine packing, embolization (occlusion of a vessel with a clot, usually in a radiological procedure), or uterine artery ligation (a simple, highly effective treatment to control bleeding that involves stitching the artery/vein to narrow its lumen and significantly decrease blood flow to the involved organ).

Optimizing Outcomes— Holistic care during management of a PPH

Best outcome: The nurse provides physiologic care in a timely manner and also serves as an advocate for the patient's pain control and reassures the patient and her family by explaining interventions as they occur. These actions help control not only the blood loss but also the patient's pain and the patient's/family's anxiety.

Figure 16-1 Bimanual compression.

Collaborative interventions for hemorrhage from genital tract lacerations are essentially the same. Patients who are experiencing hemorrhage from genital tract lacerations need a large-bore intravenous site, frequent recording of vital signs, accurate measurements of intake and output from all sources (including blood), lab work, an indwelling urinary catheter, oxygen, and pain medication. In addition, the physician or nurse midwife examines the perineum, vagina, and cervix in an attempt to locate the source of bleeding. The postpartum nurse needs to help the patient assume a lithotomy position, obtain bright lighting and examination instruments, and prepare suction equipment. The nurse continually provides support and reassurance to the patient and her family. Most physicians or midwives choose to repair lacerations in the operating room with an anesthesiologist present and the patient anesthetized.

Once the crisis has passed and immediate interventions have been completed, a debriefing of the health care team's response to the situation can be helpful as a learning opportunity. The patient's outcomes will be evident as she recovers from the postpartum hemorrhage event. Of significance is to note the family's response to the unforeseen events and include them, as appropriate, in the discussion. Because most families expect childbirth to be uneventful, a postpartum hemorrhage can provoke widely differing emotional responses. The prudent and compassionate clinician takes the time to let both the patient and the family express their feelings and affirm their concerns. The nurse must be sure to include care of and bonding with the newborn in the recovery process.

Now Can You— Discuss postpartum hemorrhage?

1. State the four "T's" that lead to postpartum hemorrhage?
2. Describe five standard nursing interventions for managing postpartum hemorrhage?
3. Discuss holistic care in the management of a woman/family experiencing a postpartum hemorrhage?

Hematomas

DEFINITION, INCIDENCE, AND RISK FACTORS

A **hematoma** is a localized collection of blood in connective or soft tissue under the skin that follows injury or laceration to a blood vessel without injury to the overlying tissue. At the time of injury, pressure necrosis and inadequate hemostasis occurs. This complication can result in a large amount of blood loss and patient discomfort if not recognized rapidly. Risk factors for hematoma formation include genital tract lacerations, episiotomies, operative vaginal deliveries, a difficult or prolonged second stage of labor, and nulliparity. Hematomas occur most frequently in the vulva, but they can also occur in the vagina and in the retroperitoneal area (Figs. 16-2 and 16-3).

SIGNS AND SYMPTOMS

The most common sign or symptom of a hematoma is unremitting pain and pressure. The pain and pressure worsen if active bleeding continues. On examination of the perineal or vulvar areas, the nurse may notice discoloration and bulging of the tissue at the hematoma site. If touched, the patient complains of severe tenderness, and the clinician generally describes the tissue as "full." If the hematoma is large, signs of shock may be evident and the patient may exhibit an absence of lochia, and an inability to void. Possible nursing diagnoses and goals for a patient experiencing a hematoma are presented in Box 16-5.

COLLABORATIVE MANAGEMENT

Assessment for the presence of a hematoma involves listening to the patient's subjective complaints, measuring vital signs, and examining the perineal and vulvar areas to identify a bulging mass. To examine the perineal and vulvar areas, the nurse assists the patient to a side lying position, gently lifts the upper buttock, and asks her to bear down. The nurse also needs to watch for behavioral signs and symptoms of shock (previously described) and assess the patient's and family's understanding of what is occurring.

Figure 16-2 Vulvar hematoma.

Figure 16-3 Vaginal wall hematoma.

Box 16-5 Possible Nursing Diagnoses and Goals for Patients with a Postpartum Hematoma

- Pain related to tissue trauma and pressure.
Patient's pain will be managed to an acceptable level.
- Anxiety and/or fear related to knowledge deficit of procedures and plan of care.
Patient will express her fears.
- Altered family processes related to physiological crisis.
Patient and her family will support one another verbally and behaviorally.
- Powerlessness related to loss of control of physiological functions.
Patient will make choices over which she has control.
- At risk for infection related to invasive procedures.
Patient will remain afebrile and her WBC will be within normal limits.
Patient's perineum will heal without evidence of drainage or separation.
- At risk for fluid volume deficit.
Patient's blood loss will be minimized.
- At risk for altered attachment related to separation from infant.
Patient will demonstrate concern for and care of infant before discharge.

If findings from the assessment are strongly suggestive of a hematoma, the nurse needs to immediately notify the physician or nurse midwife and implement pain relief measures. If the hematoma is less than 3 to 5 cm in diameter, the physician usually orders palliative treatments such as ice to the area for the first 12 hours along with pain medication, and close observation of the area for extension of the hematoma. After 12 hours, sitz baths are prescribed to replace the application of ice. Sitz baths are therapeutic in providing comfort and in facilitating reabsorption of the clot. A hematoma larger than 5 cm may require incision and drainage with the possible placement of a drain. This invasive procedure is performed in the operating room while the patient is sedated with an anesthetic.

The health care team must be particularly sensitive to the fact that large hematomas can lead to shock. In this case, the physician orders aggressive treatment that includes intravenous fluids, oxygen, frequent measurement of vital signs, urinary catheter placement, and strict

intake and output measurements to stabilize the patient before taking her to the operating room.

In the midst of the important interventions implemented to deal with the hematoma, the nurse needs to remember that the family is watching and responding to events as they unfold. Neither the patient nor the family may understand what they are seeing or experiencing. As the various treatments and medications are administered, the nurse should explain each action, along with the rationale for it. If the patient and her family can be involved, it is important to allow them to make choices, so that they do not feel as powerless. The nurse can assist the family by encouraging them to care for and bond with the infant as much as possible.

case study Patient Experiencing a Vulvar Hematoma

Molly is a 20-year-old gravida 1, para 1 who gave birth to a term, healthy baby boy, weighing 9 lbs 1 oz (4.1 kg) at 23:32 hours. She received an epidural for labor pain control, pushed for 3 hours, and required a vacuum assisted delivery. Her perineum required repair of a third-degree laceration. After birth, the nurse discontinued the continuous epidural pump, placed ice on the perineum, completed the required 15-minute checks ($\times 5$), helped Molly breastfeed, and assisted Molly's boyfriend in holding the baby and taking pictures. On arrival to the mother-baby unit, Molly requests pain medication and states that the ice is helping some but that she wants to "stay on top of it." She rates the pain as a 5 on a 10-point scale. The admission vital signs and fundal location are within normal limits. An examination of Molly's perineum reveals mild swelling and a normal amount of vaginal bleeding. Molly is tired and asks that she be allowed to sleep. Her boyfriend goes home to sleep, and the baby is taken to the nursery.

Two hours later, Molly calls for her nurse and complains of intense burning, pain, and pressure "where I had my stitches." You examine her perineum and note an 8 cm bulging mass on her left vulva. When you touch it with a gloved hand, Molly says, "Oh, that is so tender! That hurts!"

critical thinking questions

1. What factors during birth placed Molly at risk for development of a hematoma?
 2. Name two appropriate nursing diagnoses for Molly.
 3. What are the expected outcomes for Molly?
 4. List four nursing interventions along with rationales.
- ◆ See Suggested Answers to Case Studies in the text on the Electronic Study Guide or DavisPlus.

Now Can You— Discuss implications of a postpartum hematoma?

1. Describe the classic signs and symptoms of a puerperal hematoma?
2. Identify the most common anatomical locations for a postpartum hematoma?
3. Differentiate between the collaborative management for a small and a large hematoma?

Puerperal (Postpartum) Infections

DEFINITION AND INCIDENCE

Puerperal infection is a bacterial infection of the genital tract, usually of the endometrium (**endometritis**) that occurs within 28 days after miscarriage, induced abortion, or childbirth. The presence of fever often indicates puerperal infection. In the United States, the definition continues to be a temperature of 100.4°F (38°C) or greater on 2 successive days of the first 10 postpartum days (omitting the first 24 hours) measured orally at least four hours apart. A fever of 102.2°F (39°C) or greater within the first 24 hours is often associated with severe pelvic sepsis, usually resulting from Group A or B *Streptococcus* (Cunningham et al., 2005; Table 16-2).

Throughout the world, puerperal infection probably constitutes the major cause of maternal morbidity and mortality; in the United States, the postpartum infection rate is 1% to 8%, with a mortality of 4% to 8% from complications (Kennedy, 2007). Cesarean birth mothers have a greater incidence (5% to 15%) of postpartum infection than do mothers who give birth vaginally (1% to 3% incidence) (Franzblau & Witt, 2006). If a cesarean birth mother experiences a prolonged labor prior to delivery, the incidence of postpartum infection increases to 30% to 35%.

Optimizing Outcomes— Educating patients about risk factors for puerperal infection

Shorter hospital stays after birth make the nurse's role in educating the new mother and her family about signs and symptoms of postpartum infection vitally important. The nurse should alert the patient about antepartum or intrapartum events that are risk factors for the development of a postpartum infection and make certain the family understands the importance of promptly notifying their care provider if any symptoms occur.

TYPES OF PUERPERAL INFECTIONS

Infections during the puerperium most commonly involve the endometrium (endometritis), operative wound (cesarean incision; episiotomy), urinary tract, and breasts (**mastitis**). Septic pelvic thrombophlebitis may also occur.

Endometritis

During the immediate postpartum period, the most common site of infection is the uterine endometrium (Fig. 16-4). This infection presents with a temperature elevation over 101°F (38.4°C), often within the first 24 to 48 hours after childbirth, followed by uterine tenderness and foul-smelling lochia. Since urinary tract infections can occur during any part of the pregnancy and puerperium, differentiating the various signs and symptoms is important. As noted in Tables 16-2 through 16-6, other infections are more likely to occur following discharge from the hospital. Therefore, follow-up in the home or clinic by a nurse or primary care provider may offer the first opportunity to identify infectious processes.

Mastitis

Mastitis is usually unilateral and develops after the flow of milk has been established. The most common causative organism is *Staphylococcus aureus*, introduced from the

infant's mouth through a fissure in the nipple. The infection involves the ductal system, causing inflammatory edema, enlarged axillary lymph nodes, and breast engorgement with obstruction of milk flow (Fig. 16-5). Without treatment, mastitis may progress to a breast abscess. Symptoms include fever, malaise and localized breast tenderness. Management centers on antibiotic therapy (e.g., cephalosporins and vancomycin), application of heat or cold to the breasts, hydration, and analgesics. To maintain lactation, the woman may empty the breasts every 2 to 4 hours by breast feeding, manual expression, or breast pump. Since mastitis usually occurs after hospital discharge, an important component of nursing care includes teaching the breastfeeding mother about signs of mastitis and strategies to prevent cracked nipples.

NURSING ASSESSMENT

Assessment is central to the delivery of safe, effective postpartal nursing care. Ongoing, careful attention must be paid to the patient's mental status and to her vital signs, breasts, fundus, lochia, incisions, and urinary status. Temperature elevation may be the first indication of an infection. If an elevated temperature is combined with any of the following signs and symptoms, the nurse must notify the primary care provider immediately: tachycardia, uterine or fundal tenderness or pain, foul-smelling lochia, an absence or decrease in lochia, chills, decreased appetite, malaise, elevated white blood cell count (WBC), back pain (costovertebral angle tenderness [CVAT]), generalized aching, headache, dysuria, urinary frequency or retention, wound drainage, erythema, edema. Early, ongoing collaborative treatment can then be initiated.

Optimizing Outcomes— Tests to help identify a postpartum infection

To detect sources of puerperal infection, the nurse can anticipate that the following samples are likely to be obtained:

- Complete blood count (CBC) with differential
- Blood cultures if sepsis is suspected
- Urinalysis with culture and sensitivity
- Cervical, uterine, or wound culture as needed

COLLABORATIVE MANAGEMENT

All bacterial puerperal infections require treatment with antibiotics. The nurse can encourage rest and increased fluid intake and instruct the patient about the importance of increasing protein and vitamin C in her diet. In many hospitals, a nurse can refer a patient to a dietitian for instruction without a physician's order.

Comfort measures are as important in facilitating the patient's full recovery as the administration of antibiotics. Cool showers, sitz baths, warm compresses applied to the breasts, therapeutic touch and massage, soothing music, relaxation techniques, pain medications, and antipyretics are all strategies to promote patient well-being. Because of their anti-inflammatory effect, many physicians order a nonsteroidal anti-inflammatory medication (NSAID) to serve as an antipyretic and analgesic. Throughout the course of treatment, health care team members also need to provide education to the patient and her family regarding her diagnosis and prognosis, treatment plan, measures to promote good hygiene, and follow-up care.

Table 16-2 Postpartum Infection: Endometritis

Type of Infection	Risk Factors	Onset	Signs and Symptoms	Causative Organisms	Diagnosis Based on	Collaborative Treatment	Prognosis and Complications
Endometritis (inflammation and infection of the inner lining of the uterus) Incidence: vaginal birth 1–3% and cesarean birth 10–20% (Kennedy, 2005)	Cesarean birth Prolonged rupture of the membranes, multiple vaginal examinations, internal electronic FHR monitoring, low socio-economic status, poor nutrition, young age, diabetes, prior genital infection, lapse in aseptic technique, anemia, smoking, multiparity, operative vaginal delivery, poor postpartum perineal care	2–4 days following childbirth	Prolonged fever > 100.4°F (38°C), foul smelling lochia, uterine or abdominal tenderness, chills, poor appetite, malaise, increased pulse rate, cramping pain, increased white blood cell count (WBC) (above 20–30,000 mm ³)	Normal vaginal flora and enteric bacteria	Clinical signs and symptoms. Vaginal and bimanual examination. Laboratory test results: culture of lochia; elevated white blood cell count (WBC) (Must also rule out urinary tract infection)	<ol style="list-style-type: none"> 1. MD/CNM: order antibiotics 2. Treat symptoms: <ol style="list-style-type: none"> a. Rest b. Antipyretics c. Increase fluid intake d. Encourage high protein, high vitamin C foods e. Promote uterine drainage via ambulation and Fowler's position f. Instruct in perineal care 3. Explain treatments to patient/family 4. Home antibiotic therapy may need to be arranged with follow-up by a home care nurse. 5. Promote infant attachment. 	90–95% improvement within 48–72 hours after treatment. May be discharged on oral antibiotics <i>Complication:</i> Extension of infections via lymphatic system to connective tissues (pelvic infection) Dehiscence of cesarean section incision or episiotomy Peritonitis

Data from American Academy of Pediatrics & American College of Obstetricians and Gynecologists (2002); Cunningham et al. (2005); and Gibbs et al. (2004).

Figure 16-4 Postpartum endometritis.

Family Teaching Guidelines... Prevention of Infection

- ◆ Wash your hands before and after going to the bathroom, when changing pads, changing the baby's diaper, etc. Hand washing with friction removes infection-causing microorganisms.
- ◆ Use a squeeze bottle with warm water to cleanse the perineum, pat the perineum dry, and remove and replace pads from front to back. Front to back patting and pad removal/application prevents bringing rectal organisms forward to the perineum and vagina.
- ◆ Drink extra fluids (eight 8-ounce glasses of water) to increase urine production. The increased blood flow and urine production will decrease the stagnation of microorganisms in the urinary tract.
- ◆ Wash incisions with soap and water. Be sure to dry the incision completely. If necessary, use a hair dryer set on low heat to be sure the incision is dry. A dry incision is less likely than a wet one to promote bacterial growth.
- ◆ If breastfeeding, feed the infant every 2–3 hours and alternate feeding positions. Be sure the baby gets as much of the nipple and areola in his mouth as possible. These actions reduce the likelihood of injury to the nipple.
- ◆ For a breast infection to occur, a cracked or blistered nipple is necessary. Use lanolin, vitamin E, cod liver oil, or express breast milk and rub any of these into the nipple to help reduce soreness and to protect the nipple from trauma.
- ◆ Echinacea is an herb that can boost the immune system. It has anti-inflammatory effects and stimulates the production of interleukin and interferon (both of which help the body fight infection, bacterial and viral) (Lincoln & Kleiner, 2004).

ESSENTIAL INFORMATION

- ◆ Notify your health care provider if you develop pain, redness, or swelling at the site of any incision.
- ◆ Notify your health care provider if you develop a fever of 100.4°F (38°C). (If you are breastfeeding, a temperature elevation to 100.4°F [38°C] may occur when your milk production begins) (Lincoln & Kleiner, 2004).

herbal medication: Echinacea Purpurea

Echinacea (Ek-i-neigh-sha)

Pregnancy Category: Injectable form not recommended during pregnancy

Indications: Treatment of wounds, injuries, enlarged lymph nodes; prevent and reduce symptoms and duration of common cold and bacterial infections of the upper respiratory tract; used by Native Americans to treat burns and insect and rattlesnake bites.

Actions: Boosts the immune system by increasing phagocytosis of the WBCs and by inhibiting the bacterial enzyme hyaluronidase; also stimulates the production of interleukin and interferon; exerts an anti-inflammatory action.

Therapeutic Effects: Used by proponents to both prevent and treat infections; juice from leaves used as a supportive treatment for vaginal yeast infections; approved in Germany for treatment of the common cold and influenza.

Contraindications and Precautions: Herb–drug interactions with amiodarone, anabolic steroids, ketoconazole, methotrexate (possible increased hepatic toxicity) Possible exacerbation of autoimmune diseases (rheumatoid arthritis, lupus, multiple sclerosis, etc.) because of its immune system stimulation properties (no clinical evidence to support).

Is a member of the Daisy family: possible crossover allergic reaction

Adverse Reactions and Effects: No toxicity noted with even extremely high doses of oral Echinacea; most common side effects from oral form—gastrointestinal symptoms and increased urination.

INJECTIONS SIDE EFFECTS: short-term nausea, vomiting, shivering, headache, fever

Route and Dosage: Tincture, oral, injection (dosage individualized)

Nursing Implications:

1. Be sure to ask every patient if she uses herbal remedies.
2. Instruct the patient that daily dosages of Echinacea in an attempt to prevent infections may decrease the immunostimulating effects of this herb.
3. Since the U.S. Food and Drug Administration (FDA) has not approved herbal treatments/remedies, encourage the patient to be sure that she uses a reputable form of the herb to ensure its quality.

Data from Adams et al. (2005); Deglin & Vallerand (2009); and Lincoln & Kleiner (2004).

Although the infection may be easily treated and short lived, any postpartum complication can psychosocially affect a patient and her family. Prolonged treatment or hospitalization may create financial hardships, negatively impact family relationships and attachment with the infant, or result in psycho-emotional or spiritual crises. Referrals to the social worker, hospital chaplain or pastor, financial counselor, lactation consultant, community health nurse, or counselor need to be considered as an essential component of holistic care. As the health care team member who is most consistently present, the nurse has a responsibility to help the patient and her family identify when such referrals would be beneficial and to serve as an advocate to ensure that the patient receives these services.

Text continued on page 527

Table 16-3 Postpartum Infection: Wound Infections

Type of Infection	Risk Factors	Onset	Signs and Symptoms for ALL	Causative Organisms	Diagnosis Based on	Collaborative Treatment	Prognosis and Complications
Wound infections	Endometritis (infected lochia), poor hygiene, fecal contamination, hematoma	Early: 48 hours Late: 6–8 days	Pain, foul smelling discharge, edema, low grade fever	Polymicrobial, normal vaginal flora	Clinical signs and symptoms, subjective complaints	1. Antibiotics per order 2. May require incision and drainage with placement of drain to facilitate healing by secondary intention.*	Improvement usually within 24–48 hours; may require long term antibiotic therapy
Perineal Incidence: 0.35–10%	ALL wound infections: obesity, diabetes, hypertension, immunosuppression, malnutrition, anemia, hemorrhage, prolonged labor, chorioamnionitis		Sudden chills, high fever, abdominal tenderness, erythema, edema, warmth of incision, drainage from the incision	<i>Staphylococcus aureus</i> , aerobic streptococci, aerobic and anaerobic bacilli	Clinical signs and symptoms, along with a poor response to antibiotics given for endometritis. Laboratory test results: elevated white blood cell count (WBC)	If packing has been placed in the wound to keep it open and maintain drainage, alert the patient to exercise caution when changing her perineal pads to avoid dislodging the packing. 3. Perineal: sitz baths; instruct in perineal care 4. Cesarean: wet to dry dressing changes 3+ times/day	Complication: Necrotizing fasciitis, abscess, wound dehiscence
Cesarean incision Incidence: 3–5%	prolonged rupture of membranes, hematoma					5. Pain medication per order (usually nonsteroidal anti-inflammatory drugs [NSAIDs]) 6. Instructions to patient and family about wound care. 7. Possible referral for home health or community health nurse visits	

*Secondary intention: healing from the inside of the wound out to the skin. Data from Cunningham et al. (2005); Franzblau & Witt (2006); Gibbs et al. (2004); and Kennedy (2007).

Table 16-4 Postpartum Infection: Urinary Tract Infections (UTI)

Type of Infection	Risk Factors	Onset	Signs and Symptoms	Causative Organisms	Diagnosis Based on	Collaborative Treatment	Prognosis and Complications
Urinary tract infections Incidence: 2–4%	Catheterization, multiple vaginal exams, poor postpartum hygiene, genital tract trauma, epidural anesthesia, cesarean birth, premature rupture of the membranes, poor nutritional status, history of UTIs during pregnancy, diabetes, decreased bladder sensation following birth	Any time during pregnancy or after birth	May have none Dysuria (painful urination), frequency, burning on urination, difficulty voiding and/or retention, costovertebral angle tenderness (CVAT), back or suprapubic pain, hematuria (blood in the urine); fever, fatigue, nausea, vomiting	Most common: <i>Escherichia coli</i> (60–90% of all UTIs); <i>Proteus mirabilis</i> , <i>Klebsiella pneumoniae</i> , group B hemolytic streptococcus, <i>Staphylococcus saprophyticus</i>	Clinical signs and symptoms. Laboratory test results: urine C&S, presence of leukocytes and blood on urine dipstick	<ol style="list-style-type: none"> Antibiotics per order (usually sulfonamides, aminopenicillins, anti-infectives, nitrofurantoin, or cephalosporins × 3–10 days depending on symptoms). Teach importance of taking all medication. Encourage increased fluid intake, including cranberry juice. Encourage rest. Instruct in perineal care. Instruct in monitoring temperature, bladder function, normal appearance of urine. Instruct in/administer antipyretics, antispasmodics, analgesics, and antiemetics. Educate patient to avoid recurrence: <ol style="list-style-type: none"> When intercourse resumes, void following. Clean from front to back. 	Improvement within 48–72 hours following initiation of antibiotic therapy Can reoccur with bacteremia and scarring of the kidney followed by hypertension and kidney damage

Data from Cunningham et al. (2005); Franzblau & Witt (2006); and Kennedy (2007).

Table 16-5 Postpartum Infection: Mastitis

Type of Infection	Risk Factors	Onset	Signs and Symptoms	Causative Organisms	Diagnosis Based on	Collaborative Treatment	Prognosis and Complications
Mastitis	Milk stasis, plugged milk duct, infrequent breastfeeding, fatigue, nipple trauma, primiparity	3–4 weeks postpartum	Warm, tender, hardened area on breast (usually only one), enlarged axillary lymph nodes, fever (up to 102°F [38.9°C]), chills, generalized aching, headache, malaise	Most common: <i>Staphylococcus aureus</i> ; also: <i>Haemophilus parainfluenzae</i> (from infant's mouth and nose), <i>Candida albicans</i> , <i>Streptococcus viridans</i>	Clinical signs and symptoms Laboratory test results: culture of breast milk	<ol style="list-style-type: none"> 1. Notify MD/CNM 2. Initiate antibiotics. 3. Continue breastfeeding or manual/electrical expression of milk to maintain lactation. May be instructed to discard the milk. 4. Promote rest. 5. Increase fluid intake. 6. Pump breast after infant feeding to ensure breast is empty. 7. Warm compress or ice to breast for comfort. 8. Antipyretics 9. Instruct in high protein, high vitamin C diet. 10. Educate regarding hygiene and prevention of future recurrence. 11. Assess the infant's mouth for signs of thrush (oral <i>Candida</i>), an overgrowth of fungal organisms related to the mother's antibiotic therapy. 	Improvement within 24–48 hours following initiation of antibiotics Complication: Breast abscess If breast abscess occurs: must discontinue breastfeeding on the affected side—may lead to decreased maternal-infant attachment, low self-esteem and feelings of disappointment and guilt

Data from Lawrence, R., & Lawrence, R. (2005). *Breastfeeding: A guide for the medical profession* (6th ed.). Philadelphia: C.V. Mosby.

Table 16-6 Postpartum Infection: Septic Pelvic Thrombophlebitis

Type of Infection	Risk Factors	Onset	Signs and Symptoms	Causative Organisms	Diagnosis Based on	Collaborative Treatment	Prognosis and Complications
Septic pelvic thrombophlebitis	Cesarean birth, genital tract lacerations, history of varicosities, immobility, operative vaginal delivery, prolonged labor, multiple vaginal exams	48 hours to 4–6 weeks postpartum	Fever > 102.2°F (39°C) with spikes after initiation of antibiotic therapy, abdominal and/or back pain, chills, increased pulse (resting tachycardia), few or absent bowel sounds	Normal vaginal flora and enteric bacteria—is usually an extension of endometritis	Clinical signs and symptoms: Pelvic CT or MRI to confirm the clinical picture; Laboratory test results: CBC; coagulation profile; blood chemistries	<ol style="list-style-type: none"> 1. MD/CNM: prescribe antibiotics 2. Add heparin therapy to increase APTT (activated partial thromboplastin time) to 1.5–2 times the normal value 3. Rest in Fowler's position 4. High protein, high vitamin C diet 5. Increased fluids 6. Comfort measures: pain medications, antipyretics 7. Complementary therapies: heat, cold, relaxation, music, touch, etc. 8. Explain treatments. 9. Promote infant attachment. 	Improvement usually within 48–72 hours of heparin initiation; may need to continue anticoagulant therapy for 6 months (7–10 days of heparin followed by warfarin [Coumadin]) Complication Pulmonary embolism Possible decreased infant attachment; prolonged hospitalization

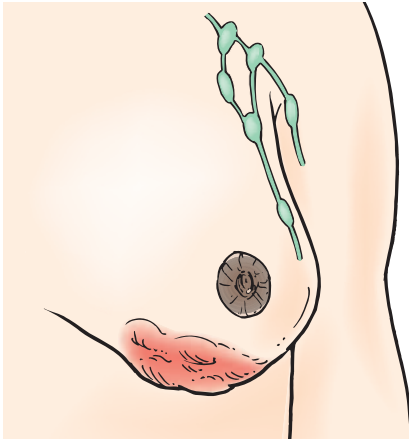

Figure 16-5 Mastitis usually occurs several weeks after childbirth. The axillary lymph nodes are enlarged and there is a warm, tender, hardened area on the affected breast.

Across Care Settings: Care collaboration to prevent postpartum infection after discharge

If the postpartum patient is at risk for the development of a postpartum infection, the nurse needs to communicate this information to health care providers and family members who may be involved in helping her after she goes home. Some hospitals routinely follow new mothers into the home with a postpartum and newborn visit by a registered nurse. The lactation consultant or breastfeeding support group, newborn's physician, or public health nurse should also be notified of events during labor, birth, or postpartum that they should address the first time they see the new mother following discharge.

Now Can You— Discuss infections that occur during the puerperium?

1. List six risk factors for the development of a postpartum infection?
2. Describe nursing assessment findings that should be reported to the physician or nurse midwife that indicate the patient has an infection?
3. Discuss ways the nurse can promote healthy family dynamics for the woman hospitalized with a postpartum infection?

Thrombophlebitis and Thrombosis

DEFINITION, INCIDENCE, AND RISK FACTORS

Thrombophlebitis and **thrombosis** are terms that describe an inflammation of the venous circulation and blood clot formation that typically occur in the lower extremities. The depth of the inflammation and the location of the involved veins determine the severity of this complication. Veins located above the fascia, such as the saphenous vein system, are superficial, and distend easily, while veins below the fascia, such as the popliteal system, are deep and less elastic.

The incidence of postpartal thrombophlebitis and deep vein thrombosis (DVT) is low and varies from approximately 0.5 to 3 per 1000 women. The decline in incidence over the past two decades is largely attributable to early postpartum ambulation, which has become the standard of care. Venous stasis and hypercoagulation, normal changes during pregnancy, are the major causes of thromboembolic disease. After the third month of pregnancy, fibrinogen levels increase, and in the second half of pregnancy, clotting factors VII, VIII, IX, and X increase in preparation for minimizing normal blood loss during birth. A decreased breakdown of fibrin, which forms the protein mesh of a clot, also occurs (Cunningham et al., 2005).

Lower extremity venous stasis results from the weight of the gravid uterus on the maternal inferior vena cava and pelvic veins. If the woman smokes, is obese, older (greater than 35 years), immobile, or a grand multigravida, the risk of DVT also increases. Chronic health problems such as inflammatory bowel disease, lupus erythematosus, antiphospholipid syndrome, varicose veins, and pregnancy-related conditions such as preeclampsia, an operative vaginal delivery, cesarean birth, hemorrhage, and sepsis are all possible precursors to the development of DVT. A woman with a positive history of DVT is also at greater risk than one with no DVT history (Colman-Brochu, 2005; Cunningham et al., 2005).

Ethnocultural Considerations— Ethnicity and factor V Leiden mutation

Ethnicity influences coagulation patterns. Approximately 5% to 7% of North American Whites, 2% of Hispanics, and 1% of African Americans have a deficiency of coagulation inhibitors, termed the factor V Leiden mutation. Individuals need factor V to convert prothrombin to thrombin. Protein C inhibits the conversion of prothrombin to thrombin. Normally, protein C levels remain constant during pregnancy. When a factor V Leiden mutation occurs, protein C is lower than normal, and the body converts prothrombin to thrombin more readily. Women with factor V Leiden mutation have an increased risk for the development of a DVT during the puerperium (Cunningham et al., 2005; Foster, 2007).

PATHOPHYSIOLOGY

DVT develops from several key factors: a hypercoagulable state, venous stasis, and vein injury. A hypercoagulable state and venous stasis routinely exist in a normal pregnancy. Vessel injury can occur from trauma to an extremity, from birth events such as operative vaginal deliveries or cesarean births, and from simple invasive procedures such as an intravenous catheter insertion or venous blood sampling. Once vessel injury occurs, platelets begin to clump, then stick to one another. Thrombus formation follows.

SIGNS AND SYMPTOMS

Superficial venous thrombosis involves the superficial saphenous venous system. The most common form of postpartum thrombophlebitis, superficial venous thrombosis is characterized by pain and tenderness in the lower extremity. Deep vein thrombosis is more common during

pregnancy and may extend from the foot to the iliofemoral region. It is associated with unilateral leg pain, calf tenderness, and swelling. However, up to 50% of all individuals with a DVT are asymptomatic. Signs and symptoms depend on the size, location, degree of vessel occlusion, and development of collateral circulation around the clot. The classic presentation of DVT involves pain, tenderness, edema, redness, and localized heat. The presence of a palpable cord, changes in skin color (“milk” or “blue leg”), a decreased peripheral pulse, and a circumference that is 2 cm larger (or more) in the affected extremity assists in the DVT diagnosis. Dorsiflexing the woman’s foot while her knee is extended may elicit a positive Homans’ sign (pain in the foot or leg) in the presence of thrombophlebitis and thrombosis (Colman-Brochu, 2005; Cunningham et al., 2005) (Fig. 16-6).

Nursing Insight— Recognizing signs and symptoms indicative of DVT

Additional signs and symptoms that may be associated with DVT include elevated temperature, cough, tachycardia, hemoptysis, pleuritic chest pain, and increasing apprehension. The presence of dyspnea and tachypnea may signal pulmonary embolism. Pulmonary embolism is a complication of DVT that occurs when part of a blood clot breaks away and travels to the pulmonary artery, where it occludes the vessel and obstructs blood flow to the lungs.

DIAGNOSTIC TESTS

Because pregnancy is frequently accompanied by various aches and lower extremity edema, the clinical presentation of thrombophlebitis and DVT may be difficult to identify. The venogram, an invasive test used to confirm deep vein thrombosis, is contraindicated in pregnancy. No specific laboratory tests can confirm or exclude deep or superficial venous thrombosis. Venous duplex ultrasonography (real-time imaging and Doppler flow studies) is the appropriate test to confirm the diagnosis of DVT.

Figure 16-6 Deep vein thrombophlebitis.

If the result of this test is equivocal, **magnetic resonance imaging** (MRI) (a diagnostic test that uses electromagnetic energy to provide images of the heart, large blood vessels, brain, and soft tissues) may be ordered to determine the extent of any pelvic vein involvement (Colman-Brochu, 2005; Cunningham et al., 2005).

COLLABORATIVE MANAGEMENT

Routine interventions for either superficial or DVT include the administration of analgesics; rest with elevation of the affected extremity; elastic support to the affected leg; increased fluid intake; and the local application of moist, warm packs. The nurse should ensure that the weight of the warmed pack does not rest on the leg, causing obstruction of blood flow. Analgesics are prescribed for pain.

clinical alert

Avoiding extremity massage when DVT is suspected

If DVT is present or suspected, it is essential to refrain from massaging the affected area. This action could loosen the clot and result in a pulmonary or cerebral embolism.

Possible nursing diagnoses and goals for the patient with DVT are presented in Box 16-6. The patient usually is given bathroom privileges for elimination needs. If the thrombosis is located in a deep vein, hospitalization for either intravenous or subcutaneous heparin therapy is generally required. The patient is usually placed on complete bedrest until the anticoagulation therapy is effective. The goal in heparin dosing is to increase the prothrombin time (PT) to 1.5 to two times higher than the control. The pregnant patient has a greater plasma volume and an increased renal clearance (due to increased blood flow to the kidneys). The combination of normally occurring heparin-binding proteins along with the breakdown of heparin often results in the need for higher doses of heparin during pregnancy. The primary purpose of heparin therapy is to prevent extension of the current clot and to prevent new clot formation (Colman-Brochu, 2005).

During hospitalization, the nurse needs to monitor the patient for any signs of unusual bleeding and make certain that the antidote for heparin (protamine sulfate) is readily available. Vital signs should be measured at least every 4 to 6 hours, analgesics administered as needed, and circulation to the affected extremity checked during every nursing shift. The circumference of the affected extremity

Box 16-6 Possible Nursing Diagnoses for Thrombophlebitis and Thrombosis

- Pain
- At risk for injury
- Altered peripheral tissue perfusion
- Altered family processes
- Self-care deficit
- Fear
- Altered individual/family coping

should be measured and recorded daily. As the therapy continues, the nurse should assist the patient in increasing her level of activity and in assuming self-care activities. Equally as important, the nurse must assess the patient and her family for signs and symptoms of depression, anger, or decreased attachment to the newborn. Many insurance companies require that the infant be discharged, even if her mother needs to stay in the hospital. Some families may choose to care for the infant at home during the first few postpartum days while the mother is acutely ill. This decision may negatively impact the new mother's ability to feed, care for, and bond with her infant and may also create family conflicts that require the assistance of a spiritual advisor, financial counselor, social worker, home health nurse, lactation consultant, or family therapist. All members of the health care team need to encourage family involvement in the patient's care. If a family member can bring the infant to the hospital daily, the patient can be assisted in holding and caring for her infant and maternal attachment can be promoted.

Warfarin (Coumadin), an oral anticoagulant, is introduced before the patient's discharge, and during this time, the heparin therapy is tapered. Since warfarin is excreted in breast milk, the breastfeeding mother is maintained on subcutaneous heparin, and the warfarin is omitted. Either medication (heparin or warfarin) is continued for a minimum of 3 months after birth. Use of this long-term therapy regimen mandates specific patient–family education and support from a variety of health care providers. An important component of the discharge teaching conducted by the nurse, dietician, or pharmacist includes a discussion about medications, side effects, and potential interactions.

Optimizing Outcomes— Teaching patients about aspirin and anticoagulants

During discharge teaching, the nurse cautions the patient on anticoagulant therapy to avoid medications that contain aspirin (salicylic acid). Aspirin, which acts as an antiplatelet agent and prevents blood clotting, can lead to prolonged clotting time and an increased risk of bleeding.

Collaboration in Caring— Education about food–drug interactions

The nurse, pharmacist, or dietitian can initiate patient and family education about food and drug interactions. Nurses do not always feel comfortable providing education on dietary topics, and the dietitian has the knowledge to discuss this information with the patient and her family. Likewise, the pharmacist has greater knowledge than the nurse about drug effects and side effects. A team approach works well with topics such as this one. Be sure to obtain an interpreter if needed, and have written information available that the patient and her family can take home.

The nurse should emphasize the importance of follow-up care for laboratory tests and medication dosage adjustments. Avoiding trauma that may result in extensive bruising, using safe care practices to avoid bleeding, and instructing the patient and her family to be alert for signs that indicate the

medication: Warfarin

Warfarin (**war**-fa-rin)

Coumadin

Pregnancy Category: X

Indications: Prevention of thrombosis (clot) formation

Actions: Inhibits the hepatic synthesis of coagulation factors II, VII, IX, and X; inhibits the action of vitamin K

Therapeutic Effects: Used in patients who are at high risk for development of or who have a history of deep vein thrombosis or other thrombophilia (love of clot formation) conditions

Pharmacokinetics: 99% binds to plasma proteins, thereby delaying the effects of warfarin.

Route and Dosage: Orally; dosage adjusted on the basis of international normalized ratio (INR) results (range is 2.5 to 10 mg daily)

Contraindications and Precautions: Drug–drug interactions occur with NSAIDs, diuretics, antidepressants, steroids, some antibiotics, vaccines, and vitamin K. Concurrent use with NSAIDs may increase the risk of bleeding.

Herbal supplements such as garlic, ginger, and feverfew may increase the risk of bleeding. Arnica may increase the anticoagulant effect of warfarin.

Even after the drug is discontinued, its effects may continue for up to 10 days. Warfarin dosage must be individualized on the basis of prothrombin time results. The INR is now used for dosage adjustments. A normal INR is 2.0–3.5.

Adverse Reactions and Effects: Overdosage leads to excessive blood loss that may appear via gastrointestinal bleeding, bleeding from the gums, nosebleeds, petechiae, excessive bruising, etc. The patient begins with heparin therapy for anticoagulation and transitions to warfarin. Because normal clotting factors circulate in the patient's blood stream routinely, several days of both heparin and warfarin therapy may be required for the anticoagulant effect

Nursing Implications:

1. This drug is dangerous. The patient and family must receive detailed information regarding follow-up care and drug–drug, drug–herb, and food–drug interactions.
2. Instruct the patient to notify the doctor of excessive bruising, take warfarin at the same time each day, and to avoid activities that could result in a bleeding injury.
3. Be sure the patient receives instructions on foods to minimize/avoid. (Involve the dietitian).

Data from Deglin, J.H., & Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

anticoagulation therapy is excessive are also important topics for instruction. Short-term referral to a home health nurse should be considered; the hospital nurse may need to mention the need for this referral to the physician.

Be sure to— Document family education

The importance of clear, concise, complete chronological documentation of all patient/family education cannot be overly emphasized. The current litigious society in the United States lends itself to lawsuits against all health care providers. The nurse has primary responsibility for both routine/standard patient/family education as well as specialized education. If another health care provider, such as a dietitian, social worker, or pharmacist is involved in any aspect of patient/family education, the nurse should note this collaboration in the medical record as soon as possible.

PULMONARY EMBOLUS

The abrupt onset of chest pain, dyspnea, shock, diaphoresis, syncope, and anxiety in a patient with DVT signals a major complication, pulmonary embolus (PE). PE is a life-threatening emergency that results from the breakup of the clot with migration of pieces through the heart to the lungs. Emergency treatment for this potentially fatal complication involves the “ABC” response used for any cardiorespiratory event. The nurse should immediately call for assistance, administer oxygen, obtain the crash cart, and begin CPR if necessary. Both the physician and respiratory therapist are important responders. Assuming that chest compressions are not needed, the nurse should elevate the head of the bed and apply an automatic blood pressure machine, cardiorespiratory monitor, and pulse oximeter. If not already in place, a large-bore intravenous line must be started immediately, so that fluids, heparin, and pain medication (usually morphine) can be readily administered. Once stabilized, patients with a PE are routinely transferred to a critical care unit for further care.

If the PE occurs while the patient is still recovering from childbirth, ensuring care for the newborn and support for the patient’s family are paramount. Until the patient’s condition improves, limitations are placed on visitors. This arrangement usually means that the family can remain with the infant. In this situation, the postpartum nurse can debrief and provide explanations to the family about events and possible future care requirements. If the patient survives, both she and her family will need detailed instructions concerning the prevention of thrombus recurrence. They also need to understand that the patient is at a much greater risk for the subsequent development of a DVT, even in the absence of another pregnancy.

Now Can You— Discuss deep vein thrombosis?

1. Describe why the postpartum patient is at risk for development of a deep vein thrombosis (DVT)?
2. Discuss routine nursing care for the postpartum patient hospitalized with a DVT? (Remember to include the baby and family in this answer.)
3. Develop a postpartum teaching plan for the postpartum patient who is discharged on warfarin (Coumadin)?

Postpartum Psychosocial Complications

The focus on physiological recovery and health in the childbearing woman and her infant can easily result in an inaccurate assumption that all is well with the new family. Beyond the physical needs of the new mother lies a gamut of emotional, spiritual, relational, and socioeconomic concerns to which the nurse must be sensitive. Because most people consider childbearing a joyful time in life, the new mother who experiences negative emotions or who cannot cope with new demands on her time, energy, or priorities may struggle to recognize her need for help. Moreover, even if she recognizes her limitations and knows she needs help, the new mother may be reluctant to ask for help. Whether working in the hospital, in home care, in a clinic, or in a physician’s office, the nurse can be a lifeline for the woman who experiences postpartum psychosocial complications.

These complications include postpartum blues, depression, psychosis, panic disorder, and the long-term sequelae from abusive relationships, homelessness, and access to care.

POSTPARTUM BLUES

Postpartum blues are common. Fifty to eighty percent of all postpartum women experience some degree of postpartum blues within the first 2 weeks after childbirth. Blues are usually self-limiting, last several days, and often peak by the end of the first week. Signs and symptoms include tearfulness, mood swings, anxiety, fatigue, sadness, insomnia, forgetfulness, and confusion (American Academy of Pediatrics [AAP] & American College of Obstetricians and Gynecologists [ACOG], 2007; Franzblau & Witt, 2006). Often, extra rest, reassurance, and therapeutic listening encourage the new mother to see beyond the immediate crisis and realize that better days lie ahead. (See Chapter 15 for further discussion.)

POSTPARTUM DEPRESSION

Incidence, Definition, and Risk Factors

Fortunately, most postpartum women recover from the blues and are able to enjoy their newborns and families. However, 8% to 15% of postpartal women progress to postpartum depression (PPD). According to the American Psychiatric Association (APA, 2000), a diagnosis of depression requires that one of two symptoms exist most or all of the day: a depressed mood or decreased interest/pleasure in previously enjoyable activities. Recognized risk factors for PPD include an undesired/unplanned pregnancy, a history of depression, recent major life changes such as the death of a family member or moving to a new community, lack of family or social support, financial stress, marital discord, adolescent age, and homelessness (APA, 2000; Cunningham et al., 2005; Nonacs, 2005).

Collaboration in Caring— Resources for the postpartal patient

A woman who presents to the hospital with no prenatal care, gives birth, and prepares to go home should be closely screened for and warned about PPD. Often these women do not have the financial resources for perinatal care. They could also be homeless or lack social support. The nurse should ensure that the social worker is involved in the screening process. To facilitate ongoing care and follow-up for the new mother and her infant, appropriate community resources should be contacted and arrangements made before discharge.

Signs and Symptoms and Diagnosis

Symptoms of PPD resemble those of other depressions (Box 16-7). The difference between PPD and other types is that the depression affects not only the woman and her adult family members, but also her newborn. The woman may have a decreased interest in the baby or may be overly concerned that “something bad” is going to happen to the baby. These fears may be expressed in a panic attack with hyperactivity and an inability to make decisions or prioritize. Male partners of women suffering from PPD

Box 16-7 Signs and Symptoms of Postpartum Depression

Decreased appetite	Excessive fears about the infant's health/safety
Insomnia or fragmented sleep	Hopelessness
Fatigue	Negativity
Inability to concentrate	Complaints about "loss of self" and a "sense of loneliness" (Clemmens et al., 2004)
Confusion	
Withdrawal	Guilt
Decreased self-esteem	Decreased interest and functioning in both self and infant care
Suicidal thoughts	
Infant neglect or abuse	

report feelings of being overwhelmed, isolated, stigmatized, and extremely frustrated. The combined negative effects of maternal and paternal depression on infant development places the child at risk (Beck, Records, & Rice, 2006; Davey, Dziurawiec, & O'Brien-Malone, 2006).

The greatest barrier in diagnosing PPD lies in differentiating it from other types of major depression. Since the presenting symptoms are similar to those of other types of depression, and the onset of the symptoms varies within the first year after childbirth, PPD is often under-diagnosed. The reasons for this are varied. Many women believe that labile feelings are a normal part of adjusting to parenthood. They fear the stigma associated with a diagnosis of depression, as well as the possible negative consequences, such as the involvement of local Child Protective Services. In addition, the emphasis on physiological recovery frequently results in an unwillingness on the part of health care providers and the woman's support systems to explore psychosocial concerns (Clemmens, Driscoll, & Beck, 2004; Logsdon, Birkimer, Simpson, & Looney, 2005; Stoops & Mann, 2004).

Etiology

PPD is a multifactorial problem. While there may be a genetic propensity toward depression, environmental factors such as financial stress and poor living conditions or psychological factors such as difficult adaptation to parenthood may push the woman toward previously unexperienced depression. Physiological factors involving changes in endorphins and the production and processing of neurotransmitters are also implicated in the onset of depression.

Assessment

Screening for the presence of PPD risk factors should begin with the first prenatal visit. The office or clinic nurse may be the first health care provider to obtain basic information, such as educational level, living conditions, financial stressors, whether the pregnancy was planned or unplanned, support systems available for the pregnant woman, and family involvement and attitudes of its members toward the pregnancy. If the nurse, physician, social worker, or other health care team member identifies risk factors, these should be noted in detail on the prenatal record. If prenatal support groups are available, the woman should be referred to one of them in an attempt to minimize the risk for PPD.

The postpartum nurse needs to be aware of previously identified risk factors. A personal history of a mood disorder or a family history of a mood disorder, mood or anxiety symptoms during the prenatal period, and postpartum blues are factors that increase the risk for PPD. Moreover, as the nurse carefully assesses the new mother and her interaction with the baby, other risk factors may be noted. Some of these may include unmet pregnancy or labor and birth expectations resulting in feelings of failure, a delay in a prolonged sleep and rest period, and a demanding newborn without the presence of family members to help. A new mother's continued dependency on caregivers despite adequate sleep and apparent control of postpartum discomforts may constitute another signal that requires close observation. If the new mother does not respond to her infant's needs or demonstrate bonding or attachment behaviors, these actions require follow-up. The hospital nurse's primary responsibility is to detect comments or behaviors that need to be referred to the social worker, home health nurse, physician, chaplain, lactation consultant, and community agencies (Goodman, 2004; Jesse & Graham, 2005; Linter & Gray, 2006).

If a home health nurse does not visit the newborn and mother within the first week, the well baby checkup that follows 1 to 2 weeks after the hospital discharge may offer the first opportunity to assess the mother-baby dyad. In this setting, the nurse needs to be alert for subtle cues from the new mother, such as making negative comments about the baby or herself, ignoring the baby's or other children's needs, as well as the mother's physical appearance. Does she look unkempt or exhausted? Is the baby clean and dry? Does the new mother say something about needing more help at home? Did she come to the office or clinic with the baby (and other children) or by herself?

“What to say” — Exploring the new mother's feelings

In a private area, the nurse should take time to explore the new mother's feelings. A non-threatening way to open the dialogue might be to say: “Tell me how the first few days at home have gone.” This statement provides the new mother with an opportunity to share both positive and negative impressions. Do not “fill the silence” if the new mother does not respond immediately. She may need to process her thoughts before speaking. Be aware, too, of nonverbal cues and body language, such as affect, eye contact, and open or closed posture.

If the nurse believes that the new mother is demonstrating signs and symptoms of PPD, several depression screening tools are available. These include the Edinburgh Postnatal Depression Scale, Postpartum Depression Predictors Inventory, Center for Epidemiological Studies—Depression, and Beck Depression Inventory II. Because they are highly predictive, these scales are valuable tools that can be combined with the informal interview during a routine postbirth checkup (Beck et al., 2006; Franzblau & Witt, 2006; Goodman, 2004; Nonacs, 2004). Nursing diagnoses for PPD may incorporate psychological, circumstantial, and physiological factors (Box 16-8).

Box 16-8 Possible Nursing Diagnoses for Postpartum Depression

Ineffective coping	Situational low self-esteem
Compromised family coping	Compromised family coping
Anxiety	Injury to the newborn
Impaired parent/infant attachment	
Impaired parenting	
Hopelessness	
Impaired sleep pattern	

Box 16-9 Medications Used to Treat Postpartum Depression

SSRIs	SNRIs	TRICYCLICs
Fluoxetine (Prozac)	Venlafaxine (Effexor)	Pamelor (Nortriptyline)
Paroxetine (Paxil)	Duloxetine (Cymbalta)	Imipramine (Tofranil)
Sertraline (Zoloft)		Doxepin (Sinequan)

where research and practice meet:
Screening Tools for PPD

Jesse and Graham (2005) tested a two-item depression screen to determine if it would correlate well with the 21-item Beck Depression Inventory (BDI). The two questions they asked were: “Are you often sad and depressed?” and “Have you had a loss of interest in pleasurable activities?” (These are the two symptoms required for a diagnosis of depression, according to the American Psychological Association.) Their findings indicated that this short questionnaire predicted those at low risk for PPD 94% of the time and at high risk for PPD 42% of the time. These statistics are similar to the predictive value of the longer BDI.

Collaborative Management

An important first step in the collaborative management of PPD involves ruling out a physical cause such as hypothyroidism. Once a physical cause has been eliminated, both traditional and complementary therapies can begin. Most often both the woman and her family will begin psychotherapy (interpersonal and group) as soon as possible. If the depressive symptoms are moderate to severe and do not respond to nonpharmacological treatment, the physician often prescribes a selective serotonin reuptake inhibitor (SSRI) or serotonin-norepinephrine reuptake inhibitor (SNRI) antidepressant. If the woman is experiencing sleep disturbances, tricyclic antidepressants may be useful (Cunningham et al., 2005; Franzblau & Witt, 2006; Nonacs, 2005) (Box 16-9).

Each of the medication groups is associated with side effects, and all antidepressants pass into the breast milk. If the woman is breastfeeding, the physician and nurse must monitor both the desired effects on the mother and any possible undesired effects on the baby. Medication dosage adjustments may be necessary, and the pharmacological treatment needs to continue for at least 6 months, even if rapid improvement occurs. If the woman does not respond to medications or psychotherapy, electroconvulsive therapy (ECT) may be used for the most severe cases of PPD (Cunningham et al., 2005; Nonacs, 2005).

Not to be discounted are complementary therapies for PPD. These therapies enhance the effects of traditional treatments, but Synder and Lindquist (2001) assert that “merely adding additional therapies to a system of care without implementing a holistic, caring approach to the care of patients will do little to improve

health” (p. 1). Since many complementary therapies can be used without a physician’s prescription, they can also empower the woman and her family in self-care and help them to feel that they are actively involved in the treatment plan.

Complementary Care: Therapies for postpartum depression

The nurse may be asked about various complementary therapies that may help new mothers and their families deal with PPD. Hypnosis enhances relaxation and an ability to focus on daily tasks. Exercise has been shown to increase levels of neurotransmitters that communicate with brain cells to increase feelings of euphoria. St. John’s wort (*Hypericum perforatum*) is an herb that has been approved in Germany for the treatment of anxiety and depression, skin inflammation, blunt injuries, wounds, and burns. It is believed to bind with neuroreceptors in the brain to prevent a response to the “depression” neurotransmitters (Lincoln & Kleiner, 2004). *St. John’s wort cannot be used in combination with SSRI antidepressants*. Biofeedback promotes relaxation and decreases anxiety, meditation helps the woman to focus on “being rather than doing,” thereby relieving stress and tension and humor has been shown to decrease anxiety, fear, tension, anger, and frustration and stimulate the immune system. Acupuncture, aromatherapy, and massage are other complementary therapies that may be beneficial.

Prognosis

The earlier that PPD is recognized and treatment begun, the better the prognosis for a full recovery. However, the woman must be prepared for a relapse should she choose to have another baby. A previous history of any type of depression places a woman at a 25% risk of PPD; those who experienced PPD with a previous birth have a 50% to 90% recurrence rate (Nonacs, 2005; Stoops & Mann, 2004). Preconception counseling with a physician, nurse, social worker, or spiritual advisor and the initiation of antidepressants early in the pregnancy (after the first trimester) are preventative strategies.

POSTPARTUM PSYCHOSIS**Definition, Incidence, and Onset**

Postpartum psychosis is a rare but severe form of mental illness that seriously affects not only the new mother but also the entire family. The incidence is low, occurring in one to four women per 1000 births. Though rare, postpartum women have a 10 to 15 times greater risk of psychosis

Nursing Care Plan The Woman Experiencing Postpartum Depression

Nursing Diagnosis: Ineffective Individual Coping related to multiple factors, including hormonal changes, addition of a newborn to the family, and time management constraints

Measurable Short-term Goal: The patient will acknowledge that she is depressed and agree to participate in individual and family therapy.

Measurable Long-term Goal: The patient will participate in activities she previously enjoyed and her affect will demonstrate positive feelings.

NOC Outcome:

Coping (1302) Personal actions to manage stressors that tax an individual's resources

NIC Interventions:

Coping Enhancement (5230)
Counseling (5240)
Medication Management (2380)

Nursing Interventions:

- Approach the patient in a calm, nonthreatening, and concerned manner.
RATIONALE: This approach may encourage the patient to be open about her thoughts and feelings.
- Ask open-ended questions and wait for a response.
RATIONALE: Open-ended questions require more than a one-word answer, which may encourage verbalization. Waiting for an answer indicates that what she says is worth the silence.
- Affirm the woman's feelings and allow her to cry should she desire.
RATIONALE: These responses demonstrate genuine concern.
- Notify the patient's primary caregiver about the patient's depressed affect.
RATIONALE: PPD may require medication or therapy.
- Provide information about PPD and gently correct any misinformation or misconceptions the patient has about depression.
RATIONALE: Correct information may instill hope and encourage the woman to continue therapy.
- Provide instructions about medications (antidepressants) that may be ordered.
RATIONALE: The patient needs to know the effects and side effects of medications so that she can report unusual symptoms.
- Ask the patient what activities she no longer enjoys that were previously enjoyable.
RATIONALE: This baseline information allows you and the patient to establish some goals for therapy.
- Involve the family in helping the patient cope with her feelings and assisting with infant care.
RATIONALE: Involvement of the patient's support system is vitally important. She needs to know that she is not alone in her struggle with depression.
- Help the patient/family establish an activity goal that she can achieve within the next week.
RATIONALE: This intervention involves the patient in her care, allows her some control, and encourages her to focus on a positive action/behavior.

than they do at any other time in their lives. Its onset may be dramatic, often occurring within the first 24 to 48 hours following birth, but it always appears within the first 8 postpartum weeks. Women with preexisting psychosis, especially bipolar disorder, are at the greatest risk for postpartum psychosis (Sadock & Sadock, 2004; Nonacs, 2005).

Postpartum psychosis may present with symptoms of PPD. However, the distinguishing signs of psychosis are hallucinations, delusions, agitation, confusion, disorientation, sleep disturbances, suicidal and homicidal thoughts, and a loss of touch with reality. This condition may also resemble a sudden manic attack. Mothers who are in a manic state require constant supervision when caring for their infant; they are frequently too preoccupied to tend to their infant's needs (Franzblau & Witt, 2006; Nonacs, 2005).

Nursing Insight— Recognizing behavioral cues that signal postpartum psychosis

When providing hospital and community care for postpartum women, the nurse should be alert to behavioral cues that may signal psychosis:

- Hyperactivity
- Agitation
- Confusion
- Suspiciousness
- Excessive complaints

Collaborative Management

Infanticide (the killing of an infant) is as high as 4% in women with postpartum psychosis. Because of this danger

and the loss of touch with reality, postpartum psychosis is a true emergency. The woman must be hospitalized, and mental health experts must become involved in her care as quickly as possible. Immediate treatment usually includes a mood stabilizer (lithium [Lithobid] or valproic acid [Depakene]), antipsychotic medications (Thorazine, Mellaril, Serenil), and anti-anxiety medications (benzodiazepines—Xanax, Librium, Tranxene, Lorazepam). If required, electroconvulsive therapy (ECT) often leads to rapid improvement. Long-term psychotherapy and pharmacological treatment follows the immediate care (Adams et al., 2005; Franzblau & Witt, 2006; Nonacs, 2005).

Women who are taking mood stabilizers need extensive counseling about the side effects associated with these medications. Patients on lithium must have serum lithium levels drawn every 6 months. Most antipsychotic medications can cause orthostatic hypotension and sedation, side effects that pose a major risk for mothers providing child care. Because the woman's thought processes may be altered, the nurse should share specific information about medication side effects with a close family member. If the mother wishes to breast feed, some sources recommend that no pharmacological agents be prescribed (Sadock & Sadock, 2004), while others advise caution when prescribing some medications (Schatzberg & Nemeroff, 2004). Current recommendations are that although most medications pass into breast milk, there are very few instances in which breastfeeding must be discontinued (Pigarelli, Kraus, & Potter, 2008). The infant's daily dose of medications is less than the maternal daily dose. With lithium, however, serum concentrations in the infant may reach 50% of maternal levels. Thus, breastfeeding is usually discouraged in mothers who are taking lithium; the American Psychiatric Association considers lithium incompatible with breastfeeding (Fankhauser & Freeman, 2005). Long-term neurobehavioral effects on the infant related to exposure to psychotropic medications in breast milk are unknown.

Prognosis

Women with postpartum psychosis have a 25% to 50% chance of reoccurrence in future pregnancies (APA, 2000; Nonacs, 2005). These women are also at greater risk for a future psychotic event unrelated to pregnancy. Counseling and educational roles of the health care team for these patients and their families is paramount to health promotion and maintenance.

Now Can You— Discuss postpartum blues, depression and psychosis?

1. State the difference between postpartum blues and postpartum depression?
2. Discuss what you would tell a woman with a history of postpartum depression about future pregnancies and the probable plan of care?
3. Describe the signs and symptoms of postpartum psychosis?

SUMMARIZING POSTPARTUM PSYCHOSOCIAL NURSING CARE

Perinatal nursing offers an opportunity to develop a therapeutic relationship with a woman and her family during one of the most vulnerable times in their lives. Most pregnancies are both planned and desired, but physiological and psychosocial adaptations to the pregnancy, birth, and

expanded family present challenges that require maturity and flexibility. The nurse can become involved with the childbearing family during the first prenatal visit. As the pregnancy progresses, the nurse becomes increasingly familiar with the woman and her family's lifestyle, stressors, successes, disappointments, and challenges. The postpartum nurse is at a distinct disadvantage because of the limited time a woman remains hospitalized after birth. However, any nurse, regardless of care setting or time constraints, can develop an attentive ear and sensitivity. By doing so, the nurse is then able to promote health and well-being for the new mother, her newborn, and the family.

During the postpartum period, the nurse can provide information that stresses the importance of asking for help if the patient feels overwhelmed. Promoting care and activities that allow the new mother and her family to attach to the infant is vitally important. Examples of bonding-oriented nursing care include rooming-in, decreasing sensory stimuli so that the family can focus on one another, and limiting visitors (if the patient desires). The postpartum nurse should note negative comments the patient makes about herself, her family, or the newborn and encourage the patient to talk about her expectations for both herself and the family. If the pregnancy and birth were difficult, the patient may be disappointed in herself and "blame" the baby for the difficulties.

Moreover, if the patient is exhausted and requires extra rest, the nurse can help her inform her friends and family about this need. The nurse should give the patient permission to send her newborn to the nursery without feeling guilty, so that when she awakens, she can enjoy the newborn rather than becoming frustrated by his demands. It is paramount for the nurse to remain sensitive to patients who are not coping well in the hospital, and advocate for follow-up by a home health nurse or social worker.

After discharge, the nurse in the office or clinic can utilize waiting time for conversation and make note of any physical characteristics that may indicate the need for some respite time from the demands and responsibilities of parenthood. The nurse should become familiar with available community support services such as a Mother's Day Out to which the mother can be referred. It is also important to involve the collaborative team—the physician, lactation consultant, social worker, and spiritual advisor—in the patient's care.

Postpartum Nursing for Vulnerable Populations

While caring for women and their families after birth, the postpartum nurse may be informed about or discover that special needs exist. If the woman received prenatal care, the prenatal history and physical examination may contain information that indicates the patient is in an abusive relationship, is living in a homeless shelter, has no transportation, is a migrant worker, or did not initiate care until the second or third trimester. These social risk factors are of concern and always require follow-up. In addition, a woman who gives birth with no prenatal care requires support from health care professionals to ensure that both she and her newborn will have their basic needs of food, clothing, and shelter met. Though many in the world view the United States as an international social welfare agency and wish to live here, some American

citizens, visitors, and undocumented immigrants live in fear, poverty, poor health, or oppression. The nurse caring for childbearing women and their families has a mandate to address these needs whether these patients are in a hospital, clinic, or private physician's office.

VICTIMS OF ABUSE

Abuse can take several forms: physical, emotional, verbal, or sexual. Unfortunately, most often someone the woman loves is the perpetrator, and the abuse may take more than one form. Physical violence during pregnancy has far-reaching effects for the infant as well as the mother. Battery during pregnancy is associated with a greater incidence of low-birth-weight neonates, preterm birth, and neonatal death (Yost, Bloom, McIntire, & Leveno, 2005). (See Chapters 9 and 11 for further discussion.) No stereotypes exist for women who are abused because the problem crosses all socioeconomic, ethnocultural, and educational lines. The National Center for Injury Prevention and Control and other researchers list multiple factors that place an individual at risk for committing intimate partner abuse and for being a victim of intimate partner abuse (Tables 16-7 and 16-8).

“What to say” — *Inquiring about intimate partner violence during pregnancy*

Physicians routinely screen pregnant women for gestational diabetes and pregnancy induced hypertension. However, more pregnant women are battered by their intimate partners than the combined total of pregnant women who develop these physiological complications (Family Violence Prevention Fund, 2008). Regardless of the setting, the nurse caring for perinatal patients at any time before or after birth can initiate a conversation about intimate partner violence. Many victims want to tell someone about the violence they are experiencing, but they must be asked directly. After establishing privacy, the nurse should be direct and say, “In this office, a part of our routine care is to ask about domestic violence. Do you currently feel safe with your partner? Have you been kicked, hit, slapped, or otherwise physically hurt within the last year? Do you have concerns about how your

Table 16-8 Risk Factors for Being a Victim of Intimate Partner Abuse

Individual Factors	Relationship Factors
History of child abuse	Marital conflict
History of physical abuse	Marital instability
History of sexual abuse	Male dominance in the family
Prior injury from the same partner	Poor family functioning
Having a verbally abusive partner	Partner history of alcohol or drug abuse
Economic stress, low income	
Tobacco, alcohol and illicit drug use	
Depression or suicide attempts	
History of sexually transmitted infections	
Young age (less than 24 years, especially adolescents)	
Lack of high school diploma	
Unplanned pregnancies (often as a result of birth control sabotage)	

partner treats you emotionally or treats you sexually?”
Be sure to wait for the answer to each question. Do not rush the answers.

Table 16-7 Risk Factors for Committing Intimate Partner Violence

Individual Factors	Relationship Factors
Young age	Marital conflict
Low self-esteem	Marital instability
Low income	Male dominance in the family
Low academic achievement	Poor family functioning
Aggressive or delinquent behavior as a child	Emotional dependence and insecurity
Alcohol or drug use	Belief in strict gender roles
Witnessing or experiencing childhood violence	Desire for power and control in relationships
Social isolation	Angry or hostile behavior toward a partner
Unemployment	

Ethnocultural Considerations— Women and battering

- In New York City, a 1999 study found that 51% of intimate partner homicide victims were foreign born.
- Sixty percent (60%) of Korean women surveyed reported battering by their husbands.
- Forty-eight percent of Latina women stated that since immigrating to the United States partner violence had increased.
- Many cultures accept battering and violence as a way of life. Women from these cultures may feel that U.S. laws and protection do not apply to them.
- If battered immigrant women attempt to flee the violence, they may not have access to bilingual shelters, financial assistance, or food.
- McCosker, Barnard, and Gerber (2003) reported from a review of literature that one in five Australian women experienced domestic violence during their lifetimes and that one in ten experienced violence during pregnancy.
- Reuters Health (2005) reported that two thirds of Native Americans overall experience some type of trauma during their lives. Native American women reported high rates of physical abuse, often by a spouse, more rape, and more sexual assault.
- Bohn, Tebben, and Campbell (2004) found that for “lifetime abuse by a current partner” (p. 565) African American and Puerto Rican women had the highest odds ratio and that African American, Puerto Rican, and Mexican/Mexican American women had a higher incidence of abuse during pregnancy.

When a postpartum nurse determines that a postpartum patient and her infant are possibly returning to an abusive environment, several interventions can occur. The nurse must first confirm the suspicions by asking direct questions. If the patient confirms that she is a victim of intimate partner violence (regardless of the form), the nurse needs to immediately enlist the help of a social worker and a chaplain. These professionals are more knowledgeable about community resources such as safe houses, churches, and child protective services to which the patient can be referred. The health care team can help empower the patient to have an action plan to escape the abuse at a later time, should she choose to delay this decision.

It is important to remember that if the patient chooses to return to the abusive environment, the nurse's role does not end. Follow-up after discharge may include a home visit or a well baby checkup, during which time further interventions can occur. When a patient has only herself to think about, she may be less likely to take protective action. However, maternal instincts may empower the woman to protect her baby and other children from abuse or violence. Even if the nurse is only able to be a therapeutic listener, this role may allow the patient to rehearse her action plan, ask questions, share information, and affirm her decisions regarding the future.

Lack of personal contact does not mean that interventions cannot occur. McFarland et al. (2004) used telephone interviews to conduct a longitudinal study on abused women. After an initial personal contact with abused women to ask about inclusion in the study and to obtain informed consent, researchers contacted the women with either six intervention and four follow-up calls (experimental group) or four follow-up calls only (control group). During the phone calls, the interviewers asked women in the experimental group to answer yes or no to a series of safety promoting behaviors. These behaviors included such actions as hiding money, hiding house and car keys, removing weapons from the house, asking neighbors to call police if violence begins, establishing a code with family and friends, and obtaining items such as birth certificates, important phone numbers, identification cards, and rent and utility receipts. The research findings indicated that women in the intervention group (those who received six additional phone calls) practiced more safety-promoting behaviors than did those in the control group and that the required nursing time was minimal. Such research findings are significant in supporting the important role that nurses and other members of the health care team can have in helping victims of intimate partner violence take control of their environments and practice positive behaviors that can break the cycle of abuse.

UNDOCUMENTED IMMIGRANTS AND MINORITY HEALTH CARE

As a nurse provides care for postpartum women and their families, ethical and legal concerns inevitably arise. One of these issues often concerns undocumented immigrants and minority health. The United States continues to attract a cosmopolitan population and to be viewed as a haven for those in search of a better life. Not all who come to the United States seek American citizenship or a legal visa for employment purposes. In particular, citizens in

states that border Mexico (Texas, New Mexico, Arizona, and California) routinely fund and provide care for undocumented immigrants. Wrongly, many Americans believe that the primary reason Latinos come to the United States is to receive free medical care, which can include delivering a baby in this country in order to have a United States citizen in the family. Berk, Schur, Chavéz, and Frankel (2000) studied undocumented Latinos in Houston and El Paso, Texas and in Fresno and Los Angeles, California. They studied Latinos because this group represents an estimated 70% of all undocumented immigrants. The sample size began with 7352 households and eventually resulted in 973 participants. From surveying and interviewing one member of each household, the investigators found that the primary reason undocumented Latinos come to the United States is to find jobs. Only in El Paso was this not the primary reason. In El Paso, 49% of respondents cited "uniting with family members and friends" as their main reason for immigrating, and this primary reason was followed by "finding work" (p. 49).

Recently, the Centers for Medicare and Medicaid Services (CMS) proposed a plan whereby those states bearing the highest cost of health care services for undocumented immigrants under EMTALA (Emergency Medical Treatment and Active Labor Act) requirements would receive reimbursement over 4 years for these services. Though this plan would help defray state costs for these services, health care providers would be expected to document the immigration status of their patients. Immediately after this proposal, the American Nurses Association leadership shared its concerns with CMS officials. Requiring this documentation would likely lead to illegal immigrants avoiding health care settings, even when seriously ill or injured (Trossman, 2004). While intended to help state budgets with the high cost of emergency health care for undocumented immigrants, many providers have also expressed concern. They assert that the need to establish immigration status may create not only a public health crisis, but also a greater financial burden, since preventative care (including prenatal care) would not be included in the reimbursement plan. Statistically, immigrant and minority women have higher rates of disability and mortality, and their overall health status is lower than that of white women (AHRQ, 2006).

The nurse needs to provide unbiased, excellent care to all patients, regardless of immigration or minority status. A new mother and her family's immigration status or nationality does not change her needs or her family's need for compassionate, holistic, and quality care. If the patient has received minimal or no prenatal care, physical and psychosocial needs may be greater and may result in complications that require greater skill on the part of every involved individual. Direct care nurses are not primarily policy experts, nor do many desire this role. A vital factor in being able to provide ongoing perinatal care is to ensure women and their families they can trust those with whom they share information and concerns. While the United States and individual state politicians debate the financial implications and resources required to provide health care for those in this country who need it, the mandate for nurses is that they be one of the most valuable resources available to meet the needs of all new mothers and families for whom they care. Nursing is as much a "calling" as it is a profession.

 **Now Can You—** Discuss issues related to the care of minority and undocumented immigrant women?

1. State the most common reason undocumented immigrants come into the United States?
2. Describe a major nursing role when caring for immigrant and minority women?
3. State some potential outcomes for women and their babies who obtain minimal or no prenatal care?

HOMELESSNESS AND LIMITED ACCESS TO CARE

Women and newborns who are homeless and without an established health care provider for follow-up constitute a particularly vulnerable population after childbirth. Better health care outcomes are positively correlated with having a usual or principal source of care. Black and Hispanic American women are much less likely than others to have a primary source of care, and this population is also more likely to be uninsured (Partnership for the Homeless, 2008).

Often these same women are those who are homeless. Whether migrant workers who follow the crops they help to harvest or individuals with socioeconomic and interpersonal challenges, homeless women and their children represent a population that requires sensitive, skilled discussions, so that they can receive appropriate follow-up care. The fact that the pregnancy rate among homeless women is almost twice that of the general population (Gelberg et al., 2001) is a statistic that requires action. The *Healthy People 2010* indicators include access to prenatal care for all women as a major initiative.

Studies designed to address barriers to perinatal care have noted similar findings. The research of both Mikhail (1999) and Bloom et al. (2004) examined barriers among homeless, pregnant women (in California and Florida, respectively). There are several barriers pregnant, homeless women face when considering whether to begin or continue prenatal care (e.g., waiting time to see a practitioner, especially when compared to the time the practitioner actually spent with the patient; lack of transportation, care for older children, or encouragement to get prenatal care from family members; concern about having their children removed from their care; and finances). Maupin, Fatsis, and Prystowski (2004) described women who give birth with no prenatal care as those who are more likely to be multiparous, living with at least one child, less educated, uninsured, and tobacco or recreational drug users. Most pregnant, homeless women surveyed did not intend to become pregnant. Ethnically, more African American and Hispanic women are likely to bypass prenatal care than are their white counterparts (Bloom et al., 2004; Frisbie, Echevarria, & Hummer, 2001).

If a woman presents to a hospital in labor and has not received prenatal care, EMTALA requires that a physician and hospital staff members deliver her baby and provide her and her newborn with care until they can be safely discharged. If it is determined that the mother is homeless, once again the nurse must solicit the help of the interdisciplinary team, including the social worker

and chaplain. The physician caring for the mother and baby needs to satisfy legal requirements before discharging the patient and newborn. Often, the nurse needs to collect newborn urine and/or meconium samples for drug screening. If the hospital or birthing center employs a nurse who conducts a follow-up visit to check on the new mother and baby and immediate housing is available, the physician may elect to discharge them with an early visit arranged.

If the woman has absolutely nowhere to go after discharge, the nurse and others have an ethical and legal responsibility to ensure that the newborn is adequately fed and clothed. Child Protective Services, the United Way Agency, or church-affiliated social programs may be sources of help for this family. Immediate solutions are required. Longer-term arrangements will take additional resources and time. Ultimately, because the newborn is completely dependent on others for his needs to be met, the best situation for the baby often drives the final decisions.

POSTPARTUM CARE OF VULNERABLE POPULATIONS

Most commonly, postpartum nurses care for women and families who are functional and healthy (physically, psychosocially, spiritually). If the nurse knows a couple or family who is unable to have children and who is exploring the option of adoption, handling dilemmas such as abuse or homelessness may be especially difficult. When a childbearing woman faces difficult challenges and requires additional support, her only source of this support may be the health care community. Regardless of personal impressions, the nurse needs to be receptive to lessons that can be learned from this patient's situation. Most new mothers want the best life possible for their newborns. Armed with this fact, nurses can grow in their ability to understand and respond with sensitivity to all families for whom they care.

 **Now Can You—** Discuss strategies in caring for vulnerable populations?

1. List important members of the health care team to involve in the continuum of care for vulnerable pregnant women or new mothers and their babies?
2. State a *Healthy People 2010* goal for pregnant women?
3. List characteristics of pregnant women who are most unlikely to get prenatal care?

summary points

- ◆ Postpartum hemorrhage may occur early (within the first 24 hours after birth) or late (after the first 24 hours but within 6 weeks after childbirth).
- ◆ Puerperal infections may involve the uterus, urinary system, incisions, and breasts. Each type of infection has common and unique risk factors, onset, signs and symptoms, causative organisms, and complications.
- ◆ Thrombophlebitis is an inflammation of the venous circulation and blood clot formation that typically

occurs in the lower extremities. Treatment involves bedrest with elevation of the affected extremity, application of moist heat, and anticoagulant therapy. If thromboembolic disease is suspected, the affected area should never be massaged because this action may cause dislodgement of the clot and the potential for a pulmonary embolism.

- ◆ Postpartum “blues” are common and usually self-limiting. Postpartum depression is a multifactorial problem that requires prompt assessment and intervention.
- ◆ Vulnerable populations include homeless, minority, and undocumented immigrant women, as well as those who are victims of abuse. Providing holistic, quality postpartal nursing care for vulnerable populations requires self-examination, sensitivity, and compassion.

review questions

Multiple Choice

1. The perinatal nurse, when using the acronym “LARRY” to remember the common causes of postpartum hemorrhage, is aware that the “L” refers to:
 - A. Lacerations
 - B. Loss of blood > 500 mL
 - C. Low platelet count
 - D. Low hemoglobin
2. As part of a postpartum woman’s assessment, the perinatal nurse observes for signs and symptoms of hematoma formation. The most common anatomical location is in the:
 - A. Rectum
 - B. Vulva
 - C. Cervix
 - D. Episiotomy site
3. The perinatal nurse promotes postpartum health and prevents infection with the inclusion of critical information about:
 - A. Good handwashing
 - B. Early ambulation
 - C. Minimal fluid intake
 - D. Restricted protein intake
4. The perinatal nurse is providing information to a postpartum woman who is being discharged from the hospital on warfarin (Coumadin) therapy. Instructions would include restrictions of which drug due to concern about interactions:
 - A. Acetaminophen
 - B. Ibuprofen
 - C. Prenatal vitamins
 - D. Docusate sodium

True or False

5. The perinatal nurse is aware that there is an increased risk of minimizing pathological symptoms during the childbearing process because of a focus on health promotion and wellness.
6. The perinatal nurse routinely screens for intimate partner violence as part of the hospital admission history, as studies have shown that women wish to be asked directly.

Fill-in-the-Blank

7. The amount of blood loss postpartum is frequently _____ estimated by perinatal nurses and other health care providers.
8. The perinatal nurse explains to a student nurse that the development of an endometrial infection following childbirth is called a _____ infection.

Case Study

9. Julia, a G4, TPAL 4004, experienced a normal vaginal birth approximately 60 minutes ago. No episiotomy was made at the time of birth. Her daughters, 5, 3, and 2 years of age have now come to visit. Julia states that her pad feels “very wet.” As the perinatal nurse, you assess the tone of Julia’s uterus and it is firm. Your next action would be to:
 - A. Massage her uterus to ensure that it remains firm
 - B. Change and weigh her pads to accurately determine her blood loss
 - C. Request that the physician come and check for internal lacerations
 - D. Request that her family members leave immediately
10. The perinatal nurse is caring for Maria, a 23-year-old G2 TPAL 1011 woman, who experienced 14 hours of labor prior to a cesarean birth for failure to progress. She is now 48 hours postbirth and is complaining of abdominal pain that is not relieved with medication given two hours ago. Her temperature is 100.8°F (38.2°C). The perinatal nurse is expected to obtain:
 - A. An accurate blood pressure
 - B. Incisional swab for culture and sensitivity
 - C. An accurate pain assessment
 - D. Additional orders for pain management

CONCEPT MAP

Physiological Transition of the Newborn

chapter 17

Our journey begins and ends with the development of a family. Becoming a mother is the beginning of a wondrous journey... The transition of that little living being within you to that amazing, beautiful newborn you will love and loves you back unconditionally...

—D. Teeple

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Explain the importance of the development of surfactant and its role in the successful transition of the neonate.
- ◆ Identify the four factors that influence the initiation of respirations.
- ◆ Discuss how the four anatomical structures that enable in utero survival must undergo significant transition following birth.
- ◆ Explain the importance of administering vitamin K to the neonate after birth and describe its effect on the hematopoietic system.
- ◆ Describe the process of nonshivering thermogenesis and the importance of brown adipose tissue in the neonate.
- ◆ List neonatal liver functions that allow for successful physiological transition.
- ◆ Name the enzymes present in the neonate's gastrointestinal system and describe their role in digestion.
- ◆ Identify the factors that influence kidney adaptation to allow for the management of bodily fluids and urine excretion.
- ◆ Identify the three primary immunoglobulins that are important in strengthening the neonate's immunological system.
- ◆ Discuss normal neonatal patterns of behavior during the first several hours after birth.

moving toward evidence-based practice Maternal Engagement

Sanders, L.W., & Buckner, E.B. (2006). The newborn behavioral observations system as a nursing intervention to enhance engagement in first-time mothers: Feasibility and desirability. *Pediatric Nursing*, 32(5), 455–459.

The purpose of this study was to explore with first-time mothers the feasibility and desirability of the Newborn Behavioral Observation (NBO) system as a nursing intervention in assisting mothers to establish engagement with their newborn. Engagement was defined as "the social process of maternal transition that enables growth and transformation and is linked to attachment and bonding." The NBO was developed

by Nugent, Keefer, O'Brien, Johnson, and Blanchford (Brazelton Institute, n.d.; Nugent et al., in press) as a tool to promote positive parent–infant relationships that could be included as part of routine maternal–child care. The tool assists the nurse in orientating parents to the characteristics and competencies of the newborn through neurobehavioral assessment items.

(continued)

moving toward evidence-based practice (continued)

The convenience sample consisted of 10 first-time mothers recruited from a mother–baby unit in a large university hospital. Characteristics of the participants were as follows:

- Six mothers were African American, two mothers were Caucasian, one mother was Asian, and one mother was Indian.
- All gave birth to healthy babies and participated in rooming-in.
- Their ages ranged from 19 to 27 years.
- Their incomes ranged from under \$15,000 to \$30,000.
- Six mothers reported a greater than a high school education; four mothers attended prenatal classes.

Methods: An NBO session was followed by an interview to determine the mother’s perception of the intervention. The interview consisted of both open-ended and closed-ended questions regarding the mother’s opinions of the effectiveness of the NBO in enhancing activities to increase engagement. After the interview the mothers completed an NBO Parent Questionnaire designed to assess “the usefulness of the NBO in teaching parents and enhancing engagement.”

Using a 4-point scale (1 = nothing; 4 = a lot), the mothers gave the NBO a high rating in regard to increasing their

knowledge of what their infant can do and how they can interact with their infant. The mothers’ participation in the intervention was also rated to determine if a relationship existed between the observed and the reported level of effectiveness in increasing engagement activities. Eight maternal behaviors, which were indicative of interest, were rated on a 3-point scale. The mothers were also asked what they liked about the intervention, what they learned about their infants, and what they knew about how to provide care. Themes that emerged from the mothers’ qualitative responses included two of the activities of engagement: experiencing the infant and active participation in care.

The researchers concluded that the NBO is an effective nursing intervention for enhancing maternal engagement during the early postpartum period.

Introduction

Once the umbilical cord is clamped and the infant takes the first breath, the transition from intrauterine to extrauterine life begins. Transition is one of the most intense and dynamic periods in the human life cycle. The transition from total dependence on another for every life-sustaining need from oxygenation and nutrition to total independence requires dramatic changes. For the neonate, the transitional phase may take minutes, hours, or days.

This chapter explores the physiological changes that take place in the newborn during the process of transition. Alterations that occur in each major body system are discussed, with emphasis on nursing assessment and interventions to facilitate a normal transition.

A & P review Normal Respiratory Function

The primary function of the respiratory system is twofold: the exchange of oxygen and carbon dioxide through respiration and maintenance of the acid–base balance.

The mechanical process of respiration is accomplished via the exchange of air between the lungs and the atmosphere (pulmonary ventilation). The two phases of pulmonary ventilation are inspiration and exhalation.

The physiological processes involved in pulmonary ventilation take place on three levels: external, internal, and cellular. External respiration is the exchange of gases (oxygen, carbon dioxide) between the alveoli and the blood through the alveolar–capillary membrane. Internal respiration is the exchange of gases between the systemic capillaries and the tissue at the cellular level. The cellular physiological process is the exchange of gases within the cell (Dillon, 2007). ♦

Adaptations of the Respiratory System

INTRAPULMONARY FLUID, FETAL BREATHING MOVEMENTS, AND SURFACTANT

After birth, the initiation of respirations constitutes the first important step in neonatal transition. Many forces that occur during pregnancy and childbirth facilitate this essential process. The amniotic fluid plays an important role in fetal lung development. Inhalation of the amniotic fluid into the lungs helps to promote growth and differentiation of the lung tissue. Normal pulmonary functioning is dependent on two factors: the alternating in and out fetal breathing movements and the formation of intrapulmonary fluid.

Nursing Insight— Fetal breathing movements

Breathing efforts are first initiated in utero as the fetus spends months practicing coordinated inhalation and exhalation movements. Fetal breathing movements (FBMs) can be observed by ultrasonography as early as 11 weeks of gestation. The breathing movements serve as an important mechanism that helps to develop the muscles of the chest wall and the diaphragm.

As the fetus approaches term, there is a decrease in the secretion of intrapulmonary fluid. The absorption of fetal lung fluid is accelerated during labor and delivery and for up to a few hours after birth. This fluid shift constitutes an important physiologic event: it assists in reducing the pulmonary resistance to blood

flow (necessary while in utero) and facilitates the initiation of air breathing (Hernandez, Zabloudil, & Hernandez, 2004). During a vaginal birth, approximately one third of the fetal lung fluid is expelled due to the “thoracic squeeze” that occurs during passage through the birth canal. Infants of cesarean births are at a higher risk for pulmonary transitional difficulties because they do not receive the lung compression benefits associated with a vaginal birth.

Lung expansion after birth stimulates the release of **surfactant**, a slippery, detergent-like lipoprotein. Surfactant causes a decreased surface tension within the alveoli, which allows for alveolar re-expansion after each exhalation. Under normal circumstances, by the 34th to 36th weeks of gestation, surfactant is produced in sufficient amounts to maintain alveolar stability (Bloom, 2006).

Many factors such as acidemia, hypoxia, shock, mechanical ventilation, and hypercapnia (an increased level of serum carbon dioxide) may interfere with surfactant metabolism. Surfactant production is decreased in infants of diabetic mothers (classes A, B, and C), infants with hemolytic disorders (e.g., erythroblastosis fetalis), and in multiple gestations. Conversely, surfactant production may be accelerated in other infants such as those of mothers with class D, F, and R diabetes, hypertension, and heroin addiction. Fetal exposure to maternal infections and placental insufficiency may also accelerate the production of surfactant.

THE FIRST BREATH

Four factors influence the initiation of the newborn’s first breath. These include internal stimuli: the chemical changes; and external stimuli: the sensory, thermal, and mechanical changes (Fig. 17-1). Each factor stimulates the respiratory center located within the medulla of the brain.

Chemical Factors

Chemical factors that initiate respirations are hypercarbia, acidosis, and hypoxia. These conditions, brought about by the stress of labor and birth, stimulate the respiratory center in the brain to initiate breathing. Hypoxia causes blood oxygen levels (PO_2) and pH to drop. Subsequently, blood

carbon dioxide levels (PCO_2) begin to rise and prompt the respiratory center within the medulla to initiate breathing. This brief period of asphyxia occurs in all newborns during the birth process. However, prolonged asphyxia that accompanies a traumatic birth is abnormal and may cause a central nervous system (CNS)-mediated respiratory depression.

Sensory Factors

The newborn experiences a vast amount of stimuli when leaving a familiar, comfortable, warm environment to enter into an extremely sensory overloaded one—filled with a multitude of tactile, visual, and auditory stimuli. These sensory experiences aid in the initiation of respirations.

Thermal Factors

After months of development in a warm (98.6°F [37°C]) fluid-filled environment, the newborn abruptly enters into a thermal environment that ranges from 70 to 75°F (21 to 23.9°C). The drastic change in temperature helps to stimulate the initiation of respirations. Sensors in the skin respond to the temperature changes and send signals to the respiratory system in the brain. Physiological changes in the neonate’s temperature may occur and as long as the temperature remains within the normal range of 97.7 to 98.6°F (36.5 to 37.0°C), no problems related to the thermal environment should develop. However, to prevent cold stress and respiratory depression, it is imperative for the nurse to immediately dry and either place the infant (skin to skin) with the mother or in a radiant warmer.

Mechanical Factors

Removal of fluid from the lungs with the subsequent replacement of air constitutes the primary mechanical factors involved in the initiation of respirations. The fetal chest compression that occurs during a vaginal birth increases the intrathoracic pressure and helps to push fluid out of the lungs. Recoil of the chest wall after delivery of the neonate’s trunk creates a negative intrathoracic pressure. This facilitates a small, passive inspiration of air, which replaces the fluid that has been squeezed out.

Figure 17-1 Chemical, sensory, thermal, and mechanical factors involved in the initiation of respirations.

Nursing Insight— Recognizing normal neonatal lung sounds during early auscultation

Continuation of respirations occurs when the pressure within the neonate's lungs increases and pushes the remaining fetal lung fluid into the lymphatic and circulatory systems. Most of the fluid is reabsorbed within the first few hours, but in some infants this process may take up to 24 hours (Fig. 17-2). The neonate's lung sounds may sound moist during early auscultation, but should become clear as the fluid is absorbed.

Now Can You— Discuss elements of pulmonary function in the neonate?

1. Discuss why intrapulmonary fluid and fetal breathing movements are important for normal pulmonary functioning?
2. Explain why surfactant is important for respirations and identify two prenatal conditions that may be associated with a decrease in surfactant production?
3. Describe the four factors that are essential for the initiation of respirations?

FACTORS THAT MAY INTERFERE WITH INITIATION AND MAINTENANCE OF RESPIRATIONS

A number of factors may interfere with the neonate's ability to initiate respirations. Conditions such as prematurity or birth asphyxia can adversely affect lung compliance (elasticity) and surfactant production. Childbirth events including trauma, maternal medications, and the mode of delivery can interfere with normal pulmonary transition.

Because of the low levels of surfactant normally present in infants less than 36 weeks' gestation, preterm infants are more likely to develop **respiratory distress syndrome (RDS)**. RDS is a developmental disorder of the respiratory system that begins at birth or very soon afterwards. It occurs most frequently in infants born with immature lungs. Lack of adequate surfactant leads to the sequelae associated with RDS: progressive atelectasis, loss of functional residual

Figure 17-2 The process of absorption of fetal lung fluid once breathing has been initiated after birth. **A.** Before labor, alveolar fluid fills the lungs and circulates with amniotic fluid. During labor, air sacs and airways remain filled with fluid. **B.** During vaginal birth, the fetal thorax is compressed (thoracic squeeze) and approximately one third of the lung fluid is expelled. **C.** After vaginal birth, the neonate's first breath expands the lungs and fluid is displaced. Spontaneous respirations happen over the next 24 hours. Air displaces the remaining fluid, which is removed by the capillaries and lymphatics.

capacity, alterations in the ventilation perfusion ratio, and poor lung compliance (MacDonald, Mullett, & Seshia, 2005). (See Chapters 18 and 19 for further discussion.)

When there is a strong likelihood that a preterm delivery will occur, the pregnant patient may receive tocolytic medications (inhibit uterine contractions) to postpone birth. The delay allows for the administration of glucocorticoids (e.g., betamethasone) to boost fetal lung maturation in an effort to improve the neonate's outcome. Betamethasone is given to the woman at least 24 hours before birth, if possible, to prompt the production of fetal surfactant and hopefully improve respiratory functioning in the neonate.

medication: Betamethasone, Dexamethasone

Betamethasone (bay-ta-meth-a-sone)

Dexamethasone (dex-a-meth-a-sone)

Pregnancy/Category: C

Indications: To prevent or reduce the severity of respiratory distress syndrome in preterm infants between 24 and 34 weeks of gestation (unlabeled use).

Action: Stimulates fetal lung maturation by promoting the release of enzymes that induce the production or release of lung surfactant.

Classification(s):

Therapeutic: Stimulates fetal lung maturation

Pharmacological: Glucocorticoids (corticosteroids)

Pharmacokinetics:

ABSORPTION: Preferred method of absorption is via injection.

DISTRIBUTION: Crosses the placenta; enters the breast milk.

METABOLISM AND EXCRETION: Metabolized in the liver and excreted by the kidneys

HALF-LIFE: 6.5 hours

Contraindications and Precautions: Contraindicated in women in whom there is a medical indication for delivery (i.e., severe pregnancy-induced hypertension [PIH], cord prolapse, chorioamnionitis, abruptio placentae), and in women with systemic fungal infection.

Adverse Reactions and Side Effects: Seizures, headache, vertigo, hypertension, increased perspiration, petechiae, ecchymoses, facial erythema, maternal infection, pulmonary edema (if administered with beta-adrenergic medications). May worsen certain maternal conditions such as diabetes and hypertension.

Route and Dosage: 12 mg IM q24h × 2 doses

Nursing Implications:

1. Inform the woman of the benefit of medication and the need to administer to prevent RDS in her preterm infant.
 2. Teach the woman the signs and symptoms of pulmonary edema; assess lung sounds.
 3. Shake the suspension well; prolonged exposure to heat and light must be avoided.
 4. Administer the medication into a large muscle; avoid the deltoid to prevent local atrophy.
 5. Vital signs must be monitored frequently and fetal monitoring should be performed according to institution policy.
 6. Accurate intake and output must be monitored and recorded.
 7. Monitor blood sugars if the woman is diabetic or at risk for diabetes.
 8. Do not administer if the woman has an infection
- NOTE: The FDA has not approved the medication for this use.

CARDIOPULMONARY TRANSITIONS

Cardiopulmonary adaptations must also occur during the transition from fetal to neonatal pulmonary functioning. As air enters the lungs, the PO_2 rises in the alveoli. This normal physiologic response causes pulmonary artery relaxation and results in a decrease in pulmonary vascular resistance. As the pulmonary vascular resistance decreases, pulmonary blood flow increases, reaching 100% by the first 24 hours of life. The increased pulmonary blood volume contributes to the conversion from fetal to newborn circulation (Fig. 17-3). Once the pulmonary circulation has been functionally established, blood is distributed throughout the lungs.

Although a variety of hemoglobins are present in the fetus and newborn, the most significant types are fetal hemoglobin (HbF) and adult hemoglobin (HbA). Since HbF has a greater affinity for oxygen than does HbA, the newborn's blood oxygen saturation is greater than that found in adults. However, there is less oxygen available to the tissues. Before birth, this situation is beneficial—the fetus must maintain an adequate oxygen uptake despite low oxygen tension levels since the umbilical venous PO_2 cannot exceed the uterine venous PO_2 .

Assessment of the neonate's cardiopulmonary system must occur immediately after birth. Overall skin color provides one of the most important indicators of how well the neonate is making the transition to extrauterine life. Caucasian infants typically exhibit a central pink hue with **acrocyanosis**, a bluish coloration of the hands and feet that may persist for up to 24 hours until peripheral circulation improves. In dark skinned infants, the mucus membranes provide a better indication of cyanosis than skin color.

The normal respiratory rate for a healthy term newborn is 40 to 60 breaths per minute. The breathing pattern is often shallow, diaphragmatic, and irregular. Abdominal movements should be synchronous with the

chest movements. The breathing pattern may include brief pauses that last 5 to 15 seconds. Termed **periodic breathing**, this pattern is usually not associated with any change in skin color or heart rate and it has no prognostic significance. **Apnea** is cessation of breathing that lasts more than 20 seconds. It is abnormal in the term neonate and may or may not be accompanied by changes in skin color or a decrease in the heart rate below 100 beats per minute. Apnea should be reported immediately. Other indicators of respiratory difficulties include expiratory grunting and retractions when the neonate is at rest or a breathing rate that is outside of the normal range.

case study Baby Girl Emily

Baby girl Emily is a 2-hour-old infant born at 40 weeks' gestation via a normal spontaneous vaginal birth. Her mother is a 20-year-old Caucasian primipara who experienced an uneventful pregnancy and has a strong support system. Baby Emily has remained with her parents in the birthing suite since her birth. Her mother expresses concern about Emily's hands and feet and asks the nurse why they are "bluish" in appearance, when the rest of Emily's body is nice and pink. She also states that at times, Emily seems to "stop breathing."

critical thinking questions

1. What would you tell Emily's parents about the bluish appearance of Emily's hands and feet?
2. What would you tell Emily's parents about Emily's breathing pattern?

◆ See Suggested Answers to Case Studies in the text on the Electronic Study Guide or DavisPlus.

Figure 17-3 Major events that occur during the transition from fetal to neonatal circulation include closure of the foramen ovale, the ductus arteriosus, and the ductus venosus.

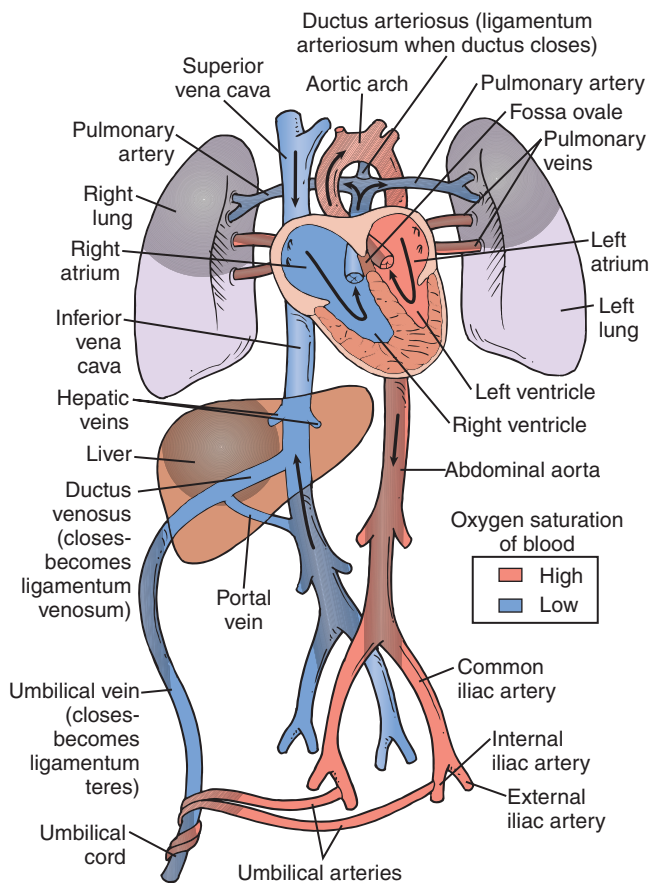

Figure 17-4 Neonatal circulation.

Cardiovascular Adaptation

CHANGES AFTER PLACENTAL EXPULSION

Expulsion of the placenta following childbirth triggers important physiological events in the transition process. In utero, the placenta serves as the exchange organ for oxygen and nutrients and for the excretion of fetal waste products such as carbon dioxide. Maternal oxygenated blood enters the fetal circulation via the umbilical vein. Approximately 40% to 60% of the blood perfuses the fetal liver while the remaining volume of blood passes through the ductus venosus and enters the right atrium via the inferior vena cava.

During gestation, the placenta is the organ primarily responsible for gas exchange in the fetus although there is a small amount of blood flow to the lungs. As a “low resistance circuit,” the placenta receives approximately 50% of the fetal circulation (Hernandez, Zabloudil, & Hernandez, 2004). The fetal pulmonary circulation is a low flow, “high pulmonary resistance circuit” that receives only approximately 10% of the ventricular output (MacDonald et al., 2005). (See Chapter 7 for further discussion.)

After placental separation at birth, the umbilical arteries and vein constrict as the fetal circulatory system is interrupted. Successful cardiopulmonary adaptation in the neonate involves five major changes: an increased aortic pressure and decreased venous pressure; an increased systemic pressure and decreased pulmonary

pressure; and closure of the foramen ovale, the ductus arteriosus, and the ductus venosus (Hernandez & Hernandez, 2004) (Fig. 17-4). A summary of the structural changes in circulation that take place in the neonate is presented in Table 17-1.

Closure of the Foramen Ovale

The foramen ovale is a flap in the septum of the fetal heart that allows blood flow between the left and right atria. Oxygen-rich blood returning to the heart from the inferior vena cava crosses from the right atria to the left atria across the foramen ovale. This pathway allows most of the oxygenated blood to bypass the nonfunctioning lungs and supply the aorta and vessels of the heart and head with oxygen. Blood flowing through the foramen ovale accounts for approximately one third of the fetal cardiac output; less than 10% is used for lung perfusion (Barzansky et al., 2006).

The right-to-left shunting ceases once the umbilical cord has been clamped. The ventricular and aortic pressures in the left side of the heart rise. The systemic vascular resistance increases while pressure in the right side decreases. The pulmonary blood vessels respond to the increase in PO_2 during lung expansion and aeration with vasodilation and a decrease in pulmonary vascular resistance. These changes cause an increase in blood flow through the pulmonary veins to the left atrium and lead to an increased left atrial pressure that results in closure of the foramen ovale (MacDonald et al., 2005). Since the foramen ovale is capable only of shunting from right to left, this physiological event closes the shunt. Because of unequal pressures within the heart, the foramen ovale is functionally closed within 1 to 2 hours after birth. Deposits of fibrin and cells seal the shunt and it is physiologically closed by 1 month of age. Permanent closure occurs by the sixth month of life. If the infant experiences difficulties such as asphyxia, acidosis, or cold stress during the physiological transition period, the shunt may reopen and allow for continued right to left shunting due to the increased pressure in the right atria.

Closure of the Ductus Arteriosus

In utero, most of the fetal blood flow occurs across the ductus arteriosus. This structure functions as the pathway between the pulmonary artery and the descending aorta. Blood flow through the ductus arteriosus occurs in a right-to-left direction due to a high pulmonary vascular resistance and low placental resistance. Once the umbilical cord is clamped, placental blood flow ceases and there

Table 17-1 Structural Changes in Circulation After Birth

Fetus	Neonate
Umbilical vein	Ligamentum teres
Ductus venosus	Ligamentum venosum
Foramen ovale	Closed atrial septum
Ductus arteriosus	Ligamentum arteriosum
Umbilical artery	Superior vesical (bladder) artery
	Lateral vesicumbilical ligaments

is an increase in the systemic blood pressure and vascular resistance. At this point, the lungs oxygenate the blood and the increased PaO₂ stimulates the closure of the ductus arteriosus.

During pregnancy, the placenta produces prostaglandin E₂ (PGE₂), a hormone-like substance that causes vasodilation of the ductus. After birth, declining PGE₂ levels contribute to the closure of the ductus arteriosus. In the neonate, a small amount of blood flowing through the ductus may produce a soft murmur. When present, it can be auscultated at the left sternal border in the area of the second intercostal space. Considered innocent, the functional murmur occurs in the absence of any cardiac anomalies and is generally asymptomatic (Miller & Newman, 2005).

Functional closure of the ductus arteriosus in a term infant typically occurs within the first 72 hours of life. Once permanent closure occurs at 3 to 4 weeks, the structure is termed the **ligamentum arteriosum**. Permanent closure results from endothelial destruction, connective tissue formation and subintimal proliferation (MacDonald et al., 2005).

The infant whose birth transition has been complicated by factors such as asphyxia or prematurity has an increased risk of a return to fetal circulation. This event results from continued blood flow through the partially opened ductus arteriosus. Low levels of oxygenated blood flowing through the shunt cause it to dilate, creating a serious transitional complication (MacDonald et al., 2005).

Closure of the Ductus Venosus

The ductus venosus links the inferior vena cava with the umbilical vein. The umbilical vein delivers approximately 50% of the placental blood flow through the ductus venosus into the inferior vena cava and then mixes with the systemic venous drainage from the lower body. Blood flow through the left hepatic vein mixes with blood in the inferior vena cava and flows toward the foramen ovale. Oxygenated blood traveling through the umbilical vein enters the left ventricles and supplies the carotid arteries with oxygen (Barzansky et al., 2006). Once the umbilical cord is clamped, cessation of umbilical venous blood return, along with mechanical pressure changes, lead to closure of the ductus venosus. Closure of the bypass route forces enhanced blood flow to the liver. Fibrosis occurs in the nonfunctional ductus venosus and the structure, which is termed the **ligamentum venosum**, usually closes by the end of the first week.

 **Now Can You—** Discuss cardiopulmonary transitions in the neonate?

1. Explain characteristics of periodic breathing in the neonate?
2. Identify when the ductus venosus functionally closes?
3. Describe the physiological event that causes closure of the foramen ovale?

ASSESSING THE CARDIOVASCULAR TRANSITION

It is important to continually monitor the newborn's cardiovascular status during transition. Immediately after birth, the newborn's pulse rate may reach 160 to 180 beats per minute but during the first 30 minutes of life, the rate

should decline to 120 to 160 beats per minute. This normal fluctuation occurs in response to the cardiovascular transition and the newborn's behavioral states.

On assessment, the systemic circulation is deemed adequate if the newborn exhibits a brisk capillary refill and stable blood pressure. Capillary refill in less than 3 seconds is considered adequate. A refill time greater than 4 seconds may be indicative of an underlying condition such as sepsis, hypoxia, or cardiovascular or central nervous system compromise.

Across Care Settings: Facilitating newborn transition in a birth center

It is essential that the nurse who assists with an unexpected birth in a nonhospital setting such as a minor care clinic or physician office be able to recognize behaviors associated with normal and abnormal physiological transition in the newborn. Since resources outside of the hospital are usually limited, the nurse must be alert to signs of transitional difficulties. As much as is possible, the environment should be manipulated to provide immediate care for the newborn during transition from the intra- to the extrauterine environment. After ensuring effective respirations, facilitating a neutral thermal environment is an essential nursing action. Ideally, a supply of warm, dry linens should be available to prevent neonatal cold stress. In the optimal situation, the nurse has time to evaluate the mother prior to delivery and can be alert to any potential maternal complications during childbirth. A reliable mechanism for the safe transport of the mother and her newborn to the hospital should be established as soon as possible. The nurse must manage care of the neonate and the mother until the transport team arrives.

Thermogenic Adaptation

Neonatal thermoregulation is essential for life sustaining physiologic adaptation. The newborn's ability to maintain a normal body temperature after birth is dependent on factors in the external environment as well as internal physiologic processes. Newborns are characteristically **homeothermic**—that is, they attempt to regulate and maintain their internal core temperature regardless of varying external environmental temperatures.

THE NEUTRAL THERMAL ENVIRONMENT

Thermogenic adaptation is closely related to the infant's rate of oxygen consumption and metabolism. The **neutral thermal environment** (NTE) is the range of temperature in which the newborn's body temperature can be maintained with minimal metabolic demands and oxygen consumption. To maintain a neutral thermal environment, the neonate may need to make certain vasomotor adjustments, such as vasoconstriction to conserve heat or vasodilation to release heat.

Factors such as the infant's body size and gestational age can affect the ability to maintain a neutral thermal environment. Although the term newborn's protective subcutaneous fat helps to maintain a barrier for prevention of heat loss, neonates have less than half of the

amount of subcutaneous fat normally present in adults. Preterm infants are born with very little adipose tissue and lack the muscle development needed to maintain a flexed position for heat conservation. Although full-term newborns have a large body area in relation to the total body mass, their normal position of flexion facilitates maintenance of body heat.

As the newborn transitions to extrauterine life, the core body temperature decreases in response to the environmental temperature. A term infant's core temperature can fall by approximately 0.5°F (0.3°C) per minute up to a total of 5.4°F (3°C) before ever leaving the birthing area. However, most term newborns are able to restore the initial decline in body temperature and stabilize at a normal temperature of 97.7°F (36.5°C) to 98.6°F (37°C) within 2 to 3 hours after birth (Hernandez & Hernandez, 2004).

FACTORS RELATED TO COLD STRESS

Exposure to low environmental temperatures, especially for a prolonged period of time, causes an increase in oxygen consumption and an increased rate of metabolism. These metabolic events lead to cold stress. All newborns are at high risk for cold stress and ineffective thermal regulation due to the following factors:

- Large body area in relation to body mass
- Limited subcutaneous fat
- Limited ability to shiver
- Their skin is thin and their blood vessels are close to body surface

PHYSIOLOGICAL ADAPTATIONS FOR HEAT PRODUCTION

When the infant is exposed to a cold environment, several physiological adaptations help him to increase heat production. These include increasing the basal metabolic rate and muscle activity to generate heat, peripheral vasoconstriction to conserve heat, and **nonshivering thermogenesis** (NST) (heat production). Unlike children and adults, newborns are unable to shiver to generate heat. Instead, they must produce heat via NST and this process becomes the key mechanism for maintaining a neutral thermal environment.

The sympathetic nervous system responds to skin receptors programmed to recognize a drop in the environmental temperature. Once low temperatures are detected, the receptors alert the sympathetic nervous system. Nonshivering thermogenesis utilizes the newborn's stores of **brown adipose tissue** (BAT) to provide heat in the cold-stressed newborn. Formation of brown adipose tissue in the fetus begins at around 26 to 30 weeks of gestation. The deposits of BAT steadily increase until 2 to 5 weeks after birth unless they have been depleted by cold stress. Stores of brown adipose tissue are located in the midscapular area, around the neck, and in the axillae. Deeper deposits are found around the trachea, esophagus, abdominal aorta, kidneys, and adrenal glands (Fig. 17-5).

Brown adipose tissue, also known as “brown fat,” is a unique highly vascular fat found only in newborns. BAT derives its name from the rich abundance of blood

Figure 17-5 Sites of brown adipose tissue stores in the newborn.

vessels, cells, and nerve endings that cause it to appear dark in color. The masses of brown fat cells accelerate triglyceride metabolism, triggering a process that produces heat. Rapid metabolism, along with the generation of heat, quickly sends heat to the peripheral circulation. However, fatty acids are released from metabolized BAT and can cause a life-threatening metabolic acidosis. When the elevated fatty acids are released into the blood stream, the infant is at risk for jaundice due to interference with the transport of bilirubin to the liver (Sedin, 2006).

Optimizing Outcomes— Preventing cold stress in the newborn

An important factor in neonatal resuscitation is the prevention of cold stress. Several body systems are affected when the infant has difficulty maintaining a normal temperature and becomes hypothermic. During nonshivering thermogenesis, the newborn metabolizes brown fat, a process that increases the metabolic rate and oxygen consumption. Over time, the newborn uses all available glucose and glycogen stores while attempting to maintain a neutral thermal environment. Utilization of the brown fat stores places the infant at risk for metabolic acidosis. Decreased oxygen causes peripheral vasoconstriction and increases the likelihood of respiratory distress. Peripheral vasoconstriction can lead to increased pulmonary vascular resistance and a return to fetal circulation as a compensatory mechanism. Elevated fatty acids can interfere with the transport of bilirubin to the liver and increase the risk of jaundice (Sedin, 2006) (Fig. 17-6).

MECHANISMS FOR NEONATAL HEAT LOSS

The nurse's role in preventing neonatal cold stress is critical. Supporting thermoregulation after birth allows the newborn to have a successful transition from intrauterine to extrauterine life. Thorough assessments of all of the newborn's systems should be aimed at maintaining a neutral thermal environment. The newborn has four mechanisms by which heat is lost after birth: evaporation, conduction, convection, and radiation (Fig. 17-7).

Figure 17-6 Metabolic events associated with cold stress in the neonate.

Evaporation

Evaporation is the loss of heat that occurs when water is converted into a vapor. If not adequately dried after birth, the neonate loses heat through the evaporation of amniotic fluid on the skin. This invisible process is termed **insensible water loss (IWL)**. Nursing interventions geared toward preventing evaporative heat loss include thoroughly drying the neonate after birth, promptly removing wet linens, and immediately placing a hat on the head to prevent evaporation through the scalp.

Conduction

Conduction is the loss of heat to a cooler surface via direct skin contact. Conductive heat loss occurs when the

infant is placed on a cold surface, such as a cold scale, mattress, or examining table. Nursing interventions to minimize conductive heat loss include placing the infant on a prewarmed radiant warmer, using warmed blankets, covering scales with blankets prior to weighing, and avoiding the use of cold instruments (e.g., stethoscope). The newborn can also be placed skin to skin with the mother to facilitate body warming and bonding.

Convection

Convection is the loss of heat from the warm body surface to the cooler air currents. Convective heat loss occurs when the neonate is exposed to drafts and cool circulating air. The nurse can help minimize neonatal heat loss through convection by preventing drafts in the birth area (e.g., no ceiling fans) and by placing the newborn away from doors or windows. Also, depending on the environment, the neonate should be warmly clothed and possibly swaddled to prevent cooling from air currents.

Radiation

Radiation heat loss occurs when there is a transfer of heat between objects that are not in direct contact with each other. The walls of the nursery or the incubator may serve as potential sources of heat loss through radiation. Nursing interventions to prevent heat loss through radiation include having a prewarmed radiant warmer present at the birth, avoiding placement of the crib or incubator by a cold window, and keeping cold objects well away from the neonate.

PREVENTING HYPERTHERMIA

It is also important to prevent neonatal **hyperthermia** (elevated core body temperature). Although sweating is the full-term infant's initial response to elevated body temperature, the sweat glands are not fully functional until after the first month of life. Before that time, the body loses heat through peripheral vasodilation and the evaporation of insensible water loss. An increase in oxygen consumption and the metabolic rate are associated with hyperthermia and when severe, brain damage, or death may result.

During the first few minutes of life, neonatal hyperthermia is most often associated with maternal fever (Hertz, 2005). An elevated core body temperature can

Figure 17-7 The four mechanisms of heat loss in the newborn. A. Evaporation. B. Conduction. C. Convection. D. Radiation.

also result from an ambient environment that is too hot for the newborn to successfully maintain a neutral temperature. Other causes of hyperthermia include infection, CNS impairment, dehydration, and medications.

Radiant warmers, essential equipment in the birth area, must be monitored closely to ensure they are in proper working order with reliable heating mechanisms. Caution must be exercised with the use of servo-controlled radiant warmers since they may cause an undesirable elevation in the neonate's temperature if not monitored correctly. In addition, if programmed to maintain a set temperature, these units may mask the signs and symptoms of an infection if the neonate is not appropriately assessed. On discharge, the nurse needs to teach parents to closely monitor body temperature when placing the newborn in a sunny location to decrease elevated bilirubin levels. (See Chapters 18 and 19 for further discussion.)

Now Can You— Discuss thermoregulation in the newborn?

1. Define nonshivering thermogenesis and discuss its effect on thermoregulation in the newborn?
2. Identify three nursing interventions to prevent heat loss by evaporation and convection after birth?
3. Explain how depletion of the brown adipose tissue stores places the term newborn at risk for respiratory distress?

Hematopoietic Adaptation

As with most of the neonate's other body systems, the hematopoietic system is not fully mature at birth. Instead, in the days following birth, the neonate's hematopoietic system transitions from an in utero oxygenation pathway to an extrauterine perfusion pathway.

BLOOD VOLUME

The full-term infant's average blood volume ranges from 80 to 90 mL/kg of body weight, as compared with a blood volume of 90 to 105 mL/kg of body weight in the preterm infant. The neonate's blood volume is determined in large part by the timing of umbilical cord clamping. At birth there is a transfer of blood from the placenta to the neonate: approximately one fourth of the fetal blood volume is transferred within the first 15 seconds; approximately one half of the fetal blood volume is transferred by the end of the first minute of life. The umbilical vessels carry approximately 75 to 125 mL of blood at birth and the neonate's total blood volume may be increased by as much as 61%, depending on a delay in cord clamping (MacDonald et al., 2005).

Currently, much debate surrounds the issue of how long the umbilical cord should be allowed to pulsate before it is clamped. Holding the neonate below the level of the placenta and delaying the clamping of the cord may allow up to a 100 mL/kg increase in the neonate's total blood volume. The increase in blood volume may facilitate an improved transition due to enhanced pulmonary perfusion and the gain of additional iron stores. A disadvantage of this practice concerns the increased risk of jaundice due to the higher volume of erythrocytes and possible resultant polycythemia.

Blood volume in the newborn varies according to gestational age, a factor that determines the amount of circulating volume, and the occurrence of prenatal or postnatal hemorrhage (Bloom et al., 2005). Maternal prenatal or perinatal hemorrhage can have a dramatic impact on the infant's hematopoietic system; following a significant hemorrhage the infant may exhibit decreased hemoglobin and hematocrit levels along with a risk of hypovolemia.

BLOOD COMPONENTS

Erythrocytes and Hemoglobin

At birth, the neonate has a greater number of erythrocytes and higher hemoglobin and hematocrit levels than those found in an adult. During early fetal development, erythropoiesis (formation of red blood cells) occurs primarily in the liver. At approximately 6 months of gestation, the bone marrow becomes the site for hematopoiesis (formation of blood cells). During the later stages of fetal development, fetal hemoglobin (HbF) is slowly replaced by adult hemoglobin (HbA) (MacDonald et al., 2005). Fetal hemoglobin carries 20% to 50% more oxygen than adult hemoglobin.

The process of erythropoiesis is stimulated by the renal hormone erythropoietin. Red blood cell (RBC) production increases in response to a rise in erythropoietin after low fetal oxygen saturation. This physiological event facilitates adequate tissue perfusion and oxygenation. After the initiation of normal respirations at birth, the neonate's oxygen saturation rises, causing an inhibition in the secretion of erythropoietin. This event inhibits the production of red blood cells. The neonate's erythrocytes (fetal RBCs) have a shorter lifespan (90 days) than do adult erythrocytes (120 days). As the neonate's red blood cell count decreases from deterioration of the fetal erythrocytes, physiological anemia of infancy may develop and persist for 2 to 3 months. The lifespan of erythrocytes in the full term neonate is 60 to 70 days; for the preterm neonate, the RBC lifespan is only 35 to 50 days. In the event of hemolysis, the hemoglobin is broken down and bilirubin is released into the systemic circulation. If large numbers of RBCs are involved, blood levels of bilirubin rise and the newborn becomes jaundiced (Pagana & Pagana, 2006). (See Chapter 19 for further discussion.)

Hematocrit

Hematocrit is defined as a percentage of red blood cells within a certain unit volume of blood. Normal neonatal blood values vary according to gestational age and the volume of placental blood that was transfused at the time of birth (i.e., delayed cord clamping) (Table 17-2). Hematocrit levels are generally higher in peripheral blood samples due to peripheral vasoconstriction and the stasis of blood cells. A peripherally drawn hematocrit for a normal infant ranges from 48% to 64%. If the hematocrit drawn from a central site is greater than 65%, the infant is considered to be polycythemic. **Polycythemia**, an abnormally high erythrocyte count, is a condition that can place the infant at high risk for jaundice and organ damage due to increased viscosity of the blood cells. Polycythemic infants are also at an increased risk for hypoglycemia and respiratory distress. Under routine circumstances, unless the infant exhibits signs and symptoms associated with

Table 17-2 Laboratory Values for the Normal Term Neonate: Blood

Blood Component	Normal Range
Albumin	3.6–5.4 g/dL
Amylase	0–1000 IU/hr
Bicarbonate	20–26 mmol/L
Bilirubin, direct	Less than 0.5 mg/dL
Bilirubin, total	Less than 2.8 mg/dL (cord blood)
0–1 days	2.6 mg/dL (peripheral blood)
1–2 days	6–7 mg/dL (peripheral blood)
3–5 days	4–6 mg/dL (peripheral blood)
Bleeding time	2 Minutes
Arterial blood gases	
pH	7.35–7.45
Paco ₂	35–45 mm Hg
Pao ₂	50–90 mm Hg
Venous blood gases	
pH	7.35–7.45
Paco ₂	41–51 mm Hg
Pao ₂	20–49 mm Hg
Calcium, ionized	2.5–5 mg/dL
Calcium, total	7–12 mg/dL
Glucose	30–125 mg/dL
Hematocrit	48%–64%
	53% (cord blood)
Hemoglobin	17–18.4 g/dL
	16.8 g/dL (cord blood)
Platelets	150,000–300,000/mm ³
Immunoglobulins, total	660–1439 mg/dL
Iron	100–250 mcg/dL
Red blood cell count	4,800,000–7,100,000/mm ³
White blood cell count	9000–30,000/mm ³

Adapted from Nettina (2007) and Pagana & Pagana (2006).

transitional difficulties, hematocrit and hemoglobin levels are not routinely assessed (Pagana & Pagana, 2006).

Leukocytes

Leukocytes (white blood cells [WBCs]) serve as the major defense against infection in the neonate. The WBCs are classified into five categories: neutrophils, eosinophils, basophils, lymphocytes, and monocytes. Neutrophils act as phagocytes that ingest and destroy small particles of bacteria and cellular debris. Eosinophils perform similar duties but are less effective. However, eosinophils survive for longer periods of time and are important mediators in

an allergic and anaphylactic response. Basophils play an important role as responders to allergic and inflammatory reactions. Lymphocytes respond to graft versus host allergic diseases and allergic reactions. Monocytes clean up old blood cells and cellular debris and remove activated clotting factors from the circulation.

An elevated leukocyte count in a normal newborn does not always indicate infection. During the first 12 hours after birth, the leukocyte count typically remains elevated before it begins to decline. The average white blood cell count in the term newborn is 18,000/mm³, but ranges from 9000 to 30,000/mm³ are considered to be within normal limits. Infection is usually associated with a decrease in the leukocyte count. Neonatal sepsis is accompanied by an increased number of immature leukocytes along with a decrease in the total platelet count (Roberts, 2005). (See Chapter 19 for further discussion.)

Platelets

Due to the absence of vitamin K at birth, the neonate is at risk for developing a blood clotting deficiency during the first few days of life. To facilitate clotting, the following blood factors must be present: factor II (prothrombin) and factors VII, IX, and X. Vitamin K, synthesized in the infant's intestinal tract, is not produced in the intestines until food and normal intestinal flora are present.

The infant is given an intramuscular injection of vitamin K₁ phytonadione (AquaMEPHYTON) during the initial care and assessment to prevent hemorrhagic disease of the newborn. (See Chapter 19 for further discussion.) The normal newborn's platelet (thrombocyte) levels range from 150,000 to 300,000/mm³ and are essentially the same as in adults. Small for gestational age (SGA) infants may have platelet counts up to 25% lower than those found in appropriate for gestational age neonates. Circulating platelets are hypoactive during the first few days of life. Although this physiological phenomenon prevents the newborn from developing thrombosis, there may be an increased risk for bleeding and coagulopathy (Pagana & Pagana, 2006).

Hepatic Adaptation

The newborn's liver is a large organ that accounts for about 40% of the total abdominal area. It is palpable approximately 2 to 3 cm below the right costal region. An essential organ, the liver is responsible for the regulation of blood glucose, iron storage, bilirubin conjugation, and coagulation of the blood.

GLYCOGEN AND BLOOD GLUCOSE MAINTENANCE

Throughout pregnancy, the fetus receives glucose by way of the placenta. During the last 4 to 8 weeks of gestation, the glucose is stored as glycogen in the fetal liver and skeletal system for use after birth. Glucose is utilized more rapidly in the newborn than in the fetus because of the metabolic events that occur during the normal transitional phase. The newborn requires added energy to accomplish several essential tasks to offset the stress of birth, to initiate breathing, to activate muscular activity, and to produce heat.

The stressful events associated with the birth process prompt the conversion of fats and glycogen to glucose. After delivery, an increase in circulating catecholamines triggers the release of glycogen from the neonate's liver. Glycogen provides a ready source of glucose to the brain and other vital organs. During the first three hours of life, a healthy term newborn may utilize up to 90% of his liver's glycogen stores (Hernandez & Hernandez, 2004). Although the brain's primary source of fuel is glucose, ketones, lactic acids, fatty acids, and glycerol can also be utilized if necessary to maintain an adequate supply of energy. The liver's ability to adequately convert glycogen to glucose for fuel is essential for a successful physiologic transition.

The blood glucose of a term infant should be 70% to 80% of the maternal blood glucose level. The maternal glucose level is influenced by a number of factors including the timing and contents of the last meal consumed, the duration and mode of delivery and the components of any intravenous fluids or medications administered during labor and birth.

During the first 4 to 6 hours of life, the newborn's main source of energy is glucose. The serum blood glucose level drops during the first 3 hours of life and then gradually rises over the next 3 to 4 hours to reach a steady state of 40 to 80 mg/dL. **Glycogenolysis**, the breakdown of glycogen into the more usable form of glucose within the body tissues, can occur if the newborn does not receive any exogenous glucose before the initial hepatic and skeletal glycogen stores have been depleted. This process prompts the release of glucose into the bloodstream as needed to maintain normal blood levels.

Hypoglycemia

Hypoglycemia can occur after any stressful events (e.g., hypothermia, hypoxia) that increase metabolic demands. Nurses must be aware of risk factors associated with neonatal hypoglycemia (Box 17-1). For example, preterm and SGA infants may not have accumulated the glycogen stores necessary to maintain serum glucose levels required for energy needs. Large for gestational age (LGA) and infants of diabetic mothers (IDM) may produce too much insulin postnatally and rapidly metabolize their glucose stores (Kalhan & Parimi, 2006). Postterm or intrauterine growth restricted (IUGR) fetuses can develop hypoglycemia related to poor intrauterine nourishment from a deteriorating placenta. Consequently, they have depleted glucose stores before birth. Neonates exposed to postbirth stressors such as asphyxia, infection, or cold stress rapidly utilize their glucose stores to assist with the transition process (Hertz, 2005). (See Chapter 19 for further discussion.)

critical nursing action Recognizing Hypoglycemia in the Neonate

When assessing the neonate during the transitional period, the nurse should be alert to signs and symptoms of hypoglycemia. These include jitteriness, diaphoresis, poor muscle tone, poor sucking reflex, temperature instability (low temperature), respiratory distress, tachycardia, dyspnea, apnea, high-pitched cry, irritability, lethargy, seizures, or coma. However, the infant may be asymptomatic. Therefore, awareness of prenatal and perinatal risk factors that may predispose to postnatal hypoglycemia is essential.

Labs: Neonatal Blood Glucose Assessment

Capillary blood obtained from the neonate's heel is commonly used to assess blood glucose. When available, a heel warmer is used to increase blood flow to the sample site. The area is cleansed with a sterile alcohol pad and the heel is gently punctured, taking care to avoid the middle area where there is a risk for nerve damage or puncture of the plantar artery. A large drop of blood is placed on the test strip and a sterile bandage is used to apply pressure on the sample site.

IRON STORAGE

During the last few weeks of pregnancy, iron is stored in the fetal liver. As RBCs are destroyed after birth, the neonatal liver stores additional iron until needed for the production of new RBCs. At term, the newborn has approximately 270 mg of iron, and of this amount, 140 to 170 mg of iron is contained in the hemoglobin. Adequate maternal iron intake during pregnancy ensures that a sufficient amount of iron is available in the infant to last up to 6 months of age. Term infants who are exclusively breastfed do not need additional iron until at least 6 months of age. However, formula-fed infants should be given an iron-fortified formula, and beginning at 6 months, all infants should receive iron supplements or iron-rich foods to prevent anemia (Luchtman-Jones, Schwartz, & Wilson, 2006).

CONJUGATION OF BILIRUBIN

Conjugation of bilirubin constitutes a major function of the newborn's liver. Conjugation is a process that converts the yellow lipid-soluble (nonexcretable) bilirubin pigment (present in bile) into a water-soluble (excretable) pigment. **Jaundice** is a condition characterized by a yellow (icteric) coloration of the skin, sclera, and oral mucous membranes. Jaundice results from the accumulation of bile pigments associated with an excessive amount of bilirubin in the blood (**hyperbilirubinemia**). This condition occurs in approximately 60% of full-term infants and in up to 80% of preterm infants. The presence of jaundice is directly related to the liver's maturity and its ability to conjugate bilirubin (MacDonald et al., 2005).

Bilirubin is produced from the hemolysis (breakdown) of erythrocytes. Removal of bilirubin begins in the reticuloendothelial system, where mononuclear phagocytes remove aging RBCs from the circulation. Heme, the oxygen-carrying component of hemoglobin, is broken down into

Box 17-1 Risk Factors for Hypoglycemia in the Neonate

- Prematurity
- Postmaturity
- Intrauterine growth restriction (IUGR)
- Large or small for gestational age (LGA or SGA)
- Asphyxia
- Difficult transition at birth
- Cold stress
- Maternal diabetes
- Maternal intake of ritodrine (Yutopar) or terbutaline (Brethine)
- Infections

three elements: iron, carbon monoxide, and biliverdin. Iron, stored in the hemoglobin, is used for a number of essential bodily functions. Carbon monoxide is exhaled through the lungs as a waste product, and biliverdin is further broken down into lipid-soluble bilirubin.

During the process of normal conjugation, bilirubin attaches to the blood albumin and is transported to the liver. In the liver, the unbound bilirubin detaches from the albumin, and is conjugated with glucuronide in the presence of the enzyme glucuronyl transferase. This process produces water-soluble **direct bilirubin**, which is excreted into the common duct and duodenum. Normal intestinal flora reduce the direct bilirubin into urobilinogen and stercobilinogen. This product is then excreted as a yellow-brown pigment in the stools, and a small amount is excreted through the kidneys. The physiological pathway for the excretion of bilirubin is presented in Figure 17-8.

The breakdown of 1 gram of hemoglobin yields approximately 34 mg of bilirubin. The normal term newborn produces 6 to 10 mg of bilirubin per kilogram per day. In comparison, adults produce 3 to 4 mg of bilirubin per kilogram per day. The increased bilirubin production in the newborn is related to the high concentration of RBCs at birth and the shortened life span of fetal erythrocytes (Hernandez & Hernandez, 2004).

Conjugated or “direct” bilirubin has been converted from a lipid-soluble, nonexcretable pigment into a water-soluble, excretable pigment. Unconjugated, or “indirect” bilirubin is fat-soluble and nonexcretable. The newborn’s liver must be

able to convert the fat-soluble (nonexcretable) bilirubin into a water-soluble (excretable) form by way of conjugation. Elevated blood levels of unconjugated bilirubin can be toxic and result in **kernicterus**, a life-threatening condition caused by the deposition of unconjugated bilirubin in the brain and spinal cord. (See Chapter 19 for further discussion.)

The total serum bilirubin level (TSB) is a measurement of both the conjugated and unconjugated bilirubin. At birth, the normal total serum bilirubin level is 3 mg/dL or less. Before birth, the fetus does not need to conjugate bilirubin; instead, unconjugated bilirubin is transferred across the placenta for maternal excretion. After birth, the neonate’s liver must be able to satisfactorily conjugate bilirubin (MacDonald et al., 2005).

Nursing Insight— Maternal medications may decrease neonatal albumin-binding sites

Maternal ingestion of medications such as aspirin and sulfa drugs may reduce the number of albumin-binding sites in the infant and result in neonatal hyperbilirubinemia.

Risk Factors for Hyperbilirubinemia

Neonatal jaundice that occurs during the first week of life most often results from excessive levels of unconjugated bilirubin. Unlike pathologic jaundice (present at birth or occurring during the first 24 hours), the signs of physiologic jaundice do not occur until *after* the first 24 hours of life. Jaundice is usually first noted on the face and sclera when the serum bilirubin levels reach approximately 4 to 6 mg/dL. The yellow coloration then progresses caudally as the total serum bilirubin level rises to 6 to 7 mg/dL (Bhutani, Johnson, & Keren, 2005). Many maternal and neonatal factors such as ethnicity, diabetes, prematurity, and delay in feeding place the infant at risk for hyperbilirubinemia (Box 17-2). (See Chapter 18 for further discussion.)

Figure 17-8 Physiological pathway for the excretion of bilirubin.

Box 17-2 Factors that May Influence Bilirubin Levels in the Neonate

- Cultural background: Chinese, Japanese, Korean, and Native American neonates exhibit higher bilirubin levels than do European and American Caucasian neonates. The elevated levels of bilirubin persist for a longer period of time and cause no apparent adverse effects.
- Perinatal events (i.e., delayed cord cutting, breech presentation, the use of Pitocin)
- Prematurity
- Maternal diabetes
- Excess bilirubin production (e.g., hemolytic diseases such as Rh isoimmunization and ABO incompatibility; sepsis; metabolic disorders)
- Delayed feedings
- Liver immaturity (i.e., prematurity; glucose-6-phosphate dehydrogenase deficiency)
- Birth trauma
- Family history of jaundice or previous child with jaundice
- Neonatal complications (i.e., asphyxia neonatorum, cold stress, hypoglycemia)

Ethnocultural Considerations— Neonatal jaundice and RBC enzyme defects

Jaundice occurs with greater frequency in infants of Chinese, Japanese, Korean, Native American, and Greek descent. In these populations, there is an increased incidence of red blood cell enzyme defects, including glucose-6-phosphate dehydrogenase (G6PD) deficiency and pyruvate kinase deficiency. G6PD deficiency, an X-linked recessive disorder, represents one of the most common autosomal recessive traits. It occurs most frequently in Mediterranean, Middle-Eastern, Southeast Asian, and African infants. An estimated 11% to 13% of African American infants who are born in the United States are affected as well (Hernandez & Hernandez, 2004). Pyruvate kinase deficiency, also an autosomal recessive trait, is the next most common enzyme deficiency. Affected infants typically display symptoms of jaundice, anemia, and reticulocytosis (MacDonald et al., 2005).

Perinatal events, such as delayed clamping of the umbilical cord, increase the volume of circulating erythrocytes and predispose the neonate to an increased breakdown of RBCs and the subsequent development of jaundice. Traumatic births that involve the use of forceps or vacuum extraction, and fetal presentations that increase the likelihood of bruising, all lead to erythrocyte destruction. Although the mechanism is unclear, there is evidence to suggest that the use of oxytocin and epidural medications may lead to hemolysis of RBCs and serve as an increased source of jaundice (Verklan & Walden, 2004).

Infants who begin feeding early and are feeding well soon establish normal intestinal flora and the regular passage of meconium, which contains large amounts of bilirubin. Infants with delayed or poor feedings have a prolonged exposure to the enzyme beta-glucuronidase, which converts conjugated bilirubin back into unconjugated bilirubin, which is then reabsorbed into the blood. Premature infants, whose livers and blood–brain barriers are immature, do not yet produce the enzymes necessary for bilirubin conjugation and thus are at an increased risk for jaundice (Hertz, 2005).

Development of Physiological Jaundice

Physiological jaundice occurs in more than 60% of term newborns and in up to 80% of preterm newborns. Physiological jaundice is the transient form of jaundice that typically occurs after the first 24 to 48 hours of life and becomes visible when the total serum bilirubin level is greater than 5 mg to 7 mg/dL. The rate at which the bilirubin level climbs and peaks in relation to the weight and gestational age of the infant is an important parameter of assessment in terms of treatment (MacDonald et al., 2005). In the presence of physiological jaundice, bilirubin levels typically peak between days 5 to 7 and then gradually decline after 10 to 14 days of life. Peak bilirubin levels are reached between the 3rd and 5th days in the term infant and between the 5th and 7th days in the preterm infant. The interaction of the following four factors can lead to the development of physiological jaundice:

- There is an increased amount of bilirubin presented to the liver. This is related to an increase in blood volume (following a delay in cord clamping) and

accelerated RBC destruction due to their shortened life span. Newborns produce and break down two to three times more bilirubin than do adults.

- There is a decreased reabsorption of bilirubin from the intestines. This is related to the decreased caloric intake common in most infants during the first few days of life. When the caloric intake is inadequate, the production of hepatic binding proteins is decreased and the levels of bilirubin rise.
- Defective bilirubin conjugation related to a decrease in glucuronyl transferase activity (as occurs in hypothyroidism, for example) coupled with inadequate caloric intake may cause saturation of the intracellular binding proteins and result in increased blood levels of unconjugated bilirubin. Also, fatty acids present in breast milk are believed to compete with bilirubin for albumin binding sites and interfere with bilirubin metabolism.
- A defect in bilirubin excretion may result from a congenital infection. A delay in the introduction of normal bacterial flora coupled with decreased intestinal motility may cause delayed excretion and increase the bilirubin deconjugation process via the enterohepatic circulation (MacDonald et al., 2005).

Development of Nonphysiological or Pathological Jaundice

Pathological jaundice occurs within the first 24 hours of life. The infant may exhibit a total serum bilirubin concentration (TSB) that increases by 0.5 mg/dL per hour or 5 mg/dL per day. The diagnosis is usually made when TSB concentrations climb greater than 12.9 mg/dL in a term infant and greater than 15 mg/dL in a preterm infant. Pathological jaundice results from disorders that cause excessive hemolysis of erythrocytes, leading to an increased production of bilirubin. Excessive blood cell breakdown may result from polycythemia or increased bruising after a traumatic delivery. Infections, metabolic disorders, and incompatibilities between the mother's and newborn's blood (Rh incompatibility) may also cause pathologic jaundice. (See Chapter 19 for further discussion on pathologic jaundice.)

Breastfeeding Jaundice (Early-Onset Jaundice)

Breastfeeding jaundice is a condition that occurs when there is a decreased intake of breast milk and a decreased passage of meconium. Breastfed infants tend to have higher bilirubin levels than bottle-fed infants. Breastfeeding jaundice generally occurs between the 2nd and 4th days of life. The total serum bilirubin levels peak at 15 mg to 19 mg/dL by 72 hours of life. Breastfeeding jaundice is believed to be associated with poor feeding practices and is not related to the composition of the breast milk. Early and frequent feedings with avoidance of formula and glucose supplementation constitutes the primary therapy for breastfeeding jaundice (Hertz, 2005).

Breast Milk Jaundice (Late-Onset Jaundice)

Breast milk jaundice typically occurs in the full-term infant, with an incidence of approximately 2% to 4%. This condition has a later onset than breastfeeding jaundice and usually appears after the first week of life and peaks around day 10. Unlike physiological jaundice, a condition characterized by declining bilirubin levels within the first

week, bilirubin levels associated with breast milk jaundice continue to rise and peak at 2 to 3 weeks of life. Meanwhile, infants typically are thriving, stooling appropriately, and gaining weight without any evidence of hemolysis (Hertz, 2005).

At one time, it was thought that breast milk jaundice was related to an enzyme in the breast milk that inhibited the action of glucuronyl transferase. Today the appearance of breast milk jaundice is believed to be related to a factor in human milk that increases the intestinal absorption of bilirubin. In most circumstances, no intervention is necessary. If the infant continues to breastfeed, the TSB gradually declines over the course of a few weeks. Some experts recommend temporarily halting breast feeding for 48 hours to allow the serum bilirubin levels to decline. It is important to carefully monitor infants and provide phototherapy or supplemental nutrition when needed (Verklan & Walden, 2004). (See Chapter 18 for further discussion.)

COAGULATION OF BLOOD

Another important function of the liver involves the production of coagulation factors to enable the newborn to effectively clot blood after birth. The coagulation factors are activated by vitamin K (AquaMEPHYTON), given to the newborn within one hour following birth. An intramuscular injection of Vitamin K (AquaMEPHYTON) given prophylactically within this first hour of life prevents hemorrhagic diseases of the newborn. Coagulation factors synthesized in the liver include prothrombin and factors II, VII, IX, and X. Circulating levels of the coagulation factors vary according to the gestational age of the infant (MacDonald et al., 2005).

Now Can You— Discuss neonatal jaundice?

1. Identify two factors that may place an infant at risk for physiological jaundice?
2. Explain why infants of Mediterranean descent are at a higher risk for jaundice?
3. Discuss why delayed cord clamping at birth can affect the development of jaundice?

Gastrointestinal Adaptation

STOMACH AND DIGESTIVE ENZYMES

The neonate's stomach capacity is approximately 6 mL/kg at birth and by the end of the first week of life, the capacity has increased to hold approximately 90 mL. In utero, the fetal gastrointestinal system reaches maturity around 36 to 38 weeks of gestation when there is sufficient enzymatic activity for digestion and the transport of nutrients throughout the body. To nutritionally thrive, newborns must be able to digest essential carbohydrate disaccharides that include lactose, maltose and sucrose. Lactose, the primary carbohydrate in breast milk, is easily digested and readily absorbed (Hertz, 2005). A deficiency of pancreatic amylase, the only enzyme lacking at birth and during the first few months of life, makes it difficult for infants to digest fats efficiently. Newborns also have a decreased production of pancreatic lipase and bile acids, which further limits their ability to absorb fats.

Production of pancreatic lipase gradually increases during the first few weeks of life.

INTESTINAL PERISTALSIS

Fetal peristalsis can be influenced by anoxia, which triggers the expulsion of meconium into the amniotic fluid. Immediately after birth, air enters the stomach and reaches the small intestine within 2 to 12 hours. Bowel sounds are present within the first 15 to 30 minutes of life due to the air that has entered the stomach and small intestines. The gastrocolic reflex is stimulated when the stomach fills, and this process helps to enhance intestinal peristalsis. The stomach empties intermittently, usually at the beginning of a feeding and up until 2 to 4 hours after a feeding. The salivary glands are immature at birth; little saliva is produced for the first 3 months of life. The cardiac sphincter (located between the esophagus and the stomach) is immature, and it is not unusual for newborns to regurgitate small amounts following feedings (Hertz, 2005).

Compared to the overall body size, the newborn's intestines are long, a feature that provides an increased surface area for the absorption of nutrients. However, if diarrhea occurs, the additional surface area places the infant at an increased risk for dehydration and water loss. Infants born at term generally pass their first meconium stool within 8 to 24 hours of life. An important nursing function includes documentation of the first meconium stool. Absence of passage of a bowel movement by 72 hours of age may be indicative of an obstructive bowel problem (Miller & Newman, 2005).

Meconium consists of particles found in the amniotic fluid such as vernix, skin cells, hair, and cells that have been shed by the intestinal tract. Meconium stools, which are characteristically greenish-black and viscous, gradually change to transitional stools that are thinner and greenish-brown to yellowish-brown. The newborn may pass stools from one to ten times a day over a 24-hour period. Following the transitional stools, stool appearance and frequency varies, depending on whether the infant is breast or bottle fed.

Now Can You— Discuss gastrointestinal functioning in the newborn?

1. Describe the fetal to newborn transition process that takes place in the gastrointestinal tract?
2. Identify the enzymes that aid in digestion and those that are deficient at birth?
3. Identify when bowel sounds become present in the newborn?

Genitourinary Adaptation

KIDNEY FUNCTION

In the term newborn, the following three major physiological factors enable the kidneys to manage bodily fluids and excrete urine:

- The nephrons are fully functional by 34 to 36 weeks of gestation.
- The glomerular filtration rate is lower than that of the adult.
- There is a limited capacity for the reabsorption of HCO_3^- and H^+ .

Although the fetal kidneys contain working nephrons by 34 to 36 weeks of gestation, the kidneys are not mature and fully functional until after birth when the newborn becomes responsible for the elimination of waste products. The neonate's elevated hematocrit (related to the high concentration of RBCs) and low blood pressure may lead to a decreased glomerular filtration rate (GFR) (the volume of glomerular filtrate that is formed over a specific period of time). With a low GFR, the newborn's kidneys are unable to dispose of fluid rapidly and tend to reabsorb excess sodium. As the kidneys mature and enlarge, the GFR rapidly increases during the first 4 months of life. Adult GFR values are reached at around 2 years of age (MacDonald et al., 2005).

In the neonate, urine specific gravity normally ranges from 1.002 to 1.010. Term newborns are unable to adequately concentrate urine (reabsorb water back into the blood) because the kidney tubules are short and narrow. This alteration may lead to an inappropriate loss of substances such as amino acids and glucose. By 3 months of age, infants are able to fully concentrate their urine (Modi, 2005). Normal laboratory values for components in the neonate's urine are presented in Table 17-3.

Along with the lungs and circulatory system, the kidneys perform an important function in helping the body maintain a normal acid–base balance. Several factors can interfere with the newborn's ability to maintain homeostasis in this system. The limited capacity for tubular reabsorption of HCO_3^- and H^+ can lead to a loss of essential substances (e.g., amino acids, bicarbonate, glucose, sodium) in the filtrate. Due to immaturity of the newborn's kidneys, there is a greater capacity for glomerular filtration than for tubular reabsorption and secretion (Cloherty, Eichenwald, & Stark, 2004).

It is important for the nurse to carefully monitor the newborn's intake and output to prevent overhydration and/or dehydration. Most newborns void immediately after birth or within the first few hours, although some

may not void for up to 24 hours. On average, approximately 68% of normal newborns void within the first 12 hours, 93% by 24 hours, and 100% will have voided by 48 hours. Recording the neonate's first voiding is an important nursing action. If voiding has not occurred by 24 hours of life, the nurse must alert the pediatrician or neonatal nurse practitioner. The infant may be experiencing hypovolemia related to an insufficient fluid intake. Failure to void during the first 24 hours of life may also indicate the presence of an obstruction in the urinary outflow system and the infant should be carefully assessed for bladder distention, restlessness, and symptoms of pain (Hernandez & Hernandez, 2004).

Initially, the newborn's bladder capacity ranges from 6 to 44 mL of urine. During the first 2 days of life, infants normally void two to six times in a 24-hour period, with a total output of 15 mL/day. Urine output is significantly higher in infants with edema. By the fourth day, the frequency of voiding should have increased to more than six voids in a 24-hour period. Since the kidneys have difficulty concentrating urine and removing waste products from the blood immediately after birth, small amounts of protein and glucose are frequently present in the urine. Urate crystals, which are pink-red in color, are excreted in the urine and can be mistaken for blood. The crystals (sometimes referred to as "brick dust spots") disappear after the first few days of life as kidney function matures.

During the first 24 to 48 hours, full-term newborns require 60 to 80 mL/kg of fluids to maintain an adequate fluid balance. This requirement increases to 100 to 150 mL/kg per day after the first few days, and a urine output of 1 to 3 mL/kg per hour is indicative of adequate fluid maintenance (Hertz, 2005). Because the neonate's kidneys are unable to tolerate large changes in volume, careful monitoring of fluid balance is essential. Large changes in fluid balance can create a problem if the infant becomes ill and needs to receive intravenous fluids during that time. Nursing diagnoses for the neonate experiencing difficulty during the transitional period may be related to the specific organ system(s) involved, environmental factors, or medical interventions (Box 17-3).

Assessing the appearance of the newborn's urine is important when evaluating genitourinary system function. When necessary, the nurse may need to apply a urine collection bag to obtain a urine sample from the infant.

Table 17-3 Laboratory Values for Urine in the Normal Term Neonate

Urine Component	Normal Range
Casts, WBC	Normal to be present for the first 2–4 days
Osmolality (maximum concentration ability)	800 mOsmol/L
(Maximum diluting ability)	25–30 mOsmol/L
pH	4.5–8.0
Phenylketonuria	No color changes
Specific gravity	1.002–1.010
Protein	May be present during first 2–4 days
Glucose	Negative
Blood	Negative
Leukocytes	Negative

Adapted from Cloherty, Eichenwald, & Stark (2004) and Nettina (2007).

Box 17-3 Possible Nursing Diagnoses Related to Newborn Physiological Transitions

- Altered Health Maintenance related to separation from the maternal support system.
- Risk for Infection related to the newborn's immature immunological system.
- Risk for Ineffective Airway Clearance related to excessive fluid present in lungs during neonatal transition.
- Risk for Pain related to increased environmental stimuli.
- Risk for Ineffective Thermoregulation related to the newborn's immature temperature regulation systems.
- Altered Nutrition: Less than Body Requirements related to limited nutritional and fluid intake and increased caloric expenditure.

After the first voiding the urine may be cloudy (from mucus) and contain (innocuous) urate crystals. The urine should be odorless and straw colored to clear in appearance as the newborn's fluid intake increases.

Immunological Adaptation

The newborn's immunological system remains immature after birth and may not adequately react to an infectious process. Signs of infection in the newborn can be very subtle and often are not as obvious as they would be in an older child. The newborn receives immunity through two types of methods: active acquired immunity and passive acquired immunity. The pregnant woman's exposure to illness and immunizations prompts the development of antibodies in a process termed **active acquired immunity**. The infant receives **passive acquired immunity** through antibodies that have been passed through the placenta by way of the IgG immunoglobulins.

There are three primary immunoglobulins: IgG, IgA, and IgM. These immunoglobulins, also referred to as humoral antibodies, are proteins that are synthesized in response to a specific antigen. Humoral immunity is important in protecting the newborn against bacterial and viral infections. Low levels of immunoglobulins and immature leukocyte function in destroying pathogens render the newborn especially vulnerable to infections.

IgG is the only immunoglobulin able to pass through the placenta before birth. Placental transfer of this immunoglobulin occurs primarily during the third trimester. At birth, full-term infants have already acquired immunity to tetanus, diphtheria, smallpox, measles, mumps, poliomyelitis, and a host of other bacterial and viral diseases. Preterm infants born before 34 weeks of gestation are at a greater risk for infection. Passive acquired immunity typically disappears by 6 months of age. The infant continues to develop antibodies by active acquired immunity either by direct exposure to an infection with the subsequent development of antibodies or through the immunization schedule recommended by the American Academy of Pediatrics (AAP) and the Centers for Disease Control and Prevention (CDC) (Cant & Gennery, 2005; Kapur, Yoder, & Poplin, 2006).

IgA is important in protecting the infant against gastrointestinal and respiratory infections. Colostrum and breast milk are important sources of IgA, and this factor constitutes yet another benefit of breastfeeding. IgA is not detectable in the newborn's system until at least 2 to 3 weeks of life, unless elevated levels are present from a viral infection (Cant & Gennery, 2005).

IgM immunoglobulins are produced in response to blood group antigens, gram-negative enteric pathogens, and certain maternal viruses. This immunoglobulin is synthesized early in utero, beginning at approximately 10 to 15 weeks of gestation. Detectable levels are reached by 30 weeks of gestation and IgM serum concentrations increase rapidly after birth. Elevated levels at birth may result from placental leaks or, more likely, from antigenic stimulation that occurred in utero. Thus, an increased IgM titer is suggestive of exposure to an intrauterine infection such as syphilis or one of the TORCH infections (toxoplasmosis, rubella, cytomegalovirus, herpes virus) (Kapur et al., 2006). (See Chapter 11 for further discussion.)

Nursing Insight— Preventing newborn infections

Newborns are especially susceptible to infections due to their immature immune system and their poor ability to fight infections. During the birth process, the neonate is exposed to a vast number of potential infectious agents, such as *Staphylococcus* and group B *Streptococcus*. Newborns do not exhibit signs and symptoms of infection in the same manner as do older infants and children. Instead, they may demonstrate subtle behavior changes and poor feeding patterns, develop respiratory distress, or become hypothermic. Maintenance of skin integrity is crucial, especially in the preterm infant, because the skin is thin and fragile. The nurse's awareness of potential risk factors (e.g., maternal group B *Streptococcus* exposure) and thorough assessment skills are essential in the prevention and early detection of newborn infections. Circumcision sites, healing heel sticks, and umbilical stumps are all potential areas for infection that can challenge the newborn's immature immune system. Providing parents with thorough discharge instructions regarding infant hygiene, proper skin care, and awareness of signs and symptoms of infection is an important component of the nursing care plan.

Now Can You— Discuss aspects of the genitourinary and immunological systems?

1. Identify three physiological factors that enable the newborn's kidneys to produce and excrete urine?
2. Explain the origin and significance of "brick dust spots" in the neonate's urine?
3. Describe what is meant by "humoral immunity"?

Psychosocial Adaptation

EARLY STAGES OF ACTIVITY

Full-term infants experience several "activity" stages during the early hours after birth. It is important to educate parents about normal neonatal behavior during this period and encourage them to enjoy this opportunity to become acquainted with their newest family member. An understanding of normal neonatal activities during the first hours of life provides reassurance and empowers them to promptly recognize and seek assistance for any signs of difficulty. The infant's psychosocial adaptation begins with two stages of activity followed by a period of sleep.

The First Period of Reactivity

This stage is the first period of active, alert wakefulness that the infant displays immediately after birth (Fig. 17-9). It may last from 30 minutes to 2 hours and is a wonderful time for parents to get to know their baby, and to perform their first full "inspection" of their infant. The newborn is very alert during this stage and moves around energetically while taking in the new surroundings. The heart rate and respirations are rapid and the infant may exhibit occasional nasal flaring and grunting that can last for up to 15 minutes. Muscle tone and motor activity are increased. Body temperature is decreased. Bowel sounds tend to be absent during this period and there is minimal saliva

Figure 17-9 The mother and her newborn become acquainted during the first period of reactivity.

production (Hernandez & Hernandez, 2004). This first period of reactivity is an opportune time for the mother to initiate breastfeeding if she wishes to do so.

Optimizing Outcomes— Promoting initial bonding in the breastfeeding mother

Best outcome: The nurse places the infant on the mother's chest for skin-to-skin contact and eye-to-eye contact for early bonding. The infant nuzzles the mother's breast, smells colostrum, and attempts to latch-on to the breast during the first period of reactivity.

The Period of Inactivity and Sleep

After being awake and alert for the first 30 minutes to 2 hours after birth, the neonate settles in to the sleep phase. At this time the infant displays decreased muscle activity and is difficult to awaken, instead resting quietly and recovering from the stress of birth. The heart rate and respirations return to a normal range. Central perfusion and general coloring should be excellent at this time, although acrocyanosis is not unusual (Hernandez & Hernandez, 2004). The sleep period may last from a few minutes to 2 to 4 hours.

The Second Period of Reactivity

At this time, the newborn awakens and becomes alert once again. Most infants show signs for feeding readiness (e.g., sucking, rooting) and are eager to begin feeding if not previously fed. During the second period of reactivity the newborn becomes increasingly more responsive to exogenous and endogenous stimulation, which can cause the heart rate to become labile. The infant may exhibit brief periods of tachycardia, tachypnea, and rapid changes in color and muscle tone. The nurse needs to be aware of normal newborn behaviors during this period that may last for minutes up to several hours. Careful and ongoing assessment allows for differentiation between normal reactions and symptoms that signal difficulty with transition (Hernandez & Hernandez, 2005).

Bowel sounds are usually present and the infant may have increased oral mucus, causing transient episodes of gagging and vomiting. The nurse should monitor the infant closely, assess for a clear airway and have suctioning equipment readily available. Parents should be taught how to use a bulb syringe correctly in the event of gagging or vomiting episodes (Hernandez & Hernandez, 2004). (See Chapter 18 for further discussion.) The gastrointestinal system becomes more active during the second period of reactivity and it is not unusual for newborns to pass their first meconium stool or void if they have not already done so.

Newborn Behavioral States

SLEEP STATES

According to Brazelton (1999), newborn behavior can be divided into the sleep state and the alert state. Two sleep states are exhibited: the deep or quiet sleep and the period of active rapid eye movement (REM). The length of time spent in each sleep cycle is dependent on the newborn's age. At term, REM active and quiet sleep occurs in intervals of approximately 50 minutes. Approximately one half of the infant's total sleep is "active" sleep. Forty-five percent is "quiet" sleep and 10% is transitional sleep occurring between the two periods. It has been suggested that REM sleep is instrumental in promoting growth of the neural system. As the infant matures, the sleep-wake cycle adjusts to a diurnal pattern of sleeping during the night and remaining awake during the day.

Nursing Insight— Recognizing sleep states in the neonate

Nurses who care for newborns should be aware of behaviors typically exhibited during deep, quiet sleep and active rapid eye movement (REM) sleep. During deep sleep, the infant's eyes are closed, no eye movements occur, and breathing is regular and even. Jerky motions are common although behavioral responses to external stimuli are delayed. The heart rate ranges from 100 to 120 beats per minute.

During REM sleep, the infant's respirations are irregular, the eyes are closed with REMs visible through the lids, and irregular sucking motions are common. There is minimal activity. Environmental and internal stimuli may prompt a startle reaction and a change of state.

ALERT STATES

The quiet alert state, which generally occurs during the first 30 minutes to 1 hour after birth, characterizes the first period of reactivity. This period is an excellent time for parents to enjoy bonding with their infant. The periods of alertness are fairly brief during the first 2 days of life as the infant recovers from the events associated with birth. After that time, the infant's alert states result from choice or necessity. Stimuli that may prompt wakefulness include hunger, cold, and heat. Once the triggering stimuli are removed, the infant tends to fall back asleep. The alert state has been subcategorized into four distinct

Nursing Care Plan Normal Newborn Transition

Nursing Diagnosis: Readiness for Enhanced Organized Infant Behavior related to effective modulation of the physiological and behavioral systems of functioning

Measurable Short-term Goal: The newborn will transition to necessary extrauterine cardiorespiratory, feeding, and elimination functions without complications.

Measurable Long-term Goal: The newborn and mother (family) will experience successful interactions and psychosocial adaptation to each other.

NOC Outcomes:

- Newborn Adaptation (0118): Adaptive response to the extrauterine environment by a physiologically mature newborn during the first 28 days.
- Parent–Infant Attachment (1500): Parent and infant behaviors that demonstrate an enduring affectionate bond.

NIC Interventions:

- Newborn Monitoring (6890)
- Environmental Management (6480)
- Breastfeeding Assistance (1054) or Bottle Feeding (1052)
- Attachment Promotion (6710)

Nursing Interventions:

1. Before birth, review maternal record for antenatal or intrapartal complications, events, or medications that may affect the neonate. Prepare room and equipment for the birth.
RATIONALE: Review allows anticipation and preparation for complications that may occur at birth.
2. Dry newborn with prewarmed blankets while on mother's abdomen. Assess respiratory effort, clear airway and stimulate as needed. Discard wet blankets, cover mother and infant with a warm, dry blanket, and place a cap on the infant's head.
RATIONALE: Prevents heat loss by evaporation and convection and helps open the airway and initiate respirations.
3. Assess newborn's heart rate and color. Complete Apgar scoring at 1 and 5 minutes of age. If the score is 7 or greater, continue to monitor infant.
RATIONALE: Heart rate and color provide information about cardiovascular transition to extrauterine function. Infants with Apgar scores of 7 or higher are considered stable.
4. Once the umbilical cord has been cut, assess the number of cord vessels and encourage mother to put the baby in kangaroo care (skin-to-skin) at the breast.
RATIONALE: It is easiest to note the cord vessels in a freshly cut cord. Kangaroo care helps the newborn maintain temperature and facilitates breastfeeding.
5. Offer instruction about breast feeding if needed and give praise and encouragement. Provide time and space for first feeding.
RATIONALE: During the first period of reactivity, the unmedicated infant is alert and ready to breastfeed. The mother should not be overwhelmed with teaching and nursing activity but encouraged to get to know her baby.
6. Continue to monitor infant's vital signs per protocol. Encourage stable infant to remain with mother in kangaroo care for first period of reactivity.
RATIONALE: The stable infant benefits most from maternal contact. Vital signs can be monitored in the mother's arms.
7. At a convenient time during the first 2 hours, place the infant under a radiant warmer with a servo-controlled skin probe in place. Perform a brief physical exam and administer vitamin K and eye prophylaxis as ordered. Place identification bands on the infant and mother.
RATIONALE: The radiant warmer and probe provide a safe source for external heat as the infant is examined. Vitamin K prevents neonatal hemorrhage and eye prophylaxis is required to prevent eye infection. Two forms of identification applied before separation help ensure that the right mother and infant are together.
8. Monitor for passage of urine and first meconium and document. Teach parents about elimination and diapering as needed.
RATIONALE: The passage of urine and meconium provides information about the normal newborn's anatomy and physiology. Every opportunity for teaching should be appreciated during the short hospital stay.
9. Observe the parents' interactions with the newborn: eye contact, stroking, talking to baby. Point out attractive features and infant's responses to parents. Offer encouragement to fathers to touch and hold their newborn.
RATIONALE: Observation helps the nurse identify appropriate behaviors related to attachment and bonding with the newborn. Encouragement provides the novice father with "permission" to parent.

phases: drowsy or semidozing, wide awake, active awake, and crying (Brazelton, 1999).

Drowsy or Semidozing

Physical manifestations include open or closed eyes; fluttering eyelids; semidozing appearance; and slow, regular movement of the extremities. There is a delayed response to external stimuli.

Wide Awake

The infant is alert and follows and fixates on attractive objects, faces, or auditory stimuli. There is minimal motor activity and a delayed response to external stimuli.

Active Awake

The eyes are open, motor activity is intense and the infant displays thrusting movements of the extremities. Environmental stimuli increases the motor activity.

Crying

Jerky movements accompany intense crying. Crying often serves as a distraction from unpleasant stimuli such as hunger and pain. It allows the infant to discharge energy and elicits a helpful response from the parents.

Now Can You— Discuss psychosocial adaptation in the newborn?

1. Compare and contrast the first period of reactivity and the period of inactivity/sleep?
2. Identify two behavioral characteristics associated with deep, quiet sleep and REM sleep?
3. Name four phases of the quiet alert state and identify two behavioral characteristics of each phase?

summary points

- ◆ Surfactant, a lipoprotein that reduces surface tension, is essential in keeping the lungs expanded during expiration.
- ◆ Initiation of the neonate's first breath is influenced by chemical, sensory, thermal, and mechanical factors.
- ◆ Successful cardiopulmonary adaptation in the neonate is dependent on five major changes related to aortic, venous, and pulmonary pressures and closure of the foramen ovale and ductus arteriosus and ductus venosus.
- ◆ A number of factors, including body size and gestational age, affect the neonate's ability to maintain a neutral thermal environment.
- ◆ Heat loss may occur through the processes of evaporation, conduction, convection, and radiation.
- ◆ The neonate's liver has essential roles in iron storage, carbohydrate metabolism, bilirubin conjugation, and blood coagulation.
- ◆ The neonate receives immunity through active acquired immunity and passive acquired immunity.
- ◆ The newborn exhibits two periods of reactivity and two behavioral states that may be divided into sleep states and alert states.

review questions

Multiple Choice (Select all that apply.)

1. The perinatal nurse explains to the new nurse that some infants have increased surfactant production prior to birth that facilitates their transition including:
 - A. Infants of mothers with gestational hypertension
 - B. Infants of mothers with placental insufficiency
 - C. Infants of mothers with abruptio placentae
 - D. Infants of mothers with a multiple gestation
2. The perinatal nurse describes a typical newborn breathing pattern to the new parents as:
 - A. Shallow
 - B. Irregular
 - C. About 40 to 60 breaths per minute
 - D. About 60 to 80 breaths per minute
3. The perinatal nurse understands that many factors stimulate the newborn to begin breathing including:
 - A. Hypercarbia, acidosis and hypoxia
 - B. Sensory stimuli
 - C. Decreased temperature in the environment
 - D. Cutting the umbilical cord
4. The perinatal nurse recognizes that the infant that develops respiratory distress syndrome is at risk for further complications such as:
 - A. Loss of functional residual capacity
 - B. Atelectasis
 - C. Poor lung compliance
 - D. Hypoglycemia
5. The perinatal nurse is caring for Sarah, a primigravid antenatal patient at 32 weeks gestation. Betamethasone 12 mg IM q24h × 2 is ordered. Appropriate nursing care includes:
 - A. Assessing Sarah's temperature and white blood count
 - B. Conducting continuous fetal monitoring for 30 minutes pre and post injection
 - C. Providing information to Sarah and her family about the benefits of this medication as well as information about the signs and symptoms of pulmonary edema
 - D. Monitoring Sarah's intake and output

Fill-in-the-Blank

6. The perinatal nurse understands that pulmonary ventilation in the newborn takes place on three levels: _____ respiration, _____ respiration and at the _____ level.
7. The perinatal nurse explains to the student nurse that _____ is a brief pause between breaths of 5 to 15 seconds while _____ is cessation of breathing for _____ seconds or more.

True or False

8. The perinatal nurse explains to the woman who has given birth to a preterm infant that part of the infant's care is to provide a dose of surfactant, a phospholipid that increases lung compliance.

9. The perinatal nurse prepares for newborn care at a cesarean birth. The nurse knows that this infant is at a higher risk for pulmonary transition difficulties due to the absence of a “thoracic squeeze” during birth.
10. The perinatal nurse assesses the newborn at 2 hours of age. The findings include: respiratory rate of 48 breaths per minute, irregular, no abdominal or chest retractions or grunting. These findings would be normal.

See Answers to End of Chapter Review Questions on the Electronic Study Guide or DavisPlus.

CONCEPT MAP

Caring for the Normal Newborn

chapter 18

A new baby is like the beginning of all things—wonder, hope, a dream of possibilities.

—Eda J. Le Shan

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Identify the components of the immediate newborn assessment.
- ◆ Describe methods for determining the gestational age of the neonate.
- ◆ Discuss how to perform a newborn behavioral assessment.
- ◆ List at least four actions to assess the neonate's transition to extrauterine life.
- ◆ Identify three sources of heat loss in the neonate and suggest strategies to prevent the heat loss for each.
- ◆ Describe strategies to prevent neonatal infection.
- ◆ Describe four activities to promote early infant bonding.
- ◆ Develop a discharge teaching plan for the mother and her newborn infant.

moving toward evidence-based practice Informing Parents About Newborn Screening

Kemper, A.R., Fant, K.E., & Clark, S.J. (2005). Informing parents about newborn screening. *Public Health Nursing, 22*(4), 332–338.

The purpose of this cross-sectional study was to evaluate current rules and regulations for educating parents about newborn screening. The sample included 51 newborn screening program coordinators from all 50 states and the District of Columbia. A 20-item telephone survey was used to obtain data about policies, rules, and regulations along with specific topics, such as types of information given to families, and strategies for informing the general public and primary care providers about newborn screening.

Data analysis revealed the following information about newborn screening programs:

- Fifty state programs use standard information to inform parents about newborn screening.
- Thirty-two state programs offer the information in languages other than English.
- Twenty-five state programs have specific requirements for informing parents about the screening; of these, 12 state programs specified who should inform the family and 9 state programs were unclear about how parents should be informed.
- No state program had specific rules or regulations about how to inform parents about newborn screening before birth although 36 state programs indicated the parents should be informed by the obstetrician.
- Thirty state programs indicated that parents should be offered information prenatally and again after delivery.
- Five state programs require parental consent before infant screening.
- Thirty-three state programs do not routinely screen for all conditions recommended by the March of Dimes and the National Newborn screening and Genetic Resource Center. These conditions include but are not limited to phenylketonuria (PKU), congenital hypothyroidism (CH), galactosemia (GALT), maple sugar disease, sickle cell disease, and cystic fibrosis.
- No state program has requirements that parents should be informed about the availability of additional screening.

(continued)

moving toward evidence-based practice (continued)

- Thirty-eight state programs have a formal process for parents who wish to refuse screening. Of these, 15 state programs do not require that parents be informed of their right to refuse; 29 state programs have a standardized refusal form; and 6 state programs offer the (refusal) form in languages other than English. Among state programs with no standardized refusal form, documentation of the refusal is left to the individual agency.
- Thirty-nine state programs use outreach education (i.e., press releases, agency Web site) to inform the general public about newborn screening. All but one state program direct educational efforts toward physicians through mailings, medical education activities, and information posted on the agency website.

The researchers concluded that although standardized information is available for parents, few agencies specify how this

information is provided and there is much variation in policy language among the screening programs. Although the majority of programs have educational outreach efforts, little information is available regarding the effectiveness of those efforts and how the information can be disseminated to increase the parents' understanding of newborn screening. The investigators suggest that parent education about newborn screening should be initiated during the prenatal period. Providing information at this critical time offers a unique opportunity and challenge for nurses in both obstetric and public health settings.

1. What might be considered as limitations to this study?
2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

Most nurses who care for newborns and their families view their specialty to be the most exhilarating and rewarding of any area in nursing. Childbirth marks the beginning of profound changes in the lives of the mother, her infant, and the family. From the moment of the parents' first interaction with their newborn, a journey of growth and exploration begins for each of them. After ensuring that the neonate is physiologically stable, the infant's nurse plays a pivotal role in preserving and protecting this most special time by not intruding or allowing any interruptions as the new family becomes acquainted.

During the transitional period after birth, nursing care focuses primarily on two goals: to safeguard and support the neonate's physical well-being and to promote the establishment of a healthy family unit. The first goal is met by close observation coupled with skilled assessment throughout the time the infant remains in the health care facility. The nurse meets the second goal by educating the family about care of their newborn. Ongoing interaction with the parents provides insights concerning the family's ethnic influences and cultural values, and this information helps to direct and guide the teaching plan. By providing culturally appropriate education along with expressions of support of parenting efforts, the nurse empowers the parents with information and knowledge about their infant's needs. Furthermore, the nurse's teaching efforts can be instrumental in heightening parents' awareness of family adjustments that may need to occur during this time of family transition and role changes (Hisley, 2006). This chapter focuses on the healthy neonate. A system-by-system guide to physical assessment of the infant is provided along with a discussion of nursing measures intended to meet the newborn's needs. Methods to determine the neonate's gestational age are presented. The chapter concludes with infant discharge planning; a list of possible nursing diagnoses for the healthy neonate is presented in Box 18-1.

Box 18-1 Possible Nursing Diagnoses for the Normal Neonate

- Risk for Altered Nutrition, Less than Body Requirements, related to inadequate formula intake
- Risk for Altered Body Temperature related to evaporative, conductive, radiant, and convective heat losses
- Risk for Ineffective Airway Clearance related to excessive secretions in the airway
- Risk for Ineffective Thermoregulation related to an immature thermoregulatory system
- Risk for Infection related to parents' lack of knowledge concerning umbilical cord care
- Acute Pain related to circumcision
- Risk for Injury related to lack of parental knowledge about normal newborn needs

The Immediate Neonatal Assessment

The newborn infant's physical condition is assessed immediately at the time of birth. If necessary, suctioning of the oral, pharyngeal, or endotracheal area is conducted according to the health facility's policy, procedure, and protocol (Procedure 18-1). The infant is carefully handed to the nurse, who receives the neonate into a sterile baby blanket and, in the ideal situation, places him upon the mother's abdomen. For most, this simple action is a deeply satisfying source of comfort for the mother and her infant and the warmth of the mother's body helps to maintain the neonate's body temperature. In addition, heated blankets placed over the neonate minimize heat loss by evaporation. In other situations, the nurse places the infant in an incubator or directly beneath a radiant heater unit to prevent evaporative heat loss. After being carefully dried off, a cap is placed on the head for extra warmth.

Procedure 18-1 Suctioning the Infant's Oral and Nasal Passages

Purpose

To clear secretions from oral and nasal passages

Equipment

- One bulb syringe
- Tissue

Steps for Oral Suctioning

1. Assess the infant for oral secretions.
2. Position the infant's head to the side or downward if he is vomiting or gagging.
3. Compress the bulb syringe.

RATIONALE: Removing the air prevents forcing secretions deeper into the respiratory tract.

4. Insert the bulb syringe approximately 1 inch into one side of the infant's cheek. Avoid contact with the roof of the mouth and the back of the throat.

RATIONALE: To prevent stimulation of the gag reflex.

5. Gently release compression of the bulb syringe and allow it to fill with oral secretions.
6. Gently remove the bulb syringe; expel drainage into a tissue.
7. Repeat the process on the other side of the infant's cheek.
8. Repeat as needed.

Clinical Alert Always suction the mouth before suctioning the nares because fluids and secretions that could obstruct the respiratory tract may be present in the mouth or the nares or both. Placing the syringe in the nares first may trigger an inspiratory gasp, causing the infant to pull mucus further into the respiratory tract.

Steps for Nasal Suctioning

1. Assess the infant for nasal congestion.
2. Position the infant's head to the side or downward if he is vomiting or gagging.
3. Compress the bulb syringe.

RATIONALE: Removing the air prevents forcing secretions deeper into the respiratory tract.

4. Insert the bulb syringe into the tip of the infant's nostril. Avoid obstructing the nasal passageway.

RATIONALE: To prevent respiratory distress.

5. Gently release the compression of the bulb syringe to allow it to fill with mucus or nasal drainage.
6. Gently remove the bulb syringe; expel drainage into a tissue.
7. Repeat as needed.

Clinical Alert An increasing respiratory rate is often the first sign of respiratory compromise or obstruction. If this occurs, measures must be initiated to maintain effective ventilation.

Teach Parents

- Proper technique for use of the bulb syringe; ask for return demonstration.
- Proper care of the bulb syringe: wash in warm, soapy water each day and after each use.
- Store the bulb syringe at the infant's bedside.

Note

Instruct the parents to position the infant's head to the side or downward if he is vomiting or gagging.

Caution: The nurse must emphasize to the parents that the bulb syringe must be compressed first and then inserted into the infant's nostril or mouth. If they insert the bulb syringe and then compress the bulb syringe, they may actually force secretions further back into the nose or throat and possibly cause an obstruction.

Documentation

6/29/10 0300 Baby boy Smith had a small amount of clear thick mucus draining from both nares, respirations 40 per minute, breathing without difficulty, and no retractions noted. Both nares suctioned with bulb syringe with a return of a small amount of clear thick mucus, procedure tolerated without difficulty.

-S. Chang, RN

Optimizing Outcomes— Placing the infant under the radiant heater

Best outcome: The nurse dries the infant before placing him unclothed on a clean, dry blanket under the radiant-heater unit. Since the generated heat from the unit warms only the outer surface of objects, it is counterproductive to cover or clothe the infant, as he will get no benefit from the radiant heat.

While performing these actions, the nurse observes the infant's respiratory effort, color, and muscle tone, and makes sure that the activities underway are stimulating the neonate to breathe deeply and cry. If needed, lightly flicking the infant's soles prompts a crying response.

Nursing Insight— Observing standard precautions when handling the neonate

Because there is a possibility of transmission of viruses such as hepatitis B (HBV) and human immunodeficiency virus (HIV) from maternal blood and blood-stained amniotic fluid, the neonate is considered a potential contamination source. Nurses must observe Standard Precautions by wearing gloves when handling the neonate until blood and amniotic fluid are removed by bathing.

During the initial assessment, the nurse remains alert for any signs of respiratory difficulty, such as rib or sternal retractions, “grunting” sounds, or nasal flaring. To check the heart rate, the nurse places the thumb and two fingers at the base of the umbilical cord and counts the pulsations. The infant's body temperature may be assessed by recording the axillary temperature or by attaching a thermoprobe and recording monitor to the skin. At this time, the infant is usually crying and turning pink, although the hands and feet remain slightly blue due to acrocyanosis, a condition related to vasomotor insufficiency and poor peripheral perfusion. If necessary, respiratory support is initiated according to hospital protocol. Oxygen may be administered via bag or mask. Obvious abnormalities are noted and the nurse also checks and records the number of vessels in the umbilical cord, which should have two arteries and one vein. If the cord contains only two vessels (one artery, one vein), the physician should be notified immediately since this finding may be associated with renal and cardiac anomalies. Further testing is indicated. A two-vessel cord may be indicative of renal agenesis, a condition in which one kidney fails to develop normally during the gestational period. The infant's weight and length are determined and recorded. Normal newborn parameters are presented in Table 18-1.

A numerical expression of the neonate's well-being, the Apgar score is assigned at 1 and 5 minutes after birth. This score provides an objective means for assessing the neonate's immediate adaptation to extrauterine life. Five categories, including respiratory effort, heart rate, muscle tone, reflex irritability, and skin color are assessed, and each component is given a score ranging from 0 to 2. If neonatal resuscitation is required, it should be initiated before the 1-minute Apgar score (American Academy of

Table 18-1 Normal Neonatal Parameters at Birth

Parameter	Normal Finding
Respirations	Rate 30–60 breaths per minute, irregular No retractions or grunting
Apical pulse	Rate 120–160 beats per minute
Temperature	97.8°F (36.5°C)
Skin color	Pink body, blue extremities
Umbilical cord	Contains two arteries and one vein
Gestational age	Full term: >37 completed weeks (should be 38–42 weeks to remain with parents for an extended time period)
Weight	2500–4300 grams
Length	45–54 cm

Pediatrics [AAP] & American College of Obstetricians and Gynecologists [ACOG], 2007). (See Chapter 12 for further discussion.)

Various newborn laboratory tests may be routinely ordered according to hospital protocol. One test may be a sample of the cord blood if the mother is Rh negative or has type O blood group. The cord blood for the infant's blood type and Rh factor is obtained by the birth attendant while awaiting placental separation. If the infant's Apgar score is low, cord blood gas analysis may be ordered as well.

When the Apgar score is less than 9 at 5 minutes of life, it is important to stabilize the infant rather than allowing him to remain with his mother in the birthing unit. Other conditions that would necessitate immediate infant stabilization include observations of nasal flaring, grunting respirations, rib retractions, heart rate below 120 beats per minute or above 160 beats per minute, pallor, serious congenital anomalies (such as a neural tube defect), preterm infant (less than 38 weeks' gestational age), infant of a diabetic mother, or an infant who appears to be small for gestational age.

critical nursing action Recognizing Immediate Neonatal Respiratory Distress

During the neonatal assessment, the nurse is alert to the following signs and symptoms that are indicative of respiratory distress. If any of these symptoms are present, the nurse must immediately notify the physician:

- Generalized cyanosis
- Tachycardia (heart rate >160 beats per minute)
- Tachypnea (respiratory rate >70 breaths per minute)
- Rib retractions
- Expiratory grunting
- Flaring nostrils

IDENTIFICATION

After the Apgar evaluation, the nurse completes the mother–infant identification process according to hospital policy. This procedure usually includes obtaining infant footprints and a fingerprint and thumbprint of the mother along with

Nursing Care Plan Maintaining Newborn Thermoregulation

Nursing Diagnosis: Risk for Imbalanced Body Temperature

Measurable Short-term Goal: The newborn will maintain a body temperature between 97.7° and 99.4°F (36.5°–37.5°C) in the first 24 hours postbirth.

Measurable Long-term Goal: The newborn will maintain a body temperature between 97.7° and 99.4°F (36.5°–37.5°C) (wrapped in blankets in an open crib) after the first 24 hours postbirth.

NOC Outcome:

Thermoregulation: Newborn (0801) Balance among heat production, heat gain, and heat loss during the first 28 days of life

NIC Interventions:

Newborn Care (6880)
Temperature Regulation (3900)
Vital Sign Monitoring (6680)

Nursing Interventions:

1. Place newborn under radiant warmer or skin-to-skin with mother after birth and dry well, discarding wet linens.
RATIONALE: The radiant warmer or maternal skin provides a heat-gaining environment. Drying the infant reduces heat loss from evaporation.
2. Monitor newborn's axillary temperature per protocol until stabilized.
RATIONALE: Monitoring the temperature will assess the effectiveness of the therapy.
3. Apply stockinet cap and instruct parents to keep infant's head covered.
RATIONALE: A cap helps prevent heat loss by convection from the large surface area of the head to the cooler room air.
4. Place the newborn under the radiant warmer with temperature probe attached and alarms turned on as needed to maintain temperature >97.6°F (36.5°C).
RATIONALE: The radiant warmer provides a heat-gaining environment and prevents heat loss from contact with a cool surface (conduction). Active alarms and use of the temperature probe assure the infant will not be under- or overheated.
5. When the temperature stabilizes, wrap the infant in two blankets and place him in an open crib. Instruct the parents to keep the crib away from windows and drafts.
RATIONALE: Keeping the crib away from windows and drafts helps to prevent heat loss by radiation and convection.

appropriate labeling. Most institutions employ a system of waterproof matching identification bracelets that show the mother's name, the baby's gender, the name of the physician or nurse midwife of record, and the date and time of birth. Two bracelets are worn by the neonate while the mother and her partner wear the others. Careful and continuous monitoring of infants is essential to prevent misidentification, baby switching, or abduction. Alerting staff about mothers who share identical last names helps to decrease the likelihood of mistakes, and special security measures such as sensing devices, video cameras, and door alarms on all mother-baby units helps allay parents' concerns about their infants' safety. (See Chapter 15 for further discussion.)

INFECTION AND INJURY PREVENTION

The prevention of infection and injury constitute important aspects of newborn care. Hand washing is essential in preventing cross contamination by all individuals caring for the newborn. In many facilities, nursery personnel are required to wear scrub clothes, remove nail polish, and keep fingernails trimmed. Other measures to prevent infection include infant bathing, umbilical cord care, care of the circumcision, and eye care. Soon after birth, the newborn receives a prophylactic ophthalmic agent to prevent ophthalmia neonatorum, eye inflammation from

gonorrheal or chlamydial infection contracted during passage through the mother's birth canal. Medications most often used are erythromycin, tetracycline, or silver nitrate.

Optimizing Outcomes— Eye prophylaxis to prevent ophthalmia neonatorum

In some birth facilities, neonatal eye prophylaxis is delayed up to an hour to allow eye contact to facilitate parent-infant bonding. However, the Centers for Disease Control and Prevention (CDC) recommends that the medication be administered as soon as possible after birth. If instillation is delayed, the facility should have a monitoring system in place to ensure that all infants receive the prophylaxis (CDC, Workowski, & Berman, 2006).

During the first few days of life, the newborn has low levels of vitamin K due to sterile intestinal contents. Vitamin K acts as a catalyst to synthesize prothrombin, needed for blood clotting, in the liver. To prevent the neonatal injury caused by hemorrhage, a single dose (0.5 to 1.0 mg) of vitamin K₁ phytonadione (AquaMEPHYTON) is administered via an intramuscular injection in the vastus lateralis or the ventrogluteal muscle.

**medication:** ErythromycinErythromycin (eh-rith-roe-**mye**-sin)

Ilotycin

Pregnancy Category: B**Indications:**

INFANTS: Prophylaxis of ophthalmia neonatorum

Actions: Suppresses protein synthesis at the level of the 50S ribosome**Therapeutic Effects:** Bacteriostatic action against susceptible bacteria spectrum: Streptococci, staphylococci, gram-positive bacilli**Pharmacokinetics:**

ABSORPTION: Minimal absorption may follow topical or ophthalmic use.

Contraindications and Precautions:

CONTRAINDICATED IN: Hypersensitivity

Adverse Reactions and Side Effects: Irritation**Route and Dosage:** Apply a thin strip to each eye as a single dose.**Nursing Implications:**

- Inform parents of medication administration.
- Prepare to administer the eye ointment to the infant 1 hour after birth.
- Apply a thin strip to each eye as a single dose.
- Start at the inner canthus and move to the outer canthus.
- Dab excess medication off gently; do not wash away the medicine.

Adapted from Deglin, J.H., & Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed). Philadelphia: F.A. Davis.

**Optimizing Outcomes—** Newborn immunization to prevent hepatitis B

Vaccination for hepatitis B, given in a series of three doses beginning at birth, is recommended for all infants. Before administration, the nurse obtains written parental consent. After injection of hepatitis B vaccine (Recombivax HB, Enerix-B) into the vastus lateralis muscle, the nurse massages the site with a gauze square to enhance absorption. Additional doses are administered at 1 and 6 months of age.

Assessment of blood glucose helps to prevent newborn injury related to hypoglycemia. In healthy term infants after an uneventful pregnancy and delivery, blood glucose monitoring often takes place within the first hour after birth. During the early newborn period of a term infant, hypoglycemia is defined as a blood glucose concentration of less than 35 mg/dL or a plasma concentration of less than 40 mg/dL. Infants with a low blood glucose level or those who exhibit signs and symptoms of hypoglycemia (jitteriness, apnea, seizures or lethargy) require immediate attention to prevent brain cell damage. Hypoglycemia is usually resolved with feeding. If the newborn continues to display signs and symptoms of hypoglycemia along with low blood glucose laboratory results, transfer to the neonatal intensive care unit for intravenous administration of glucose may be necessary.

A heel stick blood sample for hematocrit and hemoglobin may be performed to detect anemia or polycythemia (an excess number of red blood cells). Anemia can result from hypovolemia associated with complications such as placenta previa, abruptio placentae, or cesarean birth.

**medication:** AquaMEPHYTONPhytonadione (fye-**toe**-na-dye-one)

AquaMEPHYTON, Mephyton, vitamin K

Classification(s):

THERAPEUTIC: Antidotes, vitamins

PHARMACOLOGICAL: Fat-soluble vitamins

Pregnancy Category: UK**Indications:** Prevention and treatment of hypoprothrombinemia, which may be associated with excessive doses of oral anticoagulants, salicylates, certain anti-infective agents, nutritional deficiencies, and prolonged total parenteral nutrition. Prevention of hemorrhagic disease of the newborn.**Action:** Required for hepatic synthesis of blood coagulation factors II (prothrombin), VII, IX, and X. Therapeutic effects: Prevention of bleeding due to hypoprothrombinemia**Pharmacokinetics:**

ABSORPTION: Well absorbed after oral, IM, or subcutaneous administration

DISTRIBUTION: Crosses the placenta; does not enter breast milk.

Metabolism and excretion: Rapidity metabolized in the liver

HALF-LIFE: Unknown

Contraindications and Precautions:

CONTRAINDICATED IN: Hypersensitivity, hypersensitivity or intolerance to benzyl alcohol (injection only)

USE CAUTIOUSLY IN: Impaired liver function

EXERCISE EXTREME CAUTION IN: Severe life-threatening reactions have occurred after IV administration; use other routes unless IV is justified.

Adverse Reactions and Side Effects:

GASTROINTESTINAL: Gastric upset, unusual taste

DERMATOLOGICAL: Flushing, rash, urticaria

HEMATOLOGICAL: Hemolytic anemia

LOCAL: Erythema, pain at injection site, swelling

MISCELLANEOUS: Allergic reactions, hyperbilirubinemia (large doses in very premature infants), kernicterus

Route and Dosage: IV use of phytonadione should be reserved for emergencies.**Prevention of hemorrhagic disease of the newborn:**

IM (NEONATES): 0.5–1 mg, given within 1 hour of birth. May be repeated in 2–3 weeks if the mother received previous anticonvulsant/anticoagulant/anti-infective/antitubercular therapy. 1–5 mg may be given IM to the mother 12–24 hours before delivery.

Nursing Implications:

- Inform parents of medication administration.
- Prepare to administer the injection to the infant 1 hour after birth.
- Administer IM injection into the anterolateral muscle of the newborn's thigh.
- Report any symptoms of unusual bleeding or bruising (bleeding gums; nosebleed; black, tarry stools; hematuria; bleeding from the base of the umbilical cord or other open wounds).
- A decrease in hemoglobin and hematocrit levels or any bleeding may indicate that the effects of the medicine have not been achieved and that more vitamin K may be necessary. Call the physician for further instruction.

Adapted from Deglin, J.H., & Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed). Philadelphia: F.A. Davis.

Polycythemia may be related to excessive blood flow from the umbilical cord into the infant at birth. A normal hematocrit at 1 hour of life is 50% to 55%. A normal hemoglobin is 14.5 to 22.5 g/dL. Early detection of abnormal laboratory results can ensure immediate treatment.

Be sure to— Document appropriate birth information

After the baby's birth, many pieces of important information are collected during the nursery admission process. The nurse records the actual time of birth, the status of infant's respirations—whether spontaneous or assisted, the 1- and 5-minute Apgar scores, the birth weight in pounds and kilograms, the axillary temperature, and the number of vessels in the umbilical cord. Also documented is the type and amount of medication instilled for eye prophylaxis, the injection sites for vitamin K and hepatitis B vaccine administration, the findings from the general physical assessment, observations of voiding or stooling, and all laboratory testing obtained, such as blood glucose or cultures. It is the responsibility of the physician, midwife, or the birth facility to legally register the neonate. All infants are registered at the State Bureau of Vital Statistics in the state in which they were born. Essential information including the mother's name; the father's name (if the mother gives permission); and the date, time, and place of birth is required. Birth registration information is important because as the child grows older, this information is required to enter school, obtain a Social Security card, register to vote, and obtain a passport and a driver's license.

Infants who are stable may remain with their parents in the birthing area to facilitate family bonding and attachment. Newborns experiencing complications are taken to the nursery for further evaluation. After the immediate neonatal assessment, a later examination is conducted within the first 4 hours after birth. At this time, the nurse performs a brief physical assessment to estimate the infant's gestational age and evaluate the neonate's transition to extrauterine life (AAP & ACOG, 2007). Problems that place the neonate at risk are identified and evaluated. At some point before the infant's discharge, a complete physical examination and behavioral assessment are conducted to detect any emerging or potential problems. Depending on birthing facility protocol, this evaluation may be performed by the nurse, with certain components completed by a physician, certified nurse-midwife, or nurse practitioner.

Now Can You— Discuss components of the neonate's initial adaptation?

1. Recognize what constitutes normal vital signs in the infant?
2. Use the following information to calculate Baby O'Leary's Apgar score. At 1 minute of life, Baby O'Leary is crying quietly in a radiant warmer. Her hands and feet are blue and her extremities are floppy. Her heart rate is 122 beats per minute and her respiratory rate is 28 breaths per minute and irregular. The Apgar score at 1 minute is _____?
3. Identify six indicators of neonatal respiratory distress?

The Later Neonatal Assessment

The neonate is usually greeted with a whirlwind of activities immediately after birth. However, many other activities and assessments will take place later in the

newborn nursery. In the initial setting, the nurse conducts a brief physical assessment, carefully making note of body position, skin color, overall body size and symmetry, and level of interaction with the environment.

BODY POSITIONING

Not surprisingly, many infants seek comfort and security by resuming their dominant in utero position following birth. The normal newborn baby assumes a position of flexion of the upper and lower extremities. Flexed arms enable infants to use their hands to touch their faces, suck their fingers, and explore their world (Fig. 18-1).

The legs may be extended, arranged in the position assumed at the time of birth, or flexed. Most often, the infants' body positioning is symmetrical. Nurses should recognize that asymmetrical positioning at the time of the assessment may indicate injury from birth trauma. An infant's failure to move one or more extremities also signals that further investigation is warranted. When positioning the infant, nurses must be sure to follow the guidelines established by the American Academy of Pediatrics (2005a) to prevent sudden infant death syndrome (SIDS). (See Chapter 19.)

critical nursing action Safe Positions to Prevent SIDS

- All newborns should be put to sleep on their backs; avoid placing the infant in a prone position.
- When using a side-lying position, place the infant's dependent arm forward to lessen the likelihood that the infant will roll into a prone position.

Nursing Insight— Helping to meet the Healthy People 2010 national goals

One National Goal directly addresses the reduction in SIDS-related infant deaths: "increase the percentage of healthy full-term infants who are put to sleep on their backs from a baseline of 35% to 70%." Nurses can help to meet this goal by teaching parents and all infant care providers the advantage of placing the newborn on their back to sleep.

Figure 18-1 The full-term infant assumes a flexed position.

SKIN COLOR

Assessment of the infant's skin color constitutes an essential component of the general physical examination. Jaundice (hyperbilirubinemia), a yellow coloration of the skin, may be apparent in the neonate. Normally, jaundice develops gradually over several days in a head-to-toe, or cephalocaudal pattern. Any term infant less than 24 hours old who demonstrates visual jaundice is considered to have "pathological jaundice" or "hemolytic jaundice," a condition that most often results from a serious blood incompatibility between the mother and her newborn. (See Chapter 19 for further discussion of physiological and pathological jaundice.)

When conducting the skin assessment, the nurse must remember that certain characteristics of the nursery or mother's postpartum room can affect the accuracy of the exam. For example, pink walls and artificial lighting may mask the early detection of jaundice, and interfere with an accurate assessment of the degree of severity of the condition. It is best to examine the neonate's skin in natural daylight, if possible. When jaundice is suspected, the nurse can readily assess the skin coloring by pressing on the infant's forehead or nose with a finger. When blanching occurs, the nurse can observe for the yellow coloration associated with jaundice.

"Physiological jaundice" or "nonhemolytic" jaundice describes the more commonly occurring yellowing of the skin in neonates that becomes apparent after the first 24 hours of life and usually peaks by the third to fifth day. Physiological jaundice often has a nonhemolytic cause and frequently results from a failure to adequately process bilirubin due to inadequate intake or elimination, birth trauma, or from minor blood incompatibilities.

Breastfed infants may develop early-onset or "breastfeeding jaundice," which is associated with insufficient feeding and infrequent stooling. Since colostrum has a natural laxative effect that stimulates the passage of meconium, frequent breastfeeding during the early days of life is beneficial in reducing the neonate's serum bilirubin levels. Late-onset or "breast milk jaundice" sometimes affects breastfed infants during the second week of life. This type of jaundice usually develops around the fourth day when the mother's mature breast milk comes in and peaks around day 10. Breast milk jaundice is believed to be related to a factor in human milk that causes an increased intestinal absorption of bilirubin. Although usually no treatment is necessary, some physicians advise mothers to discontinue breastfeeding for 12 to 24 hours to allow the infant's bilirubin levels to decrease (Verklan & Walden, 2004).

Nurses can implement several actions to decrease the likelihood of high bilirubin levels in the neonate. Maintaining the infant's skin temperature at or above 98.7°F (36.5°C) is beneficial since cold stress can cause acidosis, a condition linked with an elevated serum bilirubin. Also, careful monitoring of the infant's intake and output, with special attention to stool characteristics and frequency is important. Since bilirubin is excreted in the feces, inadequate elimination can result in the reabsorption and recycling of bilirubin. Finally, the nurse should encourage

early (within the first hour of life) feedings when possible to promote rapid and continuous intestinal evacuation and provide the calories necessary for the production of hepatic binding proteins.

Understandably, the presence of physiological jaundice in the infant can be distressing for parents. Nurses can address these concerns by providing ongoing emotional support along with accurate explanations of the condition. Parents should be taught about the importance of adequate hydration and how to assess the infant for signs of jaundice. If the baby undergoes phototherapy (exposure to high-intensity lights) for treatment, additional days of hospitalization may be required, and the mother may have to leave the birth center without her baby. Parents should be encouraged to help meet their infant's emotional needs by holding, feeding, touching, and interacting with the baby. When the mother must leave the hospital without her infant, the nurse can support the bonding process by providing the nursery telephone number and name(s) of the baby's primary caregiver(s). Mothers should also be encouraged to call for updates and return for feedings as often as possible. Breastfeeding mothers may wish to remain in the hospital until the infant is released. In other situations, initiation of home phototherapy for the jaundiced infant may be an option. When the infant is treated in the home, nurses monitor the phototherapy regimen and obtain serum bilirubin levels as dictated by hospital or agency policy. (See Chapter 19.)

Infants with congenital heart defects often exhibit skin pallor that does not improve with time. All infants should exhibit pink skin, which is an important indicator of satisfactory perfusion to the extremities. Acrocyanosis, a common finding, is confined to the hands and feet. Neonates with central cyanosis may demonstrate a blue tint to the lips, gums, tongue, fingertips, and toes, as well as pallor under the eyes and on the cheeks. These findings are indicative of a circulatory problem and warrant immediate investigation into the suspected cause of the cyanosis. The diagnostic workup for infants with central cyanosis may include echocardiography and cardiac catheterization. Depending on the findings, treatment may involve medical or surgical intervention. (See Chapters 19 and 26.)

When stimulated by physical contact, infants should demonstrate a rapid pinking of the skin that progresses to a red color. These changes are reflective of an increased respiratory and heart rate. Observing how long it takes for the infant to return to the previous skin color after stimulation is an important component of the nurse's visual assessment of the neonate's cardiovascular system. Making an accurate assessment of the infant's "true" skin color is of paramount importance when observing for color changes related to pathological conditions. For the nurse to accurately assess the color of the neonate's skin, it is necessary to know what constitutes the "normal" skin color for that individual. It is important to remember that skin color is influenced by ethnicity. For example, the natural skin colors of African American and Hispanic infants may be infused with yellow tones that make it difficult for the nurse to determine normal skin color.

Optimizing Outcomes— Obtaining an accurate assessment of the infant's true skin color

- Use a variety of light sources (helps to ascertain the “true” color).
- Examine the infant's entire skin surface.
- Carefully inspect the palms, soles of the feet, lips, and areas behind the ears.
- Gently palpate bony prominences (nose, sternum, sacrum, wrists, ankles).
- Apply slight pressure for 1 second (“blanching”).
- Observe for true skin color, reflective of the infant's ethnic heritage.
- Record true skin color; yellow is indicative of jaundice; white is indicative of pallor.

BODY SIZE

At the time of birth, the neonate's weight and length are measured and recorded. The nurse also visually inspects the infant for symmetry of head-to-toe length along with abdominal girth. Later, the neonate's actual body measurements are correlated with a development graph to ascertain appropriateness of the physical size. As a component of the visual inspection, the nurse confirms that the infant's head appears to be the largest body part.

Now Can You— Discuss essential nursing actions associated with newborn safety and skin color assessment?

1. Describe and demonstrate how the infant should be positioned to prevent SIDS?
2. Name three nursing actions that can help minimize physiological jaundice?
3. Discuss four techniques that should be used to assess the infant's true skin color?

LEVEL OF REACTIVITY

The infant's reaction to the environment is an important indicator of the level of neuromuscular development. The nurse routinely assesses the infant's state of responsiveness and reactivity. During the exam, it is helpful to consider these questions, designed to ensure a thorough assessment:

“Is the neonate awake and quiet, or restless and crying?”

“Does the infant respond by looking and moving all extremities?”

“Is the infant's sleep pattern best characterized by quiet slumber or agitated restlessness?”

According to Brazelton (1973), neonates exhibit several discrete behavioral levels or “states” of awareness and normally progress or regress smoothly from one to the other. The distinct states include deep sleep, light sleep, drowsy, quiet alert, considerable motor activity, and crying. The neonatal behavioral assessment is an important component of the overall evaluation, since it validates a mature neuro-organizational system that allows the term infant to

readily transition from one behavioral state to another. Certain conditions such as in utero exposure to cocaine disrupt this normal development; affected neonates exhibit erratic, disorganized behavior, an excessive response to stimuli and lengthy or absent transition periods between behaviors. (See Chapter 19 for further discussion.)

The nurse may assess the infant's response to voices and physical presence to confirm the level of responsiveness and behavioral organization. An infant who displays irritability and an overreaction to voices, touch, or movement needs to be comforted and special care must be taken to provide calming measures such as swaddling the neonate in blankets, cuddling, rocking, and gentle holding. It is best to postpone the physical examination because the manipulation and handling will most likely cause further disruption and behavioral disorganization.

OBTAINING MEASUREMENTS AND DETERMINING THE GESTATIONAL AGE

Routine assessment of the neonate's vital signs is important before the physical examination and throughout the infant's hospital stay. It is essential that the nurse recognizes the normal parameters for temperature, pulse, respirations, and blood pressure so that any change in the neonate's status can be readily identified.

critical nursing action Recognizing Normal Newborn Vital Signs

When assessing newborn vital signs, the nurse must be aware of the following normal parameters:

Temperature:

Normal range: 97.7°–99.4°F (36.5°–37.0°C)

Axillary: 97.5°–99°F (36.5°–37.2°C)

Pulse:

120–160 beats per minute (count pulse rate for one full minute)

During sleep, the pulse rate can be as low as 80 beats per minute.

During crying the pulse rate can be as high as 180 beats per minute.

Respirations:

30–60 respirations per minute (count respiratory rate for one full minute)

Abdominal breathing is normal. Periodic breathing is considered normal and classified as short pauses in the breathing of the newborn that last only approximately 3 seconds. Apneic episodes are significant if they last more than 15 to 20 seconds; they may be accompanied by abrupt pallor, hypotonia, cyanosis, and bradycardia. Apnea must be differentiated from periodic breathing, which is normal in the newborn.

Caution: Withhold oral feeding if the respiratory rate >60 respirations per minute.

Blood pressure:

Systolic: 60–80 mm Hg; diastolic: 40–50 mm Hg at birth

Systolic: 95–100 mm Hg; diastolic: slight increase at 10 days of age

Procedure 18-2 Measuring the Newborn's Body Length

Purpose

To establish and document the newborn's body length

Equipment

- Standard paper tape measure

Steps

1. Place the infant on a paper-covered flat surface.
2. Fully extend the infant's body by holding the head midline.

RATIONALE: *The newborn normally assumes a flexed position and must be fully extended to obtain an accurate measurement.*
3. Gently grasp the knees and place them together.
4. Push down gently on the knees until they are fully extended and flat against the table surface.
5. Measure the crown-to-heel recumbent length by placing the paper tape measure beside the infant with the 0 end of the tape at the top of the head.

Keep the infant's body in alignment and carefully extend one leg. Ensure that the tape measure remains straight. Note the length and record it in the infant's chart. As an alternate measurement method, make a slash mark with a pen at the end points by the top of the infant's head and the heels of the foot. While providing continuous support, gently roll the infant to the side and measure between the two points with a paper tape measure that has increments designated in tenths.

RATIONALE: *Careful body positioning and use of a tape measure graduated in tenths ensures an accurate measurement. Measurements are taken and recorded to note abnormalities and to provide a baseline value.*

Documentation

3/4/10 0800 - Infant length: 50 cm.

-J. Yamato, RN

The neonate's weight, recorded in grams, and the length, recorded in centimeters, are measured in the birthing room and again during the transitional period (Figs. 18-2 and 18-3). On average, a term newborn infant weighs 3400 grams, with a normal range of 2500 to 4300 grams. Recumbent length is a crown-to-heel measurement taken with the infant in a supine position (Procedure 18-2). The recumbent length is recorded on a regular basis until the infant reaches 24 months of age. Normal length parameters for newborns are approximately 18 to 22 inches (45 to 55 cm).

The nurse also obtains and records the frontal-occipital circumference (FOC), or head measurement (Fig. 18-4). A paper tape measure with increments marked in tenths of a centimeter is used to ensure an accurate measurement.

To obtain the head circumference, the tape measure is placed on the area immediately above the eyebrows and pinna of the ears and then wrapped around to the occipital prominence at the back of the head. This location represents the area of the greatest head circumference. After obtaining the head measurement three times, the nurse records the largest finding. The normal head circumference for a full-term neonate ranges from 13 to 15 inches (33 to 38 cm). Measurement of the head circumference is repeated at subsequent physical exams until the infant reaches 36 months of age.

To obtain the chest measurement, the paper tape measure is placed on the nipple line and then wrapped around the entire thoracic area (Fig. 18-5). The head and chest measurement may be equal during the first

Figure 18-2 Weighing the infant.

Figure 18-4 Measuring the head circumference.

Figure 18-3 Measuring the infant's body length.

Figure 18-5 Measuring the chest circumference.

few days of life. A normal chest measurement is 12 to 13 inches (30.5 to 33 cm). The abdominal circumference may be obtained by encircling the infant's body with the paper tape measure placed directly above the umbilicus (Fig. 18-6). The abdomen should be approximately the same size as the chest (Dillon, 2007). Once all measurements have been obtained, the nurse plots the weight, length, and head circumference against the infant's gestational age to determine the appropriate size category (Fig. 18-7). Size categories are small for gestational age (SGA), appropriate for gestational age (AGA), and large for gestational age (LGA). If at any time the physical measurements fall outside of the normal growth parameters, the physician should be notified. Information concerning normal growth parameters for infants, children and adults is available at the CDC National Center for Health Statistics Web site: <http://www.cdc.gov/nchs/about/major/nhanes/growthcharts/charts.htm>.

Nursing Insight— Understanding classifications for newborn weight

Large for gestational age (LGA): Weight is above the 90th percentile at any week.

Appropriate for gestational age (AGA): Weight falls between the 10th and 90th percentiles for the infant's age.

Small for gestational age (SGA): Weight falls below the 10th percentile for the infant's age.

Figure 18-6 Measuring the abdominal circumference.

In 1967, the American Academy of Pediatrics recommended that all newborns be classified by birth weight and gestational age. Since that time, a scoring system developed by Ballard and colleagues (1991), which represents a modification of the Dubowitz system, has been the most commonly used method for determining the neonate's gestational age. With this assessment system, the infant examination yields a score of neuromuscular and physical maturity that can be extrapolated onto a corresponding age scale to reveal the infant's gestational age in weeks. Additional methods used to determine gestational age are fundal height measurement before delivery, ultrasonography, and eye lens vascularity. A rough approximation of the gestational age at birth can be calculated according to the date of the mother's last normal menstrual period. Since these other sources of age determination are not as accurate as the neonatal physical examination, gestational age assessments are frequently performed by the nurse and recorded on the infant's chart.

Optimizing Outcomes— Use of the Ballard Gestational Age by Maturity Rating tool

The Ballard Gestational Age by Maturity Rating tool includes a neuromuscular maturity and a physical maturity component (Fig. 18-8) that contains six characteristics to be assessed. At the conclusion of the examination, the scores from each component are added together, then mathematically extrapolated onto the maturity rating scale to determine the infant's gestational age by examination. The scoring system is designed to identify the decreased levels of muscle and joint flexibility characteristic of the premature infant, as well as the mature term infant's ability to return to the original position after movement. The nurse usually performs this assessment within the first 12 hours of the infant's life. The Ballard scoring system is more accurate when conducted on term infants who are between 10 and 36 hours of life. The order in which the assessment is conducted is unimportant.

Interestingly, gestational age maturity may occur at different rates among the various categories. For example, a score of 4 (full maturity) in one category does not indicate

Figure 18-7 Gestational age assessment.

Figure 18-8 The New Ballard score.

that all subsequent categories must also reflect a score of 4. “Half-scores” are often recorded if the examiner believes that the infant exhibits a characteristic that falls between two scoring options during the assessment. It is important to remember that the infant’s maturity scoring does not directly translate to the gestational age in weeks.

Now Can You— Obtain neonatal measurements and determine gestational age?

1. Describe and demonstrate how to obtain neonatal body measurements?
2. Identify two maturity components that are assessed in the Ballard tool? Describe when and why the Ballard assessment should be performed?
3. Discuss whether or not the Ballard maturity score should be identical to the gestational age of the neonate?

Conducting and Documenting the Neonatal Physical Assessment

The nurse conducts the neonatal physical examination with the review of systems following the general nursing assessment of the newborn. This examination should not

be initiated if the infant is crying or appears to be upset. Instead, it is best to postpone the assessment until the infant is calm. Infant registration and documentation of findings from the physical examination, along with other pertinent information (i.e., site and dosage of the vitamin K and hepatitis B vaccine injections, instillation of medication for eye prophylaxis) must be completed for each infant before hospital discharge.

ASSESSMENT OF THE NEONATE: A SYSTEMS APPROACH

Once the assessment of the infant’s general physical growth parameters and gestational age has been completed, the nurse systematically examines each body system, beginning with the skin and proceeding in a head-to-toe direction. This assessment may take place in the nursery with the infant resting comfortably in a crib, under a radiant warmer (to maintain temperature stability), or if stable, in the mother’s room. Carrying out the assessment by the mother’s bedside has several advantages. For most, the bedside is a nonthreatening environment where the mother and the nurse can “explore” the baby’s special and unique characteristics. Also, conducting the evaluation in this relaxed setting gives the nurse an opportunity to observe the mother’s ease in interacting with and touching and holding her infant. Appropriate positive reinforcement by the nurse

affirms and validates the mother's actions, enhances her sense of maternal worthiness, and strengthens the bonding relationship. For the infant, the evolving sense of trust and perception of a secure environment are two essential developmental milestones first established during these early contacts with caregivers. These experiences lay the foundation for the child's life-long development of self-esteem and self-love. A spiritual health promotion strategy for the family with a newborn centers on encouraging the parents and caregivers to shower their infants and toddlers with love and comfort (Tucker, 2002).

With the infant in a supine position, the nurse follows the steps of inspection, light palpation, deep palpation, and auscultation to facilitate the examination. When assessing the abdomen, the proper sequence is inspection, auscultation, and light palpation followed by deep palpation.

Assessment of the Integumentary System

Wearing gloves, the nurse examines the neonate's skin, scalp and body hair, and nails for color, texture, distribution, disruptions, eruptions, and birthmarks. It is important that the assessment take place in a well-lit room and additional light sources may be needed to confirm accuracy of findings. The infant's skin should be pink, a finding that indicates adequate peripheral cardiac perfusion. Blanching the skin over bony prominences should yield a pink-white color before returning to natural pigmentation.

As previously described, acrocyanosis, a bluish coloration to the hands and feet, is a normal condition related to vasomotor instability and poor peripheral circulation. To differentiate between acrocyanosis and true cyanosis, the nurse can vigorously rub the sole of the neonate's foot. If the sole turns pink, the diagnosis is acrocyanosis. If the sole remains blue, it is true cyanosis. Also, acrocyanosis disappears when the infant cries. Visual inspection of the infant's mouth, tongue, and gums confirms the skin color assessment, as these areas should be pink-red in color and darken to bright red with crying. True cyanosis produces a bluish coloration and pallor (paleness) of the lips and on the area around the mouth.

Careful, daily assessment of the newborn's skin constitutes an important nursing action that may lead to early detection of potential problems. If pallor, **plethora** (a deep purplish color related to an increased number of circulating red blood cells), **petechiae** (pinpoint hemorrhagic areas), central cyanosis, or jaundice is detected, further evaluation is warranted. The nurse describes and records in the infant's medical chart the location of any birth injuries such as forceps marks or fetal monitoring lesions. Infants born with a nuchal cord (umbilical cord around the neck) or those who assumed a face presentation commonly exhibit bruises or petechiae on the head, neck, and face. If extensive bruising is present, the infant's bilirubin level may be elevated. Although focal petechiae may be related to injury from increased pressure, the presence of petechiae scattered throughout the infant's body can be indicative of an underlying problem such as a low platelet count or infection. Periauricular papillomas, or skin tags, are a benign common finding that often run in families and usually are insignificant and require no intervention.

The term infant's skin should feel smooth and soft. In the postterm infant, the skin is often tough and leathery, with cracking and peeling. Disruptions or breaks in the skin may be related to electrode marks or lacerations. Infants

delivered by forceps or vacuum extraction may have skin disruptions or bruising on the scalp and face. Often, infants are born with pustular melanosis, a condition in which small pustules are formed prior to delivery. As the pustule disintegrates, a small residue or "scale" in the shape of the pustule is formed. This lesion later develops into a small (1 to 2 millimeter) macule, or flat spot. Macules, which are brown in color, appear similar to freckles and are frequently located on the chest and extremities. Pustular melanosis occurs more commonly on African American infants than on Caucasian infants (Miller & Newman, 2005).

Another common skin condition is **milia**, small white papules or sebaceous cysts on the infant's face that resemble pimples (Fig. 18-9). Inclusion cysts may be seen singularly or in pairs on the penis or scrotum of male infants or on the areola of female infants. Acne, a skin condition common in adolescents, may also be present in newborns and is related to excessive amounts of maternal hormones. Over time, neonatal acne disappears spontaneously from the infant's cheeks and chest. **Erythema toxicum**, a transient rash that covers the face and chest with spread to the entire body, is the most common normal skin eruption in term neonates. It is also called "erythema neonatorum," "newborn rash," or "flea bite" dermatitis. Typically, the rash consists of small, irregular, flat red patches on the cheeks that develop into singular, small yellow pimples appearing on the chest, abdomen, and extremities. The cause of this skin condition is unknown, and it may persist for up to 1 month of life. There is no treatment available to hasten the resolution of the rash, which, because of its frequently unsightly appearance, can be quite disturbing to parents.

Blisters related to repetitive sucking may form on the fingers, wrists, and upper lips of infants who often perpetuate a habit begun in utero. Although these lesions may appear to be serious, parents can be assured that they will resolve over time without intervention.

Many neonatal skin variations are characterized by color changes that are different from normal pigmentation. For example, **Mongolian spots** are areas that appear gray, dark blue, or purple and are most commonly located on the back and buttocks, although they may also be found on the shoulders, wrists, forearms, and ankles (Fig. 18-10).

Figure 18-9 Milia.

Figure 18-10 Mongolian spots.

Mongolian spots are seen most often in infants whose ethnic backgrounds include the Mediterranean area, Latin America, Asia, or Africa. Parents can be assured that these skin changes will fade and disappear as the infant grows older. Since they may be mistaken for bruises, it is important that the nurse document Mongolian spots on the infant's chart. Another condition, "cutis marmorata," or mottling, is common in neonates and is most often caused by the infant's vasomotor response to the lower environmental temperature outside of the uterus. Mottling may also be related to prolonged apnea. Usually, the mottling disappears once the newborn adjusts to the extrauterine environment. A deepened coloration of the genital skin in males and females may occur due to the influence of maternal hormones. This color change also diminishes over time.

Birthmarks are distinct areas of color that may be red, tan, brown, white, or red. Their appearance varies but generally these lesions are small and flat. It is important to distinguish birthmarks from skin lesions that result from birth trauma. The nurse documents the location, size, and color of the birthmark, and if the lesion contains hair or is located along the anterior or posterior midline, further investigation is warranted to rule out underlying tissue involvement. Hypopigmentation refers to a white or pale area of skin. When it occurs as a single lesion, hypopigmentation is not a cause for worry. However, if multiple hypopigmented areas, including lesions in a leaf pattern are present, the infant should be referred for further evaluation. These lesions, which sometimes appear on the chest, back, extremities and axilla, may be associated with tuberous sclerosis, a neurological condition. Café-au-lait marks are flat, tan spots that are quite common and insignificant unless the infant exhibits six or more marks that are greater than 1 cm in diameter. In this circumstance, the neonate should be carefully evaluated during infancy for tumors that develop beneath the skin, as he may be at risk for developing type 1 neurofibromatosis. The nurse should be aware that because café-au-lait spots and other skin pigment variations can be very difficult to identify in African American infants, extra care must be taken when performing the integumentary system assessment (Miller & Newman, 2005).

Brown **nevi** are brown skin marks, or birth marks whose color can vary from brown to deep black. Since a nevus may represent a very early form of a precancerous lesion, the nurse should teach parents to routinely check the lesion for changes in color, shape, size, shape, or elevation from the skin surface. The careful observation of

this skin lesion should be ongoing and continuous throughout the child's lifetime.

A **nevus flammeus**, often referred to as a "port wine stain," is a capillary angioma located directly below the epidermis. Usually apparent at birth, the nevus flammeus is a non-elevated, red to purple network of dense capillaries that varies in size, shape and location, although it commonly appears on the face. It does not blanch on pressure, disappear or grow in size. Sturge-Weber syndrome, a clinical condition involving the fifth cranial nerve, may be present when a nevus flammeus is accompanied by convulsions or other indicators of neurological problems (Miller & Newman, 2005).

A **telangiectatic nevus** is a red birthmark often seen at the nape of the neck and commonly referred to as a "stork bite" or "angel kiss" (Fig. 18-11). This lesion may also occur on the face between the eyebrows, on the eyelids, nose, or upper lip. It is usually irregular in shape and pale red, often turning bright red when the infant cries. The telangiectatic nevus tends to fade as the infant grows older and usually disappears by the second birthday. A **nevus vasculosus**, or "strawberry mark," is a red, raised capillary hemangioma that can occur anywhere on the neonate's body. This birthmark usually has sharp borders and a rough surface that resembles a strawberry. Although often alarming due to its appearance, the nurse can reassure parents that over time this lesion will eventually undergo a process of involution and disappear during the first year of life. Unless they interfere with a vital organ system or are located on the face, surgical removal of capillary hemangiomas is not recommended. The blue nevus appears as a distinct blue or blue-black birthmark often found on the buttocks, hands, and feet. Although sometimes mistaken for a Mongolian spot when it appears on the buttocks, nurses can differentiate the blue nevus by noting its distinct borders and brighter color, as compared to the Mongolian spot, which covers a larger area. The blue nevus is usually 1 cm or less in size.

CONDITIONS THAT MAY WARRANT FURTHER ASSESSMENT. Blemishes and other marks on an infant's skin that are related to birth trauma most often mirror the traumatizing

where research and practice meet:
The Neonatal Skin Condition Score

Providing timely, evidence-based skin care to neonates is of major importance to nurses. Nurses can implement various interventions to reduce injury to skin integrity, prevent absorption of potentially toxic agents, and promote the development of healthy skin (Lund & Osborne, 2004). The Neonatal Skin Condition Score (NSCS) is an assessment tool developed by investigators involved in the Neonatal Skin Care Project, a clinical study designed to develop guidelines for the examination and evaluation of neonatal skin care (Lund, Kuller, et al., 2001; Lund, Osborne, et al., 2001). The NSCS consists of a 9-point scale that evaluates three broad categories: dryness, erythema, and breakdown/excoriation. A score ranging from 1 (normal) to 3 (extensive) is assigned to each category; a perfect score = 3 and the worst possible score = 9. The NSCS is designed to provide a concise, objective method of accurately reporting skin conditions in the hospitalized neonate and a timely means for identifying infants with need for interventions such as monitoring for systemic candidiasis and application of emollients.

Figure 18-11 Stork bite.

instrument such as forceps or scalp electrodes. Characteristically, the color of these lesions progresses through the various skin color changes commonly associated with bruising. When assessing for birth injuries, the nurse pays close attention to the scalp, face, shoulders, arms, legs, and feet. Large infants frequently exhibit marks from trauma sustained during a difficult vaginal birth. Infants born with a nuchal cord (umbilical cord around the neck) may demonstrate considerable bruising of the neck and face. Also, neonates whose presenting part was the legs, feet, or buttocks may have extensive edema or bruising of the lower extremities. Sometimes the full extent of tissue damage cannot be appreciated by routine inspection and palpation. Instead, the nurse may note that the infant responds to positional changes and other gentle manual manipulation with excessive crying or irritability. In these circumstances, further assessment should be conducted with the infant placed in the supine and prone positions. Since excessive bruising may be associated with elevated bilirubin levels, the infant should be closely observed for signs of jaundice. Widespread petechiae or petechiae unrelated to birth trauma should be reported to the pediatrician because these findings may be associated with infection, low platelets, or congenital problems such as rubella.

Abnormally pigmented skin lesions and variations in hair patterns are other findings that may signal underlying problems. Infants who exhibit hairy pigmented skin lesions containing two distinct areas of color should be evaluated by a dermatologist. Since these findings may be related to an underlying structural defect, diagnostic ultrasound is often performed to evaluate the tissue beneath the skin surface. Hairy nevi describe skin nevi that contain individual hairs or a full tuft of hair. The presence of hairy nevi located in the posterior midline area near the spinal column may indicate a vertebral defect. When present, ultrasound examination of the spinal column is necessary in order to confirm any defects related to spina bifida or spina bifida occulta.

The nurse may identify an infant whose skin color remains deep pink or red during quiet rest or sleep. This finding may indicate plethora, a condition most often caused by polycythemia vera or hyperthermia. Polycythemia

vera, a condition characterized by an excessive number of red blood cells, occurs from the transfer of maternal blood into the neonate's circulation during the time when the umbilical cord was cut. Polycythemia vera can be confirmed by a capillary hematocrit value of 65 or greater or a venous hematocrit of 60 or more. Treatment for this condition usually involves a partial exchange transfusion. (See Chapter 19 for further discussion of neonatal exchange transfusions.) Hyperthermia can be detected by checking the infant's body temperature.

Careful examination of the infant's hair pattern constitutes another essential component of the nursing assessment. Special attention should be paid to the hair texture, color, and distribution, noting any disruptions to the hair distribution or areas of asymmetry on the scalp. Hair that covers the forehead and creates a shortened distance between the hairline and the eyebrows may be indicative of a congenital syndrome. The nurse notes any variations such as hair that is lighter in color than the surrounding hair, or hair that appears to grow in a circular pattern or whorl. Sections of white hair embedded in darker scalp hair may indicate an underlying structural defect or the presence of a congenital syndrome.

Ongoing observation and assessment of the neonate's skin allows the nurse an opportunity to confirm normalcy, identify potential problems, and prepare for possible interventions. It also provides an opportunity to educate and reassure parents about normal neonatal skin characteristics and findings that might indicate problems. Parents are often fearful about "body marks" and the nurse can allay anxieties and stress the importance of conducting routine skin observations throughout childhood.

Now Can You— Discuss neonatal skin conditions?

1. Explain what parents should be taught about treatment for their infant's erythema toxicum?
2. Identify when the presence of café-au-lait spots in the neonate warrants further investigation?
3. Discuss the significance of hairy, pigmented skin lesions in the newborn?
4. Describe why the nurse should carefully assess the neonate's hair pattern?

Assessment of the Infant's Head

Following the skin assessment, the infant's head, eyes, ears, nose, and throat are evaluated next. The nurse methodically assesses the face for symmetry, noting the placement of the eyes, nose, lips, mouth, and ears (Fig. 18-12). Eye shape and size are noted along with assessment for coordinated movement of the lids. Eye color and placement on the forehead are recorded. The lips are also assessed for movement. Birth-related damage to the 7th cranial (facial) nerve can result in a number of findings such as unilateral drooping of the tongue or mouth, unequal movement of the cheek muscles, or inappropriate eyelid movement. Special attention is paid to the shape, size, and placement of the ears. Low-set ears may signal the need for further assessment and evaluation for chromosomal abnormalities (Fig. 18-13). Placement of

Figure 18-12 The face is examined for symmetry, noting placement of the eyes, nose, lips, mouth, and ears.

one ear slightly lower than the other is a common finding that generally has no clinical significance. Nostrils should be open bilaterally and the nasal bridge should be centered with no lateral deviations. Lip color should be consistent with the tongue and buccal mucosa of the mouth. The upper and lower lips should be approximately uniform in size. The infant's chin should be readily apparent when viewed in a profile position. Micrognathia, or small jaw, may interfere with tooth development, sucking, swallowing and tongue movement inside the mouth during speech (Dillon, 2007).

The nurse carefully palpates the infant's head to assess the fontanel, the cranial suture lines, and the presence of any birth-related edema. The anterior fontanel is readily identifiable as a diamond-shaped open space formed by the anterior–posterior sagittal and frontal sutures and the lateral coronal suture (Fig. 18-14). Assessment of the fontanel includes an estimation of the overall fontanel

Figure 18-14 Palpating the fontanel borders.

size. The nurse can readily determine this dimension by palpation of the fontanel borders with use of the finger for measurements (the distance from the tip of the finger to the first finger joint is roughly 1 inch, or 2.5 cm). Variations in anterior fontanel size are common and range from 0.4 to 2.8 inches (1 to 7 cm). The posterior fontanel, located toward the back of the cranium, is a small, triangular-shaped space formed by the sagittal suture and the posterior lateral suture. At its widest point, the posterior fontanel is usually only 0.4 inch (1 cm) and may be closed at initial examination. The anterior fontanel must remain open during the first year of life to accommodate skull bone expansion that accompanies normal brain growth. Open spaces between the suture lines result from cranial molding during the birth process. Assessment of the fontanel for intracranial pressure is an important component of the examination. Normal intracranial pressure is characterized by a finding of fontanel fullness without bulging, either on visual inspection or palpation. Bulging, tense fontanel in an infant with a large head circumference are indicative of increased intracranial pressure, often associated with hydrocephalus.

The nurse may note the presence of swelling or soft tissue edema of the head that has resulted from trauma during the birth process. **Caput succedaneum** is diffuse edema that crosses the cranial suture lines and disappears without treatment during the first few days of life. **Cephalhematoma**, a more serious condition, results from a subperiosteal hemorrhage that does not cross the suture lines (Fig. 18-15). It appears as a localized swelling on one side of the infant's head and persists for weeks while the tissue fluid is slowly broken down and absorbed. During this time, the infant may exhibit signs of jaundice related to the metabolism of damaged red blood cells from the subperiosteal hemorrhage.

The nurse next palpates the neonate's eyes, ears, and nose to confirm shape and size. The eyelids are manually opened and the iris, sclera, and conjunctiva are examined. It is not unusual to detect tiny pinpoint scleral hemorrhages (related to birth trauma) in the outer canthus of the eyes. Swollen eyelids and a yellow discharge that adheres to the eyelashes may provide evidence of eye prophylaxis medication. The nurse uses an ophthalmoscope to check for bilateral red reflexes and records the findings on the infant's chart. Absence of bilateral red reflexes constitutes a medical emergency; this finding warrants immediate attention.

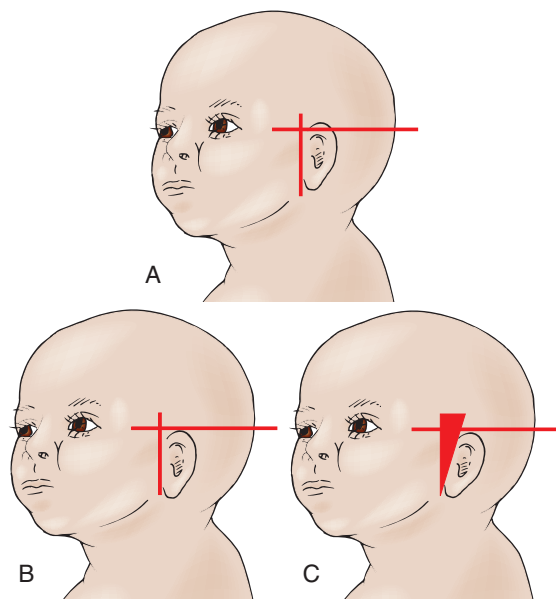

Figure 18-13 To determine ear placement, an imaginary line is drawn from the inner to the outer canthus of the eye and then to the ear. **A.** Normal ear position. **B.** Low-set ear. **C.** Slanted low-set ear.

critical nursing action Recognizing an Ophthalmic Emergency in the Infant

When using an ophthalmoscope to examine an infant's eyes, the nurse notes the following finding: Right eye: red reflex present. Left eye: red reflex absent.

What is the significance of these findings? What action should the nurse take next?

Absence of the red reflex indicates an interference with the transmission of light to the retina. This finding constitutes an ophthalmic emergency that requires immediate medical attention, since optic nerve suppression from obstructed light pathways may result in permanent blindness. The nurse must immediately notify the physician.

The nurse may assess the infant's gross vision by determining the infant's ability to direct his or her gaze at the examiner when positioned approximately 10 inches

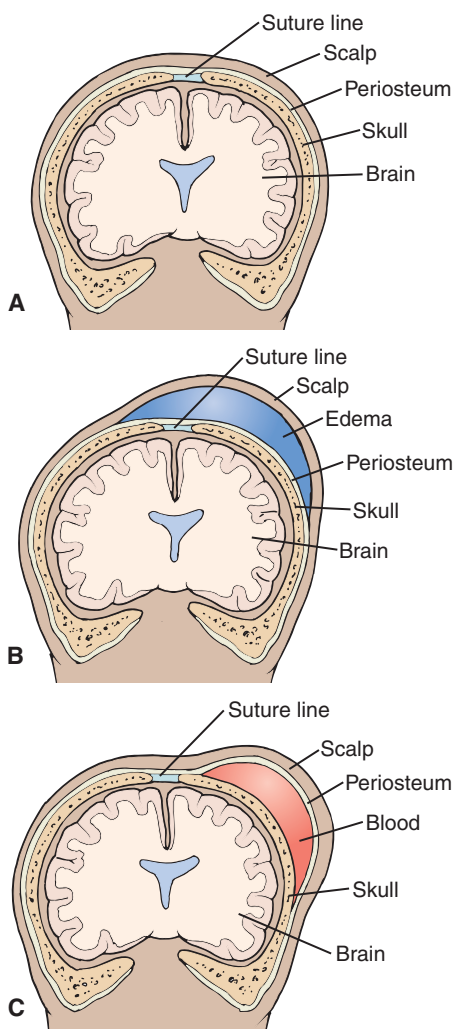

Figure 18-15 A. Normal head. B. Caput succedaneum. Localized soft tissue edema present at birth. It does not increase in size. Swelling crosses the suture lines. C. Cephalhematoma. A collection of blood from a subperiosteal hemorrhage appears after birth. It increases in size. Swelling does not cross the suture lines.

from the infant's face. The examiner then moves and notes whether or not the infant is able to appropriately readjust the gaze. The infant's nose is assessed by careful palpation of the nasal bridge to determine symmetry and the presence of fracture that may have occurred during birth. The nurse gently opens the infant's mouth and visually inspects, then palpates the gums for the presence of neonatal teeth above or beneath the gum surface (Fig. 18-16). Teeth that have emerged through the gums should be checked for looseness and may need to be extracted because of the risk of aspiration. Since the presence of natal teeth may be associated with a congenital defect, further evaluation may be indicated (Dillon, 2007).

Epstein's pearls, whitish hardened nodules on the gums or roof of the mouth, may be visualized or palpated (Fig. 18-17). These pearl-like inclusion cysts are not an unusual finding and disappear within a few weeks. The presence of the uvula in the midline is noted; a bivalve or double lobed uvula may indicate a cleft in the palate. The infant's ability to suck can also be assessed during the oral examination. The nurse inserts a gloved finger into the infant's mouth and notes and records the strength of the sucking motion. Also, at this time the hard and soft palates can be examined for size, shape, and cleft formations. When present, a cleft defect is felt as an open space or as a notched ridge. A high, arched palate may be associated with difficulty swallowing or with later speech development. Next, the gag reflex is elicited and the back of the throat, tongue, and uvula are visualized. The infant's throat is also externally palpated to check for enlargement of the thyroid gland and to ensure that the trachea is located in the midline. The nurse checks for neck rotation by observing the infant's head movement and by gently turning the head from side to side. Torticollis is a deviation of the neck to one side caused by a spasmodic contraction of neck muscles. In the neonate, a torticollis is

Figure 18-16 Natal teeth.

Figure 18-17 Epstein's pearls usually disappear within a few weeks.

apparent when the head is positioned on one side while the chin points to the opposite side. Torticollis or the presence of a congenital cervical spine defect are two serious conditions that may produce limitations in neck movement and should be reported immediately.

The nurse palpates and inspects the neonate's ears to determine the thickness of the ear lobe and pinna. Ear pits and ear tags are common preauricular ear malformations. Ear pits, tiny pinholes found near the upper curved border of the pinna, arise from the imperfect fusion of the tubercles of the first and second brachial arches during early fetal development. Since they may signal a small sinus tract between the skin and underlying structures, they should be carefully evaluated to determine whether a layer of skin covers the opening or if the pit is open at the bottom. When signs of infection (i.e., redness, edema, draining fluid) are present, the ear pits should be surgically repaired. Ear tags, fleshy bulb-shaped growths that project from the surface of the skin, should be removed for cosmetic purposes by a plastic surgeon since they frequently contain microcapillaries that bleed when cut. The ear canals are assessed for patency and gross hearing may be evaluated by softly ringing a bell near each ear.

Most states in the United States require routine hearing screening before a newborn's discharge from the hospital. The goal of newborn screening is to identify congenital hearing loss and to refer those affected for early intervention. Screening is done using automated auditory brainstem response (AABR) in which electrodes are placed on the forehead and neck and soft earphones on the ears of a sleepy, calm infant. A series of clicks are introduced, usually at the 30- to 40-decibel level. If an infant has normal hearing, the response is detected by the electrodes (Kaye, 2007). Infants whose test results are unsatisfactory should be referred for repeated testing to take place no later than 8 weeks of age. Early hearing screening allows for timely identification of problems and reduces the age at which affected infants may be treated (Johnson et al., 2005; Joint Committee on Infant Hearing, 2000; U.S. Preventive Services Task Force, 2001).

Assessment of the nose begins with an observation of the placement of the nose, normally located in the middle of the face. The nurse can draw an imaginary line from the center of the bridge of the nose downward to the notch of the upper lip. The nose should lie exactly vertical to this line. Each side of the nose should be symmetrical. It is important to note any deviation to one side, as well as asymmetry in relation to the size and dimensions of the nostrils. Remember that the bridge of the nose in African American or Asian children is normally flat.

CONDITIONS THAT MAY WARRANT FURTHER ASSESSMENT. When conducting an assessment of the head, ears, eyes, nose, and throat, the nurse is alert to findings of asymmetry, unusual shape or evidence of defects in underlying structures or congenital syndromes. Generally, findings that are immediately apparent to the nurse examiner pose the greatest problems for the neonate. For example, Down syndrome is frequently identified during the assessment of the head when the nurse notes a flattened (instead of round) occiput, a broad nasal bridge, upward slanted eyes with epicanthal folds, low-set

ears, an enlarged tongue, high arched palate, and a small chin. Open separations of the lip, mouth, nose, and hard or soft palate are indicative of cleft lip or cleft palate. Since facial disfigurement accompanies these defects, nurses should be extremely sensitive to the feelings of parents and other family members who interact with the infant.

The eye examination may provide an early indicator of several conditions that can affect the infant's well-being. For example, sclera, normally white, may appear to be blue or yellow in color. Bluish colored sclera may signal a congenital condition known as osteogenesis imperfecta, which is characterized by a loss of bone structure and integrity. Infants with this condition must be handled with extreme gentleness, and may have already suffered fractures during the birth process. Yellowing of the sclera, related to elevated bilirubin levels, is a late manifestation of jaundice in the neonate. The nurse should seek immediate medical assistance for the infant and plan for rapid intervention such as intravenous fluids and phototherapy. A disruption in the iris, called a coloboma, appears as a keyhole in the circle of the iris and pupil and will affect vision in that eye. Congenital cataracts are noted when white or pale yellow tissue covers the pupil and iris and occludes the red reflex. This finding warrants prompt referral. Occasionally, the red reflex (normally red or reddish orange in color) appears to be white, a finding that requires immediate attention since it may signal the presence of a neuroblastoma. Congenital glaucoma is an ophthalmic emergency that requires the timely instillation of eye drops to prevent blindness caused by increased intraocular pressure. This condition is characterized by protuberant eyes that appear to extend beyond the orbits and feel firm on gentle palpation.

Careful examination of the infant's facial features may provide evidence of birth defects associated with maternal alcohol use. Characteristic findings include short palpebral fissures; a flattened nasal bridge with a small, upturned nose; flat midface, thin upper lip and smooth philtrum. Alcohol-related birth defects (ARBD) also include poor growth, mental retardation (often associated with **microcephaly**, or small head), and small chin (micrognathia). This condition, also called fetal alcohol syndrome (FAS) or fetal alcohol effects (FAE), describes the range of physical and mental effects that are related to the mother's alcohol use during fetal growth and development. After birth, affected infants are often jittery, irritable, and poor feeders. Nursing interventions focus on providing a calming, quiet, nurturing environment with minimal stimulation. (See Chapter 19 for further discussion.)

The nurse's careful assessment of the infant's head, face, eyes, ears, nose, and throat constitutes an essential component of the neonatal physical examination. Since infants are frequently bundled in blankets when presented to parents and loved ones, initial impressions are often formed based on the appearance of the neonate's face and head. Because many congenital malformations affect these body parts, the nurse must be sensitive to parents' feelings and approach the initial "viewing" prepared to provide immediate emotional support and subsequent referral to appropriate resources as indicated. It is important to remember that a wide range of normal variations (i.e., birth marks, hair patterns, large eyes, nose, or ears) commonly occur and result from familial characteristics and inheritance patterns rather than from congenital syndromes.

Now Can You— Describe the assessment related to the infant's head?

1. Describe the location of the fontanel? Explain why it is important to assess them?
2. Differentiate between caput succedaneum and cephalhematoma and discuss how each is treated?
3. Describe how to conduct an assessment of the neonate's mouth and explain why this assessment is important?
4. Identify neonatal features that are characteristic of Down syndrome and maternal alcohol use?

case study Baby Boy Goldman

Baby Boy Goldman was born via a normal spontaneous vaginal birth 4 hours ago. His parents are of eastern Mediterranean descent. His mother's prenatal care was initiated during the third month of gestation and the pregnancy was uncomplicated. He is awake and resting quietly in the nursery bassinet. During a review of the infant's medical record, the nurse notes the following information, recorded approximately 1 hour earlier: axillary temperature: 98.0°F (36.7°C) pulse: 136 beats per minute; respirations: 40 breaths per minute; weight: 8 lbs. 2 oz. (17.7 kg); length: 20.5 inches (8.1 cm). At birth, Baby Goldman's heart rate was 92 beats per minute and he was crying and moving all extremities. The nurse now observes that the infant's hands and feet are bluish in color and his face contains several white "bumps" that are scattered over his nose and forehead. Dark gray areas are seen on his lower back and buttocks. On palpation of Baby Goldman's head, the nurse notes a small degree of swelling that is symmetrical and crosses the suture lines.

critical thinking questions

1. Are these findings normal or pathological?
2. What actions should the nurse take?

◆ See Suggested Answers to Case Studies in the text on the Electronic Study Guide or DavisPlus.

Assessment of the Respiratory System

When assessing the neonate's respiratory efforts, the nurse first observes for symmetry in chest movement, and at the same time notes the placement and size of breast tissue. Enlargement of the breasts in male infants is common and only a temporary condition since it is related to maternal hormones. The breast tissue and nipples should be located in the midclavicular line. This anatomical landmark is actually an imaginary line that is one-half of the distance from the midline (the lower border of the sternum) to the lateral border of the chest wall formed by the rib cage. If the breast tissue is located between the midclavicular line and the lateral chest wall, the nurse documents this finding as "wide-spaced nipples." The presence of wide-spaced nipples may signal a congenital syndrome, such as Down syndrome. Extra or "accessory" nipples may be located above or below the primary nipples. This finding is not associated with a congenital syndrome and parents can be assured that the accessory nipples will not enlarge during puberty and if desired, they may be safely removed at a later date (Dillon, 2007).

To assess for nasal patency, the nurse carefully occludes one naris while the infant's mouth is closed. A rise in the

infant's chest confirms that the nasal passageway is open and air has been inhaled. The assessment may be repeated with the other naris. If the infant demonstrates difficulty with this maneuver, he may have a developmental anomaly known as **choanal atresia** (a malformation of the buccal-nasal membrane). When present bilaterally, cyanosis is noted when the infant's mouth is closed but disappears when the mouth is open. An inability to pass a small catheter into the nares confirms the diagnosis. Since choanal atresia may be associated with other developmental anomalies, a positive finding should be reported immediately.

With the infant in a supine position, the nurse can readily assess his ease with overall breathing efforts. Respirations are counted and the pattern and any use of accessory muscles are noted. Slight sternal retractions may occur; this is a normal finding. Prominence of the xiphoid process is not unusual and with normal growth and development, the prominence will diminish. The lungs are auscultated anteriorly and posteriorly (Fig. 18-18). Infants may exhibit irregular breathing patterns accompanied by periods of apnea that can persist for up to 15 to 20 seconds. While not worrisome, it is important to alert parents that a brief cessation in respirations is common in neonates. The nurse also teaches the infant's caregivers how to recognize signs of respiratory distress: flaring of the nares, **retractions** (in-drawing of tissues between the ribs, below the rib cage or above the sternum and clavicles), or grunting with expirations. For healthy full-term neonates, a respiratory rate below 60 breaths per minute is considered normal. To obtain an accurate respiratory rate, it may be necessary to count the infant's respirations at several different times during the physical assessment. If the respiratory rate remains above 60 to 70 breaths per minute during rest, further evaluation is warranted.

Figure 18-18 A. The lungs are auscultated anteriorly. B. The lungs are auscultated posteriorly

Family Teaching Guidelines... How to Recognize Breathing Difficulties

As a component of newborn care, the nurse provides the following information to parents:

Your baby may be experiencing breathing difficulty if she:

- ◆ Has above normal respirations.
- ◆ Has prolonged (greater than 15 seconds) periods of breath holding.
- ◆ Shows sucking-in and see-saw movements around her rib cage.
- ◆ Flares her nostrils.
- ◆ Makes grunting sounds.

CONDITIONS THAT MAY WARRANT FURTHER ASSESSMENT. If the infant appears to be expending considerable energy to breathe or shows other signs of breathing difficulty, prompt evaluation of the respiratory status must be immediately sought. Signs of respiratory distress may be manifested by marked sternal or intercostal retractions. During the assessment, the nurse should gently palpate the anterior lung field to identify birth injuries, such as fractures of the clavicle or ribs. These injuries can cause an increased respiratory rate due to pain. Asymmetry of the chest wall during respirations may also signal the presence of a rib fracture. The nurse next inspects the chest wall to confirm symmetry and shape. Anatomical deformities such as pectus carinatum (pigeon chest) and pectus excavatum (funnel chest) arise from abnormal development of the ribs and sternum and may interfere with normal lung expansion. All lung fields should be auscultated anteriorly and posteriorly and the respiratory rate is counted from the auscultation, rather than from observation of abdominal movements (Dillon, 2007). Auscultation of the infant's nose can help differentiate upper airway congestion (from mucus, amniotic fluid) from lower airway congestion. When the nasal passages, throat, or upper bronchus is congested, noisy breath sounds are often detected. Using a bulb syringe, the nurse gently removes fluid and mucus from the infant's nasal and throat passages to facilitate easy respirations. After this intervention, any retractions should disappear.

If the infant continues to exhibit retractions and other signs of breathing difficulty, prompt investigation is warranted, as this finding may constitute a life-threatening event. Respiratory distress is associated with a number of conditions that may be related to the lungs or heart. Narrowing of the airways is associated with many congenital respiratory conditions while congenital heart defects often interfere with the lungs' capacity to oxygenate the blood. Congenital or acquired infection in the neonate may also cause respiratory distress. If the infant's respiratory rate remains elevated (60 to 70 breaths per minute) during periods of rest, the nurse must provide continuous observation. While the increased respiratory rate may represent a transitional period of adjustment to extrauterine life, the development of other symptoms such as nasal flaring,

grunting, or intercostal retractions is indicative of respiratory distress. (See Chapter 19 for further discussion.) To complete the assessment, the nurse should also note the infant's skin color and assess the capillary refill of his extremities, actions that provide additional information concerning the status of respiratory system functioning.

Now Can You— Discuss components of the neonatal respiratory system assessment?

1. Discuss what parents should be told about breast enlargement in their male infant?
2. Describe the significance of wide spaced or accessory nipples in a neonate?
3. Discuss why palpation is an important component of the neonatal respiratory assessment?
4. Identify the indicators of neonatal respiratory distress?

Assessment of the Cardiovascular System

The nurse assesses the neonate's circulatory system by visual inspection and auscultation. Careful inspection of the skin, lips, gums, and buccal mucosa provides reliable evidence of cardiac perfusion. At rest, the infant's skin should be pink in color and progress to red during crying or physical activity. The nurse palpates the chest to detect any thrills or heaves and the point of maximum impulse (PMI), which is auscultated at the apex of the heart near the third or fourth left intercostal space (Dillon, 2007) (Fig. 18-19). For infants, the normal heart rate should be between 120 and 160 beats per minute. A heart rate above 160 beats per minute is termed tachycardia.

To assess capillary refill in the extremities, the nurse gently pinches the end of the infant's finger or toe and then counts the number of seconds required for the skin to return to its normal color. The average refill time is 3 seconds. If more than 3 seconds lapse, there may be shunting of blood from the periphery toward the infant's trunk.

The nurse palpates all peripheral pulses for bilateral symmetry, strength, and rate. The femoral pulses on each side are carefully checked and compared to the brachial pulses (Fig. 18-20). If a decrease in the strength of the pulse between the brachial pulses and femoral pulses is noted, this finding may be indicative of coarctation of the aorta, a cardiac condition associated with a narrowing of the aortic arch. Since the aorta is the main vessel for transporting oxygenated blood to the upper and lower body, a narrowing of the aortic arch produces a compromise in blood flow and should be suspected when decreased femoral pulses are detected. (See Chapter 19 for further discussion of coarctation of the aorta.)

Figure 18-19 Auscultating the heart.

Figure 18-20 Palpating the femoral pulse.

COMMON FINDINGS. The nurse carefully auscultates all areas of the heart, including the aortic, pulmonic, tricuspid, and mitral valves, along with the base and apex. Since the normal infant heart rate is between 110 and 160 beats per minute, rates higher than 160 beats per minute are consistent with tachycardia; rates lower than 100 beats per minute are termed bradycardia. Either condition, if persistent, warrants further investigation. Heart rate auscultation in the neonate is often difficult due to the thinness of the chest wall combined with the noisiness of heart sounds that are often obscured by respirations. The nurse should listen carefully and take time in counting the heart rate. It is not uncommon to hear murmurs in infants less than 24 hours old. The murmurs are characterized by a sound (best heard near the sternal border at the second or third intercostal space on the left side) that grows louder during systole. Although a heart sound arising from a patent ductus arteriosus may be heard initially, the sound disappears within 2 to 3 days when the ductus closes. If a murmur remains audible after the second day of life and intensifies to a “whoosh” sound, further investigation is warranted, as this finding is not characteristic of a patent ductus and may indicate the presence of another type of heart lesion.

CONDITIONS THAT MAY WARRANT FURTHER ASSESSMENT. Ventricular septal defect (VSD), a condition in which a small hole exists in the ventricle wall between the right and left chambers of the heart, is the most common heart murmur in infants. The VSD produces a sound created by the leaking of blood through the small defect. Interestingly, smaller defects are associated with louder murmurs due to the buildup of pressure in the heart chambers as the blood leaks through with each contraction. Large defects are associated with softer murmurs because the ease with which blood flows through the opening produces little pressure buildup. Most ventral septal defects close with normal cardiac growth during the first year of life and require no surgical intervention. (See Chapter 19 for further discussion.)

Cardiac insufficiency describes a condition that occurs when an infant cannot adequately oxygenate and circulate blood. This condition is characterized by pallor, rapid breathing, and cyanosis around the lips. Pulse oximetry readings should be obtained immediately. Readings of less than 94% oxygen saturation are of major concern and if an infant’s oxygen saturation drops below 90%, rapid transfer to an intensive care unit for continuous respiratory and cardiac monitoring should be accomplished. Cardiac evaluation is carried out and, depending on the findings, treatment may be medical, surgical, or both.

Infants who demonstrate cardiac instability within the first 2 days of life are usually those with a genetic karyotype of trisomy 13, 18, or 21 or **tetralogy of Fallot**. Tetralogy of Fallot is a congenital heart defect that involves four distinct cardiac anomalies: transposition of the aorta and pulmonary artery, right ventricular hypertrophy, pulmonary stenosis, and ventricular septal defect. Infants born with tetralogy of Fallot demonstrate no difficulties until the ductus begins to close after the first 24 hours of life. At that point, the infant experiences severe cardiac instability and develops central cyanosis. Transfer to an intensive care unit allows for intravenous fluids, medications, and continuous cardiac monitoring to be carried out until surgical and medical evaluation can take place. (See Chapter 19 for further discussion.) When any infant is diagnosed with a cardiac problem, the nurse should be sensitive to the parents’ frequently overwhelming feelings of fear and inadequacy and be prepared to offer reassurance, support, and accurate information.

Now Can You— Identify cardiac problems in the neonate?

1. Demonstrate how to assess capillary refill and discuss why this assessment is important?
2. Identify when auscultation of a heart murmur in a neonate is considered to be a normal finding?
3. Describe a ventricular septal defect and discuss the treatment for this condition?

Assessment of the Gastrointestinal System

The nurse begins the assessment by placing the infant in a supine position to facilitate the abdominal inspection. The abdomen should be round and bilaterally symmetrical. The clamped umbilical cord should show no evidence of active bleeding or oozing. It is inspected to confirm the presence of three vessels: two arteries and one vein. If fewer than three vessels are seen, the nurse documents the findings and notifies the physician since this finding may be associated with congenital anomalies. Wharton’s jelly, the gelatinous substance that prevents compression of the blood vessels, may appear as areas of varying amounts of thickness. The abdomen may appear distended due to stool that has not yet been emptied from the bowel. The nurse carefully auscultates all four quadrants of the abdomen for bowel sounds (Fig. 18-21). To facilitate thorough auscultation, each quadrant is divided into small sections to lessen the likelihood that any one area is overlooked. Bowel obstruction in the neonate is often first identified by an absence of bowel sounds in a small, distinct section of the intestines. The nurse completes the assessment with auscultation of the upper abdomen for the gastric bubble and the heart sounds of the abdominal aorta.

COMMON FINDINGS. The nurse uses light, then deep palpation of the abdomen to assess the structure and contents of the abdomen. Light palpation is initiated at the lower sternal border and proceeds along the midline down to the umbilicus. Diastasis rectus, a thinning of the abdominal wall, may be detected. Diastasis rectus can also be identified by the presence of a long, raised “lump” along the midline that becomes prominent when the infant is crying. The nurse assesses the area surrounding the umbilicus for the presence of an umbilical hernia. Using the fingertips to

Figure 18-21 Auscultating bowel sounds.

determine the hernia size, the nurse notes whether it appears to be large or small, and documents this information in the medical record. Small umbilical hernias are common in newborns and often close without surgical intervention as the infant grows. The nurse continues palpation along the midline toward the symphysis pubis to detect any inferior extension of the hernia. Light palpation from the midline is then extended laterally toward the rib cage to assess for masses or enlarged organs.

Deep palpation facilitates examination of the organs. The border of the liver should be smooth and firm and located just below the right costal margin. The spleen, which lies beneath the left costal margin, should be palpable only at the tip. If a larger segment of spleen is palpated, this finding is reason for concern, since it is indicative of organ enlargement. Due to their small size, the kidneys may be difficult to detect. They are located approximately 1 to 2 cm above the umbilicus and are at a right angle to the umbilicus at the midline. The bladder should be present as a smooth organ in the midline below the umbilicus.

CONDITIONS THAT MAY WARRANT FURTHER ASSESSMENT. Findings indicative of a serious abdominal problem in the neonate include the following: abdominal distention, absence of bowel sounds, discharge from the umbilical cord or cord site, and palpation of an abdominal mass. Abdominal distention may involve the entire abdomen or it may be confined to small areas. Abdominal blood vessels may be readily visible in the distended abdomen. The presence of stool in the intestines is frequently detected, and this finding is not a cause for concern. Abdominal bulging that shifts when the infant's position is changed may be indicative of fluid in the abdomen. Absence of bowel sounds indicates an area of bowel that is not functioning; this finding must be immediately reported.

Necrotizing enterocolitis is a life-threatening condition that occurs when a lack of blood flow to the bowel results in destruction of the intestinal mucosa. Loss of bowel function results and toxins are released from the damaged, necrotic tissue. Immediate surgical intervention is required. (See Chapter 19 for further discussion.)

Discharge from the umbilical cord or cord site indicates the presence of infection. Unless a bacteriostatic dye has been used to paint the area, the cord should be pale yellow in appearance. An extra clamp may be applied if blood is actively leaking from the umbilical cord. If meconium was passed in utero, the cord may be stained a gray-green color. The area around the base of the cord should be kept clean and dry. During diapering, care must be taken not to allow stool or urine to come in contact with the cord or the cord base. If this occurs, the nurse should carefully clean and dry the site. The tissue surrounding the base of the cord should be inspected for redness, a finding that may indicate **omphalitis** (an infection that is readily treated with antibiotics).

Palpation to detect an abdominal mass or enlarged organ is usually facilitated by the infant's small abdominal girth. Positive findings require immediate referral for evaluation. Often, an ultrasound examination is conducted to determine the source of the clinical findings and to guide the management. In infancy, abdominal masses are frequently a form of neuroblastoma, a type of tumor that is confirmed by biopsy. The kidneys, liver, and spleen are the organs most commonly enlarged, and these findings can be confirmed with ultrasound. Enlargement may result from obstruction or it may be associated with a congenital malformation.

critical nursing action Recognizing Acute Abdomen in the Neonate

During the neonatal assessment, the nurse is alert to the following symptoms that may indicate acute abdomen:

- Rigid, board-like abdomen
- Inability to palpate abdominal organs
- Indicators of pain (continuous crying, facial changes, gross motor movements)

Now Can You— Identify gastrointestinal problems in the neonate?

1. Demonstrate how to perform the abdominal assessment on the neonate?
2. Identify findings that are associated with serious abdominal problems?
3. Describe two nursing interventions to minimize the risk of infection at the umbilical cord site?

Assessment of the Genitourinary System

The nurse begins the assessment by placing the infant in a supine position with the hips abducted. With the male neonate, the scrotum is examined to confirm that both testicles have descended. If flat or depressed areas are identified, this finding may indicate that a testis has not descended. Palpation of the scrotum is accomplished by placement of the examiner's second finger at the posterior scrotal midline with the thumb on the anterior midline (Fig. 18-22). Using the index finger and the thumb, the nurse palpates the left side of the scrotum for the presence of a testis and then uses the third finger and thumb to palpate for a testis on the right side of the

Figure 18-22 Palpating the scrotum.

scrotum. Proceeding in this pattern helps to ensure that one testis is not mistakenly being “counted” twice. If a testis is not detected, the nurse can softly stroke the inguinal canal in an attempt to locate an undescended testis. Warm soapy water applied to the inguinal area may enhance testicular prominence and help it to be more easily identified. Any infant older than 35 weeks’ gestation who has undescended testicles should be referred for a urological consultation (Dillon, 2007).

Inspection of the female genitalia begins with the labia majora. The extent to which the labia cover the surrounding tissues corresponds with the developmental maturity of the female neonate. For most term infants, the borders of the labia majora touch and the clitoris is covered completely. Occasionally, a full-term infant has delayed genital development, and on examination, the nurse can easily view the labia minora and exposed clitoris.

The anus and anal opening are also assessed at this time. While stooling confirms anal patency, it is beneficial to actually witness the passage of meconium, as it provides an opportunity for the nurse to confirm that the stool passes through only one opening. Stool in the vagina indicates the presence of a rectovaginal fistula, an opening between the rectum and vagina. To palpate the anus, the nurse gently touches the tissue around the anal opening and assesses the musculature surrounding the opening. Tiny rectal tears from the passage of stool in the anal ring are noted and the anal wink reflex is assessed. The infant is placed in a prone position and, using the index finger, the nurse gently strokes the buttocks from side to side. In response, the buttocks draw together and “wink” at the point of the anal opening. This response validates the correct anatomical position of the anal opening. In females, the anal wink reflex is useful in assessing anal openings that are positioned less than 1 cm from the vaginal opening. When the anal opening is located too close to the vaginal opening, proper muscle strength needed to evacuate the rectum as the child grows older does not develop. The wink reflex is also useful in facilitating proper placement of the anal opening during future surgical correction (Dillon, 2007).

COMMON FINDINGS. Careful assessment of genitalia is essential in both males and females. First, the nurse visually inspects, then palpates the male genitalia. Infants of various ethnic backgrounds, especially those of African American heritage, have dark-colored scrotal skin. Scrotal swelling may interfere with an accurate palpation. If swelling is present, it is important to auscultate the scrotum to ensure that it does not hold entrapped bowel.

If no bowel sounds are heard, transillumination can be used to verify the presence of fluid in the scrotal sac. The

nurse secures a penlight or ophthalmoscope, which will be used as a light source; darkens the room; and gently presses the light source against the scrotum. Fluid appears as a reddish yellow reflection. Masses do not transilluminate, and if detected, must be reported immediately. Scrotal fluid is slowly reabsorbed during the first weeks of life and no treatment is necessary. The nurse can reassure the parents that any swelling will resolve over time and the scrotum will gradually take on a more normal appearance.

clinical alert

Bowel sounds in the scrotum

To confirm that no bowel is entrapped in the scrotum, the nurse carefully auscultates the scrotum for bowel sounds. If bowel sounds are present, immediate assistance must be obtained. This is a medical emergency.

The penis is palpated to estimate the approximate length. Penile length in the full term newborn male is approximately 2 cm. The nurse gently retracts the prepuce, or foreskin, to inspect the urethral opening and to determine the location of the opening on the glans. Smegma, a waxy substance, may be present on the glans beneath the foreskin. Instead of the normal round urethral opening, or meatus, a vertical opening may be seen. When present on the ventral (instead of central) surface, this finding is indicative of **hypospadias**. Hypospadias requires surgical repair by a physician. Since the excess foreskin is used to create a properly positioned meatus, males with suspected hypospadias should not be circumcised. **Epispadias** is a similar condition. When present, the vertical urinary opening is located on the dorsal surface of the penis instead of on the glans. Epispadias is also repaired surgically with the use of excess foreskin.

During the inspection of the female genitalia, the nurse may identify vernix caseosa, a whitish, cheesy substance, covering the tissue between the labia. This is a normal finding. The hymenal tag, a small piece of triangle-shaped tissue, may also be present between the labia. The nurse gently palpates the labia majora and labia minora, an action that facilitates examination of the hymenal area. Small amounts of blood and whitish mucoid discharge (“pseudomenstruation”), related to the maternal hormones, may be noted in the vaginal area. Parents can be assured that this discharge is normal and will disappear in about a week. Smegma may also be present between the labia.

CONDITIONS THAT MAY WARRANT FURTHER ASSESSMENT.

When examining the male genitalia, the nurse may note the presence of bruising or swelling, especially if the infant was delivered in a breech presentation. Careful palpation facilitates the scrotal assessment, conducted to confirm that both testes have descended. Inspection and palpation of the penis includes assessment of the penile length. Micropenis, a penis that is less than 2 cm in length, may be associated with a pituitary tumor. Ambiguous genitalia describes a condition where the male has genital structures that mimic labia or the female has a structure similar to a penis. If the definite genitalia cannot

be determined, the infant is referred for genetic studies and evaluated for adrenal gland insufficiency. In situations of ambiguous genitalia, the nurse must be careful not to prematurely label an infant as a “boy” or “girl,” to avoid compounding the parents’ confusion. It is important that the nurse approach the parents with sensitivity and compassion.

“What to say” — Infant with ambiguous genitalia

Despite the initial birthing room determination of the neonate’s gender, careful later examination of the genitalia may prompt concerns regarding the true sex assignment. It is important to promptly alert parents of the need for further testing for gender determination. The nurse can address the parents’ concerns with reassuring statements such as:

“Since there is some question regarding your baby’s sex organs, the doctor has asked a specialist to examine your baby. Additional testing may be indicated. You may want to wait to name your baby until we know for sure. For now, it is important to spend as much time as possible with the baby as you get to know one another.”

In the assessment of the female genitalia, most concerns center around the presence of an enlarged clitoral hood and the finding of an imperforate hymen. Although maternal hormones may produce slight clitoral enlargement, a hood-shaped, grossly enlarged clitoris may be related to excessive androgen production. Since this condition may signal congenital adrenal hyperplasia, further evaluation and testing should be performed. The infant’s genitalia may also be edematous from birth trauma, making the examination difficult. The nurse should gently separate the labia and inspect the area for the location of the urethral and vaginal openings. Imperforate hymen is present when tissue obstructs the vaginal opening, necessitating later surgical correction to allow for the discharge of menstrual blood.

Male and female infants may have anal ring skin tags or an anal ring that has no opening. The skin tags are hemorrhoid-like tissues that can cause discomfort or bleeding when the infant stools. The absence of an opening in the anal ring is a condition known as **imperforate anus**.

The finding of imperforate anus constitutes a medical emergency since the infant is unable to pass stool through the anus. In approximately half of the infants with this condition, the imperforate anus occurs as an isolated event unrelated to any congenital syndrome. In the other half of occurrences, the imperforate anus is a part of a congenital syndrome associated with anal malformations, called the VATER association. At least three of the major abnormalities must be present for diagnosis. The overall prognosis is improved following the surgical correction of each anomaly. Characteristics of VATER association in the newborn include:

- V** = vertebral abnormalities
- A** = anal abnormalities (imperforate anus)
- T** = tracheal abnormalities

critical nursing action Recognizing the Infant with Imperforate Anus

The nurse observes that Infant Gracie has not passed a meconium stool since her birth 26 hours ago. Infant Gracie has been breastfed several times and her mother reports that her baby is a “ready feeder” who is “always hungry.” The mother states that she has not changed her baby’s diaper. The infant’s abdomen appears distended and feels firm on palpation. The nurse recognizes that these clinical findings may be indicative of imperforate anus and immediately notifies the physician.

The nurse’s careful assessment of the neonate’s genitalia has far-reaching implications. The findings from this examination form the foundation for future parental interaction with their newborn. While gender determination is briefly addressed at the time of birth, the nurse who later conducts the thorough assessment is responsible for identifying any problems and seeking appropriate consultation. The nurse must remain sensitive to the parents’ concerns and be ready to correct any misinformation that might affect the parents’ ability to relate to their infant in a positive manner.

Now Can You— Identify genitourinary conditions in the neonate?

1. Describe how to assess for undescended testes in the male infant and discuss the significance of this finding?
2. Describe the procedure for performing a transillumination of the scrotum and identify when this examination is used?
3. Name the two most common problems that affect the female genitalia?
4. Discuss how the infant is assessed for imperforate anus and describe the treatment for this condition?

Assessment of the Musculoskeletal System

The nurse can readily assess the functioning of the musculoskeletal system by observing the newborn in the crib where the infant has the freedom to continue and expand movements first initiated in utero. By flexing and extending the arms and legs, sucking on the fingers, and moving the head from side to side, the neonate provides a visual display of his musculoskeletal status. Any compromise in movement alerts the nurse to the location of possible birth trauma or other injury. Inspection of the extremities for differences in length or size is an important component of the assessment. Positive findings may be indicative of achondroplasia, a congenital condition characterized by a small thoracic area, an inability to extend the elbows and a marked shortening of the femurs and humerus. Often referred to as “dwarfs,” individuals with achondroplasia frequently have neurological and respiratory problems in addition to their skeletal deformities.

To assess muscle tone and strength, the nurse first places the infant in a supine position and then in a prone position. If the infant is unable to move the lower extremities, damage to the spinal cord is suspected. Asymmetry in movement suggests nerve damage or fracture related to birth trauma. If the infant does not move or appears floppy when repositioned, the nurse suspects hypotonia, or diminished muscle tone. Hypotonia may be related to an episode of anoxia, either during birth or while in utero. Increased muscle tone, or hypertonia, is characterized by

muscle tremors, twitches or jerkiness, and this finding is often associated with neonatal abstinence syndrome. Symptoms of drug withdrawal are manifest through the increased muscular movements.

COMMON FINDINGS. After the visual inspection, the nurse begins palpation of the musculoskeletal system. Starting with the shoulders, the examination progresses downward toward the lower extremities. The muscles and joints are assessed for symmetry and gentle passive range of motion is used to evaluate joint rotation. Rotation of the neck is the first and most important rotation assessed. Passive range of motion should confirm the infant's ability to accomplish full rotation of the neck. Failure to achieve full rotation may be related to torticollis or to the congenital absence of portions of the cervical vertebra. Normal growth and development in infants is enhanced by their ability to turn the head toward the location of sound and then follow the auditory cue with their eyes. Thus, normal neck rotation plays an important role in the refinement of hearing and in the development of sight. To assess head lag, the nurse carefully pulls the infant up while watching the head gently fall back (Fig. 18-23). This maneuver also provides an opportunity to inspect the neck for bulging of the thyroid gland and for assessing the muscle tone of the upper body along with shoulder and arm strength.

The nurse's attention is next directed toward assessment of the hip joint, the second most important joint evaluation in the neonate. **Developmental dysplasia of the hip** (DDH) is a congenital condition that, left untreated, can affect the infant's future ability to walk and maintain balance. It occurs when the acetabulum is flat, rather than round and cup-like in shape. DDH most often results when the developing fetus assumed a dominant breech position with upwardly extended legs during the period of bone growth. The assessment begins with inspection of the skin folds on the infant's thighs in both the prone and supine positions (Fig. 18-24).

Asymmetry of the skin folds may signal the presence of hip dysplasia. The nurse also assesses the leg length and knee height for unevenness. Next, the nurse slowly moves the infant's lower extremities in a kicking motion while observing for signs of pain or distress. The nurse's hands are placed on the infant's thigh with the fingertips around the femur head while the thumb and index finger stabilize the knee joint. While maintaining this position, the nurse performs the Barlow maneuver by exerting a downward pressure on the head of the femur in an attempt to dislodge the femur head from the acetabulum (Procedure 18-3). The Ortolani maneuver involves a circular rotation of the

Figure 18-23 To assess head lag, the infant is gently pulled up as the nurse observes his head fall back.

Figure 18-24 Inspecting gluteal skin folds.

femoral head or an inward–outward action that attempts to reposition the femur head that was displaced by the Barlow maneuver. In the normal neonate, the hip joints move easily and it is not uncommon to detect crepitus, or a slight grinding (known as a “hip click”) when the femur head is manipulated in the socket (Dillon, 2007).

It is not unusual to detect hip dysplasia in infants who maintained a breech position in utero or who were delivered vaginally in a breech position. Hip dysplasia can be confirmed by a noticeable difficulty when moving the leg in the hip joint and also by feeling the head of the femur pop out of the hip socket, sometimes referred to as a “hip clunk.” Often, infants who were in a breech position in utero have hyperextended knee joints that can give the appearance of hip dysplasia. However, subsequent examination confirms that the head of the femur remains firmly secured in the acetabulum. Parents can be assured that over time, the infant's legs will return to the normal flexed position. The nurse may also detect a “looseness” in the infant's hip joint despite a normal evaluation that shows no evidence of hip dysplasia. This finding is related to the maternal hormones that create a joint flexibility not only in mothers but in their infants as well.

Developmental dysplasia of the hip, once confirmed by x-ray exam, is managed by the placement of a special splint to keep the infant's legs in a position of abduction. The Pavlik harness, the most widely used device, does not rigidly immobilize the hip but acts to prevent hip extension or abduction. The harness is worn continuously for approximately 3 to 6 months, until new bone growth has formed around the head of the femur and a normal cup-shaped hip joint has been created.

To assess the remaining joints, the nurse performs passive range of motion and also continues to observe the infant's spontaneous movements in his crib. It is not uncommon to identify unusual positions of the foot, and these findings are most often related the infant's position in utero. Pronation, or inward turning, of both feet is common and the nurse can demonstrate to the parents how gentle stroking of the infant's insoles prompts a ready return to a normal position. When the foot is severely pronated, spontaneous normal alignment may be unattainable. In this instance, an evaluation of the posterior alignment of the infant's heel and knee is conducted. Club foot, suspected when there is a medial displacement of the heel from the posterior knee alignment, can be confirmed by x-ray exam. Soon after a diagnosis of clubfoot, a cast is placed on the affected extremity to restore proper alignment. The nurse should demonstrate how to safely stabilize the cast when holding the infant and teach the parents how to care for the cast.

Procedure 18-3 Performing the Barlow–Ortolani Maneuver

Purpose

To assess for developmental dysplasia of the hips

Equipment

None

Steps

1. Place the infant supine on a flat surface.
2. Place your thumbs on the infant's inner thighs and your fingers on the outside of the greater trochanters of the hips.
3. Flex the infant's knees and move the legs inward until your fingers touch.
4. Using gentle but firm pressure, rotate the hips outward so that the knees touch the flat surface. No clicking or crepitus should be detected.

3. Flex the infant's knees and move the legs inward until your fingers touch.

RATIONALE: The presence of clicking or crepitus indicates joint instability.

-J. Yamato, RN

CONDITIONS THAT MAY WARRANT FURTHER ASSESSMENT.

Before performing the musculoskeletal assessment, the nurse first must determine that there are no broken bones. It is important that the infant not be moved or repositioned until this has been accomplished. In the neonate, the clavicle is the bone most commonly fractured. The injury occurs during birth when the infant's shoulders do not readily rotate. The nurse should palpate the clavicles to check for a separation between the bone ends or for the presence of crepitus. Signs and symptoms of fractures include swelling at the fracture site, bruising, or discoloration of the affected area and the infant's expression of discomfort when moved. Other common sites for neonatal fractures are the ribs, humerus, and skull. An x-ray exam is used to confirm the diagnosis. Clavicular fractures heal over time without intervention and the nurse can teach the parents to position the infant on the side opposite the injury and how to hold and support the infant's head and shoulders until healing is complete. Casts are usually applied to humeral fractures while rib fractures are generally wrapped. Infants with skull fractures are most often cared for in the intensive care unit where they can be continuously monitored.

Sometimes, infants are born with extra digits (fingers) and toes (**polydactyly**) or with what appears to be

webbing of the skin between the digits and toes (**syndactyly**). On the hand, the extra digits often are located below the fourth finger and are attached to the palm by a thin line of skin. They may resemble the fourth finger and may even contain a fingernail. The nurse should palpate all extra digits for the presence of bone, which must be surgically removed. If no bone is present, the digit may be tied off with suture silk to occlude the capillary to cause necrosis and loss of the digit. Polydactyly is often a family characteristic and parents may recall other family members who were born with extra digits or toes. Webbing of the toes does not interfere with balance or walking, and parents may not wish to have their infant's toes surgically released from one another. Webbing of the fingers is often surgically corrected to facilitate dexterity and for cosmetic reasons.

The nurse inspects the palms of the hands for the presence of palmar creases. The hands of a normal neonate usually contain three or four curved palmar creases. A **simian crease** is a single, straight crease that appears in the middle of the palm on one or both hands (Fig. 18-25). When unaccompanied by other findings, the simian crease is insignificant. However, when detected along with other symptoms, a simian crease may be associated with other syndromes, such as Down syndrome.

Figure 18-25 A. Normal palmar crease. B. Simian crease.

Now Can You— Complete a neonatal musculoskeletal assessment?

1. Identify the most important joints to assess in the neonate and describe how the assessments are performed?
2. Discuss the management options for an infant with developmental dysplasia of the hip?
3. Describe the significance of polydactyly and syndactyly?
4. Recognize why the discovery of a simian crease prompts further investigation?

Assessment of the Neurological System

The physical assessment of the neonate concludes with the nervous system and reflexes. During this assessment, the nurse focuses on the reflexes and other movements that provide an indication of the infant's level of neurological function. It is helpful to divide the reflexes into two broad categories: major reflexes (reflective of normal neurological function) and minor reflexes (finger grasp, toe grasp, rooting, sucking, head righting, stepping and tonic neck). The major reflexes include the gag, Babinski, Moro, and Galant reflexes. Methods for assessing the various reflexes are displayed in Table 18-2.

The finger or palmar grasp reflex is assessed by observing the infant curl the fingers around an object (often the nurse's finger) that has been placed in the palm. The toe or plantar grasp is assessed in the same manner, by placing an object across the sole of the foot. The nurse observes the rooting and sucking reflexes by stroking the infant's cheek and watching him turn toward the finger, open the mouth, and suck on an object placed in the mouth. The head righting reflex is elicited by lifting the neonate in the prone position and then gently stroking the back in the midline, along the spinal cord. With this action, the normal infant attempts to raise the head and arch the back at the same time. To assess the stepping reflex, the nurse holds the infant in an upright position with the legs flexed. The soles of the feet are lightly brushed against a flat surface. In response to the stimulation, the infant lifts his feet and then places them back down in a stepwise pattern that imitates walking. The tonic neck or "fencing" reflex is observed with the infant in a supine position. The nurse observes the infant extend the arm and leg on the side to which the head and jaw are turned while flexing the arm and leg on the opposite side.

To assess the major reflexes, the nurse progresses methodically, taking care to document and record each finding. For the infant to successfully eat and move fluid away from the back of the throat without choking, the gag reflex must be intact. The Babinski reflex is demonstrated

by lightly stroking the plantar surface of the foot from the heel toward the toes. The infant responds to this stimulation by first incurving the toes, then uncurling and stretching them out. The nurse can assess the **Moro reflex** at the same time as the head righting reflex is elicited. As the infant's head is lifted, the nurse mimics a release and watches for extension of both arms along with flexion of the legs, movements that confirm the Moro reflex. In the past, the examiner often assessed the Moro reflex by creating a loud clapping sound near the infant in an attempt to startle him. This method of assessment is not reliable. The infant's response to the clapping stimulus may not be consistent with the Moro movements because the infant could be reacting to the movement of air across his body as the examiner makes the clapping sound, or to the sound of the clap itself. The Galant reflex, also called the trunk incurvation reflex, is elicited as the infant is held or supported in a prone position. One side of the vertebral column is then stroked. The infant responds to this stimulus by moving the buttocks in a curving motion toward the side that is being stroked.

CONDITIONS THAT MAY WARRANT FURTHER ASSESSMENT. The most frequently seen neurological injuries in the neonate involve the brachial plexus and are related to difficulties with shoulder rotation and delivery at the time of birth. The nurse must differentiate these injuries from shoulder dystocia, which is identified by a temporary decrease in the movement and muscle tone of a shoulder and upper arm. Injury related to shoulder dystocia rapidly improves after delivery.

Erb's palsy is one form of brachial plexus injury that is readily identified from the positioning of the infant's arm while in the supine position. When Erb's palsy is present, one or both arms and hands are extended and do not move into a flexed position. On palpation, the nurse notes a decrease in muscle tone, a decreased grasp reflex and an absence of arm recoil on the affected side. Sometimes called the "waiter's position," the position is reminiscent of a waiter who keeps one arm by the side while the other is held out for a tip.

Most injuries involving the brachial plexus resolve in approximately 2 weeks without treatment. The infant should be positioned with the arm in a gently flexed position and when held, care should be taken to support the arm on the affected side. The nurse should teach parents how to use gentle exercise to facilitate the healing process. Simple arm strengthening exercises that passively flex and extend the infant's arm can be practiced during each parent–infant interaction.

Infants with major neurological problems that have occurred during embryonic or fetal development, or result from events during the birthing process are assessed in the neonatal intensive care unit. Severe damage that affects the brain or muscle movement may be associated with periods of anoxia (lack of oxygen) that occurred during fetal growth or during the birth process. Cerebral palsy is one condition that results from oxygen deprivation. Infants with cerebral palsy often demonstrate a number of motor difficulties, such as difficulty swallowing, breathing, or moving. The length of the anoxic period corresponds with the severity of brain damage. When caring for infants with cerebral palsy, the nurse may deal with a spectrum of difficulties that ranges from minimal limitation to a total loss of reflexes and controlled body movements.

Table 18-2 Newborn Reflexes**Palmar Grasp**

The infant curls his fingers around an object.

Toe or Plantar Grasp

The infant curls his toes around an object that has been placed at the sole of the foot.

Rooting and Sucking Reflexes

Stroke the infant's cheek and watch him turn toward the finger, open his mouth and suck on an object placed in his mouth.

**Extrusion Reflex**

Touch the tip of the infant's tongue and the tongue will protrude outward.

Table 18-2 Newborn Reflexes—cont'd

Stepping Reflex

Hold the infant in an upright position with the legs flexed. The soles of the feet are lightly brushed against a flat surface. In response to the stimulation, the infant lifts his feet and then places them back down in a stepwise pattern that imitates walking.

Tonic Neck or Fencing Reflex

Observe the infant, in a supine position, extend his arm and leg on the side to which his head and jaw is turned while flexing his arm and leg on the opposite side.

Glabellar Reflex

Tap on infant's forehead and observe him blink for the first few taps.

Babinski Reflex

Lightly stroke the plantar surface of the foot from the heel toward the toes. The infant responds to this stimulation by first incurving the toes, then uncurling and stretching them out.

Moro Reflex

Observe the infant's head as it is lifted while the nurse mimics a release and watches for extension of both arms along with flexion of the legs.

Table 18-2 Newborn Reflexes—cont'd**Magnet Reflex**

With the infant in a supine position, flex the leg and apply pressure to the soles of the feet. Observe the infant extend his legs against the pressure.

Galant Reflex or Trunk Incurvation Reflex

Observe the infant while supported in a prone position. Stroke one side of the vertebral column. The infant responds to this stimulus by moving his buttocks in a curving motion toward the side that is being stroked.

Crawling Reflex

Place infant on his abdomen; observe him attempt to crawl.

Crossed Extension

With the infant in a supine position, stimulate one foot; observe flexion, adduction, and then extension of the opposite leg.

In utero development of the brain and spinal cord is a process initiated during the embryonic period. During the first 30 days of gestation, the primitive neural tube closes. A failure of the tube to close at the posterior end results in an open area that may be filled with fluid or with a section of the spinal cord. This condition, called spina bifida, is usually detected during routine maternal–fetal antenatal testing. When the infant is born, the lesion of spina bifida resembles a skin-covered sac located between the fifth lumbar and first sacral vertebrae. The sac, which may contain the dura mater and spinal fluid, is called a **meningocele**. This condition usually does not cause any loss of motor function, or paralysis, below the waist. A more serious lesion is the **myelomeningocele**. When present, a myelomeningocele is a sac that contains dura mater, spinal fluid and a portion of the spinal cord. Individuals with a myelomeningocele have no bladder or bowel control and there is a loss of motor function below the waist.

Treatment of spina bifida is related to the location and extent of the lesion. Most often, the sac is surgically closed to prevent infection. Spina bifida occulta is a mild variation of spina bifida. In this condition, there is a small defect in the spinal vertebrae. However, since there is no protrusion of the dura mater, spinal fluid, or spinal cord, all motor activity remains intact.

An incomplete closure of the anterior portion of the neural tube causes a condition known as **anencephaly**. Lack of closure in this location causes portions of the brain, forehead, skull, and occiput to be missing. Infants born with anencephaly are usually placed on respirators and monitored to assess viability. When caring for the mother and her family, the nurse must be extremely sensitive to the emotional impact associated with this condition and offer the parents privacy and support.

Now Can You—Complete a neonatal neurological assessment?

1. Identify the major and minor reflexes in a neonate?
2. Demonstrate how the Moro reflex is elicited and describe why this assessment is performed?
3. Recognize the signs of a brachial plexus injury?
4. Describe two types of neural tube defects?

Enhancing the Neonate's Transition to Extrauterine Life

The newborn's adaptation to extrauterine life is an amazing and complex process. In the early days of adjustment as well as through infancy, newborns need significant physical, emotional, and spiritual care. Mothers and other caregivers must learn the essential aspects of newborn care in order to promote optimal infant growth and development. Critical aspects of physical care include bathing, clothing, diapering, and feeding the infant. It is also important that parents' discharge instructions provide easy to understand information about the proper care of the infant's nails, umbilical cord, and, when appropriate, the circumcision. Bonding with the newborn is essential for emotional care and the beginnings for spiritual development are established by building trust through relationships with the primary caregiver. Parents must be educated about the

importance of timely metabolic screening for the newborn, since many life-threatening problems can be detected early enough for effective intervention.

TEMPERATURE ASSESSMENT

To prevent dangerous heat loss in the infant, nurses, mothers, and other caregivers need to understand how to protect the infant from extreme temperature fluctuations during bath time. In the hospital before the bath is given, it is important to take the newborn's temperature to ensure stability.

Temperature may be assessed by several methods. The axillary skin method, which is reflective of the infant's core temperature and the body's compensatory response to the environment, is the preferred noninvasive method that provides a close estimation of the rectal temperature. Although rectal temperature represents the closest approximation of core temperature, this route is not recommended because of the possibility of irritation and perforation of the rectal mucosa. The infant's temperature may also be assessed with a continuous skin probe (especially useful with small newborns or infants placed in incubators or under radiant warmers) or via tympanic thermometer, a portable sensor probe that is placed in the ear canal. This method employs infrared technology to measure the temperature of the internal carotid artery blood flow. As long as the temperature is maintained between 97.5° and 99°F (36.4°–37.2°C), the bath can be given. At home, it is not necessary to take the temperature before bath time.

BATHING THE NEWBORN

When bathing the newborn, the bath should take place in a warm area free from drafts. The newborn can be given a sponge bath using only warm water for the first few days of life. After the cord stump has dried completely and fallen off in approximately 2 weeks, the infant can be immersed in a small tub filled with about 4 to 5 inches of water.

Optimizing Outcomes—Ensuring safety for the newborn

It is paramount to remember that wet newborns are slippery! The nurse and parents must keep a firm hold on the baby, and continuously support the head up out of the water. When instructing new parents about the bath it is important that they understand that it is never acceptable to leave any child unattended near water, even a small amount of water. Submersion injury is the second leading cause of accidental death in children.

Newborns do not require a daily bath; bathing them once a week is adequate. However, the face and hands can be wiped off daily. The infant's bottom and genital area should be cleansed several times during the day. Because the newborn's skin may be sensitive, a mild, unscented soap is recommended for the bath. The initial bath after birth takes place after temperature stabilization. The procedure for the bath after birth and at home is fairly simple. The bath should proceed from head to toe. Parents must understand that good hygiene, including clean clothes, hair, nails, and teeth is important in promoting proper growth and development for their infant. At home, newborns can be placed in 4 to

5 inches of water in a small nonskid surface infant bathtub. Infants who are immersed in water for bathing have a tendency to be calmer and quieter and experience less heat loss than infants who are sponge bathed. Immersing the infant's body with water facilitates thorough distribution of the water to ensure even temperature and decreased evaporative heat loss. Benefits of immersion include a soothing feeling, hydration to the skin, and tactile stimulation.

If dry skin is a problem, baths may be given less frequently and a moisturizing lotion can be applied after the infant is dried. Since the newborn's skin can be sensitive to scented lotion, it is best to use an unscented product. Bath time is an ideal time for the nurse to assess the newborn's physical condition, muscular activity, behavior, state of arousal and alertness, and the act of showing parents how to properly bathe their infant provides a perfect opportunity to observe and encourage maternal and family bonding.

NAIL CARE AND UMBILICAL CORD CARE

Newborn nails are rarely trimmed in the hospital or birthing center in the initial days of life due to the increased potential for injury to surrounding tissue that may result in infection. After about a week, the nails more readily separate from the skin and often break off naturally. In the early days, to prevent the infant's nails from scratching the face, filing the nails with a fine emery-textured board or covering the infant's hands with a cuffed T-shirt or mittens are safer options. However, covering the hands should be avoided if possible because this action prevents the infant from sucking on the fingers for self-consolation. In the home, parents may continue to file their newborn's nails or they may be taught how to carefully trim them, often while the infant sleeps.

The umbilical cord appears as a gelatinous white stump with two arteries and one vein. Immediately after birth, the cord is cut with a sterile scissors and clamped. Goals of cord care center on the prevention and early detection of hemorrhage or infection. Because it provides an excellent medium for bacterial growth, the cord stump is a potential source of infection (Miller & Newman, 2005). The Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN) recommends that the cord initially be cleaned with sterile water or a neutral pH cleanser and thereafter with water (AWHONN, 2001). The cord begins to dry out in approximately 1 to 2 hours. The cord clamp must remain in place for 24 hours when it can be removed with a special cord clamp remover. By the third day, the cord appears to be discolored and shrunken. By 10 to 14 days, the cord has usually detached completely and parents often find the remnants in the infant's diaper or on the bedding.

Optimizing Outcomes— Teaching parents about umbilical cord care

Information regarding umbilical cord care should be included as a component of discharge teaching. Parents are taught about the cord's normal appearance and shown how to fold and position the diaper below the cord stump. Remind parents to keep the area free from urine and wetness during bathing and when to expect complete cord detachment. It is also helpful to alert them to potential danger signs such as bleeding or a foul odor.

CLOTHING

Understanding the concepts of thermoregulation is also important when clothing the newborn. In the hospital or birthing center, the infant often wears a T-shirt, diaper, and booties. Frequently, two or three blankets and a hat are required to help the newborn maintain body temperature within a normal range.

Nursing Insight— Importance of temperature assessment

If the newborn's temperature drops to 97.5°F (36.4°C) or below, it is essential that the nurse immediately initiate temperature stabilization measures such as skin-to-skin contact by placing the infant directly on the mother's unclothed arms, chest, or abdomen or move him to a radiant warmer. When the newborn's temperature reaches 98.6°F (37.0°C) or above, he can safely be dressed in a T-shirt and hat and covered with two or three blankets.

At home, the type and amount of clothing for the newborn is dependent on the local climate and temperature. The infant can be dressed like other family members are dressed; that is, appropriate for the temperature and season. Special attention should be given when the newborn is outdoors. A cap or bonnet decreases body heat loss and protects the newborn from dangerous sun rays and wind drafts to the ears. During warm weather, babies should be covered in lightweight clothing and placed in shady spots when outdoors.

clinical alert

Protecting the infant from the sun

While specially formulated sunscreens especially made for infants are available, it is important to advise parents to check with their health care provider about use of these products. Many health care providers do not recommend use of sunscreens until the infant is at least 6 months of age.

DIAPERING

Many families prefer the convenience of disposal diapers, which vary in style, size, functionality, and cost. It is important to remember that the infant's sensitive skin may react adversely to the perfume in the diaper. If diaper rash or dermatitis occurs, parents can be advised to try another brand of diaper, but should contact their health care professional if the problem persists. Other parents prefer cloth diapers, which may be provided by a commercial diapering service or personally purchased and laundered. Parents need to be taught that cloth diapers must be laundered separately from other clothing articles, using $\frac{1}{4}$ cup detergent. Presoaking is often necessary to remove stains. When teaching parents about the advantages of breastfeeding, remember to include information that a breastfed baby's stools do not have an odor or cause diaper stains.

Ethnocultural Considerations— Diapering Practices

While diapering practices vary widely according to personal preference, custom, or culture, the nurse can teach the caregiver from any culture how to prevent diaper rash:

- Keep the baby's diaper area clean and dry.
- Change the baby's diaper often.
- Carefully clean the baby's bottom between diaper changes, using a mild soap and plain warm water.
- During a wet or soiled diaper change, allow the baby's skin to dry completely before putting on another diaper.
- Allow the baby to go without a diaper whenever possible to let the air dry the skin.
- If diaper rash persists, contact the health care provider.

FOSTERING ATTACHMENT

Attachment describes a mutually reciprocal relationship that takes place between the parents and their infant during the moments after birth. Attachment is critical to the child's ongoing optimal growth and development. One of the nurse's most important roles is observing for healthy attachment behaviors and helping the family to establish a good relationship with their infant. By observing parental behaviors and engaging in meaningful dialogue with the mother and father, the nurse may uncover important cues that could have an impact on the infant's growth and development. Remember that after 9 months of pregnancy and perhaps a difficult labor and birth, parents often feel tired and overwhelmed with the realization that their newborn is totally dependent on them. They may be too embarrassed to ask questions or clarify information previously given to them. The nurse must create a non-threatening and nonjudgmental environment in which parents can openly express ideas and ask questions. An important concept for the nurse, mother, and other caregivers to understand is that healthy bonding is essential for adequate physical, emotional and spiritual growth. Early infancy is an ideal time to establish a trusting relationship between the newborn and the primary caregiver.

“What to say” — *Questions the nurse can ask the mother to assess attachment*

On the first day after giving birth, a the mother states that she doesn't want to hold her baby. The nurse responds by asking...

- Can you tell me more? Are you in pain? Are you feeling sleepy? Are you afraid?
- Does your baby have a name yet?
- Do you have any concerns about basic care for your baby such as holding, feeding, diapering, or bathing?
- How will you respond when your baby fusses or cries?

Minutes after the infant's birth, most parents are given an opportunity to spend quality bonding time with their newborn. To accurately assess this first expression of

Family Teaching Guidelines... Promoting Family Attachment

Nurses can promote family attachment in many ways:

- ◆ Provide time in the first few hours after birth for privacy and time for the new family to get to know one another.
- ◆ Delay any unnecessary procedures immediately after birth, such as measurements and other admission procedures. Instead, allow the family adequate time alone after birth to spend time getting to know one another.
- ◆ Encourage early breastfeeding by providing proper education and support.
- ◆ Teach parents about infant behavioral cues for feeding (rooting, sucking on their fingers or fist, increasing motor activity, or crying) and how to respond to them.
- ◆ Help parents understand that crying is the infant's way of communicating, and all newborns have distinguishable cries for hunger, pain, tiredness, fussiness, or getting attention.
- ◆ Teach parents that newborns have a built-in capacity to console themselves and do so by sucking, motion, and distraction.
- ◆ Help parents to recognize the joys and frustrations that go along with ongoing parenting. Assure them it takes time to feel comfortable in meeting their newborn's unique needs.
- ◆ Introduce the concept of anticipatory guidance to help prepare parents for important developmental milestones that will occur.
- ◆ Encourage the parents to invite siblings and other family members to visit for short periods of time to share the joy and to provide support.
- ◆ Provide consistent nurses during the hospital or birthing center stay.

parent–infant attachment, it is important for the nurse to watch for and understand the behaviors commonly observed. Mothers and fathers usually begin with an exploration of their infant's physical characteristics. First, they examine each tiny fingertip. Next, they carefully explore their baby's extremities. Finally, they view and softly stroke the full length of the infant's trunk. During this entire process, the parents assume the **en face** position where they establish and maintain direct visual contact with their infant (Fig. 18-26). This initial exploration of gentle touch, coupled with reciprocal eye contact, helps to lay the foundation for a loving bond between the parents and their infant.

Nurses can be instrumental in facilitating a healthy parent–infant attachment. Taking time to teach, provide assistance when needed and listen to concerns help encourage and foster healthy parenting skills and enhance the newborn's potential for optimal growth and development.

Figure 18-26 The en face position allows parents and their newborn eye-to-eye contact.

Ethnocultural Considerations— Accepting customs and traditions

It is important for nurses who work with childbearing families from various ethnic backgrounds to be aware of differences in cultural beliefs and practices related to pregnancy and newborn care. While many facets of the Western lifestyle may be readily adopted, families from other countries often wish to preserve certain customs and traditions brought from their native countries. Not surprisingly, valued health beliefs frequently extend to the area of infant care. For example, persons of the Latin American or Filipino cultures may apply an abdominal binder or protective “belly band” to the infant’s umbilical stump to protect against dirt, injury, or hernia. Cradle boards may be used by Native American mothers, notably the Navajos, to carry the infant and maintain close contact. Persons of Iranian heritage may breastfeed female infants longer than male infants. Some Asians, Hispanics, Eastern Europeans, and Native Americans delay the initiation of breastfeeding because of the belief that colostrum is “bad” (D’Avanzo & Geissler, 2003; Dillon, 2007).

CIRCUMCISION

Circumcision is a surgical procedure that involves removal of the foreskin on the glans penis. Although commonly done to promote hygiene and easier cleaning, circumcision may primarily be requested because of family tradition or social and cultural factors. Historically based on a religious rite of passage from the Jewish and Muslim traditions, circumcision has gained widespread acceptance in the United States.

The 1999 American Academy of Pediatrics circumcision policy statement indicated that it is important that parents be knowledgeable about this surgical procedure. The policy advises that physicians give parents correct and impartial information about the benefits and risks and that they understand that circumcision is an elective procedure. Parents need to have the opportunity to examine all of the facts surrounding circumcision, ask questions,

and then without pressure from health care professionals, decide whether or not to have their baby circumcised (Ressler-Maerlender & Sorensen, 2005). The American Academy of Pediatrics Task Force on Circumcision: Circumcision Policy Statement (1999) also recommends that if parents choose to circumcise their infant, appropriate analgesia be provided. Bleeding, infection, dehiscence (separation of the approximated edges of skin), and trauma are complications that can be associated with the procedure.

Nursing Insight— Factors that may influence the parental decision for infant circumcision

The American Academy of Pediatrics Task Force on Circumcision (1999) concludes that although there are associated risks (i.e., hemorrhage, infection, penile injury), circumcision does provide some benefits for the infant (e.g., reduced incidence of urinary tract infections and decreased risk for sexually transmitted infections, penile cancer, and human papilloma virus [HPV] infection). Additional reasons for choosing infant circumcision may include the parents’ desire to ensure that their son’s body likeness is consistent with that of peers from the same area, region, or country, and to avoid complications that are associated with circumcision performed on a child who is older than 1 month of age.

While the surgical removal of the foreskin is a fairly simple procedure that can take place in either in the hospital or community setting, it must be performed using sterile technique. The infant is restrained on a board or chair. Hospitalization is necessary if the infant is older than 1 month. The newborn must be stable and a physical examination by a physician or other health care provider should have been completed before the circumcision. The procedure involves removing the prepuce, which is the epithelial layer of skin on the penis. This small piece of skin is separated and removed from the glans penis. Newborn circumcision is frequently performed with the use of a surgical device such as the Gomco or Yellen clamp or the Mogen clamp. Once the procedure is completed, a

where research and practice meet: Providing Pain Management During Circumcision

Three types of pain management can be used for circumcision. A ring block is considered the most effective method (buffered lidocaine is subcutaneously injected on each side of the penile shaft). Alternatively, a dorsal penile nerve block (DPNB) (buffered lidocaine is subcutaneously injected at the 2 o’clock and 10 o’clock positions at the base of the penis) may be used. In other settings, a topical anesthetic such as prilocaine-lidocaine cream (i.e., eutectic mixture of local anesthetic [EMLA]) is applied to the base of the penis 1 hour before the procedure (Weise & Nahata, 2005). Nonpharmacologic interventions such as non-nutritive sucking, swaddling, and containment, along with oral acetaminophen and a concentrated oral glucose solution may also be used. Research has shown that a combination of swaddling, ring block or DPNB, topical anesthetic, nonnutritive sucking, oral acetaminophen, and a concentrated solution of oral sucrose given during the procedure by syringe or applied to a pacifier or nipple provides the most effective pain relief (Anand et al., 2005).

petrolatum gauze dressing is applied for 1 to 2 days to prevent the diaper from adhering to the surgical site. Another method involves use of the PlastiBell device, which is fitted over the glans and remains there until it falls off in approximately 5 to 7 days (Fig. 18-27). No petrolatum gauze dressing is used after circumcision with a PlastiBell device (Glass, 2005). Nursing care for the circumcised newborn focuses on alleviation of pain and the prevention of infection. Parent/caregiver education is also an important component of care. Therapeutic touch is a beneficial comfort measure for all infants and is especially useful following painful procedures.

Complementary Care: Therapeutic touch enhances comfort

The use of touch to promote healing and comfort dates back to more than 5000 years ago, when Asian therapists used a variety of touching methods as an important strategy in the healing ritual. Over the ages, other ancient cultures, such as the East Indians and Native Americans, also found value in the power of “hands on” healing. Many spiritual traditions, including the Judeo-Christian doctrine, view healing by the “laying on of hands” as a key element in the promotion and restoration of physical and mental health.

Touch plays an important role in fostering healthy human development. It has been shown to boost the functioning of

the immune system and enhance overall feelings of well-being. Touch is a basic human expression that conveys caring and nurturing. The mother intuitively places a comforting hand to her child’s feverish head, pinched finger, or scraped knee. Friends instinctively reach out to touch one another in an expression of caring and compassion. Nurses have long recognized and embraced the value of touch as an important therapeutic tool useful with patients of all ages.

For the neonate, life’s initial impressions, wrapped in a halo of warmth, love, and pleasure, are all conveyed through touch. The infant’s growing knowledge and awareness of those around him is directly shaped by the way in which he is handled. His sense of comfort, security, and well-being are powerfully influenced by the nature of his mother’s or caregiver’s touch. Touch experiences occurring during the hours and days after birth, and the infant’s feelings that are shaped by these experiences, serve to set the foundation for feelings about people throughout life. Premature and sick infants in the intensive care unit can also benefit from a light, calming touch that promotes a sense of security and warmth.

Reasons for not circumcising a newborn may be related to the surgical risks and/or pain associated with the procedure. If the parents choose not to have their son circumcised, they need to receive information about how to keep their son’s penis clean.

“What to say” — Teaching parents who choose not to have their son circumcised

When parents who have decided against infant circumcision inquire about personal hygiene for their son, the nurse may make the following suggestions:

“When your son is 4–5 years old, he can learn how to keep his penis clean just as he will learn to keep other parts of his body clean. The foreskin usually does not fully retract for several years and should not be forced. For an infant, the uncircumcised penis is easy to keep clean by gently washing the genital area while bathing. You do not need to do any special cleansing, such as with cotton swabs or antiseptics.

Around the age of 4–5 years, when the foreskin fully retracts, boys should be taught how to wash underneath the foreskin every day. Teach your son to clean his foreskin by gently pulling it back away from the head of the penis and then rinsing the head of the penis and inside fold of the foreskin with soap and warm water. After washing, the foreskin should be pulled back over the head of the penis.”

Now Can You— Discuss aspects of circumcision?

1. Discuss the benefits and risks of circumcision?
2. Explain how to promote parents’ increased knowledge and understanding about circumcision?

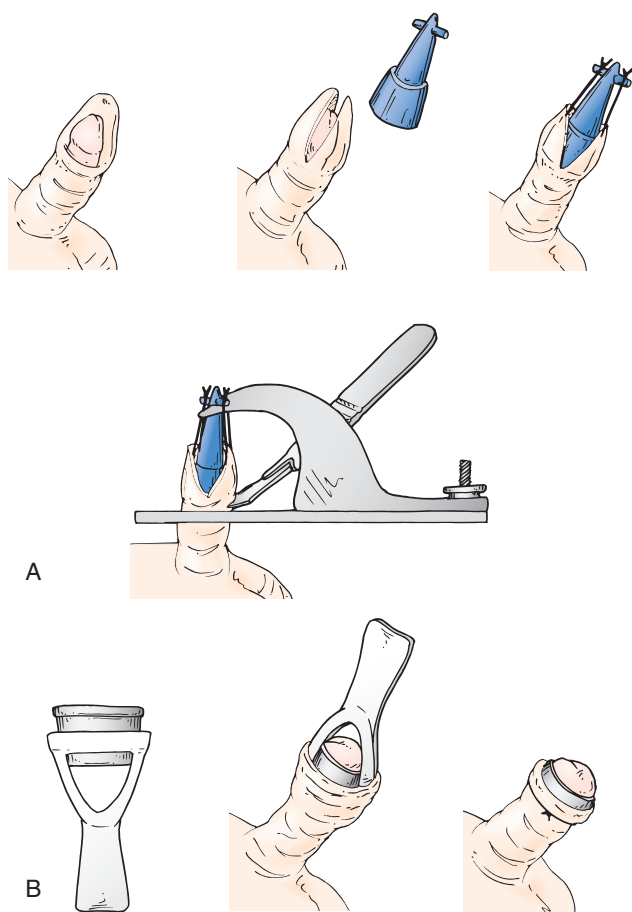

Figure 18-27 Removal of the prepuce during circumcision. **A.** Yellen clamp procedure. **B.** PlastiBell procedure.

ENSURING OPTIMAL NUTRITION

Most parents begin to consider feeding options for their baby during the prenatal period. How to feed a newborn after birth is an important decision with implications for

the entire family. Two feeding choices are available for newborns: breastfeeding with the mother's natural milk or bottle-feeding with a commercially prepared cow's milk formula. It is paramount that the infant's diet be sufficient to optimally meet his rapidly changing physical and psychosocial needs and adhere to the current recommended dietary allowances. The diet must include essential nutrients such as protein to support rapid cellular growth, carbohydrates to provide energy, and fat to supply the needed calories, regulate fluid and electrolyte balance, and sustain development of the brain and neurological system. Water intake, essential for tissue hydration, should amount to 140 to 160 mL/kg per day. Because the bioavailability of iron in breast milk is much greater than in formula preparations, full-term infants who are breastfed do not need supplemental iron until they reach 6 months of age. At that time, breastfed babies require iron-fortified formula in combination with the breast milk. Infants who are bottle-fed should be given a commercial formula fortified with iron from the beginning. Adequate calories are also necessary and daily requirements of 105 to 108 kcal/kg per day have been established. (See Chapter 15 for further discussion about infant feeding.)

Discharge Planning for the Infant and Family

The new family is discharged from the hospital or birthing center as early as 24 hours after birth, so early initiation of the discharge planning process is crucial. If this is the couple's first child, discharge planning becomes even more important. The nurse must use every opportunity, beginning during the prenatal period, to teach the family about newborn care. The astute nurse gathers cues about family adaptation to the new baby by observing how the members interact with one another and their level of comfort when holding, feeding, diapering, and dressing the newborn. Questions such as "Tell me how you will care for your new baby?" or "Who is available to help you care for your new baby?" may give the nurse insight as to the type of information the family may need.

Across Care Settings: Providing parenting information

Offering essential information in any setting through individual instruction, educational videos, or parenting classes about such topics as health promotion, growth and development, handling, nasal and oral suctioning, hygiene, diapering, dressing, comforting, nutrition and elimination, rest and sleep, safety and anticipatory guidance may help the mother and family gain confidence about caring for their baby. It is also helpful to educate parents about routine laboratory screening tests that may be performed in the hospital, home, doctor's office, or community clinic.

Discharge from the hospital or birthing center is an ideal time to discuss and implement car seat safety measures as automobile accidents are a safety concern for new parents. In moving vehicles, infants and older children must always be transported in a safe seating device.

Infants up to 20 pounds must be placed in a rear-facing position in the back seat of the car. Infants must not be placed in the front seat as inflating front seat air bags may cause suffocation (AAP Committee on Safety, 2002).

Across Care Settings: Car seat safety

The nurse can assist the new family by providing information and guidance to resources on car seat safety:

- When purchasing a car seat, parents need to be aware that the seat must meet certain federal guidelines. A label on the seat tag or packaging box states whether the product has met these guidelines. The American Academy of Pediatrics Web site (www.AAP.org) also lists the guidelines. It is important to emphasize that the car seat instructions must be followed when installing the car seat.
- Several community resources are available to the family that will rent or loan a car seat for the initial dismissal. The hospital or birthing center may have a car seat program. Other resources include the American Red Cross, the Local Health and Safety Council, and the State Department of Health.
- The infant must be dressed so that the clothing facilitates ease of positioning and strap placement. To ensure correct fit, the infant can wear a single layer of clothing, preferably pants, so that the strap can fit between the legs. Sack sleepers are not recommended and bundling is discouraged because the strap may not fit snugly. Head support is recommended. Parents can use a commercially made product or place a rolled-up receiving blanket around the head and neck area. To protect the infant from burns and overheating in warm weather, parents should check the temperature of the car seat by touching the surface.
- Trained professionals may be available to perform safety checks to help parents with proper car seat installation and use. New cars are required to be equipped with tethers and lower anchors to ensure child safety.

CHILD CARE

When the new family arrives home, they have many decisions to make about the new baby. One important decision is who will care for the child when the parent(s) return to work.

Over the past 35 years, caring for children has shifted from home care to care away from the home. It is essential that the child care facility offer an environment of trust along with safe and competent care. In addition, the child care provider must offer ways to stimulate growth and development as well as meet the physical and psychosocial needs of the developing child. The nurse's responsibility is to help guide the family when choosing a child care facility. There are several options available for families today. In-home care refers to a child care provider such as a nanny, baby sitter, family member, or friend who comes into the family home. Work-based group care occurs when the child is placed in a facility that is directly associated with the parent(s)' employment. Another child care option involves placement of the child in another family's home. This type of care can be licensed or unlicensed and may be

considered more informal. Established business day care centers offer more formal licensed care settings that comply with set standards and follow state regulations. These day care centers have specific policies that include minimum child to worker ratios. Sick-child care may also be available to the family in times of illness. These care facilities are often offered in community or hospital settings.

Collaboration in Caring— *Child care for new families*

The nurse can encourage the family to:

- Communicate their needs and express their concerns about child care.
- Interview the facility director along with other individuals who may be involved in the child's care.
- Evaluate the educational programs related to qualification of teachers and structure of the learning environment (structured or unstructured).
- Investigate the provision of meals, nutrition, and related sanitation.
- Visit the child care facility on a few occasions, announced and unannounced.
- Identify practical aspects of child care such as location, hours of operation, fee requirements and payment schedule, child to worker ratio, environmental safety, indoor and outdoor space, sick day policies, and availability of care during a holiday or inclement weather.
- Evaluate the infection control and injury prevention measures.
- Gain broader information about the facility related to breast feeding, discipline, nurturing, diapering/toileting, stimulating growth and development, play, nap/rest time, and field trips.
- Discover state regulations and read the care facility's policies and related public records.
- Become familiar with early childhood program that offer voluntary accreditation such as the National Academy of Early Childhood Programs.

Newborn Metabolic Screening Tests

Newborn screening, designed to identify newborns with genetic, metabolic, and/or infectious conditions, is an essential part of preventative care. Through screening, many life-threatening problems can be detected early enough for effective intervention. Conditions commonly discovered through early screening include biotinidase deficiency, hemoglobinopathies, medium-chain acyl Co-A dehydrogenase deficiency, phenylketonuria (PKU), galactosemia, cystic fibrosis, congenital adrenal hyperplasia, congenital hypothyroidism, sickle cell anemia, and phenylketonuria (PKU). PKU, which occurs in approximately 1 in 10,000 to 25,000 births, is a genetic metabolic disorder. It is characterized by a deficiency of the enzyme phenylalanine hydroxylase, which the body needs to convert phenylalanine to tyrosine. A lack of proper conversion results in a build-up of toxic blood levels of phenylalanine, a condition that causes central nervous system (CNS) damage (Edwards, Howell, & Lloyd-Puryear, 2006). (See Chapter 19 for further discussion.)

Under state law requirements, screening of neonates has been routinely performed in the United States since the 1960s. However, no universal screening policy has been in place to assure uniformity. Instead, policies concerning routine neonatal screening vary from state to state and are frequently based on local demographics, cost, reimbursement, politics, and ready availability of resources. To address the lack of uniformity in screening practices, the American Academy of Pediatrics (AAP) convened a national Task Force on Newborn Screening. An important outcome of this work was the directive that each newborn have a medical home. A medical home means that every newborn should receive the benefit of a pediatrician or other primary care health professional who works in partnership with the newborn's family to ensure that appropriate screening is completed, test results are reported, and appropriate follow-up is conducted (AAP, 2000; AAP, 2005b).

On the federal level, members of congress recently directed the U.S. General Accounting Office to compile information related to newborn screening programs and state variations. The report revealed that most states screen newborns for only eight or fewer disorders. Furthermore, most states selected the disorders for screening according to whether or not they were treatable. Based on these findings, the Department of Health and Human Services (DHHS) suggested that a common set of disorders be established for all states, along with selection criteria for which disorders would be tested (U.S. General Accounting Office, 2003).

It is essential that nurses recognize that early detection of various disorders allows for timely intervention that can prevent or minimize complications. Before mothers and their infants are discharged from the hospital or birthing center, the nurse should educate the family about the importance of newborn screening. Emphasis should be placed on the long-term benefits of neonatal screening since early detection can allow for the initiation of timely treatment and the development of a plan for ongoing follow-up care. From a community perspective, universal screening and timely intervention can lead to a national reduction in infant disabilities, morbidity, and mortality.

While a positive screening test may indeed indicate that the newborn has a disorder, a diagnosis is generally not made from a single laboratory result. Instead, subsequent testing is conducted since "false positives" (a positive finding although the infant does not have the disorder) can occur. A false-negative result can occur if the specimen was collected at too young of an age, or if the quality of the specimen was in some way jeopardized.

Optimizing Outcomes— Newborn metabolic screening

Best Outcome: Understand the effects of various disorders detected by metabolic screening and advocate for universal routine screening of all newborns. At present, the minimum mandatory newborn screening tests in most states in the United States are for inborn errors of metabolism such as PKU, galactosemia, hemoglobinopathy (sickle cell disease and thalassemias), and hypothyroidism. In Canada, newborn screening testing varies by province (CDC, 2005).

diagnostic tools Newborn Metabolic Screening

Approximately 24 hours following birth, a small sample of blood is taken from the infant's heel. The specimen should be obtained as close to the time of the infant's hospital discharge as possible and not later than 7 days. A blood sample taken before 24 hours of age may be unreliable in detecting several conditions. However, if the newborn is discharged from the hospital or birthing center before completing the first 24 hours of life, a sample must be obtained and the infant's parents must be instructed to contact the physician within 2 weeks to arrange to have another specimen drawn.

Neonates born at home must also be screened for disease. The parents or the person registering the birth must make the proper arrangements with a doctor or health care provider to have the tests completed prior to completion of the first week of life. If the 1-week time period is missed, the infant should be tested anyway, as he may still benefit from early intervention for certain disorders.

Now Can You— Discharge the new family?

1. Identify cues that may indicate how the family is adapting to the newborn?
2. Develop a discharge teaching plan for the family of a normal neonate?
3. Counsel parents about metabolic screening for their new baby?

summary points

- ◆ Key components of the immediate nursing assessment of the neonate center on ensuring adequate respiratory function and the prevention of heat loss.
- ◆ The later assessment of the newborn is conducted in a systematic manner that includes careful evaluation of each body system.
- ◆ Important aspects of newborn care focus on the prevention of infection and injury.
- ◆ The nurse provides newborn care in an environment that is safe and protective, enhances the transition to extrauterine life and one that fosters parent–infant bonding.
- ◆ Parents must be given correct and impartial information that includes the risks and benefits of circumcision, an elective surgical procedure.
- ◆ Neonatal pain must be readily identified, assessed, and appropriately managed.
- ◆ An essential role for nurses involves teaching and discharge planning for the new family.

review questions

Multiple Choice

1. The nurse's use of prewarmed blankets to wrap the newborn at birth is intended to decrease heat loss by which mechanism:
 - A. Evaporation
 - B. Convection
 - C. Conduction
 - D. Radiation
2. During the reflex assessment, the nurse places the infant in the prone position and strokes one side of

the vertebral column. The nurse is assessing which reflex?

- A. Moro
- B. Galant
- C. Babinski
- D. Stepping

3. The perinatal nurse understands that soft tissue diffuse edema of the infant's head is a condition best described as:
 - A. Caput succedaneum
 - B. Cephalhematoma
 - C. Subperiosteal hemorrhage
 - D. Periorbital edema

Select All that Apply

4. During Baby G.'s initial examination, the nurse observes a two-vessel cord. The nurse's immediate response is to notify the health care provider as this finding can be a sign of abnormality in which system?
 - A. Renal
 - B. Cardiac
 - C. Neurological
 - D. Musculoskeletal
5. Infant admission documentation completed by the perinatal nurse includes information concerning the following:
 - A. Passage of meconium
 - B. Vitamin K injection site
 - C. Ballard score
 - D. Rectal temperature recording
6. The perinatal nurse observes for behaviors reflective of the early expression of parent–infant attachment, which include:
 - A. Assuming an en face position with the infant
 - B. Examining the infant's fingertips
 - C. Stroking the infant's trunk
 - D. Exploring the infant's extremities

True or False

7. The nurse recognizes that the noisy breath sounds heard during an infant's examination are caused by mucous or amniotic fluid in the upper airway.

Fill-in-the-Blank

8. The nurse recognizes that behavioral assessment in the neonate is measured by the infant's response to _____.
9. _____ is a normal finding in the assessment of the infant's head, eyes, ears, and nose.
10. The perinatal nurse explains to the new parents that the normal healthy term infant's usual position of comfort is _____ of the upper and lower extremities.

See Answers to End of Chapter Review Questions on the Electronic Study Guide or DavisPlus.

CONCEPT MAP

Caring for the Newborn at Risk

chapter 19

Be gentle with the young.

—Juvenal, Roman poet & satirist (55 AD–127 AD)

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Identify the criteria for classification of high-risk newborns such as gestational age factors, birth weight, and intrauterine growth restricted parameters.
- ◆ Describe the conditions for a small for gestational age newborn.
- ◆ Describe the conditions for a large for gestational age newborn.
- ◆ Discuss the physical assessment of the premature infant.
- ◆ Explain the conditions affecting the premature newborn.
- ◆ Explain the conditions affecting the postmature newborn.
- ◆ Describe other conditions affecting the high-risk newborn.
- ◆ Prioritize nursing care interventions for the high-risk newborn.
- ◆ Develop a discharge-teaching plan for the parents of the high-risk newborn.

moving toward evidence-based practice End-of-Life Care for the Neonate

Moro, T., Kavanaugh, K., Okuno-Jones, S., and VanKleef, J. A. (2006). Neonatal end-of-life care: A review of the research literature. *Journal of Neonatal Nursing, 20*(3), 262–273.

The purpose of this integrative review of the literature was to synthesize existing empirical research about neonatal end-of-life care. The neonatal period was defined as the time from birth to 27 days of life. Articles published before 1997 and those that dealt with ethics or considered to be clinical in nature were not included in the review.

Two readers reviewed all of the research studies and mutually agreed on a total of 10 articles that met the study criteria, based on the definitions of palliative and end-of-life care in neonates. Prematurity was the most common infant diagnosis for end-of-life care. The following four categories were included in the synthesis:

- Practices for withdrawing or withholding life-sustaining treatment
- Pain management during ventilator withdrawal
- Parents and the decision-making process
- The dying process

The sample consisted of more than 800 participants. The following were practices for *withdrawing* or *withholding* life-sustaining treatment:

“*Withholding* of treatment” was defined as refusing to administer cardiopulmonary resuscitation. The decision to withhold treatment has increased in the recent past and occurred in up to 69% of the cases reviewed. Decisions to *withhold* treatment were made in situations where treatment attempts were believed to have been futile (74%), and these cases primarily involved a diagnosis of extreme prematurity and/or extreme neurological damage.

“*Withdrawal* of treatment” was defined as the removal of mechanical ventilation. Decisions to *withdraw* treatment primarily included situations where continued support was considered to be futile (74%). Most deaths occurred after the decision to *withdraw* treatment had been made.

(continued)

moving toward evidence-based practice (continued)

Pain management during ventilator withdrawal consisted of the following: Opioid analgesia was used in up to 84% of the cases after life support was withdrawn or withheld. Sixty-five percent of the infants receiving opioid analgesia were diagnosed for major congenital anomalies/chromosomal abnormalities and necrotizing enterocolitis. (A previous study on these conditions found that although analgesia was used when mechanical ventilation was removed, only 22% of the infants continued to receive analgesia after ventilation withdrawal.)

In most cases, the parents were involved in the decision-making process although the level of involvement varied. One study found that parental participation in the decision-making process was not documented in 17% of the cases.

- In the cases where the physician made the decision alone, most infants (67%) were treated with a maximum effort.
- In the cases where parents were involved, the more likely decision was to limit, withhold, or withdraw treatment.
- Several studies found that parents' perceptions and experiences with providers had a major impact on the decision-making process. Parents were more likely to accept the decision if they believed that they were well informed and had a good level of interaction with the care provider.
- Parents also believed that it was important for the provider to be perceived as honest and a clear communicator. Overall, the parents who felt involved with the decision-making process were more inclined to trust the provider when considering treatment limitations.

With regard to the dying process, the studies reported:

- Most parents were present by choice at the time of their infant's death.
- A few parents (4%) did not wish to watch their baby die.
- 17% of the time there was no documentation about whether the parents were present or the reason for their absence.
- Parents were often unprepared for the neonatal dying process; 22% found the experience to be very distressing.
- The parents' specific concerns related to not knowing what to expect, e.g., how long the dying process would take, changes in breathing patterns and skin color following removal of the ventilator.
- Parents of infants whose death was prolonged after removal of the ventilator more often questioned whether or not the correct decision had been made.

The researchers concluded that an increased availability of palliative care services may help parents resolve some of the issues surrounding the understanding of neonatal pain control, continuity of care, and acceptance of the infant's end-of-life experience.

1. What might be considered as limitations to this study?
2. How is this information useful to clinical nursing practice?

Introduction

Newborns can be put at risk any time during their intrauterine (in utero), intrapartum (from the beginning of the first stage of labor to the end of the third stage of labor), or extrauterine development (once the newborn is born). They can be placed at risk in their prenatal or intrauterine environment by genetic disorders (associated with inheritance), congenital anomalies (an abnormality a newborn acquires in utero), or maternal factors such as disease states, trauma, and drug use. Newborns are at risk based on a stressful intrapartum environment resulting in conditions of asphyxia (lack of oxygen) and birth injuries (trauma associated with delivery) or they can be placed at risk in the immediate neonatal or extrauterine environment as a result of conditions such as hypothermia (low body temperature), poor oxygenation, prematurity, or congenital anomalies (Table 19-1 and Box 19-1).

A & P review

It is important that the high-risk newborn have lung, circulatory, and neurological maturity.

Lung Maturity: Fetal lung maturity develops in utero progressively until term. Fetal lung maturity is determined by the L/S ratio (lecithin and sphingomyelin) and PG (phosphatidylglycerol) values, which are essential in

Table 19-1 Risk Factors that Compromise the Newborn

Intrauterine	Intrapartum	Extrauterine
Genetic disorders	Asphyxia	Hypothermia
Congenital anomalies	Birth injuries	Poor oxygenation
Maternal disease	Complications of labor	Prematurity
Trauma	Multiple gestation	Congenital anomalies
Drug use	Poor presentation	Metabolic disorders
	Maternal infection	

promoting oxygenation of the lung alveoli. They act on the pulmonary surface and are needed for lung stabilization. L/S ration and PG values are often mature at 35 weeks' gestation, before this time newborns are at risk for respiratory distress syndrome (RDS).

Circulatory Maturity: Fetal circulation functions in utero to oxygenate the organs needed for intrauterine growth. Blood is shunted away from the lungs and liver because the placenta performs those functions and more blood is circulated to the brain and heart to accommodate

Box 19-1 Risk Factors for Premature Delivery

Mother smokes
 Mother older than 35 years at delivery and younger than 20 years
 Maternal drug abuse
 Female partner abuse
 Multiple gestations
 Maternal uterine abnormalities
 Fetal anomalies
 Maternal infection (especially: chlamydia, gonorrhea, and bacterial vaginosis)
 Maternal cervical anomalies
 History of previous preterm birth (carries twice the risk)
 African American descent
 Genetic susceptibility

rapid growth. The circulatory system of the fetus also develops strength and resiliency with increasing gestational age. At birth the fetal shunts (ductus arteriosus, foramen ovale, and ductus venosus) close and circulation converts to adult circulation to accommodate oxygen intake by the lungs and filtering of blood by the liver. If the shunts fail to respond to extrauterine oxygen and pressure levels, there is a structural deformity in the circulatory system and the newborn is at risk. The preterm newborn is at increased risk because of a fragile circulatory system that is overexerted by the stress of the extrauterine environment.

Neurological Maturity: The neurological system, including the central and peripheral nervous systems and the parasympathetic and sympathetic nervous systems, are underdeveloped at birth. Neurologically, newborns are immature due to limited synaptic and dendritic interconnections in the brain and immature myelination of the nerve cells. The preterm newborn has an increased risk resulting in the inability to cope with the extrauterine stimuli at birth. Neurological deficits are experienced both short and long term in newborns at risk due to interrupted neuronal development (Klaus & Fanaroff, 2005). ♦

The High-Risk Newborn

Nursing care of the high-risk newborn has become an extremely technologically enhanced specialty over the past 50 years and has rapidly evolved into a dynamic field of nursing care. Advances in neonatal intensive care units (NICUs) are steadily increasing the survival rate of newborns at risk but they still have a significantly higher mortality and morbidity rate when compared to uncomplicated, full-term newborns. The majority of newborns who are cared for in NICUs are preterm newborns (newborns born at 37 weeks of gestation or earlier). The preterm rate in the United States is 12.1% as of 2002, which shows an increase over previous years, and this has been associated with increased multiple gestations. In 2001, 41% of newborns born before 28 weeks of gestation did not survive 1 year. The mortality rate decreases to 5% for preterm newborns born between 28 and 31 weeks of gestation. Currently, the age of viability or the gestational

age at which a newborn can survive is approximately 23 to 24 weeks' gestation. Newborns less than 22 weeks do not survive and those between 22 and 23 weeks rarely survive (Klaus & Fanaroff, 2005).

CLASSIFICATION OF HIGH-RISK NEWBORNS

High-risk newborns are classified according to two main criteria: gestational age (GA; length of time in utero) and birth weight (recorded in grams in the NICU). Another classification is intrauterine growth restriction (IUGR). It is important to consider all criteria when assessing a newborn.

Gestational Age

Term newborns are neonates delivered at or after 38 through 42 weeks of gestation because this is the optimal developmental time for adjustment to the extrauterine environment. A neonate born at or before 37 weeks of gestation is preterm and behaves differently and has different nursing care needs than does a full-term newborn. A newborn delivered on or after 42 weeks of gestation is postterm and also has different nursing care needs than a full-term newborn. Some clinicians use the terms postconceptual age (PCA) or postmenstrual age (PMA) to designate the gestational age of a newborn (Sahni et al., 2005).

Nursing Insight— Understanding newborn classification

Preterm newborn: A newborn born before 37 completed weeks of gestation

Term newborn: A newborn born between weeks 38 and 42 of completed gestation

Postterm newborn: A newborn born after week 42 of completed gestation.

VIABILITY. Only 10% of newborns at 23 weeks of gestation survive, whereas 33% of 24-week gestational age newborns survive. At 25 weeks, 58% of newborns survive (Box 19-2). These criteria do not address the developmental and neurological delays of the extremely premature or preterm newborn (Taeusch, Ballard, & Gleason, 2005).

Box 19-2 Viability Related to Newborns Classified According to Gestational Age (GA)

Viable: Newborns whom all neonatal clinicians agree should be treated (GA greater than or equal to 25 weeks)

Nonviable: Newborns that nearly all neonatal clinicians agree should not be treated (GA less than or equal to 22 weeks)

Viability uncertain: Newborns in which clinicians debate, discuss and often disagree whether they should undergo resuscitation or treatment (GA 23–24 weeks).

Source: Taeusch, H., Ballard, R., & Gleason C. (2005). *Avery's diseases of the newborn*. (8th ed.). Philadelphia: Elsevier Saunders.

Table 19-2 Newborn Classification by Birth Weight and Gestational Age

SGA: Small for gestational age	Weight below the 10th percentile for gestational age
AGA: Average for gestational age	Weight between the 10th and 90th percentile for gestational age
LGA: Large for gestational age	Weight above the 90th percentile for gestational age

Birth Weight

Previously, newborns were classified as high-risk solely on the basis of birth weight. Now birth weight is compared to gestational age for a more accurate assessment of risk factors and specific growth patterns. Newborns born with a weight between the 10th and 90th percentile on the developmental growth chart have less mortality and morbidity than those above the 90th percentile or below the 10th percentile. Birth weight must be compared to gestational age to make an accurate assessment of risk for each newborn. Newborn classification by birth weight and gestational age is shown in Table 19-2.

Ethnocultural Considerations— Converting weights

Record the newborn's weight into pounds if the parents are from North America and kilograms if they are European or Asian.

There are other classification systems that use newborn weight as a criterion for classifying premature newborns but do not consider the gestational age in relation to weight (Fig. 19-1). This clinical terminology uses low birth weight (LBW) or very low birth weight (VLBW) or extremely low birth weight (ELBW). Low birth weight (LBW) refers to a newborn weighing less than 2500 grams (7.8% of all births), and very low birth weight (VLBW) refers to a

Figure 19-1 A high-risk newborn in the neonatal intensive care unit.

where research and practice meet: Measurement of Growth and Gestational Age

The measurement of growth and gestational age of the newborn is dependent on graphs developed during research trials. Some current research indicates that birth weight may be increasing in the general population and that growth charts may not consider specific populations and obstetrical conditions (Fok, Wong, Chang, Lau, & Lee, 2003).

newborn weighing less than 1500 grams (1.46% of all births). Extremely low birth weight refers to newborns who weigh less than 1000 grams. The numbers of LBW and VLBW newborns have been steadily increasing owing to the increased incidence of multiple births. LBW newborns die at a rate five times higher than an AGA newborn, and VLBW babies have a 100 times higher risk of dying than a normal birth weight newborn (NCHS, 2004).

INTRAUTERINE GROWTH RESTRICTION

Intrauterine growth restriction (IUGR) is a term used to denote a lack of intrauterine fetal growth which usually results in an SGA newborn. An older term previously used in clinical practice was “intrauterine growth retardation,” but it is no longer used because the lay person may equate the word “retardation” with cognitive (intellectual) development, whereas in fact it was a reference to somatic (body) development of the newborn.

Small-for-Gestational-Age Infants

Small-for-gestational-age (SGA) infants are those born at any gestational age who have a birth weight that falls below the 10th percentile on the growth charts. The SGA condition is a result of intrauterine growth restriction (IUGR) and can be classified into two categories: asymmetrical and symmetrical. Asymmetrically small newborns have an appropriate size head circumference that measures between the 10th and 90th percentile for their gestational age when plotted on the head circumference chart but their weight falls below the 10th percentile. Asymmetrical SGA is sometimes called “brain sparing” SGA. Symmetrically small newborns are not only below the 10th percentile for weight but also have a small head circumference that measures below the 10th percentile for their gestational age. Symmetrical SGA is sometimes called “non-brain-sparing” SGA.

SGA newborns are small because they have suffered a nutritional or oxygenation deficit in utero due to maternal causes, fetal causes, or a placental or cord malfunction. If the fetus experienced the deficit in the first trimester, the newborn is usually symmetrically SGA but if the deficit started after the 20th week of gestation he is more likely to be asymmetrically SGA. Interestingly, in developed countries, such as the United States, one of the most common factors related to intrauterine fetal growth restriction is maternal smoking. In developing countries, the leading causes are maternal nutritional deficits and infections such as malaria. Some conditions that can produce an intrauterine environment leading to a SGA newborn are listed in Box 19-3.

Box 19-3 Conditions that Can Produce SGA Newborns

Genetic factors	
Chromosomal factors	Mother has diabetes
Mother has fibroids	Mother has systemic lupus erythematosus
Mother has asthma	Intrauterine factors
Mother has hypertension	Twin to twin transfusion
Drug use	Abnormal uterine anatomy
Mother has congenital heart disease	TORCH infections

SGA newborns are not only smaller but often have a characteristic appearance. In asymmetrical SGA newborns the head appears large in relation to the body. The body of both types (symmetrical and asymmetrical) of SGA newborns looks wasted because of lack of brown fat. The chest is often scaphoid and the eyes appear large with a “wise old man” look. The fingernails are often long and a meconium-stained thin cord is often present (Klaus & Fanaroff, 2005).

CONDITIONS AFFECTING THE SGA NEWBORN

Morbidity and mortality are significantly higher for SGA newborns. Delivery problems include asphyxia and low Apgar scores (see Chapter 18). Four immediate conditions in SGA newborns that are frequent nursing concerns are hypothermia, pain, hypoglycemia, and polycythemia (Doctor, O’Riordan, & Kirchner, 2001).

Hypothermia

SGA newborns have decreased brown fat and subcutaneous tissue to protect them from the cold. They also have higher caloric needs and rest needs are increased to conserve energy needed for growth. They have high metabolic rates and low glycogen stores which predispose them to hypothermia.

SIGNS AND SYMPTOMS. Hypothermia occurs when the baby becomes cold and loses heat at faster rate than the body can create heat. Hypothermia in the newborn is a body temperature below 36.2°C (97°F). Other signs and symptoms include shivering and cold, pale or bluish skin.

DIAGNOSIS. Diagnosis is based on the infant’s temperature, nursing assessment, and signs and symptoms.

Nursing Insight— Cold stress

Cold stress is more likely in SGA and preterm newborns because they not only have less brown fat but are also less flexed and have thinner skin. In VLBW newborns, water loss can be 8 to 10 times greater than in an adult and heat loss 5 to 6 times greater. Cold stress increases metabolic needs and places the SGA and preterm newborn at further risk for respiratory distress and metabolic acidosis. The nurse understands the need to assess for the signs of cold stress: poor feeding, lethargy, central cyanosis or pallor, respiratory distress, and bradycardia (Klaus & Fanaroff, 2005). Nursing care can prevent cold stress by maintaining a thermoneutral environment using artificial heat source and reducing heat loss related to convection, radiation, conduction, and evaporation

NURSING CARE. Nursing care includes providing a thermoneutral environment via an artificial heat source if the newborn cannot maintain an adequate temperature. After rewarming, the infant is then bundled (wrapped in blankets) in an open crib. The most commonly used artificial heat sources include radiant warmers and incubators.

A radiant warmer that is used in the newborn nursery is an overhead heater that accommodates an open crib underneath. The nurse can assess and bathe a newborn under the warmer and then remove the crib from the warmer once the newborn’s body temperature is stable. The radiant warmers used primarily in the NICU have a flat table-like mattress with low sides that can be taken down for easy accessibility to the newborn. During warming, the infant’s temperature is monitored continuously with a skin probe.

Nursing Insight— Temperature

Normal skin temperature: 97–98°F (36.2–36.8°C)

Normal axillary temperature: 97.7–99.5°F (36.5–37.5°C)

Normal rectal temperature: 97.9–100.4°F (36.6–38°C)

Incubators are used to provide longer periods of artificial heat. They are double-walled containers with port holes that are covered in plastic to allow caregiver access. They can also be set on two different modes: skin (servo) or air (ambient). The skin mode works via the same mechanism as the radiant warmer servo mode. The servo mode uses a skin probe on the newborn (which should not be placed over the liver or a bony prominence). The probe is attached to the newborn with a reflective adhesive to help the heat source record the temperature of the skin. The probe should be positioned on the newborn’s body so the adhesive piece is exposed to the heat source above. The air mode maintains a set temperature within the incubator and the newborn regulates his own body temperature in the warmer environment. The newest models of incubators open from the top, thereby maintaining some of the heat, as does a radiant warmer. Incubators are often covered with a baby blanket to protect the newborn from excessive light (Fig. 19-2).

Figure 19-2 Incubator used in the NICU.

critical nursing action Weaning the Newborn from the Incubator

When the newborn is being “weaned” from the servo (skin) mode of the incubator the temperature is decreased gradually every few hours while the body temperature is checked. Once the newborn can maintain his temperature above 97.7°F (36.5°C) axillary; he is switched to air mode and dressed. The newborn’s temperature, weight gain, and behavioral status are observed closely during the weaning process.

Another way to provide a temporary heat source is to wrap the newborn in blankets that were warmed in a blanket warmer. This is a temporary method since the blankets cool fairly rapidly. To prevent cold stress in a newborn, a head covering, such as a stockinet hat, is also effective in preventing heat loss.

The nurse can also have a parent provide kangaroo care (skin-to-skin holding of the baby who is dressed only in a diaper). The baby is held next to the mother’s or father’s chest, preferably with an ear over the parent’s heart to allow the baby to hear the familiar heartbeat (Johnson, 2005). Kangaroo care is an effective way of maintaining newborn temperature and is recommended for a growing newborn who is stable and can tolerate periods of time out of the incubator. Kangaroo holding has been found to produce benefits for both the mother and the baby by enhancing mother–baby interaction as well as promoting bonding and newborn growth and development (Johnson, 2005; McCall, Alderdice, Halliday, Jenkins, & Vohra, 2005).

Across Care Settings: The Linus Project

Growing newborns in the NICU use a large amount of clothing, blankets, and linens. Volunteer groups such as the Linus Project (<http://www.projectlinus.org/index.shtml>), senior groups, and local high school home economics classes are often happy to crochet or knit warm blankets and hats for NICU newborns that can often be sent home with the family when the newborn is discharged.

Pain

High-risk newborns undergo much life-saving interventions, many of which produce pain. Pain should be assessed during both procedural and routine care.

SIGNS AND SYMPTOMS. Pain has detrimental physiological effects on the newborn’s cardiovascular, respiratory, endocrine, metabolic, immunological, and coagulation systems that lead to an increase in heart rate, blood pressure, and respiratory rate. Pain in the newborn also produces shallow respirations, pallor, flushing, diaphoresis, palmar sweating, and decreased oxygen saturation. The newborn also displays pain in facial expressions, including lowering the brows and drawing them together, crunching the forehead and revealing vertical furrows between the brows, closing the eyes tightly and squaring off the mouth while holding the lips tight. The newborn’s cry can also be an indicator of pain because it becomes higher pitched with long pauses in breathing before it eventually becomes a rhythmic rising and falling pattern of crying. The newborn’s body movements also display pain reactions by limb withdrawal from touch, rigidity or flaccidity, and clenched fists. Pain alters the wake–sleep cycles of newborns.

DIAGNOSIS. A pain diagnosis can be based on the Premature Infant Pain Profile (PIPP) or other neonatal pain scale.

NURSING CARE. Pain management is an important nursing consideration in the NICU. Pain is considered the fifth vital sign in the NICU and is assessed every 3 hours or with nursing care. Pain can be accurately assessed using a verified pain scale. More than 35 different pain scales are available for assessing newborn pain (Duhn & Medves, 2004). Some pain assessment scales are for the term newborn while others are specific to the preterm newborn. A commonly used pain assessment in the NICU is the Premature Infant Pain Profile (PIPP) (Stevens, Johnston, Petryshen, & Taddio, 1996). The PIPP rates six

where research and practice meet: The Pain Assessment Tool (PAT)

The Pain Assessment Tool (PAT) was recently developed for all newborns cared for in the NICU regardless of gestational age. It is user-friendly and has been tested on 144 newborns. The PAT score was shown in this study to be a valid, reliable, and clinician-friendly pain assessment measurement tool for all newborns in the NICU that may increase the consistency of nursing assessment (Spence, Gillies, Harrison, Johnston, & Nagy, 2005)

Premature Infant Pain Profile (PIPP)

	0	1	2	3
GA	>= 36 Wks	32–36 6/7 Wks	28–31 6/7 Wks	<= 28 Wks
Behavioral state	Active/awake	Quiet/awake	Active/sleep	Quiet/sleep
HR	0–4 beats/ minute Inc	5–14 beats/ minute Inc	15–24 beats/ minute Inc	25 beats or > Inc
O2 Sats	0–2.4% Decrease	2.5–4.9% Decrease	5–7.4% Decrease	7.5% or Decrease
Brow bulge	None	Minimum	Moderate	Maximum
Eye squeeze	None	Minimum	Moderate	Maximum
Nasolabial furrow	None	Minimum	Moderate	Maximum

Figure 19-3 A commonly used pain assessment in the NICU is the Premature Infant Pain Profile (PIPP).

parameters within four different age groups (Fig. 19-3). Many NICUs have protocols that treat a newborn for a PIPP score higher than 6 or 7. A score of 12 indicates severe pain and requiring immediate attention (Pasero, 2002) (Fig. 19-4).

Nursing Insight— Newborn pain

Many people have myths about newborn pain [e.g., newborns do not feel or react to pain, newborns do have memory of pain]. The response to pain is subjective and determined very early in life and is in part a socially learned reaction. Not adequately medicating newborns and children for pain can have life-long effects (Young, 2005).

Hypoglycemia

Hypoglycemia occurs more rapidly in newborns. SGA and preterm newborns have higher glucose needs than do term newborns. In utero, glucose is provided by continuous placental transfer from maternal circulating glucose. After the umbilical cord is cut and the glucose supply is halted, the newborn has to use liver glycogen and adipose tissue stores for glucose control. Gluconeogenesis and ketogenesis are underdeveloped and glucose levels can fall rapidly after birth.

SIGNS AND SYMPTOMS. Hypoglycemic symptoms in the newborn may range from no symptoms at all to lethargy, jitteriness, poor feeding, cyanosis, high pitched or weak cry, eye rolling, and seizures.

DIAGNOSIS. When glucose levels fall below 60 mg/dL a diagnosis of hypoglycemia can be made. The newborn may also start building up ketones.

NURSING CARE. The nurse must provide proper nursing care to the newborn experiencing hypoglycemia to ensure the best outcome and long-term good health.

Figure 19-4 Many NICUs have protocols which treat a newborn for a PIPP score higher than 6 or 7. A score of 12 indicates severe pain and needs immediate attention.

critical nursing action Hypoglycemia in the Newborn

The nurse must understand the dynamics of hypoglycemia and remember not all newborns are symptomatic:

- Glucose levels should be monitored carefully in SGA newborns. Many times glucose testing is done by heelstick (capillary blood sampling). A heelstick is done by pricking the heel and scooping the dripping heel blood into the appropriate neonatal laboratory tubes that require approximately 1 mL of blood for testing (Fig. 19-5).
- Optimal glucose levels are 70–100 mg/dL, as they are in adults. The lowest clinically acceptable level is 60 mg/dL. At a level of 40 mg/dL the newborn may become symptomatic.
- Many NICUs have protocols requiring blood glucose levels at specific intervals for SGA newborns. Many nurseries have protocols that continue to check newborn glucose levels at birth and 1, 2, 4, and 8 hours of age (Klaus & Faranoff, 2005). Some NICUs even repeat glucose levels at 12 and 24 hours of age.
- For newborns on IV therapy, since a basic component of the parenteral fluid is glucose, nurseries maintain routine blood glucose checks. IV therapy consists of providing glucose at a rate of 4 to 8 mg/kg per minute.
- If a stable newborn is found to be hypoglycemic on routine blood glucose check, enteral feedings should be started immediately. After the feeding the glucose level should be rechecked at 30 minutes.

Polycythemia

Polycythemia is a condition of too many circulating red blood cells (RBCs) in the newborn and can have several causes. Newborns who experience oxygen deprivation in utero produce additional RBCs to increase the circulation of oxygen. Some of the common conditions in utero that produce polycythemia in the newborn are listed in Box 19-4. Polycythemia may also occur when a newborn (either SGA or LGA) is exposed to an intrapartum environment that allows the blood in the cord and placenta to enter his circulation by gravity or “milking the cord” at delivery. Polycythemia greatly increases the viscosity of the circulating volume, which can produce multiple organ damage.

SIGNS AND SYMPTOMS. Polycythemia includes plethoric (ruddy) skin and delayed capillary refilling, hematuria, proteinuria, necrotizing enterocolitis (NEC), pulmonary hypertension, thrombocytopenia, jaundice, and neurological sequelae including central nervous system irritability, seizures, and cerebral infarction (Klaus & Faranoff, 2005).

DIAGNOSIS. Diagnosis is made when the venous hematocrit is 65% or greater.

NURSING CARE. The nurse initiates care by performing a urine analysis. Macroscopic urine analysis can be done by dipsticking urine for a rapid assessment. Hemoglobin, hematocrit, and bilirubin levels can be done by peripheral blood drawing or heelstick.

critical nursing action Hemoglobin and Hematocrit Levels

Hemoglobin and hematocrit levels need to be monitored closely, as do bilirubin levels. To prevent neurological deficits in newborns, exchange transfusions may be ordered for hematocrits greater than 65% in the

Figure 19-5 A heel stick is done by pricking the heel and scooping the dripping heel blood into the appropriate neonatal laboratory tubes that require approximately a mL of blood for testing.

first 24 hours of life. Exact hematocrit values at which complications will occur are difficult to determine since different newborns become symptomatic at different levels. Nursing care should include monitoring questionable hematocrit levels via venous blood because capillary hematocrits are less exact. Assess the newborn for neurological symptoms such as high-pitched cry, feeding problems, irritability, and apnea. Testing urine for blood and macroscopic analysis is also recommended (Klaus & Fanaroff, 2005).

Optimizing Outcomes— Preventing hemolysis

Best outcome: To prevent hemolysis, transport the blood specimen to the lab as soon as possible.

nursing diagnoses The SGA Newborn

- Risk for activity intolerance related to increased metabolic needs
- Possible ineffective feeding pattern related to increased metabolic needs
- Nutritional imbalance related to hypoglycemia
- Risk for impaired parenting related to increased care needs
- Caregiver role strain related to increased care needs
- Risk for growth and developmental delays related to intrauterine nutritional and oxygenation status
- Risk for imbalanced body temperature related to decreased subcutaneous tissue and brown fat (Doenges, Moorhouse, & Geissler-Murr, 2005)

Box 19-4 Conditions that May Produce Polycythemia in the Newborn

- Placental insufficiency
- Maternal hypertension
- Pregnancy at high altitudes
- Maternal diabetes
- Trisomies

Large-for-Gestational-Age Infants

Newborns who are large for gestational age (LGA) are over the 90th percentile on the growth chart (this is a newborn who weights approximately 3750 grams or 8 pounds and 4 ounces at 40 weeks gestation). A macrosomic newborn weighs more than 4050 grams and is always LGA. Excessive fetal size is found in 9% to 13% of all deliveries. LGA newborns have a higher morbidity rate than AGA newborns.

There are two reasons why newborns may grow to a larger than average size in utero. They can be genetically large or, more commonly, they are exposed to an imbalance of nutrients in utero. The most common energy and growth source in utero is glucose. It is easily transported by diffusion across the placental barrier. If the maternal circulation contains excessive glucose levels the fetus' circulation will have a higher than normal glucose level also. The intrauterine conditions that place a newborn at risk for LGA are listed in Box 19-5. Delivery of a LGA newborn places the newborn at a greater risk for complications (Box 19-6).

Infants of diabetic mothers are often LGA. LGA newborns are also at risk for transient tachypnea, hypoglycemia, hypocalcemia, hypomagnesemia, birth injuries, brachial plexus injuries, and fractures (Klaus & Fanaroff, 2005).

Box 19-5 Risk Factors Contributing to LGA Newborns

- Increasing parity
- Increased maternal age
- Increased maternal height
- History of other LGA newborns
- Prolonged pregnancy
- Maternal obesity
- Maternal glucose intolerance
- Large pregnancy weight gain

Box 19-6 Complications Associated with LGA or Macrosomic Newborns

- Shoulder dystocia at delivery
- Brachial nerve plexus
- Asphyxia
- Hyperinsulinemia and hypoglycemia
- Hypocalcemia

CONDITIONS AFFECTING THE LGA NEWBORN**Infant with a Diabetic Mother**

Infants of diabetic mothers may experience a chronic hyperglycemic state (greater than 125 mg/dL in the full-term infant and 150 mg/dL in the preterm infant) in utero due to elevated maternal glucose levels. The effects of the maternal glucose levels on the newborn depend on several factors such as the maternal glucose control, the onset of the diabetic state, and the length of gestation. Glucose readily passes through the placenta but insulin, due to its molecular size, does not. Therefore, the fetus produces larger than normal amounts of insulin to keep up with the extra glucose. This makes the glucose accessible to the cells, producing a large newborn. When the cord is cut at delivery the glucose supply is abruptly stopped but the newborn's pancreas is still hyperstimulated and producing insulin resulting in a severe hypoglycemic state.

SIGNS AND SYMPTOMS. The nurse must determine if the infant is in a hypoglycemic or hyperglycemic state. Hyperglycemia is usually asymptomatic but can be detected by routine screening (heel sticks) soon after birth, many times within 15 to 30 minutes and be completed at regular intervals.

Nursing Insight—Hyperglycemia in the high-risk newborn

Hyperglycemia is rarer than hypoglycemia but is still significant. A blood glucose level above 150 mg/dL is considered hyperglycemia and can cause dehydration and weight loss. Severe hyperglycemia may also cause cerebral hemorrhage (Taeusch et al., 2005).

NURSING CARE. If the infant is in a hyperglycemic state, insulin infusion is sometimes started and urinary output is carefully monitored to detect glycosuria and possible osmotic diuresis. It is important to communicate the baby's condition to the parents.

nursing diagnoses The Infant with a Diabetic Mother

- Impaired physical mobility related to possible fractures
- Nutrition: Imbalanced, less than body requirements related to somatic size and glucose needs
- Pain (chronic) related to possible birth injuries
- Impaired gas exchange related to transient tachypnea of the newborn
- Infection, at risk or related to increased hospital procedures
- Parenting, impaired related to newborn with special needs

- Disturbance in sensory perception related to eye covers for phototherapy (Doenges & Moorhouse, 2005)

Transient Tachypnea of the Newborn

Respiratory distress syndrome type II or transient tachypnea of the newborn (TTN) is common in infants of diabetic mothers. TTN is a delayed clearance of fetal lung fluid as a result of hyperaeration of the fetal lungs and transient pulmonary edema from the fetal lung fluid (which is different from amniotic fluid) in the alveoli. The air is trapped in the alveoli and hypoxia results due to poor lung ventilation. The onset of labor appears to be the mechanism by which the lungs reabsorb fluid which puts newborns who have not experienced labor at even a greater risk for TTN. Many LGA and IDM newborns are delivered by scheduled cesarean section and do not experience labor.

SIGNS AND SYMPTOMS. Clinical signs of TTN include a high respiratory rate of 60 to 120 breaths/minute, grunting, retractions, and nasal flaring (Fig. 19-6).

DIAGNOSIS. Blood gas usually shows respiratory acidosis (Table 19-3).

Nursing Insight—Metabolic acidosis

Metabolic acidosis increases pulmonary resistance. Bicarbonate therapy is used less now that oxygenation of newborns is better through ventilation methods. Bicarbonate is given IV push 1–2 mEq/kg in a maximum concentration of 0.5 mL (Taeusch et al., 2005) (see Table 19-3).

NURSING CARE. The treatment is often continuous positive airway pressure (CPAP) at 40% oxygen for 24 to 48 hours. Complete resolution takes 2 to 3 days. TTN is self-limiting with no reported long-term complications (Taeusch et al., 2005).

Nursing Insight—Continuous positive airway pressure (CPAP)

CPAP is oxygen most often delivered through nasal prongs to avoid intubation with an ET tube. CPAP maintains the patency of the upper airway and is usually set at pressures of 2–6 cm H₂O. The nasal prongs fit snugly into the newborn's nose and are usually held in place by pinning the tubing to a stokinette cap.

**critical nursing action** Transient Tachypnea of the Newborn

The nurse must perform an accurate assessment of the respiratory system because immediately after birth or into the transitional period (within 1–2 hours) the neonate's respiratory rate should be below 60 with *no* retractions, nasal flaring, grunting and a peripheral pulse oximeter reading of greater than 92%. If any of these clinical signs appear immediately after birth or persist into transition period immediate attention and supplemental oxygen is warranted.

Observation of Retractions

	Upper chest	Lower chest	Xiphoid retractions	Nares dilation	Expiratory grunt
Grade 0	 Synchronized	 No retractions	 None	 None	 None
Grade 1	 Lag on inspiration	 Just visible	 Just visible	 Minimal	 Stethoscope only
Grade 2	 See-Saw	 Marked	 Marked	 Marked	 Naked ear

Figure 19-6 The Silverman and Andersen Index Evaluation of Respiratory Status.

Hypoglycemia

One of the most important nursing actions for an LGA newborn is the close monitoring of glucose levels. A glucose level below 60 mg/dL is cause for immediate action. Feeding of 5% glucose, formula or encouraging breastfeeding is often the best way to raise the glucose level. Many nurseries have protocols that check LGA newborn glucose

levels at birth and 1, 2, 4, and 8 hours of age similar to the protocol used for the SGA newborn.

Hypocalcemia

Calcium levels should be above 7.5 mg/dL in preterm newborns and 8 mg/dL in term newborns. Low calcium level can produce seizures in the newborn and may be present

Table 19-3 The Relationship Between pH and Concentration of Arterial Blood Gases

	pH	Pco ₂	PaO ₂	PHCO ₃ ⁻
	Measures blood acidity.	Partial pressure of carbon dioxide in blood.	Partial pressure of oxygen in blood.	Partial pressure of bicarbonate (alkaline or base) in blood.
Normal Neonatal Values	pH = 7.25–7.45	Pco ₂ = 35–40 mm Hg	PaO ₂ = 50–80 mm Hg	PHCO ₃ ⁻ = 20–22 mEq/L
Respiratory Acidosis (due to poor ventilation)	↓ pH	↑ Pco ₂	WNL	WNL
Metabolic Acidosis (anaerobic metabolism from hypoxia, diarrhea or kidney disease)	↓ pH	WNL	WNL	↑ PHCO ₃ ⁻
Respiratory Alkalosis (hyperventilation)	↑ pH	↓ Pco ₂	↑ PaO ₂	WNL
Metabolic Alkalosis (vomiting, diarrhea, hypocalcemia)	↑ pH	WNL	WNL	↑ PHCO ₃ ⁻

WNL = within normal limits.

Adapted from Noerr, B. (2000). Neonatal respiratory disease and management strategies, May 18. Hershey, PA. A continuing education service of Penn State's College of Medicine at the Milton S. Hershey Medical Center.

along with hypoglycemia. Other reasons for hypocalcemia in the newborn are trauma, hemolytic disease, asphyxia, and maternal hypocalcemia (Taeusch et al., 2005).

SIGNS AND SYMPTOMS. Symptoms of hypocalcaemia can range from asymptomatic to seizures and are similar to the symptoms of hypoglycemia and often difficult to differentiate. Often a hypoglycemic newborn may also be hypocalcemic. Other symptoms may include jitteriness, hyperalertness, increased tone, poor feeding and high-pitched cry.

DIAGNOSIS. The diagnosis is made by laboratory study. Where the calcium level is below 7.5 mg/dL in preterm newborns and 8 mg/dL in term newborns (Klaus & Fanaroff, 2005).

NURSING CARE. The nurse understands that return to a normal calcium level is facilitated by feeding the infant soon after birth. Other treatment can include physiological correction of hypoparathyroidism, administration of calcium supplements, and in severe cases the administration of 10% calcium gluconate.

Hypomagnesemia

Magnesium is necessary for proper parathyroid function. Hypomagnesemia frequently coexists with hypocalcaemia.

SIGNS AND SYMPTOMS. The decreased magnesium in the blood is usually accompanied by increased neuromuscular irritability.

DIAGNOSIS. Hypomagnesemia is present when the magnesium levels are below 1.5 mg/dL (normal newborn range is 1.5 to 2.8 mg/dL). It can be caused by low maternal magnesium levels, SGA or LGA growth patterns, and hypoparathyroidism.

NURSING CARE. Nursing care consists of magnesium replacement by giving magnesium sulfate. Magnesium may be given orally (PO) in the form of citrate, gluconate, and chloride. Levels should be checked every 24 hours to prevent hypomagnesaemia that can produce hypotonia, poor feeding, and respiratory distress (Klaus & Fanaroff, 2005).

Birth Injuries

A thorough physical assessment is warranted for the LGA newborn to assess for birth injuries related to difficult deliveries. Birth injuries or traumas are usually one of two types: neurological injuries or bone fractures.

SIGNS AND SYMPTOMS. Signs and symptoms are directly related to the specific birth injury or trauma.

DIAGNOSIS. Diagnosis can be made by a thorough nursing assessment, x-ray exam, or appropriate laboratory studies.

NURSING CARE. Nursing care includes neurological assessment for intracranial bleeding and includes assessing posture, cry, seizure activity, and coordination of sucking and swallowing. Any abnormalities in these signs must be reported immediately. Head circumference should be measured in centimeters every hour if neurological symptoms are present. The nurse also assesses for bone fractures and can suggest an x-ray exam to the pediatrician if suspicious.

Brachial Plexus Injuries

Brachial plexus injuries (BPI) affect 5400 newborns in the United States each year. The brachial plexus is a complex nerve supply that is responsible for the movement of the shoulders, chest, and arms. Shoulder dystocia in labor is the leading cause of BPI.

SIGNS AND SYMPTOMS. BPI is classified by type and degree. A first-degree injury consists of stretching of the nerve fibers called neurapraxia, and recovery is usually complete within a few days. Second-degree BPI is called axonotmesis and the nerve is compressed and becomes edematous. Recovery of second-degree BPI takes longer but is often complete. In third-degree injuries, axonotmesis, the sheath is damaged and full recovery is never achieved. Fourth-degree injury is caused by formation of a neuroma that prevents full nerve regeneration, and fifth-degree injury is a disruption of the nerve at the spinal cord and results in incomplete loss of nerve function.

DIAGNOSIS. Diagnosis is made through a complete neurological assessment to determine the exact damage including the type and degree as well as the extent of nerve impairment.

NURSING CARE. Nursing care focuses on assessment, resolution of the trauma, and addressing any complications. The nurse can assess the Moro, biceps, and radial reflexes. The grasp reflex is usually intact. It is important to prevent contractures that usually involve limb immobilization. The limb is gently placed across the abdomen where the hand cuff of the T-shirt is pinned so that the arm is in a flexed position to produce a loose splint. Passive range-of-motion (ROM) exercises usually begin soon. This condition usually improves rapidly without long-term consequences.

Nursing Insight— Erb's or Erb-Duchenne palsy

Upper root injuries produce Erb's or Erb-Duchenne palsy and the newborn usually holds the affected arm limp and turned inward often called the "waiter's tip" position. Lower root injury is called Klumpke's palsy and produces a weak turned out arm and limp hand. Complete nerve injury is called Erb-Klumpke's or total paralysis. An assessment will reveal lack of flexion and movement in the affected arm. The position in which the newborn holds his arm may indicate the sight of the BPI (Benjamin, 2005).

Fractures

Fractures are also common birth injuries and usually involve the clavicle, humerus, or femur.

CLAVICLES. Broken clavicles are the most common fractures from birth (2 to 35:1000 births). Fractured clavicles can occur alone, with brachial plexus injury or with a fractured humerus. Risk factors for a broken clavicle include LGA newborns, forceps use, and shoulder dystocia.

Signs and Symptoms. Symptoms of a broken clavicle include asymmetrical arm movement, asymmetrical Moro reflex, swelling, and "crepitus" detected on palpation of the bone. Crepitus describes the assessment of bone rubbing against bone which can be felt and sometimes even heard on examination. Clavicles heal spontaneously with very little intervention.

Diagnosis. If a course crackling is heard or felt during the physical examination. An x-ray exam will confirm the diagnosis. In addition, a palpable soft mass (hematoma or edema) may also be a sign of a fractured clavicle.

clinical alert

Fractured clavicles

The T-shirt is sometimes pinned so that the arm is in a flexed position to produce a loose splint. The affected arm is pinned to the opposite shoulder by the hand cuff of the newborn T-shirt. Pain management may be needed if the newborn appears uncomfortable. Keep the newborn off the injured side to decrease pain and promote alignment.

LONG BONE FRACTURES. The incidence of a fractured humerus is less than that of clavicle fractures. When they occur they are often treated with soft splinting to immobilize the arm for approximately 2 weeks. Healing is rapid and complete in most cases. Femoral fractures happen at a rate of 0.13/1000 and most often occur in twin gestations. Other risk factors for long bone fractures are breech presentation, prematurity, and osteoporosis. Femoral fractures can be treated with a Pavlik harness which immobilizes the hip and leg and allows the femur to heal. All long bones should be examined by inspection and palpation.

Signs and Symptoms. Some of the symptoms to observe for any birth fractures are crepitus on palpation, pain on palpation, asymmetrical movement or Moro reflexes, swelling and discoloration, or malalignment of the extremity.

Diagnosis. Definitive diagnosis is made by x-ray exam (Tausch et al., 2005).

Nursing Care. The nurse understands that the fractured humerus must be immobilized immediately. The nurse must conduct neurovascular checks frequently. Elevation of the extremity above the level of the heart can facilitate circulation. Cold therapy can help reduce swelling, and pain medication administration is essential. The nurse must remember to communicate the infant's condition to parents and what care measures will be implemented.

Now Can You— Discuss SGA and LGA?

1. Can you discuss conditions affecting SGA infants?
2. Can you discuss conditions affecting LGA infants?

The Premature Newborn

Premature delivery before 37 weeks is still a major health problem in the United States because each year 12.3% of newborns are premature. Prematurity is classified by the weeks of gestation. Severe prematurity is classified as birth at 23 to 26 weeks; moderately premature is birth at 26 to 30 weeks. The risk factors increase as the size and gestational age of the newborn decrease. A newborn can be SGA as well as preterm. Premature newborns are at risk for a number of complications and are responsible for more than half of the 36.7 billion dollars spent each year on newborn care in the United States (March of Dimes, 2006). Premature deliveries have increased over the past 20 years.

Ethnocultural Considerations— Racial disparities

Healthy People 2010 calls for a reduction in preterm deliveries to a national average of 7.6%. The United States is well off that mark and obvious racial disparities exist. White and Asian women have preterm newborns at a 10.7% rate while African American women have premature births at a 17.6% rate. Hispanic women deliver preterm newborns at a rate of 11.4% (Cuevas et al., 2005).

PHYSICAL ASSESSMENT OF THE PREMATURE NEWBORN

The preterm newborn is not only smaller than a term newborn but also has specific characteristics due to his abbreviated development in utero (Table 19-4).

case study Premature Newborn

Ms. Jones, an 18-year-old G-1, comes into the labor and delivery suite at 6 cm cervical dilatation. She is 33 weeks' gestation by last menstrual period (LMP). Baby girl Jones is delivered within the hour and weighs 2000 grams. She breaths spontaneously and her heart rate is 166 beats per minute. She is thoroughly dried, suctioned with a small size bulb syringe for excessive nasal pharyngeal fluid, placed under the radiant warmer, and an initial assessment is done. Her rectal temperature is 98.2°F (36.8°C). Her PIPP pain score is 2 (1 for gestational age and 1 for increased HR). The results of a skin assessment are no skin lesions, birthmarks, or reddened areas. Respirations are 70 per minute with slight nasal flaring, intercostal retractions, and an expiratory grunt. Her extremities have full ROM but poor flexion.

critical thinking questions

1. What classification by gestational age is baby girl Jones?
2. What condition is associated with her respiratory assessment?
3. What are important nursing interventions for baby girl Jones?

◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

CONDITIONS AFFECTING THE PREMATURE NEWBORN

Premature newborns are at risk for respiratory distress syndrome, apnea of prematurity, jaundice, retinopathy of prematurity, anemia of prematurity, and sudden infant death syndrome.

Respiratory Distress Syndrome

Respiratory distress syndrome (RDS) is a developmental respiratory disorder affecting preterm newborns due to lack of lung surfactant. In RDS there is diffuse atelectasis with congestion and edema in the lung spaces. On deflation the alveoli collapse and there is decreased lung compliance. Lecithin-sphingomyelin (L/S) ratio and phosphatidylglycerol (PG) levels are low and inadequate to keep the immature alveoli of the lungs open. Preterm newborns may also have underdeveloped alveoli.

Nursing Insight— Respiratory Distress Syndrome

Respiratory distress syndrome (RDS) affects 40,000 newborns a year in the United States. Respiratory distress may also be referred to as hyaline membrane disease (HMD), surfactant deficiency, or idiopathic respiratory distress. As gestational age decreases the incidence of RDS increases (at 29 weeks of gestation, 60% of newborns experience RDS while at 39 weeks of gestation almost no newborn will experience RDS). RDS has an increased incidence in males, Caucasians, and newborns delivered by Cesarean birth (Taeusch et al., 2005).

SIGNS AND SYMPTOMS. The clinical signs of RDS begin shortly after birth. Premature newborns are often cyanotic in room air. Breathing is rapid (tachypnea) with labored (retractions), and it is often accompanied by an expiratory grunt. If untreated the arterial blood gas values show oxygenation deficits with hypercarbia and metabolic acidosis.

DIAGNOSIS. A pulse oximetry can assist with diagnosis to determine hypoxia. Laboratory studies such as blood glucose (hypoglycemia) serum calcium (hypocalcemia), and Pao₂ (hypoxia) blood gas measurements for serum pH (acidosis) also help in the diagnosis of RDS.

Collaboration in Caring— Radiology

The x-ray findings of RDS reveal a reticulogranular pattern that looks like “ground glass”, possible atelectasis which looks like “white out,” and obscure heart borders (Noerr, 2000).

NURSING CARE. Oxygenation is the priority intervention for the newborn with RDS. The first action to promote oxygenation is mechanical ventilation via endotracheal intubation. Mechanical ventilation is used for preterm newborns with respiratory distress who have very little capacity to oxygenate their alveoli on their own.

An endotracheal tube is placed by a clinician certified in intubations and neonatal resuscitation for delivery of mechanical ventilation. Endotracheal intubation (ET) is done by inserting an endotracheal tube orally or nasally to create an open secure airway in which to ventilate the newborn. Mechanical ventilation with positive end-expiratory pressure (PEEP) is usually needed when newborns weigh less than 1000 g at birth.

After an airway has been established, the administration of synthetic surfactant within 15 to 30 minutes of birth is required. The synthetic surfactant is administered through a catheter in the endotracheal tube. For newborns less than 1000 g it is given to coat the alveoli to keep them open so that they can perfuse with oxygen. Newborns larger than 1000 g benefit from surfactant therapy at any time during the first 2 to 6 hours of life. Continued mechanical ventilation after administration helps the medication to be spread throughout the lung tissue.

medication: Beractant (Survanta)

Classification(s): Sterile nonpyrogenic pulmonary surfactant.

Indications: Lowers minimum surface tension and increases pulmonary compliance and oxygenation in preterm newborns. Prevent and treat RDS in premature newborns.

Action: Lowers surface tension at alveoli level.

Storage: Refrigerate and protect from light.

PHARMACOKINETICS: Absorption: Absorbed only in lungs.

DISTRIBUTION: Does not get absorbed systemically.

Contraindications and Precautions: Monitor heart rate and respiration.

Adverse Reactions and Side Effects: Transient bradycardia, oxygen desaturation, possible increased nosocomial infections.

Route and Dosage: Intratracheal 4 mL/kg q 6 h × 4 (maximum of four doses in first 48 hours)

Nursing Implications:

1. Give within 15 minutes of birth to premature newborns.
2. Naso-oral suction before administration.
3. Warm vial 20 minutes to room temperature.
4. Do not suction for 1 hour after administration.
5. Discard vial after use—do not re-refrigerate once it is warmed.

Data from Deglin, J.H., & Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

Newborns are generally “weaned from mechanical ventilation as soon as possible to avoid complications of oxygen such as bronchopulmonary dysplasia (BPD) and retinopathy of prematurity (ROP). Often they are placed on an alternative oxygen source such as continuous positive airway pressure (CPAP).

Another mode of delivering oxygen is via nasal cannula, which is continuous flow of low-level oxygen to supplement the newborn's own intake. Oxygen by mask is an unreliable method for a newborn.

On occasion an oxygen hood is used to keep a baby in an oxygen-rich environment for a short period of time. Hoods are easy to use and provide easy access to the newborn for procedures and assessment. The newborn with RDS will require blood gas monitoring as well as blood analysis for electrolytes, calcium and glucose levels.

Optimizing Outcomes— Oximeter

Best Outcome: To ensure adequate oxygenation (above 92%) keep the newborn on a pulse oximeter whenever oxygen is being used.

Apnea of Prematurity

Apnea, a spontaneous pause in breathing, is a common occurrence in preterm newborns. The inspiratory center in the medulla oblongata of the brainstem, the central and peripheral chemoreceptors, and the neuroregulators are immature and do not provide the normal negative feedback loop to hypoxia and hypercapnia.

Table 19-4 Assessment of the Preterm Infant

Skin	Head	Chest	Cardiac
Skin tags	Irregular shaped head, molding after delivery, caput succedaneum cephalhematoma	Funnel or pigeon chest	Apical heart rate is assessed for a full minute
Translucent	Large anterior and posterior fontanels present Fused sutures Bulging or depressed fontanels	Supernumerary nipples or nipples are flat on the chest wall	The heart rate may normally be above 160 bpm but it should not be above 180 bpm.
Lanugo covering the shoulders, back, thighs, forehead and ears	Ear pinnas are flat and readily fold upon themselves	Ribs are visible	Heart auscultation is done in the second and fourth right and left intercostal spaces as well as the apex and axillae area
Little subcutaneous fat	Eyes are fused before 24 weeks gestation	Grunting, nasal flaring or retractions (subcostal, sternal or suprasternal) are signs of respiratory distress	Auscultation of heart sounds should be done routinely to detect murmurs which may or may not be innocent
Fragile and easily injured	Nose flattened or bruised Nasal patency Low placement of ears	Auscultate anterior, posterior and at the sides of the chest	Blood pressures on all four extremities are done to determine any wide variations that may be indicative of a ductal defect
Mottled related to poor peripheral perfusion	Facial anomalies	Auscultate respiratory rate for a full minute	Persistent central cyanosis
Prominent veins		Respiratory rate is between 60 and 80 respirations per minute	Displacement of apex
Covered in vernix		Respiratory rate above 80 respirations per minute are not within normal limits	Cardiomegaly
Pale (pallor) related to anemia from blood loss		Asymmetrical chest movement may suggest respiratory conditions such as pneumothorax or diaphragmatic hernia	
Congenital strawberry hemangiomas		Excessive secretions will affect the oxygen intake	
Diaper rash is common related to the increase in irritation of the stool when the newborn is on antibiotics and due to the fragility of the skin			
Soles of the feet are smooth			

Nursing Insight— *Apnea verses periodic breathing*

Apnea must be differentiated from periodic breathing which is normal in the newborn. Periodic breathing is classified as short pauses in the breathing of the newborn that only last approximately 3 seconds. The incidence of apnea increases as the gestational age of the newborn decreases. The apneic spells many times is accompanied by a bradycardiac episode which has led to the clinical term “A&B spell.”

SIGNS AND SYMPTOMS. Apnea spells are significant if they last more than 15 to 20 seconds and many times are accompanied by abrupt pallor, hypotonia, cyanosis, and bradycardia. Apnea, and many times the resulting bradycardia and desaturation, is due to several factors such as neurological immaturity, increased resistance to rising PCO₂ blood levels and immaturity of the respiratory receptors which respond normally to increasing CO₂ levels.

DIAGNOSIS. Apnea is diagnosed if the spell last more than 20 seconds and is accompanied by the other signs and symptoms.

Abdomen	Musculoskeletal	Genitalia	Neurological/Sensory
Cord does not have two arteries and 1 vein	No flexion of extremities resulting in increased susceptibility to heat loss and skin breakdown	Male scrotum has no rugae and the testes are often undescended	Marked head lag in all positions
Palpate for masses	Assess for fractures or Developmental Hip Dysplasia or fractured clavicle	Female clitoris is often prominent and not covered by the labia minora. The labia majora is also small	Consistent caregivers read the cues and notice subtle changes
Auscultate bowel sounds		Inguinal hernias are common	Sucking and gagging reflexes are often absent until 32 to 34 weeks gestation
Abdominal circumference is done to assess for distention that may indicate necrotizing enterocolitis (NEC)		Female absence of vaginal or male urethral opening covered by prepuce	Moro reflex may be absent to weak
		Meconium found in the vaginal opening	Any signs or symptoms of increased intracranial may be related to cerebral insults
Enlarged liver or spleen		Ambiguous genitalia	Hypotonia or hypertonia
		Bladder exstrophy	Twitches, jittery, myoclonic jerks
			Eye lids edematous, drainage present, minimal reactivity to light, congenital cataracts, absence of red reflex, inability to follow object or bright light
			Eyes have nystagmus strabismus ruptured capillaries

NURSING CARE. Most preterm newborns are on a cardio-respiratory (C-R) monitor (Fig. 19-7). The C-R monitor is attached to the newborn by three electrodes. Two electrodes are placed on either side of the chest and the third on the abdomen. The electrodes are changed often based on NICU protocol. Every time the electrodes are changed they are applied to a new area of skin to prevent breakdown from the adhesive. The C-R monitor is set to alarm if the newborn fails to breathe spontaneously for 20 seconds, the respiratory rate falls below a certain rate (usually 20 respirations/min) or the heart rate drops below a certain rate (usually 80 to 100 beats per minute). An alarm notifies

the nurse of an impending apnea or bradycardic spell or combined A&B episode.

Preterm apnea usually resolves at 37 to 38 weeks postconceptional age (PCA) but may last longer. Many preterm newborns are sent home on home monitoring systems that alarm if respirations stop longer than 20 seconds or the heart rate drops (Stokowski, 2005). If newborns are discharged without monitors they usually need to be A&B spell free in the hospital for at least 5 to 7 days (Hummel & Cronin, 2004).

The pulse oximeter is a small plastic light-emitting probe that is a noninvasive and can be secured to the newborn's extremity. The newborn is maintained on

Figure 19-7 Most preterm newborns are on a cardiorespiratory monitor.

continuous pulse oximeters to guard against desaturation episodes. Oxygen saturation is calculated from the hemoglobin flowing under the light and then the percent is displayed on the monitor. It is easy to use and the saturation measurements are fairly reliable when compared to arterial samples of blood. The saturation should be maintained above 92% (Klaus & Faranoff, 2005).

The pulse oximeter is also set to alarm during a low peripheral O₂ saturation (usually below 88%). If the newborn desaturates without a corresponding A&B spell is called a desaturation episode. An apneic, bradycardic, or desaturation episode requires immediate attention. There are different severities of A&B spells. Some newborns take a deep breath and regulate themselves back into a normal cardiorespiratory pattern without intervention, which is often called a self-limiting episode. Some newborns continue the apnea, bradycardia, and desaturation spell and need mild stimulation to induce them to take a deep breath and regain a normal cardiorespiratory pattern. Stimulation is done by rubbing their backs or flicking their feet. Periodically, newborns need aggressive stimulation to regain cardiorespiratory control which includes increasing existing oxygen flow or using positive pressure through bag and mask ventilation (Fig. 19-8).

Nursing Insight—Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia (BPD) or Chronic lung disease (CLD) is a condition in which the newborn becomes oxygen dependent past 36 weeks gestation (Sahne et al., 2005). BPD is a complication produced by long-term oxygen use. Although oxygen is needed by the preterm to maintain proper tissue perfusion until the maturing lungs can resume that function, supplemental oxygen can also damage lung tissue by suppressing compliancy. Because oxygen is administered, the lungs fail to develop the normal compliancy needed to force adequate levels of air in and out. Sometimes the preterm newborn ends up with noncompliant lungs that need oxygen via cannula for an

Figure 19-8 Some newborns need aggressive stimulation to regain cardiorespiratory control which includes increasing existing oxygen flow or using positive pressure through bag and mask ventilation.

extended period of time, sometimes up to a few years, in order to properly oxygenate their growing bodies. Newborns with BPD are often sent home on O₂ after the parents have been educated in oxygen administration. The amounts of oxygen needed through the cannula vary with the severity of the BPD but often it is a small flow at anywhere from ¼ to 1 liter flow rate with anywhere from 21% to 30% of oxygen.

Jaundice

Newborn physiological jaundice (hyperbilirubinemia) is common and occurs because of the newborn's immature liver (especially the preterm newborn). The liver cannot conjugate the bilirubin as quickly as needed. The excess bilirubin in the circulatory system moves into the skin, sclerae, nails, body fluids, as well as other body tissues resulting in jaundice. Jaundice that appears on the second or third day of life usually peaks on day four and declines on day five.

Nursing Insight—Jaundice

Bilirubin is a byproduct of the breakdown of hemoglobin. Newborns have higher levels of fetal hemoglobin at birth which breaks down faster because it has a shorter life span than adult hemoglobin.

The fetal hemoglobin is broken down by the reticuloendothelial system and bilirubin is released into the circulation. The circulating bilirubin or total serum bilirubin (TSB) binds to plasma albumin. This circulating bilirubin is unconjugated (UCB) and not water soluble. The bilirubin is then converted in the liver to conjugated (water-soluble) bilirubin. The conjugated bilirubin is excreted in the bile by the gastrointestinal tract and then excreted in the stool.

The two categories of jaundice are physiological and pathological.

Premature infants develop physiological jaundice at a rate of 90% compared to 60% of full-term newborns due to the extreme immature live functions and polycythemia. Physiological jaundice occurs in the first 24 hours of life and lasts about 5 days. The infant does not display any other signs of illness.

Pathological jaundice usually happens at less than 24 hours of age and lasts for longer than the first week of life.

More serious conditions such as obstructive (biliary atresia) or metabolic disorders, hemolysis, infections, or toxic disorders are the reason for this type of jaundice.

If jaundice is suspected, a total serum bilirubin level (the sum of conjugated and unconjugated bilirubin) blood specimen is collected stat and then care is given as determined by the medical doctor's order.

Transcutaneous bilirubinometry (TcB) is a noninvasive way of monitoring bilirubin in the skin. Over time, multiple readings at a consistent site (forehead or sternum) provide the most accurate measurement of the bilirubin. However, once phototherapy has begun the TcB monitor is no longer a useful screening tool and serum blood specimens must be drawn every 6 to 12 hours.

In addition, other laboratory samples, such as liver enzymes (GGT), alkaline phosphatase, prothrombin time (PT), and partial thromboplastin time (PTT) are drawn. If a more serious abnormality is suspected a radiological evaluation is done.

Nursing Insight— Jaundice in breastfeeding infants

Early jaundice in breast fed infants begins at 2–4 days and most likely results from decreased fluid intake and caloric intake. After the milk supply is well established this type of jaundice resolves.

Late jaundice in breastfed infants begins at 4–7 days and can peak during the second week of life. Factors in the breast milk are thought to inhibit the conjugation or decrease the excretion of excess bilirubin. This type of jaundice may resolve on its own or the infant may need further care.

SIGNS AND SYMPTOMS. Normally unconjugated bilirubin values are between 0.2 and 1.4 mg/dL. Visible jaundice (a yellowish discoloration) is usually seen at a level of 5 mg/dL within the first 24 hours of birth.

DIAGNOSIS. Jaundice is diagnosed in term infants with a serum bilirubin level greater than 12.9 mg/dL and in pre-term infants with a serum bilirubin greater than 15 mg/dL. In addition to serum blood levels other factors that help determine the extent of the jaundice is evidence of hemolysis, gestational age at birth, family history (including maternal Rh factor), timing of the appearance, and method of feeding. If jaundice appears, a bilirubin level to determine the bilirubin risk factor is plotted on the bilirubin graph in relation to hours of age (American Academy of Pediatrics [AAP], 2004) (Fig. 19-9).

NURSING CARE. Treatment of jaundice is based on the underlying cause. Infants who are plotted on the graph in the high-risk zone on the bilirubin risk chart undergo phototherapy (bilirubin lights). Phototherapy uses daylight, cool white, blue, or “special blue” fluorescent light tubes. Fluorescent lights are the most effective form of phototherapy and are placed around and above the newborn (Fig. 19-10). The level of bilirubin in the blood determines if the newborn is placed under single, double, or triple phototherapy. Fiber-optic systems (Bili-blanket) can also deliver phototherapy in a blanket form placed under or around the newborn.

Figure 19-9 Laboratory evaluation of the jaundiced infant of 35 or more weeks' gestation.

Figure 19-10 The eyes and genitalia of the newborn are always covered to prevent tissue and retinal damage.

critical nursing action Care of the Jaundice Infant

The nurse must remember that when a newborn is under phototherapy the eyes must be shielded by an opaque mask. The nurse assesses the newborn's eyes every 4 hours to assess for discharge or corneal irritation. It is important to remove the mask during feedings so the infant can receive visual stimulation. The infant's genitalia area must also be covered. Also, during phototherapy or use of the Bili-blanket, the newborn should be kept warm. The infant is susceptible to hypothermia due to skin exposure and the temperature needs to be monitored closely. In addition, it is important that the infant receive proper nutrition to ensure the clearance of the bilirubin. The breast or formula feeding mother can be encouraged to feed the child as often as every 2 hours. These treatment measures must be explained to parents to help decrease their anxiety. Parents need to report any changes in the infant's condition such as an increase in jaundice, poor feeding, lethargy, or vomiting.

Other treatments for hyperbilirubinemia include hydration with an electrolyte solution if the newborn shows signs of dehydration such as dry skin and mucus membranes, poor intake, concentrated urine, or limited urine output and irritability (AAP, 2004).

Without appropriate screening and treatment of hyperbilirubinemia in the newborn, complications can occur.

Bilirubin encephalopathy describes the clinical findings when the serum bilirubin level is so elevated that the central nervous system is affected. The newborn becomes lethargic, hypotonic, and has feeding difficulty. This is a severe hyperbilirubinemic condition that warrants exchange transfusions to prevent a condition called kernicterus (AAP, 2004).

An infant with untreated jaundice is at risk for kernicterus. If bilirubin crosses the blood–brain barrier it can permanently damage a newborn’s brain (Shapiro, 2005). Not all newborns with bilirubin encephalopathy progress to kernicterus, and the exact level of serum bilirubin required to cause damage is not yet known. The damage caused by kernicterus can be cerebral palsy, auditory dysfunction, dental-enamel dysplasia, upward gaze, as well as intellectual and other handicaps (AAP, 2004).

Retinopathy of Prematurity

The retinal vessels of the preterm newborn are frail and immature. Retinopathy of prematurity (ROP) is a result of immature retinal vasculature followed by hypoxia. The concentration and duration of supplemental oxygen are thought to play a role in the development of ROP.

ROP is inversely related to gestational age. Therefore, the younger the infant the greater the likelihood he has of developing this condition. Risk factors include gestational age of less than 32 weeks, birth weight of less than 1500 g, hypothermia, sepsis, and high-intensity lighting. The extent of retinal damage in the preterm newborn is dependent on three criteria: (1) the gestational age of the newborn, (2) the length of exposure to oxygen, and (3) arterial pressure.

SIGNS AND SYMPTOMS. In the first stage of ROP, the retinal vessels react to oxygen administration with vasoconstriction. If the vasoconstriction of the vessels is prolonged, abnormal vessel growth ensues. In the second stage vessel hemorrhages and edema into the vitreous occurs. In the third stage the vessels fibrose. The fourth stage is severe and is classified by retinal detachment.

DIAGNOSIS. Retinopathy of prematurity is diagnosed based on five stages, ranging from mild to severe.

- Stage I — abnormal blood vessel growth is mild.
- Stage II — abnormal blood vessel growth is moderate.
- Stage III — abnormal blood vessel growth is severe.
- Stage IV — the retina is partially detached.
- Stage V — completely detached retina. This is the end stage of the disease.

NURSING CARE. During oxygen administration, fluctuations in arterial concentrations of oxygen must be prevented. The nurse understands that the PaO₂ should not be set greater than 80 mm Hg and that the preterm newborn should be weaned off oxygen as soon as possible. In addition, the nurse can decrease the constant bright lights in the infant’s environment. A blanket can be placed over the incubator during the day. Nap time can be designated where the lights are lowered and other environmental stimuli are decreased.

The preterm newborn should be checked routinely for signs of ROP by a specialist. Examinations should be started at 4 to 6 weeks of age and continue until vascularization of the retina to reduce the risk of visual impairment (usually myopia) and blindness. Most babies who

develop retinopathy of prematurity have stages I or II. If ROP is untreated it will destroy the infant’s vision (National Eye Institute, 2008). Cryotherapy is used to treat ROP (Kraus & Fanaroff, 2005).

critical nursing action Retinopathy of Prematurity

Because retinopathy of prematurity (ROP) may be a complication of oxygen therapy, the nurse must maintain the lowest level of oxygen as possible to maintain the pulse oximeter reading above 92%.

Anemia of Prematurity

Premature newborns are often anemic for several reasons. One reason is that the newborn undergoes many lab evaluations. Even though small amounts of blood are taken for each study, multiple studies are done and it reduces circulatory volume. A second reason for anemia is the rapid growth a preterm newborn undergoes in a short period of time. A third reason has to do with erythropoietin release. Erythropoietin is not released until 34 to 36 weeks of gestation and then responds when hematocrit levels are low. There is an approximately 1-week delay between erythropoietin release and the production of reticulocytes.

SIGNS AND SYMPTOMS. Typical sign and symptoms include fatigue, shortness of breath, headache, dizziness, and pale skin.

DIAGNOSIS. A drop in hemoglobin below the average hematocrit value (between 35% and 45%) is the definitive sign of anemia.

NURSING CARE. Nursing care consists of transfusions of blood, although many times necessary, actually delay the erythropoietin mechanism. Anemia of prematurity is treated with recombinant human erythropoietin (r-HuEPO) subcutaneous to stimulate erythropoiesis. It is given until 34 to 35 weeks of gestation (Fike, 2004; Klaus & Fanaroff, 2005). The nurse assesses hematocrit levels per hospital policy.

Sudden Infant Death Syndrome

“Back to sleep” is the American Academy of Pediatric (AAP) campaign to educate parents and families who are involved in newborn care to prevent sudden infant death syndrome (SIDS). Since US public education started in the early 1990s there has been a 50% reduction rate in SIDS deaths. The current incidence of SIDS is 1:2000 newborns.

NURSING CARE. Priority nursing care includes education about sudden infant death.

The following recommendations are incorporated into the care of the preterm newborn in the NICU. Newborns who have been in the NICU and are preparing for discharge in the near future must be taught to sleep on their backs even though the prone position may have been used as a care intervention to increase gastric motility. Home monitors are not recommended for SIDS prevention although preterm newborns may be sent home on monitoring for other reasons. Most preterm newborns are well acquainted with a pacifier long before their discharge date to assist with their sucking and swallowing coordination, so this practice should be continued.

Family Teaching Guidelines... Preventing Sudden Infant Death Syndrome

- ◆ Put all newborns on their backs to sleep.
- ◆ Use a firm mattress.
- ◆ Ensure there are no toys, soft bedding, or extra linen in the newborn's sleeping area.
- ◆ Encourage the use of pacifiers as they decrease the incidence of SIDS (although the exact reason why is not known).
- ◆ Do not allow smoking in the home.
- ◆ Be aware that commercial home monitoring devices do not decrease the incidence of SIDS.
- ◆ Never allow newborns to sleep in parental beds.
- ◆ Newborns should sleep in close proximity of their parents/guardian (usually interpreted as in the same room).
- ◆ Avoid overheating the newborn.

Essential information: The current guidelines of the American Academy of Pediatrics (AAP) apply to all newborns but it is important to remember that the preterm newborn is at a higher risk for the SIDS. These recommendations have been made by the AAP as of October 10, 2005.

The Postterm Newborn

Postterm newborns are also considered high-risk. Although fewer pregnancies are carried to post-term today due to elective inductions there are still incidences where a newborn is born after 42 weeks of gestation. Postterm newborns may or may not be LGA. The newborn may have actually lost weight in utero because of declining placental ability to transport nutrients and oxygen.

Because these newborns are in utero after the optimal growth time they undergo developmental changes including skin desquamation or peeling. The skin of a post-term infant is often parchment-like and is often cracked on the abdomen and extremities. The fingers appear long and are often peeling and sometimes general muscle wasting is evident.

Postterm newborns are at risk for passing meconium stool in utero, which increases their chances of meconium aspiration pneumonia and persistent pulmonary hypertension (PPHN). Often the cord is meconium stained on assessment indicating that meconium was passed in utero at some time well before delivery (Klaus & Fanaroff, 2005).

CONDITIONS AFFECTING THE POSTTERM NEWBORN

Meconium Aspiration Pneumonia

Meconium aspiration pneumonia occurs in 10% to 26% of all deliveries and the incidence increases directly with gestational age (before 37 weeks of gestation there is a 2% incidence and at 42 weeks of gestation a 44% incidence). The passage of meconium in utero is believed to be either

a response to intrauterine hypoxia or a maturational occurrence for the newborn. Meconium can be aspirated at birth if it is not removed from the trachea at delivery.

Meconium in the lungs causes obstruction in the small airways and hyperinflation with areas of atelectasis (collapse of a portion or the entire lung due to blockage of air passage) leading to hypoxia. Some newborns with meconium aspiration pneumonia have elevated pulmonary arterial pressures and develop persistent pulmonary hypertension (PPHN).

SIGNS AND SYMPTOMS. Signs of meconium aspiration are meconium-stained skin, nails, and umbilical cord. The newborn usually has initial respiratory distress tachypnea and often has a barrel shaped chest from overinflated lungs. Rales and rhonchi are heard on auscultation.

The respiratory symptoms get progressively worse over the first 12 to 24 hours. Meconium aspiration pneumonia is often complicated by pneumothorax (collection of gas in the space surrounding the lungs) and pneumomediastinum (condition in which air is present in the space in the chest between the two lungs). Pneumothorax is an emergency situation and requires chest tubes.

DIAGNOSIS. Meconium aspiration pneumonia can be visualized in the infant's vocal cords and respiratory passages using a laryngoscope. Diagnosis is confirmed through a chest x-ray exam.

diagnostic tools X-Ray Films

The chest x-ray film usually shows: patchy infiltrates, overexpansion, atelectasis, flattened diaphragm, and bulging intercostal spaces (Noerr, 2000).

NURSING CARE. Nursing care of meconium aspiration pneumonia consists of chest physiotherapy (PT) and oxygen administration. Chest physiotherapy can be done by percussion with a small cup, base of a feeding nipple, or specifically made neonatal chest PT device or vibration by a battery-operated vibrator. Chest PT should be done every 3 to 4 hours to help maintain a clear airway. Postural drainage with percussion or vibration is followed by suction.

CPAP is frequently used to provide oxygen. Oxygen by noninvasive means such as hood or cannula is often not sufficient. If the newborn cannot maintain a PaO₂ of 50 mm Hg or higher in 100% oxygen then mechanical ventilation is used.

Because the newborn is postterm and neurologically more mature than ventilated preterm newborn, neuromuscular medications such as Pavulon (Pancuronium) or vecuronium (Norcuron) may be used to increase the effectiveness of ventilation efforts. Analgesic and sedative medications may also be used such as fentanyl (Sublimaze), lorazepam (Ativan), morphine sulfate (Astramorph), or demerol (Meperidine) so the newborn does not "fight" the ventilator (Taeusch et al., 2005).

Persistent Pulmonary Hypertension of the Newborn

Persistent pulmonary hypertension of the newborn (PPHN) was once termed persistent fetal circulation because there is right-to-left shunting of blood across the foramen ovale and through the ductus arteriosus. The meconium in the newborn's lung induces platelet aggregation in the microcirculation of the pulmonary system,

keeping the arterial pressure elevated. The PPHN is vascular resistance in the pulmonary system which can be caused by sepsis or pneumonia but the most common cause of newborn PPHN is meconium aspiration pneumonia. This occurs when pulmonary vascular resistance does not decrease after birth so the transition to normal adult-type circulation to the pulmonary system is resisted, forcing fetal circulation to persist. PPHN produces a right ventricular overload and poor left ventricular filling. The critical cycle of PPHN is shown in Figure 19-11.

SIGNS AND SYMPTOMS. PPHN usually affects term or postterm newborns because they are frequently born through meconium stained amniotic fluid. The newborn has brief respiratory distress at birth and then responds normally. By 12 hours after birth the signs of PPHN are displayed. The newborn is centrally cyanotic and tachypneic. Grunting and retracting is usually not evident. They may have an audible murmur due to tricuspid insufficiency but their blood pressure remains normal.

DIAGNOSIS. Diagnosis is confirmed from the clinical signs and symptoms and chest x-ray exam. There is often hypoglycemia and hypocalcaemia. Arterial blood gases show oxygen desaturation. Ultrasonography of the heart is done to rule out cardiac anomalies and to visualize any right to left shunting (Taeusch et al., 2005).

NURSING CARE. Nursing care of the newborn with (PPHN) is critical with the optimal outcome of good oxygen saturation as well as overall stabilization.

critical nursing action Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) is used for newborns who are not responding to conventional or high-frequency ventilation (Fig. 19-12). ECMO has only an 80% success rate and it is used as a last resort for respiratory support. Delivering ECMO is a complicated procedure and is a heart and lung bypass procedure used mainly for newborns with meconium aspiration pneumonia, neonatal pneumonia, and congenital diaphragmatic hernias. Newborns less than 34 weeks' gestation or 2000 g are not candidates due to the need for heparinization of the blood which can cause a cerebral hemorrhage in small or preterm newborns. ECMO is accomplished by inserting a catheter into the right internal jugular vein that extends into the right atrium and another catheter inserted into the right carotid artery into the aorta arch. The system drains venous blood and replaces arterial blood with oxygenated packed red blood cells, platelets, and fresh frozen plasma. The procedure is expensive, work intensive, and carries a multitude of complications. It is available only at select Level III neonatal centers (Taeusch et al., 2005).

Additional Conditions Affecting The High-Risk Newborn

Many conditions are now diagnosed prenatally with ultrasound. High-risk newborns may have several conditions that impact their health. Any condition can be devastating for the family and may require emergency treatment. Some significant conditions include metabolic, neurological, and gastrointestinal anomalies as well as abdominal

Figure 19-11 Persistent pulmonary hypertension of the newborn.

Figure 19-12 Extracorporeal membrane oxygenation (ECMO) is used for newborns that are not responding to conventional or high frequency ventilation.

wall defects, infections, and a condition that causes developmental delay. The nursing care for the infant is holistic and individualized.

METABOLIC CONDITIONS

Metabolic disorders are diagnosed after birth, and 4 million newborns undergo metabolic and genetic screening each year. Four thousand identified newborns are then diagnosed

Nursing Care Plan Persistent Pulmonary Hypertension of the High-Risk Newborn

Nursing Diagnosis: Ineffective Tissue Perfusion: Cardiopulmonary, related to persistent pulmonary hypertension of the newborn (PPHN).

Measurable Short-term Goal: The newborn will maintain peripheral oxygen saturation levels of 92–95%.

Measurable Long-term Goal: The newborn will maintain adequate tissue perfusion on room air.

NOC Outcomes:

- Tissue perfusion: Pulmonary (0408) Adequacy of blood flow through pulmonary vasculature to perfuse alveoli/capillary unit
- Respiratory status: Gas Exchange (0402) Alveolar exchange of carbon dioxide and oxygen to maintain arterial blood gas concentrations

NIC Interventions:

- Respiratory Monitoring (3350)
- Oxygen Therapy (3320)

Nursing Interventions:

1. Monitor respiratory rate, lung sounds, effort of respirations, color, and oxygen saturation frequently (specify how often) for 24–48 hours after meconium-stained delivery.

RATIONALE: PPHN sometimes develops after the first 12–24 hours of life.
2. Notify the caregiver of signs of respiratory distress: tachypnea, grunting, nasal flaring, retracting, cyanosis, or decreased oxygen saturation.

RATIONALE: Respiratory distress related to PPHN can occur rapidly.
3. Record a preductal (right radial) pulse oximeter reading and postductal (left radial or either foot) pulse oximeter reading simultaneously.

RATIONALE: A difference of 5% may be helpful in diagnosing the right-to-left shunt produced by PPHN.
4. Take four extremity blood pressures.

RATIONALE: A difference of >10–15 mmHg preductal and postductal may suggest a right-to-left shunt.
5. Provide and monitor oxygen and respiratory support as ordered (specify) to maintain a pulse oximetry reading of >92%.

RATIONALE: Oxygen therapy may be needed to maintain adequate saturation levels.
6. Maintain infant in a neutral thermal environment without excessive noise or stimulation.

RATIONALE: A thermoneutral environment decreases metabolic needs and decreased environmental stimuli may avoid excess neurological stimulation.
7. Administer sedation as ordered (specify drug, dose, route, and time)

RATIONALE: (Specify action of the drug) Sedation may reduce metabolic needs.
8. Closely monitor intake and output. Restrict fluids as ordered (specify).

RATIONALE: Excessive fluids can increase pulmonary workload and increase respiratory distress.
9. Provide information and support to the family.

RATIONALE: These newborns can become critically ill and are often transferred out to the most technologically advanced Level III NICU for Extracorporeal Membrane Oxygenation (ECMO) support.

with metabolic disorders. All 50 states (and Puerto Rico) screen for phenylketonuria and hypothyroidism, 46 states screen for galactosemia and 45 for hemoglobinopathy. Maple syrup urine is included in the screening for 25 five states. Other disorders are screened for in various states such as homocystinuria, biotinidase deficiency, congenital adrenal hyperplasia (CAH), cystic fibrosis (CF), and toxoplasmosis. The screening that is done for these conditions can promote early intervention, thereby decreasing devastating complications (AAP, 2005). States vary greatly among the different tests screened for and new tests that can be included in regular screening are being discovered on a regular basis (Kenner & Moran, 2005) (Box 19-7).

Box 19-7 Metabolic Diseases of the Newborn

- Tyrosinemia
- Adenosine deaminase deficiency (ADA)
- Arginase deficiency (AD)
- Urea cycle defects
- Duchenne muscular dystrophy (DMD)
- Glucose-6-phosphate dehydrogenase (G-6PD) deficiency
- Pyroglutamic aciduria
- Medium-chain acyl-CoA dehydrogenase deficiency (MCAD)

Phenylketonuria

As early as 1961, Dr. Robert Guthrie developed a blood test to diagnose newborns with phenylketonuria (PKU). It was the first metabolic disease that prompted universal screening for metabolic diseases and it is currently screened for in all U.S. states/territories. It is a disease transmitted by an autosomal recessive gene. The incidence varies greatly by race from 1:6000 in Caucasian to 1:60,000 in newborns of Japanese descent. There is a deficiency of phenylalanine hydroxylation and phenylalanine cannot be broken down.

SIGNS AND SYMPTOMS. There are no signs or symptoms at birth. Accumulations of phenylalanine eventually cause developmental delays, mental retardation, and seizures.

DIAGNOSIS. Phenylketonuria is diagnosed through a blood test.

NURSING CARE. The nurse communicates to the parents that phenylketonuria is controlled by a phenylalanine-free diet with the elimination of proteins (including breast milk and formula). The diet is continued for child's entire life. Parents can find information about this condition and diet at Centers for Disease Control and Prevention (PKU) (<http://www.cdc.gov/>; AAP, 2008).

Galactosemia

Galactosemia is screened in 46 U.S. states/territories. The incidence is 1:60,000-80,000. It is an inherited metabolic deficiency. Children with galactosemia cannot metabolize galactose and it results in failure to thrive, vomiting, liver disease cataracts, mental retardation, and even death.

SIGNS AND SYMPTOMS. The signs and symptoms of galactosemia cause the inability to use galactose to produce energy.

DIAGNOSIS. Galactosemia is diagnosed through a blood test.

NURSING CARE. Children diagnosed with galactosemia are placed on a galactose-free diet that needs to be maintained for life (AAP, 2008).

Maple Syrup Urine Disease (Branched-Chain Ketoaciduria)

Maple syrup urine disease is screened for in 25 U.S. states/territories. It is an autosomal recessive disorder that results in high body fluid levels of ketoacids and can lead to lethargy, irritability, and then progress to coma and death. This specific metabolic deficiency has a high incidence in the Mennonite population (1 in 760) but should be considered for any newborn with severe acidosis in the first 10 days of life.

SIGNS AND SYMPTOMS. There are no symptoms at birth. Urine has a characteristic odor. If left untreated the newborn will show neurological signs, poor feeding, vomiting, increased reflexes, and seizures.

DIAGNOSIS. Maple syrup urine disease is diagnosed through a blood test.

NURSING CARE. A low-protein diet is initiated and thiamine supplements may be given. The parents are told that the dietary treatment must begin as soon as possible and continued throughout life (AAP, 2008).

Homocystinuria

Homocystinuria is screened for in 22 U.S. states/territories. The incidence is 1:50,000. It is an autosomal recessive genetic transmission. There is a deficiency in cystathionine beta-synthase which causes high levels of serum methionine. Children with homocystinuria have ocular abnormalities and thromboembolisms that affect both legs.

SIGNS AND SYMPTOMS. Signs of homocystinuria can include skeletal abnormalities, displacement of the eye lens, an increase risk for blood clots, and as the child grows problems with learning and development.

DIAGNOSIS. Homocystinuria is diagnosed through a blood test.

NURSING CARE. Diet therapy includes high doses of vitamin B₆ and methionine and cystine restriction (AAP, 2008).

Biotinidase Deficiency

Biotinidase deficiency is screened for in 21 U.S. states/territories. It is an autosomal recessive metabolic disorder in which leads to carboxylase deficiency due to faulty biotin recycling.

SIGNS AND SYMPTOMS. Without treatment, symptoms show at 7 weeks to 3 years and include developmental delay, hypotonia, uncoordinated movement, alopecia, rash, hearing loss, optic nerve atrophy, seizures, and mental retardation. Untreated cases progress to metabolic acidosis that can lead to death.

DIAGNOSIS. Biotinidase deficiency is diagnosed through a blood test.

NURSING CARE. The nurse communicates to the family the infant must receive Pantothenic acid or biotin (types of B vitamins). These vitamins must be replaced every day because they are essential to growth and help the body break down and use food. Pantothenic acid and biotin are also found in foods such as eggs, fish, milk and milk products, whole grain cereals, lean beef, legumes, and broccoli (AAP, 2008).

NEUROLOGICAL CONDITIONS

Intraventricular and Periventricular Hemorrhage

Acute intracranial hemorrhage (ICH) of the newborn is bleeding into the epidural, subdural, or subarachnoid areas of the brain. An ICH can be minimal or extensive and present clinically from asymptomatic to seizures activity.

SIGNS AND SYMPTOMS. The ICH is often categorized by extent and involvement. Grade I hemorrhages bleed into the subependymal only; grade II hemorrhages bleed into the subependymal and the ventricles but do not produce distention of the ventricles. Grade III hemorrhages bleed into the ventricles and produce dilatation of the ventricles which can lead to hydrocephalus. Grade IV hemorrhages produce the same bleeding as in grade III but the bleeding extends to the parenchymal.

DIAGNOSIS. ICH are diagnosed by cerebral ultrasound and followed up with magnetic imaging or CT scan (Taeusch et al., 2005). Diagnosis can also be made by observing altered states of consciousness in the preterm newborn as well as behavioral changes. In addition, an

enlarging head circumference needs immediate attention and is indicative of a worsening IVH or periventricular hemorrhage (PVH).

NURSING CARE. The priority nursing care centers on recognition of infant seizures so treatment can begin immediately. Phenobarbital (Luminal Sodium) is the drug of choice as well as phenytoin (Dilantin), lorazepam (Ativan), and diazepam (Valium). It is also essential to prevent cerebral damage as well as maintain adequate oxygenation. Parents will need information about their infant's status and subsequent care.

Neurological sequelae related to IVH and PHV are associated with the severity of the bleed. Severe bleeds can lead to seizures, mental deficiencies, and cerebral palsy. Head ultrasounds are done routinely in the nursery, usually every week in order to evaluate the presents of IVH and PVH in the preterm population. If the bleed causes obstruction of cerebral spinal fluid (CSF), a shunt is needed to prevent hydrocephalous.

critical nursing action Intraventricular and Periventricular Hemorrhage

When caring for a neonate with intraventricular or periventricular hemorrhage the nurse must observe for neurological symptoms including poor oxygenation readings on pulse oximeter, poor feeding (if the newborn is being fed), lethargic behavior, increased apnea and bradycardic spells and seizures may also occur. Critical nursing actions include keeping accurate and frequent measurements of head circumference in centimeters, reporting any sudden increase in head circumference, and monitoring fontanels to ensure they are soft, flat and open on palpation.

Anencephaly

Anencephaly is a condition in which the skull and cerebrum is malformed but the anterior lobe of the pituitary is intact. These newborns can be born alive but the condition is lethal so they die in a short period of time. Anencephaly has a higher incidence in girls than boys. The defect is visually disturbing because most of the skull is not present (Taeusch et al., 2005). Nurses provide palliative and spiritual care with no effort at resuscitation. The family requires emotional support to cope with the infant's devastating condition.

Encephalocele

Encephalocele is a neural tube defect that is noticeable at birth because there is protrusion of the brain through a skull defect. Sixty to 80% of the time it occurs in the occipital area but it can also occur in the parietal, frontal or nasal regions. This defect often accompanies other congenital anomalies and surgical repair is attempted to close the defect and prevent infection. The mortality rate is higher than 30% and the many of the survivors have neurological deficits. Like anencephaly, encephalocele requires care that is directed at the defect, including the neurological and developmental effects (Taeusch et al., 2005).

Microcephaly

Microcephaly may be caused by an autosomal recessive disorder, toxic stimulus during prenatal development, or a chromosomal abnormality. Microcephaly means the infant

has a smaller than normal head circumference. It is defined as a head circumference 2 standard deviations below the mean for gestational age and is identified by progressive head circumference measurements. Microcephalic newborns may have other congenital malformations but in many cases do not show a recognizable syndrome (Vargas, Allred, Leviton, & Holmes, 2001). There is no treatment for microcephaly and nursing care is supportive. The nurse teaches parents how to rear the child according to the most realistic developmental level.

clinical alert

Microcephaly

It is critical to maintain accurate and consistent head circumference measurements by plotting on the growth chart and monitoring the newborn for neurological symptoms.

Holoprosencephaly

Holoprosencephaly is a condition in which the cerebral matter fails to form as two distinct hemispheres. There is no fissure between the brains' hemispheres and often the ventricular system of the brain is malformed. These newborns often have facial deformities from the midline. These defects can be as severe as having one eye or nostril. These newborns are often stillborn or die shortly after birth (Taeusch et al., 2005). Nursing care includes the perinatal bereavement nurse that is sensitive to the grieving needs of the family.

GASTROINTESTINAL CONDITIONS

Cleft Lip and Cleft Palate

Cleft lip (CL), cleft palate (CP), or both is a multifactorial congenital defect that has genetic and environmental predispositions. It is the fourth most common congenital birth defect. During intrauterine fetal life the primary palate does not fully fuse and any one of several variations of clefts can occur depending on the timing of the insult. Cleft lip is sometimes detected prenatally on ultrasound.

SIGNS AND SYMPTOMS. A cleft lip can occur unilaterally or bilaterally. Either type can occur with or without a cleft of the hard and/or soft palate. Also, both or either of the palates can be cleft without the lip. The uvula can also contain a cleft.

DIAGNOSIS. Cleft lip is obvious but cleft palates call for a thorough examination of the newborn's mouth with a good light source.

NURSING CARE. The focus of nursing care is on maintaining adequate nutrition because cleft lip and palate present feeding difficulties. The nurse understands that newborns with cleft lip and palate can be successfully breastfed. Breastfeeding may be interrupted for a period of time based on the need for surgical repair. Bottle feeding is usually initiated with a special nipple that is longer than a regular newborn nipple to help prevent aspiration. One type of nipple is the Haberman nipple, which is longer and has a reservoir to regulate the flow of formula.

Newborns with clefts are fed in an upright position to decrease the incidence of regurgitation. Surgical repair of cleft lip is typically done at 3 months of age and cleft palates are usually repaired before 18 months. Some clefts require more than one surgical procedure to reconstruct. Parents must be supported by having all the treatments, feeding methods, and course of care explained. Emotional support is needed to assist in the grieving process of dealing with the reality of the nonperfect child with surgical needs (Merritt, 2005).

“What to say” — *Communicating to parents about cleft lip and palate repair*

The nurse can provide parents emotional support related to their newborn's cleft lip and palate repair. The nurse can also refer parents to Web sites that contain valuable information. Some Web sites provide the parents with suggestions on wording for the birth announcement so that family and friends are informed about this issue prior to seeing the baby.

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is another complication that affects mostly preterm newborns. It is due to an ischemic episode of the bowel. When a lack of oxygen occurs in any human, blood is shunted from the nonessential organs (bowel) to the essential organs: lungs and brain. If the ischemic attack is severe it can decrease the circulation to the bowel to the point of ischemia. The extent that any portion of the bowel is affected depends on the severity of the ischemic attack. Once the bowel is necrotic or the tissue dies from lack of O₂ there is no peristalsis to move food or gas and it builds up in that section of the bowel. NEC is dangerous because it can easily produce septicemia in the preterm newborn (full-term newborns who experience a severe asphyxia can also experience NEC).

SIGNS AND SYMPTOMS. NEC is suspected if there is lack of bowel movements, abdominal distention, or an increase of 1 to 2 cm in abdominal circumference from the last feed, or newborn irritability or lethargy.

DIAGNOSIS. NEC is diagnosed via x-ray exam where a sausage-shaped dilation of the intestine is present. Laboratory findings show leukopenia, metabolic acidosis, anemia, electrolyte imbalance, and leukocytosis. A dangerous sign is free air in the abdomen that may indicate perforation.

NURSING CARE. When providing care to an infant suspected with NEC oral feedings are immediately stopped and the primary care provider is notified.

The nurse understands that if only a small portion of the bowel is affected, a rest period may reinstate enough

circulation for future functioning. If a large section of the bowel is affected, a surgical bowel resection may be warranted and sometimes it can lead to a colostomy that may or may not be permanent.

critical nursing action Necrotizing Enterocolitis (NEC)

When caring for a child with necrotizing enterocolitis the nurse must measure and record frequent abdominal circumferences, auscultate bowel sounds before every feeding, and observe abdomen for distention (observable loops or shiny skin indicating distention).

Before a feeding, the nurse must check for aspirates at each feed for undigested formula or breast milk. If excessive (20%) undigested breast milk or formula is found, the nurse must follow the hospital's protocol, which may suggest that the next feeding be held and the primary care practitioner notified. All bowel movements must be recorded: amount, consistency, and frequency. Hematesting stools may be needed to detect occult (nonvisible) fecal blood.

ABDOMINAL WALL DEFECTS

Gastroschisis and Omphalocele

Gastroschisis is a congenital anomaly that is usually diagnosed during a prenatal ultrasound. In gastroschisis, the stomach and intestine herniate through the abdominal wall (Fig. 19-13).

Omphalocele (exomphalos) is a congenital condition in which the intestines protrude into the umbilical cord region of the abdominal wall. It is often associated with trisomy 13 and 18, and urinary tract anomalies.

SIGNS AND SYMPTOMS. In gastroschisis the abdominal wall fails to close, usually on the right side of the umbilicus, and the intestines are exposed (DiTanna, Rosano, & Mastroiacovo, 2002)

In omphalocele, if the abdominal wall defect is less than 4 cm it is usually considered an umbilical hernia and does not usually require repair.

DIAGNOSIS. Diagnosis can be made by visualization and assessment of the defect.

Figure 19-13 The newborn with gastroschisis.

NURSING CARE. Surgery is performed immediately on the infant with gastroschisis to prevent intestinal atresia resulting in obstruction. Surgical repair should be done within 2 to 4 hours of birth if the repair can be accomplished in one stage. The amount of displaced intestines determines the course of treatment of an omphalocele (Taeusch et al., 2005).

In gastroschisis, the nurse keeps the abdominal contents sterile by covering them with moist gauze and wrapped in plastic. Extreme care should be taken to position the newborn supine and prevent the mesenteric vessels from kinking so adequate blood supply continues to flow to the bowel.

Both conditions may require either a nasogastric or orogastric tube to eliminate air in the bowel. The nurse replaces fluids intravenously at 1.5 times the normal maintenance volume due to insensible water loss from the exposed bowel. Antibiotics are started preoperatively to prevent against infection.

Nursing Insight—Gastroschisis

For larger bowel exposure a silo device is used to cover the abdominal contents and they are pushed back into the abdominal cavity gradually over 7–10 days, then repair is accomplished (Taeusch et al., 2005).

Postoperative care for either condition should be focused on fluid and electrolyte balance, nutritional support with total parental nutrition (TPN) through a central line, infection protection, and pain management. Supportive care is given to all other related problems as well as the infant who requires mechanical ventilation. Parents must be kept informed about the infant's condition and treatment regimes.

INFECTIONS IN THE NEWBORN

Herpes Simplex

Genital herpes simplex virus (HSV-2) is one of the fastest growing sexually transmitted infections in the United States. Mothers who contract a primary infection in the third trimester are more likely to transmit the infection to the newborn. A small percentage of newborns can acquire an HSV-2 infection transplacentally in utero or through a reoccurring genital infection. Newborns can acquire HSV type 1 infections from people in the environment with herpes lesions of the mouth

SIGNS AND SYMPTOMS. Genital HSV-2 may be asymptomatic but can be activated anytime because the virus persists in the dorsal root ganglia for the lifetime of an infected individual. This neonatal infection can be disseminated or involve multiple organs, or localized involving the brain or skin, eyes and mouth. Disseminated infections carry a high mortality rate and chance for neurological sequelae.

DIAGNOSIS. HSV is cultured from the stool, urine, cerebrospinal fluid (CSF) conjunctivae, nasopharynx, and skin.

NURSING CARE. Nursing care involves the administration of acyclovir (Avirax) for a minimum of 14 days (Klaus & Fanaroff, 2005). In addition, the nurse pays attention to

other associated needs of the infant and family. The nurse can ensure that the infant receives proper developmental stimulation.

Neonatal Sepsis

The incidence of sepsis is 1 to 10:1000 for newborns but is increased in the high-risk newborn population to 13 to 27:1000. Mortality rate can be anywhere from 13% to 50%.

Newborn sepsis is a systemic infection and can be due from any number of causes. The most common causes include preterm delivery, prolonged labor, rupture of membranes greater than 18 hours, maternal fever, amnionitis, or maternal group B streptococcal infection. Sepsis is classified according to the time of onset. Early onset occurs within the first 5 to 7 days of life and can progress rapidly. Late-onset sepsis is most common after a week of life and it often results in meningitis. Nosocomial sepsis occurs in high-risk newborns who have extended periods of stay in the NICU. The most common causes of neonatal sepsis according to onset of symptoms are listed in Table 19-5.

SIGNS AND SYMPTOMS. Sepsis in the newborn may be asymptomatic, so risk factors and maternal history need to be evaluated carefully. When symptoms do appear the first indications of sepsis may be behavioral changes which is a good reason to have consistent nursing care in the nursery and NICU because a nurse who “knows the newborn” may pick up subtle changes earlier than someone who has not previously cared for the newborn.

Newborns respond differently to systemic infections than adults. Some newborns may get hypothermia while others become hyperthermic. Lethargy, hypoglycemia, and poor feeding are other signs of sepsis.

DIAGNOSIS. If a newborn displays signs of sepsis or is from an environmental condition that is predisposing him to sepsis, the appropriate laboratory tests should be done and interpreted for a definitive diagnosis.

NURSING CARE. The diagnostic workup includes a complete blood count with differential, C-reactive protein level (CRP), platelet count, and blood culture. Some septic workups may include a spinal tap and urinalysis. No one test is sensitive so an evaluation of all the data is important. Neutropenia (low neutrophils in the blood) may be a significant sign because neutrophils battle bacterial infections and may be depleted if the newborn has an infection. Many nurseries use a formula that analyzes the ratio of immature to total neutrophils (I/T ratio) in the white blood cell (WBC) count.

Table 19-5 Most Common Causes of Neonatal Sepsis Broken Down into Onset of Symptoms

Early Onset and Late Onset	Nosocomial Onset
Group B streptococci (GBS)	Staphylococci epidermidis
Listeria monocytogenes	<i>Pseudomonas</i>
Staphylococcus	<i>Klebsiella</i>
Streptococci	Serratia
<i>Haemophilus influenzae</i>	Proteus

Labs: Differential White Blood Cell Count

The formula for an I/T ratio is bands divided by segs + bands or

$$\frac{\text{bands}}{\text{segs} + \text{bands}}$$

$$\frac{7 \text{ bands}}{54 + 7} = 0.11 \text{ shift}$$

Example:

This is < 0.3 shift and is not indicative of an infection.

Most neutrophils should be segmented (SEGS) or mature cells. When 20% to 25% of the neutrophils are immature or bands (sometimes called juveniles or stabs) or unsegmented neutrophils it is suspicious of an infection. If a shift of 0.3 or greater is detected, the newborn is treated for sepsis.

Antibiotic treatment is started for a minimum of 48 hours at which time the reports on the cultured specimens should be known. A broad spectrum antibiotic or a combination of antibiotics is started as soon as possible. The usually antibiotics of choice are ampicillin (Marcillin) and gentamicin (Garamycin) (Klaus & Fanaroff, 2005).

Nursing Insight— Group B Streptococcus (GBS) infection in the newborn

Group B Streptococcus (GBS) is the leading cause of neonatal sepsis in the United States. One in three women has colonized GBS in her vagina and it can be spread to the newborn during the labor process, which is vertical transmission. Before the recognition of GBS as a cause of newborn sepsis in the 1970s the mortality rate was 55%. Today mortality rate is less than 5% of those newborns contracting GBS because of protocols in place to treat women in labor or to treat the newborn if the woman was not adequately treated in labor. All women should be screened for GBS at 35 to 37 weeks of gestation. For newborns delivered in which the maternal GBS status is unknown due to premature delivery or inadequate prenatal care the newborn should be carefully observed for signs of sepsis including poor feeding, inability to maintain body temperature, inability to maintain blood glucose level over 60 mg/dL, lethargy, and seizure activity (Dremer, Lee, & Few, 2004).

DEVELOPMENTAL DELAY

Neonatal Abstinence Syndrome

There are 250,000 to 300,000 female IV drug abusers in the United States. More than 50% of them are in the childbearing age group (Coyle, Ferguson, LaGasse, Liu, & Lester, 2005). An infant of a drug-abusing mother (IDAM) is a newborn who has been exposed to drugs in the intrauterine environment which can cause withdrawal symptoms in the extrauterine environment (Gomella, 1999) (Table 19-6). Drugs that are abused have low molecular weight and transfer easily across the placenta. These drugs have a long half-life in the fetus and bind to CNS receptors, causing fetal cell damage. Some drugs such as cocaine are vasoconstrictors and affect blood flow to the fetus.

SIGNS AND SYMPTOMS. The signs and symptoms of withdrawal or neonatal abstinence syndrome (NAS) to determine if a newborn is an IDAM are listed in Box 19-8

Table 19-6 Drugs that Can Cause Withdrawal Symptoms

Opiates	Barbiturates	Others
Codeine	Butalbital	Alcohol
Heroin	Phenobarbital	Amphetamine
Meperidine	Secobarbital	Chlordiazepoxide
Methadone		Clomipramine
Morphine		Cocaine
Pentazocine		Desmethylinipramine
Propoxyphene		Diazepam
		Diphenhydramine
		Ethchlorvynol
		Fluphenazine
		Glutethimide
		Hydroxyzine
		Imipramine
		Meprobamate
		Phencyclidine

Box 19-8 Signs of Neonatal Abstinence Syndrome

Irritability	Hypertonia
Tremors	Seizures
Wakefulness	Exaggerated rooting reflex
Uncoordinated feeding pattern	Regurgitation and vomiting
Loose stools	Tachypnea or apnea
Yawning or hiccups	Sneezing and stuffy nose
Poor weight gain	Lacrimation

(Gomella, 1999). The maternal history may be a clue if there is a history of inconsistent prenatal care.

DIAGNOSIS. Laboratory tests are often done to reveal if the drugs are in the newborn's system. Urine tests are most frequently done but reflect only the last few days of intrauterine environmental exposure. Meconium is being used more and more to test for drugs in the newborn's system. It can be obtained up to 3 days and reflects a longer period of time of intrauterine exposure than urine testing.

NURSING CARE. These newborns are a nursing challenge because they sleep very little and are irritable. Newborns that have tested positive for drugs or display neonatal abstinence syndrome should be assessed using a neonatal abstinence scoring tool for signs and symptoms approximately every 3 hours.

Newborns with neonatal abstinence scores greater than 7 for 3 consecutive scorings are uncomfortable and need to be treated with medication to decrease the severity of the withdrawal effects (Box 19-9).

Box 19-9 Medications Used to Treat IDAM

Paregoric (camphorated tincture of opium)	Chlorpromazine (Thorazine)
Phenobarbital (Luminal)	Diazepam (Valium)
Clonidine (Catapres)	

Nursing Insight— Using Naloxone (Narcan) in a newborn with neonatal abstinence syndrome

Naloxone (Narcan) use may increase the severity of drug withdrawal in IDAMs. If the mother is a suspected drug abuser it should not be used.

Care of the High-Risk Newborn

Care of the high-risk newborn is multifaceted and complex. The nurse provides general care measures, interventions tailored to specific conditions, holistic and developmental care, as well as ensuring a safe nurturing environment. A thorough physical assessment is completed and vital signs are monitored frequently. Vital signs include temperature, pulse, respiration, and blood pressure. Pain is considered the fifth vital sign.

BLOOD PRESSURE

Blood pressure measuring in newborns is an indicator of cardiovascular function. In high-risk newborns hypotension is encountered more often than hypertension. Hypertension although rare is usually related to neonatal renal dysfunction.

Systolic, diastolic, and mean arterial pressure (MAP) should be assessed on the high-risk newborn. MAP is the average pressure during the entire cardiac cycle and it is reported on cardiac monitors and may differ by birth weight. Arterial pressure can be calculated by internal blood pressure monitoring done through an umbilical vessel. Pulse pressure is the difference between the systolic and diastolic pressures and is another, less significant, cardiac indicator. A wide pulse pressure is sometimes indicative of a patent ductus (the average values are 25 to 30 mm Hg in term newborns and 15 to 25 mm Hg in preterm newborns).

Most NICUs use oscillometry methods to take noninvasive blood pressure readings in the neonate. Studies have shown that non invasive blood pressure readings by oscillation are consistent with invasive blood pressure readings.

To take a blood pressure reading accurately on a neonate several things need to be considered. The equipment needs to be reliably and calculated correctly for neonates. The appropriate cuff size needs to be chosen. Blood pressures can be greatly affected by the newborn's temperature, activity, or posture (newborns that are awake and sucking average 10 to 20 mm Hg higher). Single and four extremity blood pressures can be done (Stebor, 2005).

Single blood pressure reading should be done for all high-risk newborns on a regular basis. Four extremity blood pressures are done if a cardiac murmur is heard to determine if the MAP of the upper and lower extremities are similar. Blood pressure is normally slightly greater in the lower extremities. A difference (20 mm Hg or higher in the upper arms) may indicate aortic coarctation (Procedure 19-1).

NUTRITIONAL CARE

Adequate nutritional intake is a major concern for the preterm newborn. Feeding readiness in preterm newborns is determined by each individual newborn's behavioral states. Alert states around feeding time are assessed to determine newborn feeding readiness. Preterm newborns spend less time in wake states than full-term newborns (White-Traut, Berlbaum, Lessen, McFarlin, & Cardenaas, 2005).

The nutritional needs of the preterm newborn are complicated for three reasons:

1. They have not had the time in utero to build up nutritional stores.
2. They have extrauterine complications such as RDS which increases their metabolic expenditure.
3. They should be gaining weight daily at rates double those of a full-term newborn. In addition the preterm newborn may not be able to feed due to regurgitating the feeding, losing weight or cold. If an infant is not ready to feed by mouth, the nurse uses alternative ways to ensure proper nutrition such as intravenous or enteral feeding.

Intravenous Feedings

Initially fluids are given parenterally. Peripheral lines are used for shorter periods of time and most preterm newborns are placed on parenteral fluids for the first few days of life. The goal for the infant in the first few days of life is to provide sufficient fluid to result in an urine output of 1 to 3 mL/kg per hour, and a urine specific gravity of no greater than 1.012.

A central line placed in the umbilical artery (UA) or vein (UV) is used for longer periods of time and provide the high-risk newborn with fluids, nutrients, blood components and medications. Another type of line called a peripherally inserted central catheter (PICC) line is also used for long term parenteral therapy.

Total Parenteral Nutrition

Total parenteral nutrition (TPN) is the initial essential nutritional support for high-risk newborns and is used to establish positive nitrogen and energy balance to promote growth (Premji, 2005). TPN also increases protein synthesis and reversal of any negative nitrogen effects that may take place in the first days of life.

The TPN solution is a calculated combination of glucose, amino acids, and electrolytes. TPN is usually started by the third or fourth day. After the first days of TPN intravenous lipid emulsions are added to the parenteral therapy as a piggybacked or secondary solution in concentrations of 10% to 20% over a slow continuous infusion. This is done to reverse fatty acid deficiency and provide energy for tissue healing and growth.

Procedure 19-1 Taking a Newborn's Blood Pressure

Purpose

Taking the blood pressure is an indicator of a newborn's state of health. Blood pressure means the pressure of blood as it is forced against the arterial walls during a cardiac contraction.

Equipment

Appropriate size cuff
Blood pressure (B/P) machine
Method to record results

Steps

1. Choose the appropriate size cuff by measuring the midpoint of the limb.

RATIONALE: Cuffs that are either too narrow or too small affect the accuracy of the blood pressure measurement. Choose a cuff that has a width that is approximately 40% of the arm's circumference. A properly fitting cuff will cover about 2/3 or entire upper arm (or other extremity).

2. Do not use an extremity that has an IV.

RATIONALE: This prevents trauma or damage to the IV site.

3. Do not apply to broken skin areas.

RATIONALE: This prevents further damage to the skin.

4. Do not extend cuff over a joint.

RATIONALE: This prevents an inaccurate measurement.

5. Inspect the cuff for intactness and decompress it to ensure it is not leaking.

RATIONALE: Proper function equipment is essential for accurate blood pressure measurement.

6. If the cuff has an arterial mark, palpate the artery and line up the mark.

7. Wrap cuff snugly.

RATIONALE: A properly fitting cuff is essential for accurate blood pressure measurement.

8. Connect the cuff to the air hose.

9. Start the blood pressure device.

10. Remove the cuff and inspect the skin (Stebor, 2005).

Clinical Alert Attempt to take blood pressure while the newborn is sleeping or use a pacifier to quiet the newborn for the procedure.

Note

The B/P is usually slightly higher in the legs.

Caution

A wide pulse pressure may indicate A-V malformation, truncus arteriosus, or PDA. A narrowed pulse pressure may indicate: peripheral vasoconstriction and cardiac failure. A systolic pressure in the arms that is 20 mm Hg or higher may indicate aortic coarctation.

Teach Parents:

The nurse can teach the parents that the blood pressure is an indicator of a newborn's state of health.

Documentation

2/17/10 1300 Murmur auscultated, HR 160 BPM, pulse

O₂ = 97%, 4 extremity B/PS done.

-R. Wittmann-Price, RN

Enteral Feedings

Enteral feedings of prescribed formula or breast milk given through either a nasogastric or orogastric tube are started as soon as the preterm newborn is stable. A continuous infusion pump method ensures safe administration of the feeding. As the infant grows and becomes more stable, bolus feedings every 3 hours are eventually started because the newborn can now tolerate this kind of feeding. As the feedings are increasingly tolerated by the preterm newborn the parenteral therapy can be decreased.

Bottle- and Breastfeeding

Once the newborn reaches 32 weeks of gestational age and is stable, bottle and or breastfeeding is attempted usually once a day and increased as tolerated. The feedings should start slowly and advance over several days.

clinical alert

Aspiration

Newborns with greater than 60 respirations/minute should never be PO feed because they have an increased risk of aspiration pneumonia

There are many different types of formulas used for newborns. Each type of formula has a different nutritional goal. When preparing a formula feeding for high-risk newborns the procedure should be done on a clean surface with only one formula preparation being done at a time with proper labeling.

Breastfeeding should be encouraged for families who choose it as soon as the newborn is able to spend limited amounts of time out of the incubator and is more than 32 to 34 weeks postconceptual age. Preterm newborns can be successfully taught to breastfeed if there is a planned approach that supports the family's decision (Callen & Pinelli, 2005).

Breast milk has benefits for the preterm newborn. Breast milk can supply IgA and other proteins that decrease the incidence of infection in the preterm newborn. Neurological benefits have also been suggested with the use of breast milk (AAP, 2005).

Non-nutritive Sucking

Non-nutritive sucking (NNS) is promoted for the preterm and high-risk newborn for physiological and psychological reasons. Using a pacifier promotes comfort (Klaus & Fanaroff, 2005) and NNS may promote breastfeeding in

where research and practice meet: Breastfeeding

The number one issue related to unsuccessful breastfeeding after discharge from the NICU was low milk supply. Mothers who decide to breast feed must be encouraged to pump regularly and often in order to maintain their milk supply until their premature newborn can be regularly breastfed (Callen, Pinelli, Atkinson, & Saigal, 2005).

the high-risk newborn (Spatz, 2005). Pacifiers are made in different sizes to accommodate the size of the newborn.

Other Nutrients Needed for High-Risk Newborn Growth

Calcium phosphate and magnesium is needed to prevent under mineralization of bones, fractures, and rickets. Calcium is given at 185 to 200 mg/kg per day, phosphorus at 100 to 113 mg/kg per day and magnesium 5.3 to 6.1 mg/kg per day as the recommended doses and is usually started after the first day or so of TPN. Vitamin D is also required for metabolism of calcium, phosphate, and magnesium for the preterm newborn. Trace elements of copper, zinc, selenium, manganese, and chromium are also added to parenteral nutrition to prevent deficiencies.

Vitamin intake for the preterm newborn is calculated on weight and can be delivered in the TPN or lipid solution. Vitamin A is also placed in the TPN.

Intake and Output

High-risk newborns are maintained on strict intake and output (I & O) until they are growing adequately. Adequate growth means a sustained pattern of weight gain. The actual intake of a newborn is calculated on total daily amount of calories (kcal/kg per day) and fluid requirements (mL/kg per day). To maintain adequate growth newborns need a caloric intake of 100 to 120 kcal/kg per day and a fluid intake of 150 to 180 mL/kg per day.

clinical alert

Calculating standard newborn formulas

$$\text{kcal/kg/day} = \frac{\text{kcal/mL} \times \text{Total mL of formula}}{\text{Weight}}$$

The normal output for a preterm newborn is 1 to 3 mL/kg per hour. Oliguria is defined as <0.5 to 1 mL/kg per hour (Fig. 19-14).

where research and practice meet: Non-nutritive Sucking

A recent study by Pinelli and Symington (2005) showed a significant decrease in length of stay (LOS) for newborns who were provided with non-nutritive sucking (NNS). There was no significant difference in weight gain between newborns who had NNS and those without NNS.

Figure 19-14 Newborn output is calculated by weighing the diaper on a gram scale.

DEVELOPMENTAL CARE

Although more preterm newborns are surviving, many still have negative consequences, including developmental disabilities and delays, as well as vision and hearing deficits (Cuevas, Silver, Brooten, Younglut, & Bobo, 2005). Appropriate developmental care in the NICU may be a key to decreasing long-term developmental disabilities for the preterm newborn. There is increasing evidence in the literature that environmental issues, such as excessive noise and uncontrolled lighting is detrimental to the developing preterm newborn (Graven, 2000). The NICU environment should replicate a smooth transition from the intrauterine environment as much as possible and limit excessive stimuli to ensure maximum developmental growth.

Preterm newborns do not have the neurological and social development needed to deal with the sudden stimuli of extrauterine life. Cortical organization in the preterm newborn is immature and preterm newborns are poorly equipped to self-modulate their behavior. Overstimulation from environmental factors can have long-term detrimental developmental effects.

Providing an environment for optimal growth is the primary philosophy of developmental care. Developmental care assists to modulate preterm newborn's behavioral states. Some of the environmental issues that can be controlled by the nurse in order to promote developmental growth include noise, lighting, handling, and positioning.

Noise

Sensory systems of the fetus develop in sequences. The sensory modalities develop in the third trimester. Premature birth exposes the newborn to excessive stimuli before this sensory sequencing is established. The preterm newborn is suddenly in an unnatural environment that demands use of the different systems out of sequence

and ultimately becomes a source for developmental problems.

The most vulnerable period of development occurs during neuronal differentiation. It has been argued that the harsh and noisy NICU environment may affect normal development and that auditory system is most vulnerable. Noise can cause damage to the cochlea, and cause outer hair cell loss with significantly lower intensity levels than would be expected.

The noise level in the traditional NICU may be very disruptive to a premature newborn compared to the intrauterine environment. Noise in NICUs can easily exceed acceptable limits for optimal growth and development. The Report of the Fifth Consensus Report of the Newborn ICU Design Committee states that noise should not exceed an overall background limit of 50 to 55 decibels (dB) and maximum intermittent sound should not exceed 70 dB (Understanding Decibels, 2005).

Prevalent neurological and behavior deficits such as disruptive sleep, poor motor function, attention deficit, and sensorineural hearing loss could be the results from the traditional noisy NICU environment. Environmental changes can be made to decrease in the noise level and offset adverse effects (Thear & Wittmann-Price, 2006). The nurse can provide a quiet environment to prevent hearing loss, neurological and behavior deficits, and stress in the high-risk newborn.

Lighting

Most NICUs keep the lights subdued to mimic the intrauterine environment. Studies are now showing that newborns with light-dark cycles imposed in the external environment have better weight gain and better sleep patterns than those newborns cared for in non cyclic lighting (Rivkees & Hao, 2000). The nurse can provide an environment that promotes a natural sleep wake cycle for the infant. Creating a designated nap time during which incubators are covered with small blanket may help regulate the infant's circadian rhythm.

Handling

Minimal stimulation is advised to reduce oxygen consumption and prevent rapid increases in blood pressure that may cause cerebral hemorrhage (Taeusch et al., 2005). This has prompted most NICUs to organize nursing care into "cluster care." Cluster care is a concept in which all the nursing care for a risk newborn is done at one time usually at three hour intervals. With cluster care there are 1 to 3 hours of undisturbed time in between vital signs, feedings, and treatments. Organization and collaboration of multidisciplinary care to enhance minimal disturbance of the high-risk newborn is a goal in NICU. Current philosophy, such as that being taught by the Newborn Individualized Developmental Care and Assessment Program (NIDCAP), view the newborn as an active participant in care. Care is regulated not by task and time but by the behavioral assessment of the newborn (NIDCAP, 2006).

Parents should be included as a partner in discharge planning for the preterm newborn and is initiated as soon as the newborn is admitted. Many aspects of care must be taught to the family before discharge. The nurse can ensure that cluster care is used along with including the parents in the care of the child.

Complementary Care: Premie massage

Premie massage as an adjunct therapy to developmental care has shown great benefits including increased weight gain, improved nervous system development, lower levels of cortisol, increased muscle tone, better sleep-wake patterns, shortened length of stay (LOS) and improved cognitive and motor development at 8 months of age. Massage is done to simulate the tactile stimulation the newborn would have felt in utero (Molloy, 2006).

Positioning

Positioning is done with the goal of providing comfort and modulation. Premature newborns have normally extended extremities compared to flexed full-term newborns. "Nesting" is a concept in which the linen is used to safely contain the newborn in a flexed position. Specially made bean bag rolls and "frogs" are used to provide security to body parts and keep them in position. The nurse can use nesting as an intervention to promote comfort to the high-risk newborn.

The Neonatal Intensive Care Unit

The NICU is a frightening place for parents. The first visit to the NICU is extremely difficult and the parents must be prepared for what they are about to experience. The rules of the unit must be outlined and the expectations gently discussed. The newborns are extremely small and fragile and there are several pieces of highly technical equipment, all with alarms. The nurse can explain that the NICU keeps the lighting dimmed to increase rest for the newborn and voices low to promote developmental care. Care is done in clustering and the nurse tries to schedule all the procedures needed on the newborn during the assessment period, which is usually every 1 to 3 hours depending on the acuity of care for threat newborn. The nurse can also explain that NICU tries to simulate an intrauterine environment as much as possible. This means decreasing the stimulus to the newborn as much as possible to allow normal growth and development.

Some of the NICU care concepts create a difficult adjustment for parents. Most parents are back to work long before their newborn is discharged. Many parents have an overwhelming desire to interact with their newborn but are not available during the care times. Creating partnership in care between the NICU staff and family benefits the newborn and every effort needs to be made in order to communicate and collaborate with parents. The family of the NICU newborn is encouraged to bond with their newborn just as if it was in the newborn nursery. NICU nurses must encourage them to visit and assist with cares whenever possible.

Parents of NICU newborns actually go through some developmental phases until they can become partners in their newborns care along with the staff. First, the environment of the NICU is overwhelming but most parents are able, after a short time, to focus on the baby and keep the environmental distractions in the background. Second, the parents begin to develop a relationship with the newborn

and take ownership of their infant. This is sometimes difficult because the nurses are providing the care. Third, the parents eventually take an active role in the newborns care and become the voice of the newborn. This stage lends itself to parents as partners in providing the best individual developmental care for the newborn (Heermann, Wilson, & Wilhelm, 2005).

Most NICUs practice primary care nursing in order for the parents to have a consistent contact person to ask questions and to call when they are home. Some NICU staffs make routine phone calls to the family to give updates.

From the very first visit onward, the parents are encouraged to touch the newborn. Touch is a very important act for bonding with the newborn. Kangaroo care is also encouraged as soon as the newborn is stable enough to be taken out of the incubator. Many parents have the need to stay at the bedside for extended periods of time. The NICU nurse must assist the parents in finding a realistic routine that enhances the newborn's health care needs. Fathers should be included in the educational and care process of the newborn. Studies show that parents of NICU newborns report stress and anxiety about the future of the newborn years after discharge. Education about developmental care and continuity of care that includes home care are most important to the high-risk newborn (Bakewell-Sachs & Gennara, 2004). Parents also have anxiety about the newborn's discharge, so the nurse must prepare them to care for their child at home.

critical nursing action The Neonatal Intensive Care Unit

- Orient the parents to the NICU environment and policies and procedures and HIPAA regulations.
- Assign one primary care nurse as the main contact for the parents.
- Explain the rationale for policies and procedures.
- Listen to the parent's expectation of their role in the NICU.
- Explain the integration of caretaking roles between parents and staff.
- Use a white board at the newborn's bed to relay messages back and forth.
- Encourage parents to call the NICU and inquire about their newborn 24/7.
- Encourage parents to bring in the newborn's personal clothes when the newborn can be dressed.
- Encourage parents to verbalize dissatisfaction with newborn's care.
- Try to incorporate parent's suggestions into care when possible.

Be sure to— Explain HIPAA

Explain to parents that HIPAA [Health Insurance Portability and Accountability Act of 1996 from the U.S. Department of Health and Human Services (HHS)] is taken seriously within the unit and should be addressed during parent orientation to the unit including:

- Parents may be asked to step out of the unit during medical rounds, nursing report times, and possibly in emergencies to protect the privacy of all newborns.

- Phone inquiries can only be done by the parents after they identify themselves by the infant's medical record or bracelet number and they have signed a consent permitting nursing and medical personnel to discuss information on the phone with them.
- Nurses and physicians will not answer questions regarding the condition of other newborns in the unit.
- Pictures of their own newborn are allowed but they cannot photograph other newborns in the unit.

For more information on Protecting the Privacy of Health Information go to: <http://www.hhs.gov/news/facts/privacy.html>

CLASSIFICATION OF THE NEONATAL INTENSIVE CARE UNIT

NICUs are classified according to level of care. Regionalization is a concept in care that arose in the 1980s to conserve health care dollars, consolidate services, and improve outcomes. Today hospitals often compete within the same geographic area to have the largest and most recognized services in specialty care areas. Level I nursery care is for well newborns and can stabilize high-risk newborns for transport. Level II nurseries can provide the same care as Level I nurseries plus provide premature care, give oxygen by hood and start intravenous therapy. Level III NICUs are the most sophisticated of the nurseries because they ventilate newborns (Klaus & Fanaroff, 2005).

TRANSPORTING THE PRETERM NEWBORN

Newborn transport is done if more technologically advanced care is needed then can be safely provided at the institution (Fig. 19-15). Most Level III NICUs have a specially trained transport team who go to the referring institution, stabilize the newborn, and bring the high-risk newborn back to the regional Level III center by ambulance or helicopter. The terrain, location, and weather of each referring NICU determine the safest transport mode.

Figure 19-15 Neonatal transporter.

Transport of newborns is traumatic for the newborn and family and should be avoided when at all possible (Klaus & Fanaroff, 2005).

The Transport Team

Neonatal transport teams are comprised of a physician or nurse practitioner from the Level III nursery along with nursing and respiratory staff that are educated in stabilizing the newborn. Specific protocols are followed and the team should be able to contact the referring neonatologist during transport for any unanswered questions.

The S.T.A.B.L.E. Program is a program designed to assist health care professionals in the post resuscitation/pre transport phase of neonatal care. It is an acronym for aspects critical to stabilization of the high-risk newborn (Box 19-10). It is a program promoted by the March of Dimes and American Academy of Pediatrics as an adjunct to neonatal resuscitation to improve neonatal outcomes (STABLE program, 2006).

“What to say” — Communicating to parents about transporting the newborn

Parents often ask if it is necessary for the newborn to be transported. The nurse can explain the advantages of treatment offered at the referring hospital and make sure the parents have a direct number to the unit and the name and number of the admitting neonatologist.

Discharge Planning

Discharge planning must be started as soon as the newborn is admitted. Most NICUs use standards for discharge such as respiratory stability, consistent weight gain, and successful oral feedings as discharge criteria (McGrath & Braescu, 2004). Studies show that nursing follow up and phone calls decrease parental anxiety and hospital readmission (Monsen, 2005). Parent information on discharge topics can be obtained at www.advanceinneonatalcare.org.

The newborn at risk may have immediate and long-term disabilities. Newborns are extremely resilient but the lack of neurological development associated with interrupted intrauterine growth affects them not only physically but socially and developmentally. NICU “graduates” often need intensive follow-up care. They are sometimes referred to specialists for sight and hearing

follow-up (Wittmann-Price & Pope, 2002). They often need intervention from developmental and educational specialists, physical therapists, and occupational therapists. Case management is an invaluable resource in the NICU when coordinating follow-up efforts with insurance reimbursements plans. Many NICU units host social events that increase parent-to-parent support after discharge.

summary points

- ◆ Newborns can be put at risk any time during their intrauterine or extrauterine development, by genetic disorders, congenital anomalies, maternal factors, asphyxia or birth injuries resulting from conditions such as hypothermia, poor oxygenation, prematurity or congenital anomalies.
- ◆ Small-for-gestational-age (SGA) infants are newborns born at any gestational age and have a birth weight that falls below the 10th percentile on the growth chart and have suffered a nutritional or oxygenation deficit in utero due to maternal causes, fetal causes or a placenta or cord malfunction.
- ◆ Newborns who are large for gestational age (LGA) are over the 90th percentile on the growth chart because of genetics or, more commonly, have been exposed to an imbalance of nutrients in utero.
- ◆ Infants of diabetic mothers are often LGA. LGA newborns are also at risk for transient tachypnea, hypoglycemia, hypocalcemia, hypomagnesemia, birth injuries, brachial plexus injuries, and fractures.
- ◆ Premature newborns are at risk for respiratory distress syndrome, apnea of prematurity, jaundice, retinopathy of prematurity, anemia of prematurity, and sudden infant death syndrome.
- ◆ Postterm newborns are at high-risk for complications such as meconium aspiration pneumonia and persistent pulmonary hypertension.
- ◆ Appropriate developmental care in the NICU may be a key to decreasing long-term developmental disabilities for the preterm newborn.
- ◆ Discharge planning includes respiratory stability, consistent weight gain, and successful oral feedings as discharge criteria. Discharge planning must be started as soon as the newborn is admitted to the NICU.

review questions

Multiple Choice

1. Immediate conditions that pose nursing concerns for the small for gestational age (SGA) newborn include which of the following?
 - A. Long-term chronic or end of life care
 - B. Bronchopulmonary dysplasia and ischemia
 - C. Muscle contractures and hyperthermia
 - D. Hypothermia and pain management

2. Upon assessing the newborn, the nurse notes shallow rapid respirations, palmar sweating, decreased oxygen saturation, and a high-pitched cry. These clinical assessments are indicative of which of the following?
 - A. A neurological problem
 - B. Hypoglycemia
 - C. Pain
 - D. Transient tachypnea of the newborn (TTN)
3. A 24-hour-old newborn is being treated for hyperbilirubinemia with phototherapy bilirubin lights. The patient is in an incubator fully undressed. All EXCEPT which of the following measures should be included in the nursing plan of care?
 - A. Apply eye patches to prevent retinal damage and a covering over the genital area.
 - B. Ensure periodic removal from the incubator for feedings and bonding purposes.
 - C. Apply a head covering (stockinet hat) to prevent heat loss.
 - D. Maintain adequate hydration to promote excretion.
4. A 42-week gestational aged newborn is assessed 20 hours after delivery by the nurse. On assessment the nurse auscultates rales and rhonchi, notes the newborn is tachypneic and has meconium stained nails. The nurse suspects that the newborn has:
 - A. Sepsis
 - B. Meconium aspiration pneumonia
 - C. Transient tachypnea of the newborn (TTN)
 - D. Respiratory distress syndrome (RDS)
5. A 30-week gestational aged neonate has anemia of prematurity. The neonatologist has ordered recombinant human erythropoietin 250 U/kg subcutaneous 3 times a week. The nursing implication related to this medication include:
 - A. Administering the medication prior to feedings
 - B. Applying pressure to the injection site for 5 min
 - C. Assessing hematocrit levels as per hospital policy
 - D. Assessing electrolyte levels weekly

True or False

6. When discussing survival rates with nursing students the NICU nurse teaches that newborns who are 24 weeks of gestational age have a 58% chance of survival.
7. The nursery nurse is aware that the infant with a diabetic mother may experience a chronic hyperglycemic state.
8. The NICU nurse recognizes that the infant born at 28 weeks of gestational age has a greater chance of developing respiratory distress syndrome (RDS) than the infant born at 36 weeks gestational age.
9. The NICU nurse understands that the administration of synthetic surfactant is the first line of defense to treat and prevent bronchopulmonary dysplasia (BPD).
10. Nonnutritive sucking is promoted for the preterm and high-risk newborn for physiological and psychological reasons.

Fill-in-the-Blank

11. A nurse should perform an accurate respiratory assessment of the infant with a diabetic mother to assess for transient tachypnea of the newborn (TTN) 1 to 2 hours post delivery. The neonate's respiratory rate must be below _____, without any _____, nasal flaring, _____ and a peripheral pulse oximeter of greater than _____% in room air. Otherwise immediate attention and supplemental _____ should be administered.
12. Abdominal circumference of the preterm newborn should be measured frequently by the nurse in order to assess for distention which may indicate the development of _____.
13. The NICU nurse must perform a neurological assessment of the preterm newborn, which includes measuring the _____ and assessing for a bulging _____.
14. The nursery nurse alerts a group of nursing students that newborns with a respiratory rate of greater than 60 should never be fed orally because of the risk of _____.
15. One of the main nursing priorities for a preterm infant is assessing adequate intake and output. Adequate urine output for a preterm infant is _____. Oliguria is defined as _____.

Caring for the Child and Family

Caring for the Developing Child

chapter 20

You rose into my life like a promised sunrise, brightening my days with the light in your eyes.

—Maya Angelou

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Describe the principles inherent in the developmental process.
- ◆ Identify and explain physical, emotional, cognitive, moral, and spiritual theories of growth and development.
- ◆ Discuss the important Touchpoints in the development of infants, toddlers, and preschoolers.
- ◆ Address the discipline needs for each developmental stage.
- ◆ Develop a plan care for the child and family across care settings.

moving toward evidence-based practice Grandparents

Butler, F.R., & Zakari, N. (2005). Grandparents parenting grandchildren: Assessing health status, parental stress and social supports. *Journal of Gerontological Nursing, 31*(3), 43–54.

The purpose of this study was to describe the physical and emotional health of grandparents who were raising grandchildren and the extent to which their health was impacted by this role. The study consisted of both qualitative and quantitative data obtained from a sample of 17 grandparents 46 to 83 years of age. All of the actual participants were women, although grandfathers were present in five of the homes. The sample included 15 black grandmothers and 2 white grandmothers. The participants resided in a three-state metropolitan area of the United States.

The following were criteria for inclusion in the study: (1) the children lived with the grandparent on a daily basis; (2) the grandparent had responsibility for raising the children; (3) the children were younger than 18 years of age; and (4) the birth parent who also may have resided in the home was considered a minor.

Strategies for data collection included: (1) a self-report questionnaire to obtain demographic characteristics; (2) an in-depth interview that was audiotaped; and (3) an observation about the home environment. In addition, the grandparents completed a Parenting Stress Index (PSI) Likert scale tool (Abidin, 1995) as well as a personal home assessment. Home visits, which lasted 1–2 hours, were made over a 10-month period by the primary investigator.

Frequency distribution and Pearson's Product-Moment Correlation were used to determine the relationship among the variables including age, income, physical and mental health, socioeconomic resources, and stress level. Qualitative analysis was used to identify codes and categories, which were further collapsed into themes.

Demographic data indicated that 47% of the participants reported being married. Their incomes ranged from \$3,600 to \$94,900 per year, with an average of \$31,605. The mean for educational achievement was completion of 12th grade; 35% of participants were employed; 65% were retired or unemployed. In 66% of the families, incarceration of the birth parent as a result of drug addiction led to the grandparent's role change. For the remainder (24%) of the participant families, the birth mother died as a result of addiction or terminal illness.

The researchers reported that although there was wide variation in the participants' physical and mental health status, most scored high in the area designated as "parental stress." Analysis of the PSI scores revealed that 47% of the participants had exceptionally high stress scores. Areas of significant concern included to the participants were financial problems, disrupted

(continued)

moving toward evidence-based practice (continued)

social activities, and alterations in family processes. All but three participants indicated a need for child support, medical benefits, and transportation resources. The participants rated social support, provided by other family members or friends, as very good to excellent. However, finding time for personal social activities was reported to be difficult.

Sixty-four percent of the participant grandparents reported high blood pressure as the most common health concern, followed by arthritis (52.9%), circulatory problems (41.1%), and

diabetes (29.4%). Eight grandparents rated their mental health to be good to excellent; eight considered their mental health to be impaired.

1. Based on this study, do you believe that the results can be generalized to other populations?
2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

It is important for the pediatric nurse to have a good knowledge base of growth and development in order to tailor care to the specific needs of the child and help the family understand normal limits. It is impossible to divide the stages of development into discrete age groups. The following groupings are acceptable standards. *Newborn* refers to the stage immediately after birth until 1 month. *Infancy* is the period from 1 month until 12 months. The *toddler* stage is from 12 months until approximately 3 years. The next developmental stage is interchangeably referred to as *Early childhood* or *Preschool*. Children in this group range from 3- to 6-year-olds. *School-age* children are 6 to 12 years old. *Adolescence* begins around 12 or 13 and lasts until the beginning of adulthood.

Influences on Growth and Development

The debate over nature versus nurture is longstanding. Which is the more powerful influence in the formation of a person's essence? Nature describes the traits inherent in the infant: biologically imposed idiosyncratic factors that create what and how each person "is." Nurture, on the other hand, refers to the influence of external events such as parenting received, culture, or the "times" in which a child lives. It appears that both are intrinsically influential. "Generally speaking, genes are responsible for the basic wiring plan – for forming all of the cells (neurons) and general connections between different brain regions – while experience is responsible for fine-tuning those connections, helping each child adapt to the particular environment (geographical, cultural, family, school, peer-group) to which he belongs. Genetic potential is necessary, but DNA alone cannot teach a child to talk" (Zero to three. Brain Wonders, n.d).

Principles of Childhood Growth and Development

It is inherently pleasurable to watch a baby grow and develop. Each child moves at her own pace and in her own way. One child may move quickly through physical

tasks, only to be slower with words. Another child may be emotionally tuned into the needs of others while peers are still very self-focused. Despite these differences, a nurse needs to be aware of certain universal factors in addressing the developmental needs of children. Growth refers to the continuous adjustment in the size of the child, internally and externally. Development, on the other hand, refers to the ongoing process of adapting throughout the lifespan. Growth and development is a continuous process from conception to death. Although development advances in an orderly sequence, each child progresses through the predictable stages within a certain timeframe. The established guidelines are just that, guidelines that have been developed through observation over time. In addition, within each individual, body systems develop at differing rates. For the child, growth "spurts" tend to be followed by periods of relative "rest" as it takes plenty of energy to continue the growth process. The periods of rest allow the child to incorporate the new growth or the newly developed skill into their personal repertoire more completely before attempting the next level.

Regardless of the rate of growth and development, children progress developmentally in a prescribed fashion. There are three primary considerations related to growth and development. First, development proceeds in a cephalocaudal direction. Cephalocaudal is a progression from head to tail; top to bottom. For example, the baby's brain develops quickly; therefore, the head grows first in comparison to the rest of the body. The child gains control of his head and neck before learning to grasp or to sit up. The baby's sensory and motor skills also begin developing from the head down. Second, development proceeds proximodistally, meaning from near to far and midline to periphery. For example, the torso develops before the arms and legs. Development proceeds to the hands and feet, and then fingers and toes. The third consideration is that development proceeds from gross motor skills (e.g., walking, jumping, riding a bike) to fine motor skills. Gross motor skills provide the foundation for fine motor developments such as eating, coloring, or buttoning a shirt.

T. Barry Brazelton, a renowned pediatrician, developed the Touchpoints model of child development (Box 20-1). Brazelton described Touchpoints as "periods during the

first three years of life during which children's spurts in development resulted in pronounced disruption in the family system" (Brazelton, 1992, p. xvii). Brazelton mapped the psychological development of children, focusing on the periods of regression that occur just prior to periods of growth. "The cost of each new achievement can temporarily disrupt the child's and even the whole family's progress" (Brazelton, 1992, p. xvii). Brazelton tracked the variations in these Touchpoints and offered anticipatory guidance for parents and professionals in moving through the stages with the child.

Brazelton and Sparrow went on to develop specific aspects about the Touchpoints that related to temperament, learning, moral development, relationships, independence, and separation issues for each of the years from ages 3 to 6. Responding to these Touchpoints gives parents the tools to help the child develop healthily.

It is important to know that Touchpoints represents a positive and well-integrated way of conceptualizing developmental progress. Its perspective assumes, among other things, that parents know their child better than they know anyone else (Brazelton & Sparrow, 2002). With that in mind, the nurse works with the family at the various Touchpoints to help them anticipate and move through the periods of disequilibrium (Box 20-2).

Optimizing Outcomes— Understanding growth and development

Best outcome: The nurse can use the multidimensional developmental framework of Drs. Brazelton and Sparrow (2002) to anticipate developmental transition points to help both families and caregivers deal with the difficulties that may arise during these times.

Growth and Development Theories

Growth and development can be discussed in terms of theoretical approaches or developmental domains. A theoretical approach explains, describes, and predicts the various aspects of growth and development. A developmental domain refers to a way of understanding the total child in relation to the mind, body, and spirit. Understanding both the theoretical and developmental aspects is important because each contributes to a broader understanding about the child. A variety of theories will be discussed as well as the following developmental domains: Physical, Psychosocial (emotional, psychological, and social), Cognitive (including language and intelligence), Moral/Spiritual, and Family Development. Some of the theories are stage-related, meaning that the theorist identified specific stages and ages through which a child progresses.

Each child develops at her own pace and the stages are not rigid. It is also important to note that there is variability within each child. For example, a child may be ahead or behind physically and within normal cognitive and emotional limits, or any combination of these patterns. Growth and development takes energy. How each child expends that energy is a result of individual, family, and social variables. In contrast to the stage theories that are described, the non-stage theories are less concerned with specific ages or timeframes, but focused on the process or trajectory of developing maturity.

PSYCHOSOCIAL DEVELOPMENT THEORIES

The psychosocial domain refers to the psychological and emotional progression of the child as well as the relationships with others who are involved in the child's life. While there are many psychosocial theorists, this chapter describes the well-known theories of Sigmund Freud and Erik Erikson.

Sigmund Freud, Psychosexual

Sigmund Freud (1856–1939) believed that development was most influenced by biological instincts. Freud observed that these instincts were psychosexual in nature, meaning that a child progresses through developmental stages based on resolution of conflicts surrounding urges and rules (Box 20-3). Through observation, Freud developed a framework that is widely known today and that set the stage for modern psychoanalysis.

Freud also described the development of three essential aspects of the human personality. The initial aspect, the id, is the emotional part of the personality. The id is present at birth and is predominantly unregulated. For instance,

Box 20-3 Freud's Stages of Psychosexual Development**ORAL STAGE (BIRTH–1 YEAR)**

The infant is fixated on oral curiosity (whatever he can put in the mouth). The infant derives pleasure from and relieves anxiety through oral sensations; for example, the infant sucks on his mother's breast or his bottle and is fed and pleased. The infant puts his fist in his mouth, or uses a teething ring. Children at this stage often use pacifiers or thumbs to decrease anxiety and increase comfort.

ANAL STAGE (1–3 YEARS)

By the time the child reaches this stage; the child is ready to control elimination. Some children readily use the "big kid" potty; others resist. This is a time of increasing control in other areas of the life of the child. The child recognizes that this newfound control can run a collision course with the world, hence the term "the terrible twos." For example, the child explores, asserts, and learns boundaries about where to play safely. The child may struggle against these boundaries by escaping the backyard and running down the block.

PHALLIC STAGE (3–6 YEARS)

By early childhood, sexual difference is discovered. The child begins to compare both the male and female bodies simply out of curiosity. For example, the child notices that girls are physically different from boys. During this time, a girl child wants to push mommy aside and marry daddy or vice versa.

LATENCY STAGE (6–12 YEARS)

Freud believed that the child "takes a break" psychosexually during this period of development. This allows the child to focus more intently on other aspects of growth and learning. For example, the child spends time with his same-gender friends, excelling in sports or video games. At this age, the child presumably has little interest in issues of sexuality.

GENITAL STAGE (12–18 YEARS)

By the time the child reaches puberty, sexuality and relationships are the focus. For example, this is a time for exploring relationships and of developing a sense of romanticism.

the infant responds to all stimuli emotionally. The infant cries, laughs, or coos automatically and without thought. The id is the part of the personality that relies solely on instinct. During the baby's first year, the ego begins to develop to provide balance between the competing id and reality. The ego provides a sense of identity separate from others and promotes the ability of the child to function individually. During infancy, the ego helps the baby begin to learn that the mother is not simply an extension of his body. They are separate. Between the ages of 3 and 6 a superego, which serves to help regulate behavior, is developed. In this stage, the child develops cognitively and learns about rules and the needs of others. The superego functions as not only a center for conscience, but as a sense of what and how the child perceives self. An example of the superego is the young child obeying the parents' rules by picking up toys even though the child would rather continue playing. The child is learning that there is a difference between right and wrong and that they are not the "center of the universe" as previously believed. The child knows that a "good" boy obeys his parents.

During adolescence, the ego again provides a balance, this time between the id and the superego. When the adolescent refuses to drink alcohol with friends because it is against the child's conscience and the law, it shows that the ego has prevailed.

Erik Erikson

Erik Erikson (1902–1994) was a contemporary of Freud's. Unlike Freud, who attributed personality formation only to the interplay within a person's family of origin, Erikson focused on the influence of social interaction. Erikson identified seven stages of development. Mastery of each stage requires that the individual achieve a balance between two tasks (conflicting variables). Each stage represents a crisis that must be resolved in order to move on healthily to the next stage. Erikson's stages are well known, and used often in tracking the development of children.

Trust versus Mistrust

Trust versus mistrust occurs between birth and 1 year. The task of this stage is for the baby to recognize that there are people in his life, generally parents that can be trusted to take care of basic needs. The baby's struggle becomes evidenced in the recognition that not everyone or every situation is "safe." Through trust the baby learns to have confidence in personal worth and well-being along with connectedness to others. Failure to master this stage leaves a sense of hopelessness and disconnectedness. Examples of this disconnect can be seen in infants with failure to thrive or with attachment disorders. Difficulty in trusting can be seen even in adults who have problems maintaining significant relationships.

Autonomy versus Shame and Doubt

Autonomy versus Shame and Doubt occurs between 1 and 3 years. The task of this stage is for the child to balance independence and self-sufficiency against the predictable sense of uncertainty and misgiving when placed in life's situations. It is the time for the child to establish will-power, determination, and a can-do attitude about self. An example of this stage happens when the toddler wants to choose clothing and dress independently. The struggle happens when the parents allow the child to make personal choices yet expect the choices to be socially acceptable. At this age, the child is able to do many new things and wants to explore everything. This newfound independence is accompanied by new rules that may cause internal conflict. The child must develop personal abilities while struggling with both fears and wishes.

Initiative versus Guilt

Initiative versus guilt occurs between 3 and 6 years. The child's task during this stage is to develop the resourcefulness to achieve and learn new things without receiving self-reproach. It is difficult for a young child to resolve the conflict between wanting to be independent and needing to stay attached to parents. The child's writing plays or new songs, games, or jokes are good examples of initiative. The child feels confident to try new ideas. It is important that parents and teachers encourage this initiative to help the child develop a sense of purpose. If initiative is discouraged or ignored, the child may feel guilt and lack of resourcefulness.

Industry versus Inferiority

Industry versus inferiority occurs between the ages of 6 and 12. In this stage, the child develops a sense of confidence through mastery of tasks. This sense of accomplishment

can be counterbalanced by a sense of inadequacy or inferiority that comes from not succeeding. The realization that the child is competent is one of the important building blocks in the development of self-esteem. Industry is evident when the child is able to do homework independently and regulate social behavior. Performing the prescribed tasks at school or home also show industry. If the child cannot accomplish realistic expected tasks, the feeling of inferiority may result.

Identity versus Role Confusion

Identity versus role confusion occurs between the ages of 12 and 18. This is a time of forging ahead and acquiring a clear sense of self as an individual in the face of new and at times conflicting demands or desires. During this stage the adolescent wants to define “what to be when I grow up.” She begins to concentrate on goals and life plans separate from those of peers and family. At this point, the child has the ability to think about self as well as others and proceeds accordingly.

“What to say” — When a parent inquires about the development of their child

When parents ask the nurse about a delay in their child’s development the nurse can respond by saying “It is important to note that your child may not have reached the ‘appropriate’ developmental stage based on chronological age alone. There may be events or variables that stunt your child’s attempts to move forward such as an illness.”

ATTACHMENT THEORIES

Attachment refers to the bond or emotional and physical connection that develops between an infant and caregiver that tends to endure (Ainsworth, 1978). Early theorists associated attachment with the mother who met the infant’s innate drive to be fed and nurtured. Other examples of attachment behaviors are dressing, bathing, diapering, cuddling, loving, playing, and comforting. In contrast, Bowlby in 1978 and Ainsworth in 1978 refocused on the attainment of and subsequent quality of the bonding relationship between the infant and caregiver. Both the infant and the caregiver rely on the quality of the interaction between them. In other words, a healthy infant–mother relationship is contingent on the characteristic value of the communication between them. While researchers generally concentrated on the birthmother as the primary attachment figure in the infant’s world, Bowlby (1978) also referred to attachment with a “mother-substitute” (p. xxvii).

John Bowlby

In the early 1900s, John Bowlby, a British psychologist (1907–1990) was fascinated with children and the influence that separation had on their ability to bond with their caregivers. Bowlby became particularly interested in the impact of separation of young children from their mothers, identifying three phases of response to that separation: protest (in response to the anxiety produced by separation), despair (related to the grief and mourning caused by prolonged separation), and detachment (a defense against the feelings associated with despair). Bowlby viewed attach-

ment as biological and evolutionary adaptation. The infant develops an attachment to his mother as a means of surviving the vulnerability of infancy, rather than as a simple response to having, his biological needs met. As the infant begins to explore the world and the other people in it the mother is perceived as “home base.” When the infant becomes frightened or threatened, home base is found. If the infant feels secure in the knowledge that the home base is reliable, the infant can move on to develop additional relationships and attachments.

Mary Ainsworth

Mary Ainsworth (1913–1999) was a colleague of Bowlby’s and added to the work with studies about infants in unfamiliar situations. Through the use of the “strange situation” room, the researcher introduced infants (10 to 24 months old) to a series of situations that tested the strength of their attachment to their mothers. The situations demonstrated three patterns:

- Secure attachment: Baby cries when the mother leaves and is happy when the mother returns.
- Avoidant attachment: Baby rarely cries when the mother leaves and avoids the mother upon return.
- Ambivalent attachment: Baby becomes anxious prior to the mother leaving, is very upset when the mother leaves, and seeks contact with her while pushing her away on return.

Ainsworth’s research in Uganda, and later in Baltimore was important because it was the first truly empirical studies related to Bowlby’s original attachment theory.

Ethnocultural Considerations— Attachment

Infants from various cultures bond with parents and caregivers in the manner appropriate to each culture. Some cultures are more comfortable with physical touch; others with verbal exchange. Infants respond based on the cultural norms.

LEARNING THEORIES

Beginning with the Ivan Pavlov work in 1890 about “classical conditioning,” learning theorists began to understand development as a cognitive/learning process. There were two main types of learning theorists, behavioral and

where research and practice meet: Attachment

Relationships are important in the development of humans. Bowlby (1978) and Ainsworth (1978) pioneered the study of the initial relationship between the birthmother and the baby. Understanding attachment theory provides a base from which researchers can study the development of relationships throughout the lifespan. Research has substantiated that bonding and attachment is important for normal development to occur where the infant is born into a loving home. Each theoretical perspective adds to this important body of knowledge and it is important to note that the ability to connect with others is vitally important throughout the life of a child (Table 20-1).

Table 20-1 Phases of Attachment

Phase	Bowlby (1978)	Ainsworth (1978)	Manifestation
Phase I (birth–2 months)	Orientation and signals without discrimination of figure	The initial preattachment phase	The infant responds to everyone in his environment without discrimination.
Phase II (8–12 weeks)	Orientation and signals directed toward one or more discriminated figures	Attachment-in-the-making phase	The infant responds most to those significant caretakers in his life.
Phase III (6–7 months)	Maintenance of proximity to a discriminated figure by locomotion and signals.	Clear-cut attachment	The baby attaches to his caretaker crawling toward the caregiver, reaching for or cooing at the caregiver.
Phase IV (around age 3)	Implications of the partnership for the organization of attachment behavior during the preschool years	Goal-corrected partnership	The preschool child begins to develop an understanding of the caregiver's goals. The child knows that a tantrum might get the mother to fulfill demands.

social learning scientists. Behavioral scientists saw the learner as passive, while social learning scientists emphasize the interplay of the individual within his environment. J.B. Watson, a behavioral scientist, sought to understand observable behavior. B.F. Skinner, also a behavioral scientist, described growth and development as a process of responding to stimuli within the environment (positive and negative reinforcement) that created new learning along with adaptive behaviors. While both types of scientific investigation are important, this chapter discusses the theories of the social learning theorists, Albert Bandura, Lev Vygotsky, and Urie Bronfenbrenner.

Albert Bandura

Albert Bandura's (1925–present) theory of development does not rely on predetermined stages. Bandura proposed that learning occurs within a social context through observation and modeling. The child pays attention to a new concept/task, retains that image, and then reproduces the action physically. Each successful approximation (reproduction) of the action increases the child's perception of personal effectiveness, which then contributes to the development of new social skills. For example, a newborn has no sense of self as separate from others. As the infant develops new skills, inadvertently at first, he becomes motivated to continue learning. Bandura also describes self-efficacy (sense of self) and refers to several foundations for developing self-efficacy. They are mastery (being successful), modeling by others (imitation), "social persuasion" (pairing situations in which success is likely to occur after positive feedback), and being able to decrease the perception of stress and threat (a conscience willingness to continue using the senses for learning rather than simply for surviving).

As the infant acquires this sense of self and begins to differentiate himself from others, the infant develops new skills, and, hopefully resilience in the face of life's difficulties along with adaptations to surviving developmental transitions. Conversely, children who have not had adequate positive modeling, or who have not had access to

success-inducing experiences, may suffer negative consequences and lack good self-efficacy.

Lev Vygotsky

Vygotsky (1896–1934) was a Russian psychologist who studied the influence of culture on development. Vygotsky was a contemporary of Albert Bandura. He emphasized that culture and certain factors within the child's environment have a dramatic impact on language development. He believed that development occurs on two levels: personal (intrapsychological) and social (interpsychological). Vygotsky coined the term "zone of proximal development," which means that one learns much more successfully when assisted by another person. In other words, a child left alone to their own devices would accomplish fewer developmental tasks, not nearly to the degree if the child had assistance of another person.

Urie Bronfenbrenner

Urie Bronfenbrenner (1917–2005) studied the effects that social environment has on a child's development (1979). Within this ecological approach, Bronfenbrenner defined four systems in each child's life. The microsystem refers to the systems where the child is actively involved. Typically, in a child's life, the microsystem would be family, school, and peer group. Mesosystem refers to the interaction between two microsystems, such as the interplay between a child's home and school. The exosystem refers to those systems that may have an impact on the child, but with which the child is not intimately involved, for instance, the parent's work. The parent's work affects the child's life, yet he is not directly involved in it.

COGNITIVE THEORIES

Cognitive theory focus on how an individual thinks and how thinking influences worldview. The capacity to think develops overtime and with experience. Jean Piaget discussed cognition (thought) and how it influences development.

Jean Piaget

Jean Piaget (1896–1980), a Swiss psychologist, studied the development of cognition in children. In Piaget & Inhelder's book, *The Psychology of the Child* (1969) information was presented about how children think and learn. Thinking and learning for children takes place through four distinct stages. The initial period, the sensorimotor stage, takes place from birth to age 2. During this time, the infant's primary means of cognition is through the senses. The child takes in and processes information strictly on a physiological or emotional level.

At the age of 2, the child begins to use cognitive processes to respond to the world physically. The preoperational stage (ages 2 to 7 years) takes into account the development of motor skills and is divided into two sub-stages: *preconceptual* and *intuitive*. The child is still not capable of logical thinking, but due to increased ability to use words and actions together, the child is increasingly able to connect cognitively with the world.

The third stage is the concrete operational stage. At this stage, the 7- to 11-year-old-child is much more able to organize thought in logical order. The child is able to categorize and label objects. It is also possible at this stage for the child to solve concrete problems.

Piaget's final stage of cognitive development is the formal operational stage during which time the 11- to 15-year-old child uses abstract reasoning to handle difficult concepts and can analyze both sides of an issue.

INTELLIGENCE THEORIES

Intelligence is defined in the Merriam-Webster's Online Dictionary (n.d.) as “the ability to learn or understand or to deal with new or trying situations by using reason, which is the ability to apply knowledge to manipulate one's environment or to think abstractly as measured by objective criteria (as tests).” Intelligence has been studied most in terms of how it is measured. As in all other developmental dimensions, intelligence does not exist in a vacuum. The ability to bring in and retain new information and skills relies on the interconnectedness of cognitive, emotional, and environmental factors. Traditional standardized measures of intelligence have relied on assessing cognitive abilities, most specifically math and verbal. Many of these measures are criticized as not taking into account varying cultural and socioeconomic factors. In other words, a child may test as less intelligent than the norm, when in fact his test responses are based on his experience culturally. Standardized IQ tests have also been criticized for not measuring varying learning styles.

Ethnocultural Considerations— Perception of intelligence

When providing nursing care it is important to understand that culture or ethnicity can influence perception of intelligence. For example, a Hispanic immigrant child in grade school may not understand his food choices in the school cafeteria based on his cultural knowledge about food. The child may be misinterpreted as unintelligent rather than growing up with different food choices than his peers.

Howard Gardner studied intelligence from a different vantage point. In his book, *Frames of Mind* (1993), he describes eight forms of intelligence: bodily-kinesthetic, interpersonal, intrapersonal, linguistic, logical-mathematical, musical, naturalistic, and spatial (Davidson, 2005; Gardner, 1993). The particular type of intelligence people have varies and Gardner believes these types of intelligence are equally important (Table 20-2).

MORAL DEVELOPMENT THEORIES

Study of moral development deals with a child's perception about right and wrong. Piaget, Lawrence Kohlberg, and Carol Gilligan are the three of the most well known theorists in this area. Of these, Kohlberg is the most often cited for understanding moral development in children.

Piaget (1969–1980) studied the progression of moral thinking in children based on the ability to reason and understand the environment. Piaget identified two stages of moral judgment. The first stage describes the way in which children younger than 11 years old experience right and wrong as concrete, black-and-white concepts. Simply put the child understands that an act is good or bad, right or wrong. The second stage coincides with Piaget's Formal Operational Stage of cognitive development during which the child is better able to think abstractly. Rules are important, but not always absolute or “carved in stone” (Table 20-3).

Table 20-2 Multiple Intelligences

Bodily-Kinesthetic	A child who learns through movement or touch. The child excels in physical tasks and may love to dance and move, or touch.
Interpersonal	A child who learns through relating to others. The child has good use of verbal and nonverbal communication skills.
Intrapersonal	A child who learns through self-reflection. This child pays attention to the moods of others as well as to his own.
Linguistic	A child who learns by auditory means. The child will hear and say things in order to understand and remember them.
Logical-Mathematical	A child who learns through making connections. The child will work to figure things out by applying logic and systems.
Musical	A child who learns through making a song. The child may excel by singing songs or playing a musical instrument.
Naturalistic	A child who learns best in the natural or animal world. This child loves spending time with animals or plants or nature.
Spatial	A child who learns visually using charts, maps, movies, pictures. This child enjoys picture books and videos.

Lawrence Kohlberg

Lawrence Kohlberg (1927–1987) based the theory of moral development (1984) on the thinking processes involved when making moral decisions. Kohlberg identified three levels of moral development: preconventional, conventional, and postconventional. Each level of moral development represents a major modification in the child's thinking and is further separated into stages (Table 20-4). Within Level I, Preconventional Level, the child's thinking is concrete and egocentric. Obedience and punishment are unquestioned and understood as either good or bad. The child behavior is based on which actions are rewarded or punished. Individualism and exchange occurs when the child begins to define right and wrong and develops an individual sense of fairness and personal justification. As the child matures and is confronted with opposing views, he begins to recognize that not everything is black and white. The child's sense of morality is still concrete but the child begins to take into account personal reasoning. If the child can justify an action, then, in his mind, it is acceptable to bend or break rules.

Transition to the Level II, Conventional Level for the child, is marked by the child's incorporation of social and interpersonal relationships. The good interpersonal and relationships stage is where the child's actions are justified by personal motivation to "do good" for family members or other individuals. The child understands that maintaining the social order means that society as a whole may benefit by her actions.

Level III, Postconventional Morality, is divided into social contract and individual rights and universal principles both of which require significant degrees of personal deliberation and maturity. These stages are sequential and require a level of cognitive development, they are not necessarily age-related. In fact, an adult may have reached only the preconventional level of moral development and has not reached the postconventional level of moral development because progression through the levels is influenced by a variety of factors such as experience, health, socioeconomic status, family structure, and culture.

Carol Gilligan

Carol Gilligan (1936–present) initially worked with Kohlberg as a research assistant. Gilligan became concerned that Kohlberg's studies of moral development were based only on norms for males. When girls were compared to boys using Kohlberg's framework, girls appeared morally weaker or slower to develop than their male counterparts. In Gilligan's book, *In a Different Voice* (1982), previously held beliefs about female moral development were questioned by interviewing both women and men about their life experiences. Gilligan identified two tracts of moral development. One was based on autonomy and justice (Gilligan, 1982), as seen in Kohlberg's interviews with men. The other was based on caring and relationship (Gilligan, 1982), which Gilligan attributed to women. Gilligan's work helped to define moral development for women in a different way than men. Even though Gilligan later withdrew the charge of gender bias, Gilligan continued to champion the study of female moral development (Box 20-4).

Table 20-4 Lawrence Kohlberg's Stages of Moral Development

Level I. Preconventional Morality Morality is determined by external sources—rules, laws, possibility of punishment.	Stage 1: Obedience and Punishment—The child will obey in order to avoid being punished.
	Stage 2: Individualism and Exchange—The child thinks that it may be okay to do something wrong if a good comes from it (in other words, the end justifies the means).
Level II. Conventional Morality Morality is determined by being a "good person." The intent is to please others and to do the "right thing."	Stage 3: Good Interpersonal Relationships—The child's moral decisions are based on the "goodness" of motivation and on what others expect.
	Stage 4: Maintaining the Social Order—The child's good moral decisions are those that preserve the needs of society.
Level III. Postconventional Morality	Stage 5: Social Contract and Individual Rights—The individual's thinking is characterized by a deeper questioning of social order versus an individual's personal rights. A person in this stage would work tirelessly to change unjust laws.
	Stage 6: Universal Principles—An individual incorporates a deep awareness of justice. An example would be breaking an unjust law to save lives of innocent people.

SPIRITUAL DEVELOPMENT THEORIES

James Fowler (1981) identified seven stages related to faith and spiritual development. Fowler defined faith outside the usual "religious" definition. Fowler believed that faith is commonly experienced and that it is the individual striving for something "more than the self." The development of faith depends on a certain level of cognitive achievement. Deepening levels of belief rely on the ability to think abstractly. Understanding Fowler's stages are important in providing complementary care to children and their families (see Complementary Care: Understanding Spirituality).

Box 20-4 Gilligan's Three Levels of Moral Development

Level 1: *Orientation of individual survival.* As the girl transitions through this level, they move from *selfishness to responsibility* where they consider other people.

Level 2: *Goodness as self-sacrifice.* This level involves looking at the world through the needs of others. The girl sacrifices her own needs and considers herself responsible for others.

Level 3 (*the transition level*) requires movement from *goodness to truth*. In other words, the woman recognizes that choice is importance when doing for herself or others, rather than focusing on being good for the sake of being good.

Complementary Care: Understanding spirituality

Stage 0: Undifferentiated (infancy): Prestage during which the infant is learning “fundamentals of basic trust and the relational experience of mutuality with the one(s) providing primary love and care” (Fowler, 1981, p. 121). This foundation of trust sets the stage for developing a spiritual faith.

Stage 1: Intuitive-projective (ages 2–6 or 7): Corresponds with the child’s imaginative period. Beliefs and faith are unquestioning. It is a time of fantasy and magical thinking.

Stage 2: Mythical-literal (ages 6–12): The child retells the spiritual stories and takes them literally and concretely.

Stage 3: Synthetic-convention (typically begins around 12 or 13 years): The young person begins to personalize beliefs. The youth looks beyond his family to include values encountered in relationships, in school, and in society in general. Sometimes adults remain in this stage.

Stage 4: Individuating-reflexive (may begin late adolescence or early adulthood, or not at all): The individual takes responsibility for personal beliefs and commitments. The individual invests personal energy in what spiritually makes sense, regardless of what others believe.

Fowler goes on to describe two additional stages of faith that may occur in adulthood, *Conjunctive Faith* and *Universalizing Faith*.

FAMILY DEVELOPMENT THEORIES

There are many theories describing family interaction. Duvall’s (1977) theory is based on Erikson’s individual stages of psychosocial development and is the most well known. The family development stages are as follows:

Marriage. The task of couples in this stage is to establish themselves as a pair and to prepare for parenting. This is also a time for realigning with both families of origin from the position of a new family.

Family with Infants. During this stage, the family adjusts to its new structure while the couple begins to adjust to their new role as parents. Grandparents adjust to their new role too.

Family with Preschool Children. As the oldest child enters the stage of early childhood, the family functions to socialize the children, helping them to cope with separation involved in starting school.

Family with School Children. As the children develop friendships and launch socially outside the family, the system must adjust.

Family with Adolescent. The oldest child turns toward launching and independence. At this point, the parents begin to refocus on their marriage.

Family Launching Young Adult. This stage begins when the oldest child leaves home. If there are other children, it ends when the youngest leaves home. Family tasks during this stage center on the development of individual and independent identities, both children and parents. The marriage continues to be a major area of energy.

Middle-age Family. The family continues to focus on reinvesting in the couple relationship. Relationships with extended family are realigned.

Aging Family. During this stage, the family copes with the process of and losses involved in retirement and aging.

Nursing Insight— Applying Duvall’s theory

Duvall’s theory provides a framework for observing the development of families. It is important to understand that this framework applies to specific family types and styles such as those families with children who remain married and whose children leave home in the appointed timeframe. Remember, when caring for children from other family types the nurse must consider family make-ups such as divorced families, single parent families, child-free families, children who return home after launching, and culturally diverse families. The nurse needs to consider a multitude of factors and approach families using a non-judgmental demeanor and help the family understand and explore solutions based on their unique family.

Collaboration in Caring— The health care team

Various members of the health care team oversee growth and development across care settings, throughout the life of a child. Both nurses and physicians assess a newborn while in the hospital and a lactation consultant may be involved if the newborn is breastfed. Well-child visits to the family physician or health care provider at the child’s medical home at regular intervals help track a child’s growth and development and intervene if problems arise. Public health nurses may also assess the child, particularly at times of immunizations. Complementary and alternative health practitioners such as chiropractors, massage therapists, and naturopaths may also play a role in caring for a child.

Now Can You— Apply theories to nursing practice?

1. Describe the importance of using theoretical based knowledge in the care of children and families?
2. Discuss the different types of theories used in the care of children and families?
3. Educate families about what to expect during growth and development?

Temperament

Children come in all shapes and sizes and represent all temperamental profiles and personality styles. Children are not simply “miniature adults.” They require professional assessment and attention across care settings based on their level of development.

Temperament refers to those characteristics present at birth that govern the way in which an infant responds to their surroundings. There is a strong biological and environmental basis for temperament. Likewise, the baby’s temperament generally has a profound influence on their interactions with caretakers and the environment itself.

Thomas & Chess (1977) studied temperament. Nine temperamental traits present at birth that persist throughout

life were identified. These traits exist on a continuum depending on the infant's reaction to the environment. To help ensure effective parenting the nurse can teach parents about their infant's temperament traits.

Across Care Settings: Infant temperament

During a normal daily routine the child may be exposed to a variety of settings and exposed to several people; a day care center, visiting extended family, physician's office or in public places in the community. Understanding an infant's temperament is essential in the care of the child to help both the parent and child adapt to these experiences. Based on the work by Thomas, Chess, and Birch (1968) the following descriptors are used to help recognize the infant's unique personality.

Regularity: The child needs regularity in sleeping, eating, and bowel habits. A child who is "easy" is one who can adapt to relatively flexible schedules. A child who is "difficult" has difficulty when the schedule has been disrupted.

Reaction to new people and situations: The "easy" child responds easily to new people in their environment. Another child may stand back or withdraw when something or someone new is present.

Adaptability to change: This trait refers to a child's willingness to change routine. An "easy" child makes transitions with little or no discomfort. A slow-to-adapt child will become distressed with even the smallest changes, for instance, taking a different route home from school.

Sensory sensitivity: An "easy" child with lower sensitivity will appear much less meticulous or disturbed by her senses. A "difficult" child with high sensitivity may react strongly when exposed to sensory stimuli. The child may chafe against certain textures, tastes, smells, or sounds.

Emotional intensity: An "easy" child shows little or no response to a situation. An intense child reacts dramatically and profoundly, whether that reaction is loud or withdrawn.

Level of persistence: This trait refers to the child's willingness to stay engaged regardless of setbacks. A persistent child has difficulty giving up until the goal is reached. A less persistent child is more flexible and may give up easier.

Activity level: An "easy" child will generally be less frenetic with activity. A "difficult" child has difficulty with inactivity, preferring to always be on the move.

Distractibility: The distractible child has difficulty concentrating on tasks in which they are not immersed; not the same as Attention Deficit Disorder (ADD). A less distractible child stays with a task longer.

Mood: An "easy" child tends to see the world in a more positive way. A "difficult" child will react more negatively.

The ability to recognize these traits is helpful for determining the goodness of fit between the caregiver(s), family members, and the child along with helping families strategize to improve the fit. This way of understanding the child takes into account that each person in the child's life has also a unique temperamental style, which complements, becomes enmeshed with, or antagonizes that of the child.

Newborn and Infant

The entire infant period of development encompasses the development from 1 to 12 months of life. This period of development continues to be a time of rapid change in all aspects of development. The baby develops on all levels, at a varying pace. It is important for the nurse to remember that each infant moves at his pace and with his own style.

The neonate's movements are random and erratic. The neonate can move the head from side to side, but has little control of her neck and back muscles.

REFLEXES AND NEUROLOGICAL DEVELOPMENT

Primitive reflexes are those adaptive and innate mechanisms that protect the developing infant while the brain is maturing (see Chapter 18 for more information). The reflexes are controlled by the lower brain centers. There are several reflexes present at birth or shortly after. They naturally disappear by 9 months.

clinical alert

Reflexes

As the nurse performs an assessment it is imperative to note important infant reflexes:

- Rooting: baby's head turns and begins to suck when her cheek or lower lip is stroked.
- Sucking: motion of lips, mouth, and tongue allowing infant to take in sustenance.
- Moro: Startle response with sudden jarring causes extension of the head. The arms abduct and move upward. The hands form a "C"
- Grasping: When palm of hands or soles of feet are stroked
- Babinski: Turning in of foot and out of toes when sole of foot is stroked

At birth, the lower portions of the nervous system (spinal cord and the brainstem) are already developed. They are necessary for the infant to sustain life (basic body functions and primitive reflexes). As the infant matures, the higher sections of the nervous system become more developed. For instance, the limbic system and the cerebral cortex are responsible for ongoing learning that occurs during the lifespan.

SENSORY DEVELOPMENT

Touch is an extremely important sense and is the first sense to develop. The ability to feel objects, textures, and other people opens up the newborn's world of learning. It is important for the infant to experience soft comforting textures. The ability to experience pain is also an extremely important element, particularly as a protective device. If the infant has a pain experience, he reacts to pain with the whole body by quickly extending and then retracting the extremities. Along with this reaction, the infant cries.

Smell and taste begin developing in utero and intrinsically connected. Infants respond to smells within the first

Figure 20-1 At 3 months of age an infant can lift her head and chest while on her belly (*top*) and roll on her side (*bottom*).

few days and have an innate preference for sweet tastes. The nurse is aware that infants can recognize their mother's smell long before they achieve visual recognition.

Hearing is well developed at birth. A newborn can immediately recognize the difference between male and female voices and will generally turn toward the female voice. By the second week, the newborn can recognize the sound of the mother's voice. A newborn's ability to discriminate sounds develops quickly, contributing to language development. By the time the infant is 3 months, the infant jabbars and begins to imitate sounds. During the next few months, the infant becomes more adept at responding to and imitating familiar sounds by smiling and cooing.

Vision is the least developed of the senses at birth. Newborns are fascinated with faces and with designs or objects that resemble faces. While a newborn is able to remember an object, he remembers it only in the exact form originally seen (e.g., if the child sees his sister in pigtails, the child does not recognize the sister with her hair down). Infants are most attracted to bright colors and to black and white because of the limited nature of their vision. The newborn generally has poor peripheral vision until 10 weeks of age. Within the first 3 months, the infant can watch faces intently, follow moving objects, and recognize familiar objects and people at a distance. There can also be the beginnings of eye–hand coordination. Binocular vision (ability to use both eyes to see) develops about 4 or 5 months of age. The capacity to distinguish colors and to see things in the distance develops throughout the first 7 to 12 months.

PHYSICAL DEVELOPMENT

Growth is rapid. Infants gain 1.5 pounds (680 g)/month, double their weight by 6 months and triple it by 1 year. Height increases by 1 inch (2.5 cm) for the first 6 months

and slows down during the second 6 months. A newborn's head is proportionally larger than the rest of the body, which is in keeping with the cephalocaudal course of development. The newborn's head grows rapidly during the first month as the brain grows. By the time the baby reaches 1 year of age, the head and chest circumferences are about the same.

In order for the infant to move or to perform actions (motor skills), he must have adequate muscle development. At birth, the newborn's movement is involuntary. It takes the infant time to mature physically in order to be able to demonstrate motor skills. Gross motor skills (the ability to use large muscles for movement) are the first to develop in the newborn and infant. Generally, by the end of the first 3 months of life, she can raise her head and chest while lying on her belly and stretch the legs out and kick from a prone position, and roll from side to side (Fig. 20-1). She can turn over completely at about 6 or 7 months of age. By 8 to 9 months of age, the infant begins to crawl and then by using high objects the infant can begin pulling up. Once the infant has mastered an upright position, he may begin to then cruise (walking while holding on to furniture) or even attempt to walk. Again, development is variable on each individual child. One child may be walking before his first birthday, while another does not walk until later.

Fine motor skills (the use of muscles to accomplish minute tasks like pinching or picking up food) build on the gross motor skills (Fig. 20-2). Other fine motor skills that develop between 6 and 12 months include the ability to stack large objects, scribble, bang on pots and pans, and transfer objects from one hand to another and back again.

COGNITIVE DEVELOPMENT

Infancy corresponds to Piaget's sensorimotor stage of development. The infant uses the five senses to explore and to learn about the world. For instance, the infant learns that lip smacking when hungry leads to a full

Figure 20-2 One of the first fine motor skills to develop is the ability to pinch to pick up small objects like food.

Family Teaching Guidelines... Introducing Solid Foods to Infants

TOPIC: Introducing Solid Foods:

The baby is ready for the introduction of solid foods at approximately 6 months of age. To help determine if the baby is ready for solid foods, look for developmental cues such as the ability to sit well with support. The baby may watch very intently as you eat, and may seem hungry between bottles or breastfeeding.

- ◆ Iron-fortified rice cereal is recommended as the baby's first solid food for a couple of reasons. It is the least allergenic of the grains, and the iron will help the baby replenish the iron stores received in utero. The term "solid food" is something of a misnomer. When introducing the rice cereal to the baby, you can mix it with formula, breast milk, or boiled and cooled water until it is very soupy. As the baby adapts to solids, you can increase the consistency of the cereal.
- ◆ When the baby is eating about 4 tablespoons of cereal twice per day, begin to introduce vegetables and fruits. Starting with vegetables may help to increase acceptance by the infant not yet exposed to the sweet taste of fruits.
- ◆ Introduce one food at a time, waiting 3–5 days between new foods so you will be able to identify any reactions to particular foods.
- ◆ Introduce food before formula or breastfeeding when the infant is hungry, and follow each solid food meal with a bottle or breast.

Seeking Additional Help: If the infant is not growing or gaining weight, cannot suck or swallow or shows any sign of allergic reaction, it is important to seek help from the primary health care provider, nearby clinic, or emergency room if the problem is emergent.

ESSENTIAL INFORMATION

- ◆ Avoid salt, sugar, and additives.
- ◆ Never put food in bottles or mix with formula (to avoid aspiration).
- ◆ Pay close attention while feeding and keep bites small to avoid choking.

Source: American Academy of Pediatrics (2008).

stomach. When the infant's belly is full, physical needs are met and the infant can then begin to explore the environment. Ultimately, the infant learns that he can have an impact within that environment. The infant must achieve three major tasks during this phase of development:

Separation. Recognizing that here is no merging with or attachment to familiar people (family members)

Object Permanence. The infant knows that an object or person still exists even if covered up or removed from sight; this is why babies respond so strongly to peek-a-boo.

Mental Representation. The ability to use symbols to communicate.

Piaget also identified six substages within the sensorimotor stage that describes mental representation. It is important to note that four of these substages occur during the first year of life. The first substage, Use of reflexes is present at birth. The majorities of the reflexes are necessary for survival and disappear during the first 9 months. The second substage, Primary circular reactions (1 to 4 months) takes place when the infant responds to things that give pleasure. The infant's response encourages caregivers to continue providing pleasurable experiences. The third substage, Secondary circular reactions, begins when the infant recognizes cause and effect. For example, the actions that the infant can perform independently begin to their capture attention (e.g., shaking a rattle). The fourth substage begins around 8 to 12 months when the infant becomes deliberate with their actions. During substage 4, Coordination of secondary schemes, the infant intentionally seeks out objects. The infant now knows that punching the button starts the music on a toy. During this substage, the infant also develops object permanence. The remaining substages, Tertiary circular reactions, and Mental combinations happen during the toddler stage of development.

LANGUAGE

Babies initially communicate through cries (a universal language) that indicate physical discomfort or loneliness. As a mother or father responds to the cries, the infant learns to communicate more deliberately. The nurse must recognize that an infant's early speech is evidenced by crying, babbling, and imitation. Influences on language development include maturation of the brain and the degree and quality of social interaction. If families respond favorably to baby's sounds, like "ba" for bottle or "da" for daddy, the baby is more likely to repeat these sounds bringing the infant closer to the native language.

PSYCHOSOCIAL DEVELOPMENT

In infants, the first displays of emotions, crying and smiling, are related to physiological needs rather than psychological stimuli. For example, the newborn wails loudly when uncomfortable physically and smiles involuntarily during sleep. However, by the time the baby is two weeks of age, the smiles begins to signify contentment and elicit positive family response. The infant's smile then becomes social and interaction with the environment occurs.

Corresponding with Erikson's psychosocial stage of trust versus mistrust, the nurse knows that it is a critical time for the newborn to absorb the whole environment and the related experiences. The caretaker's task is to respond to the infant in such ways as to engender a sense of security and well-being. Essentially, the baby's mission is to develop a sense that caretakers are reliable and present.

Ainsworth described four stages of attachment. During the first stage (birth to two months), the newborn and infant randomly responds to anyone. By the second stage (8 to 12 weeks), the infant begins to respond more to the

mother than to anyone else, but the infant continues to respond indiscriminately to others. It is not until the third stage (6 or 7 months) that the infant demonstrates a strong connection to the mother and possibly develop a fear of strangers. Not all babies develop stranger anxiety as was historically thought. Throughout the first year, the infant is developing attachments to all of the important people in the family. Achieving the necessary milestones is essential for the infant to move on to the next stage of psychosocial development. An example of psychosocial development is the infant becoming more aware of others and responding to people (or animals) that are physically on the same level (Fig. 20-3).

DISCIPLINE

Discipline plays an important role in the psychosocial development of the infant. Merriam-Webster's Online Dictionary (n.d.) defines discipline as "training that corrects, molds, or perfects mental capacities or moral character." The definition additionally identifies teach as a synonym. In the best of all worlds, discipline and teaching would be the same. In reality, much of what is designated as discipline is in fact punishment. Punishment, as defined in Merriam-Webster's online dictionary, is "suffering, pain, or loss that serves as retribution." It is important for the nurse to be aware of these definitions when helping parents and caretakers determine how they plan to provide for the correction, molding, and refining of their children's mental capacities and moral characters.

It is important for the nurse to include information about discipline when teaching the parents about the infant. Teaching parents about discipline helps the infant learn about maintaining safety measures, develop satisfying relationships, and become a good global citizen. The American Academy of Pediatrics (1998, 2004) indicates that early forms of discipline take place when the caregiver molds and structures the infant's daily routines and by responding to the infant's needs. Limit setting functions to acclimate the infant to the world and to keep the infant out of harms way. It is important to note that parents often learn how to discipline from their own

Figure 20-3 An example of psychosocial development is when an infant becomes more aware of others by responding to people or animals that are physically on the same level.

experiences as children. It is essential that parents be taught what to expect at each of the developmental stages and how to recognize appropriate strategies for teaching and limit-setting.

critical nursing actions Anticipatory Guidance

Anticipatory guidance is a way of providing caregivers with information and examples about what to expect in the future regarding their child's next developmental phase. A few examples of important topics may include discipline, nutrition, safety, schooling, elimination, immunizations, or play.

It is important that the nurse teach parents that infants do not misbehave on purpose. Exploration and crying are normal behaviors for infants. The purpose of discipline at this age is to keep the child safe. Using a firm tone of voice or facial expression while telling the child "no" or "stop" as he or she reaches for the stove helps the infant know that there are limits to his actions. The infant can then be redirected to a similar experience such as reaching instead for a toy off a countertop.

Toddler (1 to 3 years)

PHYSICAL DEVELOPMENT

By the time, the infant reaches 1 year of age, physical growth has slowed. Between ages 1 and 3, each year the typical toddler gains 4 to 6 pounds (1.8 to 2.7 kg) and grows 3 inches (7.5 cm) taller. Much of the toddler's energies during this period are directed to other realms of development. As the physical growth rate slows, the toddler develops skills (physical, cognitive, and emotional), that help him to become more independent. As the toddler develops mobility, he explores how things work and his senses become more refined. The toddler uses newly acquired gross motor skills to run, jump, and move up and down stairs with increasing ease. Around age 3, he may learn to ride a tricycle or slide down the slide in the park without help. All this newfound freedom and movement create many opportunities for danger as the toddler moves quickly from one new experience to another.

Fine motor skills continue to develop rapidly also. The toddler can hold a spoon or a large crayon appropriately and continues to make artwork that is more representative of the object she is trying to depict. He is increasingly able to manipulate smaller toys.

COGNITIVE DEVELOPMENT

Early toddlerhood corresponds with Piaget's fifth substage of cognitive development, Tertiary circular reactions, during which the toddler experiments and learns new behaviors. The toddler then moves into Piaget's sixth substage, Mental combinations, during which she begins to understand cause and effect and is able to imitate others.

The toddler loves to imitate (Fig. 20-4). Much of the toddler's behavior is through replicating what she sees and hears. The toddler also learns through repetition. This is why a toddler may want the same book to be read over and over, staying engrossed in the story every time.

Figure 20-4 Toddlers love to imitate.

A toddler also likes order and often responds with difficulty to any disruption in routine. The level of response is related to the temperament of the child. Some toddlers may revolt with pure temper tantrum while others can calmly transition. Regardless of temperament, most children at this stage respond favorably to predictable routines.

LANGUAGE DEVELOPMENT

Because toddlers are increasing in cognitive development, they are able to listen to and understand short explanations. This is a time when the child develops a more understandable language system. Language is about fulfilling needs; “I do” or “want drink.” The toddler moves from using single words to short phrases. Some parents worry when their child does not fall exactly within what are considered normal language parameters. The nurse can reassure parents that it is important to assess what the child understands and what the child is able to communicate, with or without words, rather than exact correctness in pronunciation.

PSYCHOSOCIAL DEVELOPMENT

Toddlers typically exemplify characteristics of Freud’s *anal stage*. The child begins to develop a sense of self as separate from his mother. The toddler’s task is to move away from the primary caregiver while in some way maintaining enough connection to feel secure. This process, called *rapprochement*, is healthy and expected.

Toddlerhood also corresponds with Erikson’s stage of autonomy versus shame and doubt. It is a time when the child makes every effort to “do it myself.” Mastery is an extremely important task of this stage of development. Since the toddler’s abilities begin to surpass cognitive judgment, it is also a time of potential hazard for the developing child. Caregivers must walk the fine line between allowing exploratory independence and “mastery” on one hand and vigilance on the other. It is often a time of bumps and “boo boos.”

Often dubbed as the “terrible twos,” this entire stage can be a tumultuous time for both caregivers and toddlers. The child must begin to internalize behavioral standards at a time when establishing independence is important. The nurse can help parents understand that the toddler does not set out to make life miserable. The toddler simply has few internal mechanisms in place to accomplish what needs to be done safely. It is frustrating to the toddler when confronted with blocks to budding mastery. The word “no” begins to signify the toddlers simple response to frustrated emotions encountered.

MORAL DEVELOPMENT

Cognitively, the toddler is still a very concrete thinker and knows that something is “good” or “bad,” but does not know why. At this stage, the toddler identifies good and bad, right and wrong by virtue of whether or not it is rewarded or punished. This corresponds to Kohlberg’s preconventional level of moral development.

DISCIPLINE

The purpose of discipline is to teach the child socialization and safety. It is the responsibility of the parent to provide a firm structure so the toddler can explore the world while offering safe limits. Most children will repeatedly test rules, while also unconsciously learning to rely on the security those limits provide. Having a structured environment for the child does not necessarily mean rigid or inflexible. Parents must learn to structure the toddler’s surroundings that allow enough flexibility to test limits.

A child at this stage needs much guidance in determining how to act appropriately. The toddler thinks concretely and must rely on others to help give realistic parameters. Some parameters may create a great deal of conflict when what the toddler *can* do does not match what the toddler *wants* to do, which may result in a temper tantrum. Praise becomes an excellent component of discipline as most children want to please the parent.

TEMPER TANTRUMS

Because this is a time of intense exploration and discovery and a time when the toddler is establishing a sense of herself as a competent doer, there will be “bumps in the road.” A tantrum is a normal way for a toddler of working things out internally. Parents and caregivers need to know that tantrums are normal for the toddler. It may be possible for parents to anticipate when tantrums are most

apt to occur (e.g., when the toddler is tired, hungry, or overwhelmed by new situations, reserves are low and therefore, he may be more likely to explode or “melt-down”). Tantrums may be avoided or minimized if anticipated. Get a tired child to rest or feed a hungry child to decrease his frustration level. If a tantrum does develop, there are coping strategies that a nurse can teach a parent. When the child is wailing and thrashing, but not doing any harm, ignore her. Often this is not possible, and it may be necessary for the parent to intervene quickly and decisively to remove the child to a quieter or safer place. Touching and distractions may help soothe a tantrum; while another child may need to continue the tantrum under the watchful eye of the parent. The latter requires that the parent be present, but not engaged in direct communication with the child. The goal is for the child to feel (and be) safe without being reinforced (positively or negatively) for having a tantrum.

When faced with the sometimes daunting task of caring for a “willful” toddler (one who is regularly asserting her power), parents are often confused. It is indeed difficult to know how and when to avoid the power struggles inherent in a clash of wills. It is essential to be able to create boundaries that limit the toddler’s scope of power. Inevitably, there are times when the toddler must be disciplined, so seeking help from a professional child counselor is essential (Box 20-5).

“What to say” — Tips for effective discipline

During effective discipline, allow for negotiation and flexibility, which can help build the child’s social skills. Also, allow the child to experience the consequences of behavior.

- Speak to the child as you would want to be spoken to if someone were reprimanding you.
- Never resort to name-calling, yelling, or disrespect.
- Be clear about what you mean.
- Be firm and specific.

Note: Whenever possible, the consequences must be delivered immediately, relate to the rule broken, be short enough in duration and emphasize the positives. In addition, the consequences must be fair and appropriate to the situation and the child’s age.

Box 20-5 Discipline Strategies

Distraction: Provide a toy to divert the child’s attention.

Time-out: Move the child to a “cooling-off” place where the child can calm down.

Removal of privileges: Withhold a favorite toy until the child’s behavior is appropriate.

Verbal reprimands: Give spoken warnings or disapprovals without berating the child or judging the child as “bad.”

Corporal punishment (e.g., spanking, swatting, grabbing): Not recommended.

Early Childhood (Preschooler) (3 to 6 years)

PHYSICAL DEVELOPMENT

Children at this age come in various sizes, shapes, and body types. As a rule, preschoolers begin to grow taller and thinner. Their bellies flatten as they grow and their abdominal muscles strengthen, and their pelvis straighten. The physical growth rate for this stage of development is slow but steady. The preschooler average weight gain is about 4.5 to 6.5 pounds (2 to 3 kg) and growth is 2.5 to 3.5 inches (6.2 to 8.7 cm) per year. The 4-year-old’s posture straightens and the young child is able to move around in a more balanced fashion. Preschoolers become stronger as their muscles become more developed. Their faces become more like they will be when they grow up with narrowing of the face, enlargement of the nose, and a more adult-like appearance to the skin.

The preschooler is much more agile. The preschooler can climb stairs using alternating feet and is able to ride his tricycle. At 4, the preschooler can climb up and down the stairs comfortably using alternating feet. The preschooler can skip and hop and is much more coordinated on the balance beam.

Fine motor skills rely on the use of the forefinger and the thumb. As the brain becomes more developed, she is better able to pick things up with the fingers. Hand dominance (whether or not the child is right- or left-handed) begins to develop around the age of 3. At this time, the preschooler may show a preference in using one hand over the other. By the age of 4, that preference is established.

COGNITIVE DEVELOPMENT

This period of development corresponds with the first substage of Piaget’s preoperational stage (2 to 4 years). During this time, the preschooler increases the ability to verbalize. The preschooler can symbolically use language to represent concepts that need to be conveyed. The young child is still egocentric (focused only on his own sense of things) and therefore is limited socially. This is in large part due to concrete thinking processes and the inability to abstractly shift focus from self to others. The preschooler is also not able to transfer attention from one aspect of an object to another (e.g., a child at this stage can identify a dog’s collar, but is not able to describe its texture).

LANGUAGE

The preschooler has increased ability to verbalize; vocabulary increases from 1500 to 2000 words between the ages 3 and 5. The preschooler uses sentences and is much more able to convey an intended message. When the young child is more able to use words, tantrums generally begin to subside. The preschooler loves silly words, rhymes, and asks many questions, generally those that begin with “why?” To meet the needs of the preschooler, keep answers simple and avoid giving too much information. Bombarding the preschooler with overwhelming answers can be quite disconcerting for the child. The nurse can tell the parent that a preschooler may stutter as he tries to get out all of the words faster than he is able to speak them. Stuttering generally resolves fairly quickly.

case study Early Childhood Development

Mrs. James brings Steven, her three-year-old son, into the clinic for a well-child visit. She states she is concerned because Steven does not talk as well as his peers. She describes how at play group, the other 3-year olds talk more than Steven, and states that Steven barely says a word. When asked how Steven communicates what he wants, Mrs. James states that he points to things and sometimes say one word such as “more” or “juice.” Mrs. James added that Steven often gets frustrated when his parents do not understand what he wants. A review of his medical history reveals that Steven was born 39 weeks, weighed 8 lbs, 1 oz (3.7 kg) and had an unremarkable delivery. He has had no difficulties with feeding or sleep. He began babbling at 6 months but did not speak his first word until 14 months. By 19 months he could say “mama,” “dada, and “juice.” Presently, Mrs. James states he uses approximately 10 words but does not combine them.

critical thinking questions

1. What further assessments would you complete for Steven?
2. What would you say to Mrs. James about Steven?
3. What nursing interventions would be appropriate at this time?

◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

PSYCHOSOCIAL DEVELOPMENT

Early childhood is a wonderful time of exploration of new skills and about finally being able to figure out how to get and do things for oneself. As the preschooler develops, he is presented with many situations where he can truly excel. The preschooler has learned many new skills and is becoming a “big kid.” The preschooler enjoys positive feedback for accomplishments. The fact that the preschooler is able to do many new things creates a dilemma and the preschooler must decide which things are most important. Parents may not approve of the decisions made by the preschooler and he may become conflicted when limits are set. Often times the preschooler ponders doing “the right thing” or do “the wrong thing” and risk the mother’s dismay? Conscience develops and begins to guide the child through the maze of wants versus cans.

The preschool child has a good deal of magical thinking. In a preschooler’s desire to do what she wants to do, she may angrily wish something bad would happen to another person, often a parent. If something bad actually does happen, the preschooler will believe that her thinking caused the outcome.

Freud described this period as the phallic or oedipal period. The child is becoming more aware of gender differences. The preschooler may want to marry mom or the girl in preschool, rather than relate to his best male friend.

Family is very important to the preschooler. However, the preschooler is now discovering the joys of having friendships. The young child looks to his peers for new ideas and information and begins to develop an understanding of what it means to be kind. The preschooler is more social and is often more willing to share toys with others than when he was a toddler.

MORAL DEVELOPMENT

Early childhood typically corresponds with Kohlberg’s preconventional morality stage (4 to 10) when the major impetus for moral judgment is to avoid punishment. It is not uncommon for the child in this age group to tell lies to avoid consequences. A child at this age may judge an action to be wrong only if caught. The young child is only guilty if the parent has seen the actions.

DISCIPLINE

Since the preschooler is beginning to understand that actions have consequences, caregivers can take advantage of this understanding. The preschooler is able to understand that there are rules and that not obeying those rules leads to consequences. It is best if rules are explained before infractions occur. At the very least, the rules should be addressed before disciplining the child. This helps the preschool child to learn more clearly how to behave. Consequences can, as much as possible, follow naturally and fit the behavior being punished (e.g., having the child clean up his own messes, or miss a favorite show if he dawdles).

A typical discipline strategy instituted at this stage of development is having the child take time-out. Whether that time-out is in a specified chair, or section of the room, it is important to help the child know that the purpose of the time-out is to calm himself and to shift gears and act appropriately.

Many parents begin using behavioral charts (charts constructed to praise positive behavior) at this age to help their toddler visually see what is expected and to be rewarded when “good” behavior is shown. For many preschoolers, simply getting a star or sticker on the chart is reward enough to encourage behavior. For others, a more sophisticated measure of rewards is needed. Again, the goal of discipline and limit-setting at this stage of development is to begin teaching the preschooler to begin regulating own behavior.

School-Age Child (6 to 12 years)

PHYSICAL DEVELOPMENT

Early in this stage (ages 6 to 9), boys and girls follow similar growth trajectories. Both begin to grow taller, reducing their “baby fat” even more. Children at this age gain about 4 to 6 pounds (1.8 to 2.7 kg) and grow 2 inches (5 cm) per year. As their abdominal muscles strengthen, their posture straightens. Facial features become more refined. Still, there are many variations in size and shape of children in this period. These variations are influenced not only by familial and cultural genetics, but also by environmental factors (e.g., diet and exercise).

Most school-age children (boys and girls) begin to develop axillary sweating. In girls, hips begin to broaden and the pelvis widens in preparation for childbearing. Breasts begin to enlarge and become tender. The vaginal pH changes from alkaline to acidic and the vagina develops a thick mucoid lining. Usually, pubic hair begins to develop between the ages of 8 and 14. While menarche can begin as early as 8 to 10 years of age, the average age in the United States is 12 years of age.

Ethnocultural Considerations— Puberty

African American girls tend to develop secondary sexual characteristics and begin menses somewhat earlier than Caucasian girls.

clinical alert

Privacy

At this age, it is important to guard the child's privacy. As a nurse be aware of self-conscious behavior related to physical changes occurring in the body. Along with privacy the nurse must be aware of other issues affecting the child and family related to menstruation, secondary sexual characteristics, hormone imbalances, mood swings, social needs well as other specific areas identified by the child and family.

Boys also begin sexual development at these ages. Their bodies become more muscular. About 10 to 12 years of age, a boy's testes begin to change. During this stage, the testes are more sensitive to pressure, the skin of the scrotum darkens, and pubic hair begins to develop. Boys often experience gynecomastia, a temporary enlargement of breasts. This can be embarrassing and should be explained to the child and family as a temporary condition.

COGNITIVE DEVELOPMENT

The school-age child is better able than the younger child to use logical thinking. This logic in thinking corresponds with Piaget's concrete operations stage of cognitive development. While the child's thinking is still quite concrete, she can begin to solve problems. During this childhood stage, she begins to replace his ever-present "why" with "how?" Mastery is in the arena of figuring out how things work. The school-age child builds on experience and begins to recognize consequences of actions. In school, she works on tasks requiring awareness of space (where things are in relation to other things), causality (logical consequences), categories (how things fit together), conservation (physical quantity can remain constant even when state is altered), and numbers. She is also capable of metacognition, the ability to think about thinking. This age child is aware of his own thinking and is able to assess how he came to conclusions, eventually leading to critical thinking.

Memory deepens as the child grows. She becomes more adept at processing and working through information. Memory improves because the brain developmentally retains more information. A child in this age group is also more able to determine what is important to remember and what is not. This helps her filter out irrelevant data, leaving memory space available.

LANGUAGE DEVELOPMENT

Language improves considerably. The child uses words more accurately, particularly verbs, metaphors, and similes. The child is able to elaborate on concepts that she wants to get across.

PSYCHOSOCIAL DEVELOPMENT

There is vast emotional growth during the middle child years. Erikson described this stage as one of industry versus inferiority. Unlike the younger child who believes he can do almost anything, the 6- to 10-year-old child begins to assess what they can and cannot accomplish. A school-age child has a more definite sense of self-esteem or competence based on the ability or lack of ability to perform.

Early in the middle childhood period (ages 6 to 9), the child is still self-focused. School-age children continue to exhibit magical thinking, in that they still may feel responsible for bad things happening. Later (ages 9 to 12) children at this stage are increasingly independent, although they want approval and validation. Competing and winning become important in the growing sense of self-competence. Friendships are exceptionally important at this stage. The school-age child looks more to friends than family, but family is still important. Best friends tend to be of the same gender, although mixed gender groups of school-age children become common as they reach the preteen and early teen years (Fig. 20-5).

MORAL DEVELOPMENT

For the first several years, the school-age child is still operating within preconventional morality. The younger child sees things as black and white and as self-referenced, rather than connected with more generalized rules and concepts. By the age of 10, the child enters Kohlberg's conventional morality stage. During this time, the child has internalized rules and is intently gaining approval. The older child operates within a morality of cooperation that implies recognition of the interaction between the self and a "bigger" worldview. Most children at this age are motivated by adhering to laws as a way to keep order.

Figure 20-5 Establishing strong friendships is very important to school-age children.

DISCIPLINE

Since the child in this stage of development is beginning to internalize rules, it is important to allow the child more independence, and thus more awareness of the natural consequences of behavior. An effective parent technique is to refrain from “rescuing” their child from the consequences of their behavior (e.g., do not rush home to retrieve a forgotten piece of homework whenever the child calls rather allow her to learn a valuable lesson).

While many school-age children respond appropriately to natural consequences, some do not yet understand responsibility. In addition, most children opt at some time to ignore the natural consequences. Parents may need to impose the previously discussed time-out strategy (e.g., grounded for a period of time or pleasures restricted).

Adolescence (12 to 19 years)

PHYSICAL DEVELOPMENT

Adolescence technically begins with the onset of puberty when the pituitary gland relays messages to sex glands to manufacture hormones necessary for reproduction. It is a period of great growth, second only to infancy. While the growth rate is not as dramatic as that of the earlier stage, it is still significant. It is not unusual for girls to gain 15 to 55 pounds (6.8 to 25 kg) and grow 2 to 8 inches (5 to 20 cm) and boys to gain 15 to 66 pounds (6.8 to 30 kg) and grow 4 to 12 inches (10 to 30 cm) before they reach maturity. While girls develop earlier than boys, they tend to have a smaller overall physical structure. Both boys and girls develop primary and secondary sex characteristics at this stage. The timing of development is variable.

COGNITIVE DEVELOPMENT

Adolescence corresponds with Piaget’s formal operations stage. The teenager is able to think abstractly and uses logic to solve problems and to test out hypotheses. In addition, the teen uses deductive reasoning and can think about thinking. Teenagers are often beginning to be concerned with such things as philosophy, morality, and social issues. They are able to project their thoughts over the long term, thus making plans and setting life goals. They often compare their beliefs with those of peers.

LANGUAGE

By adolescence, children have highly developed language skills. They have the ability to speak and write correctly as well as communicate alternative points of view. They have sophisticated communication skills.

PSYCHOSOCIAL DEVELOPMENT

According to Erikson, the adolescent crisis is concerned with identity versus role confusion. The adolescent must begin to identify who they are and who they will be in life. The three major issues that must be confronted; establish and subscribe to a set of values, and to have developed a satisfactory sexual identity.

Be sure to— Include the adolescent in the informed consent process

An informed consent is a way to elicit permission that is given freely that protects a person’s right to autonomy and self-determination. Informed consent is given when the person understands the usual procedures, their rationales, and associated risks. A legal parent or guardian customarily gives informed consent on behalf of the child. As children gain critical thinking skills they can become more active in the consent process. Depending on state law, children 18–21 years of age can give legal informed consent under these circumstances: when they are minor parents of the child patient, when they are between 16 and 18 years old seeking birth control, counseling or help for substance abuse or when they are self-supporting (emancipated). In many states, a pregnant teen is considered emancipated and can provide informed consent. The physician is ultimately responsible for explaining the procedure and related risks while the nurse’s role is to serve as a witness to the parent’s signature for the child or an emancipated adolescent’s signature. The nurse is responsible to notify the physician if the parent (or legal guardian) does not understand the procedure or related risks.

MORAL DEVELOPMENT

At this stage, conflicts emerge between what the adolescent has believed to be right or wrong, and what others may believe. This is a time of great questioning and consternation as the adolescent learns that it is possible for several views of morality to exist. Kohlberg defines this stage as postconventional morality.

“What to say” — Helping the teen make good decisions

The nurse can be influential in helping the teenager make healthy decisions. This can be accomplished by the employing the following techniques:

- Listen: Pay close attention not only to what the adolescent is saying, but also to his nonverbal cues. Try to understand his view of the world and stay open minded.
- Discuss without judging: The nurse can share her understanding of the issues and her perspectives while respecting those of the teenager.
- Encourage critical thought: Allow the teenager to explore and further develop his options.

DISCIPLINE

The adolescent is at the stage where she begins to internalize responsibility for behavior. The adolescent still needs parental input and guidance in terms of rules (curfew, homework, chores, etc.) and possible consequences for infractions, but the adolescent is much more able than in any previous stage to monitor and regulate her own actions based on her own critical thinking. It is important in this stage, as in all others, that the parent focus on the

positives of the teen's behavior. Natural consequences are powerful motivators, but by this time, the adolescent may have learned that he can avoid consequences by being crafty. Removing privileges may be an effective consequence for the teen's poor decisionmaking.

summary points

- ◆ Information about growth and development, newborn through adolescence, is important information for the nurse and family.
- ◆ Principles of growth and development can assist the nurse when teaching the family about their child.
- ◆ While all children grow and develop in their own manner, each child typically follows a designated pattern or trajectory.
- ◆ Characteristics of children can help the nurse and family understand about the uniqueness of the child.
- ◆ Prominent theories of development allow the nurse and family to have a deeper understanding of the "why" behind developmental tasks and stages.
- ◆ Understanding growth and development provides the nurse with tools to develop a plan care for the family across care settings.

review questions

Multiple Choice

1. The pediatric nurse assesses the toddler's fine motor skills by observing which one of the following?
 - A. Buttoning a shirt
 - B. Writing with a pencil
 - C. Holding a spoon to eat
 - D. Using the pincer grasp
2. According to Piaget, an infant uses his senses to learn and explore the environment. The pediatric nurse understands the concept of object permanence by:
 - A. Playing the game of peek-a-boo
 - B. Encouraging the infant to shake a rattle
 - C. Pushing a button on an overhead mobile
 - D. Placing the child in a stroller and going for a walk
3. The pediatric nurse is promoting anticipatory guidance about safety to the mother of a 10-month-old infant. Included in the teaching, the pediatric nurse includes all of the following except:
 - A. "Do not leave small objects on the floor as your baby will be crawling soon."
 - B. "Keep the side rails up to prevent your baby from falling out of the crib."
 - C. "Put safety locks on all cabinets to prevent accidents."
 - D. "Allow your baby to stay alone for short periods of time to promote independence."
4. The mother of a 26-month-old toddler tells the pediatric nurse that she is having trouble disciplining her daughter. The mother states; "She really knows how to push me to my limit. I don't know what to do

with her!" What is the best therapeutic response the nurse can make?

- A. "The terrible two's are a difficult time. You have to show her that you are the boss!"
 - B. "When she does something wrong, tell her she is a bad girl and has to be punished for her actions."
 - C. "Grab her by the arm and give her a time out on a chair in the corner."
 - D. "Take away her favorite doll and tell her that she cannot have it back until she changes her behavior."
5. The parents of a toddler ask the nurse how to best prepare the toddler for a planned medical procedure. The pediatric nurse recognizes that:
 - A. The toddler is too young to understand what will happen and does not need an explanation.
 - B. The use of short explanations can best help the toddler understand the planned procedure.
 - C. Allowing the toddler to explore the procedure room may be helpful.
 - D. It is beneficial for the nurse to demonstrate the upcoming procedure to the toddler.
 6. The father of a 4-year-old is concerned about his son's reaction to an injury of his friend. He told the nurse that the child stayed in his room over the weekend and cried himself to sleep. When the pediatric nurse questioned the child, he described an argument that he and his friend had about a week prior to his friend's injury. The nurse recognizes that the preschooler is suffering from.
 - A. Magical thinking
 - B. Inferiority
 - C. Guilt complex
 - D. A morality issue
 7. Key aspects in a teens' environment that help him make good decisions include all of the following except:
 - A. Ability to think abstractly
 - B. Ability to use deductive reasoning
 - C. Ability to make long-term plans
 - D. Ability to use logical thinking

True or False

8. The pediatric nurse is aware that although developmental advances occur in an orderly fashion, each child progresses through the predicted stages within her own time frame.
9. The nurse is teaching parents of a school-age child about discipline. The nurse stresses to the parents that if the child does not follow family rules they should use corporal punishment.
10. The use of a pacifier or thumb/sucking is a concern during toddler years.

Fill-in-the-Blank

11. According to Erikson's psychosocial stage of _____ vs. _____, the infant will learn to trust his environment if his needs are consistently met.

12. When caring for the developing child, _____ refers to the continuous adjustment in the size of the child and _____ refers to the ongoing process of adaptation.

CONCEPT MAP

chapter 21

Caring for the Child in the Hospital and in the Community

It is when we include caring and love in our science, we discover our caring-healing professions and disciplines are much more than a detached scientific endeavor, but a life-giving and life-receiving endeavor for humanity.”

—Jean Watson (from *Caring Science as Sacred Science*, p. 3)

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Discuss how to gather the history of the child and family.
- ◆ Discuss the physical assessment of an infant, toddler, pre-schooler, school-aged child and adolescent, as well as resources available for families.
- ◆ Identify general care measures for the child in the hospital or clinic setting.
- ◆ Examine ways to prevent injuries in children.
- ◆ Identify common procedures for the child in the hospital or clinic setting.
- ◆ Explore the common practices when medicating the child.
- ◆ Discuss the child in pain.
- ◆ Identify the needs of the child in the family who is living with disabilities.

moving toward evidence-based practice Parent Satisfaction with Care of Developmentally Disabled Children

Liptak, G.S., Orlando, M., Yingling, J.T., Theurer-Kaufman, K.L., Malay, D.P., Tompkins, L.A., & Flynn, J.R. (2006). Satisfaction with primary health care received by families of children with developmental disabilities. *Journal of Pediatric Health Care*, 20(4), 245–252.

The purpose of this study was to examine the perceptions of families who had children with developmental disabilities in relation to care and differences based on a specific condition. The sample included patients and their families who received services through a developmental center at a children’s hospital in New York. This center provided care to children with both physical and developmental disabilities, such as spina bifida, cerebral palsy, autism, and mental retardation.

Three hundred potential participants with the aforementioned four conditions were identified through the hospital database and received mailed surveys; responses were returned from 121 families. The survey consisted of three parts: demographic information, the Multidimensional Assessment of Parental Satisfaction for Children with Special Needs (MAPS) developed by Ireys and Perry (1999), and general questions regarding health care.

The MAPS was described as a valid tool for measuring satisfaction with provider care in five areas: coordination of care, family-centered care, developmentally appropriate care, and interpersonal and technical competence of the provider. The MAPS has been shown to have a standardized alpha coefficient (a measure of internal consistency) of 0.87. The Pearson correlation coefficient ranged from 0.85 to 0.91 in terms of validity between the satisfaction scale and the mean score of the three items used in the study. Seven general questions regarding health care, including baseline attitudes toward providers in general, were added. The questions measured the attitudes toward physicians in primary care as described by Hulka, Zyzanski, Cassel, and Thompson (1970). Data from the MAPS were scored using the method established by Ireys and Perry (1999), i.e., those answering fair or poor were combined into one group

(continued)

moving toward evidence-based practice (continued)

and those answering very good to excellent were placed in another group.

Thirty-three percent of the sample rated the primary care physician's ability to put them in touch with other parents as fair or poor, a finding that was lower than data from previous studies. Twenty percent of the sample rated physicians as "fair" or "poor" in: understanding the impact of the condition on the family; their ability to answer questions regarding the condition; and their ability to provide preventive guidance. Physicians' knowledge about complementary and alternative medicine and their ability to manage the care of the disabled child were also ranked below satisfactory. The parents of

children with autism ranked overall care including community support and the use of alternative or complementary medicine lower than did the parents of children with other disabilities. Providers received the highest ratings for their sensitivity to the needs of the children and in their ability to keep up with new aspects of care.

1. What implications for the care of the developmentally disabled child and families can be drawn from this study?
2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

The standards of nursing practice describe a competent level of care for the nursing profession (American Nurses Association [ANA], 2004). Several themes that are fundamental to many of the standards include providing age-appropriate and culturally sensitive care, maintaining a safe environment, educating patients about healthy practices, and assuring continuity of care (ANA, 2004). For a pediatric nurse, these themes are fundamental to a holistic and caring practice.

Registered nurses are held accountable for thinking critically through conclusions derived in the course of their practice. The judgments made and actions taken are based on a core body of knowledge. This chapter provides the basis of that core in several areas.

First, the chapter presents a complete assessment of the child and family. Age-appropriate and culturally sensitive topics are interspersed throughout the chapter in relation to history-taking and the physical assessment of the child.

Second, the chapter presents an assessment of developmental milestones and the patterns of daily life for the developing child. The nurse becomes acquainted with the norms of pediatric nursing practice and must also understand that the nurse's practice must be individualized for the unique needs of the patient. Since each patient has a personal story to share, nurses are in a privileged position to guide and educate that patient.

Last, the chapter presents the fundamentals of general care measures the nurse provides in the clinic and hospital setting. Maintaining a safe environment is an essential component for some general care practices, such as the use of restraints and infection-control measures. Explaining procedures gives nurses the opportunity to educate the patient about healthy practices, to relieve anxiety and to promote well-being.

Caring for the developing child is an ongoing task and the day-to-day responsibilities of childrearing can be formidable. Families must adapt emotionally as well as financially to the new responsibilities. Processes of adaptation continually evolve as the child grows and develops and parents learn to nurture the child. Along the way, parents must also adapt parenting skills to meet daily challenges. Often, the parents are unprepared for the parenting role,

with no frame of reference other than the role-modeling of their own parents. Raising a family can be a time of both intense joy and intense angst, especially when confronted with unfamiliar developmental challenges such as temper tantrums, or a more serious illness or injury.

Parents caring for the developing child born with or who develops an emotional or physical condition are faced with even greater challenges. They must learn to cope with multiple "out of the norm" aspects of child care, especially when the child's condition necessitates frequent clinic or hospital visits, or when clinical assessments define future challenges faced by the child. For instance, if a child is born with a physically disfiguring or mental condition such as Down syndrome, the parents and child must overcome both social attitudes and possible ongoing medical challenges. No matter what the configuration or situation of the family, the nurse can assist the family to meet the physical, emotional, and spiritual needs of the developing child.

Gathering the Child's Health History

ESTABLISHING A RELATIONSHIP WITH THE PATIENT AND THE FAMILY

Assessing a child's health history can be a daunting task. Children vary in language skills, clarity of speech, cognitive abilities, and social skills. Some children can verbalize where they hurt while others may only react by crying. Each child must be approached with these differences in mind, while note must be taken of any differences that fall out of the realm of what is considered normal growth and development. In addition, the nurse must remember to use the Health Insurance Portability and Accountability Act of 1996 ("HIPAA"). This privacy act ensures that the child's health information is protected while allowing the flow of health information needed to ensure high-quality health care (U.S. Department of Health and Human Services, 2007).

For an infant or a nonverbal child, the nurse begins the health history with an interview of the parent. Grandparents, foster parents, step-parents, nannies, older siblings, and guardians are adults who may accompany the child to the office or hospital. After introductions are made, it is important to clarify the identity of the person who has brought the child in for care.

Young children need to feel secure before engaging in conversation with the nurse. In this instance, the nurse should establish a rapport with the parent first. Once the child feels comfortable with the nurse present, the child may be more apt to contribute to the interview process. The child may be able to add an important piece of information needed for optimum care.

The older child may elect to be interviewed without the parent in the room. In this case, the nurse should speak with the parent separately to determine if the child has specific concerns or issues that may need to be addressed during the visit.

With the preadolescent and adolescent, the nurse may ask the parent to leave the room during the discussion of issues related to social and sexual content. The older child needs to know that a discussion can take place without the parent's knowledge. In this way, appropriate medical and nursing care can be given to ensure the safety of the child. Exceptions to maintaining confidentiality involve situations concerning abuse or life-threatening situation.

Ethnocultural Considerations— Avoiding stereotyping

Stereotyping an individual or family based on a specific racial or cultural background, or assuming that all members of a particular culture subscribe to the traditions, beliefs, and customs associated with that culture, must be avoided. Length of time in the country, level of education, level of acculturation, and economic status all affect the degree to which the culture shapes the parent's approach to health care (Salimbene, 2005).

ASKING QUESTIONS

The interview is conducted in a comfortable room with available seating for the parent, and with eye-level interaction with both the parent and the child. An unhurried environment encourages the parent to ask questions appropriate to the health of the child. The nurse projects a genuine interest in and a desire to help the child and family. This lays the foundation for a positive therapeutic relationship.

Beginning with open-ended questions allows for concerns to be explored, as the nurse invites the child or parent to tell his story by asking, "How can I help you today?" or, for a problem-oriented visit, "What made you come in today?" (Bickley & Szilagyi, 2007). This type of question allows the parent to recount the history of the present condition, also known as the chief complaint. A focused or problem-oriented health history is then obtained.

When clarifying the child's history, the nurse may use the mnemonic **OLD CAT** (Bickley & Szilagyi, 2007, p. 31) to ask the appropriate questions:

Onset: "When did the child become ill?"

Location: "Where is the pain?"

Duration: "How long does the pain last?"

Character: "Can you tell me on a scale of 1 to 10 how bad it is?" Or, for a younger child, parent, "How much pain do you think the child is experiencing?"

Aggravating/Alleviating: "What has made the pain better or worse?"

Timing: "When does the pain start/stop?"

After the chief complaint is determined, the child's past medical history is reviewed. This includes past acute illnesses and history of chronic illnesses, immunization history, hospitalizations, emergency room visits, serious injuries, operations, and current medication usage. Inquiries are made as to the use of any over-the-counter medications, herbal preparations, or folk remedies, as well as any history of allergic reactions to food, medications, and environmental allergens. Information regarding reactions experienced by the child to a reported allergen is noted on the patient's chart.

The impact of the current illness is evaluated by inquiring about the child's daily activities, using the mnemonic **SODA** to ask the appropriate questions:

Sleep: "How has your child been sleeping?"

Output: "How many times per day do you _____?" (Use the expression the family has adopted to convey urine/stool output). Or, for the younger child ask, "How many wet diapers has he had today?"

Diet: "How much fluid has your child taken in today?" "Has the illness affected the child's appetite or diet?"

Activity: "Has the child's activity level changed since he has been ill?"

Interviews are commonly concluded by asking if the parents have any other concerns or problems they would like to discuss.

COMPREHENSIVE HEALTH HISTORY

When a child is seen for a well-child visit, a comprehensive health history is necessary. Components of a child's health history include family medical and social history, immunizations, past medical history, developmental milestones achieved, patterns of daily activities, and a review of systems.

Family Medical and Social History

The family medical and social history includes documenting the current household make-up as well as the age and health of each family member. Document the following:

- Ages and cause of death of any deceased parents, grandparents, and siblings
- Chronic illnesses experienced by family members
- Inherited diseases
- Parents' professions, religious affiliations or spiritual beliefs, and family activities
- For the older child, interviewed without the presence of the parent, the social history must also include information regarding grade level, friendships, drug or alcohol use, smoking, sexual activity, and safe sex practices

Past Medical History

A thorough birth history can provide valuable information about the health status of a younger child. The history of the pregnancy, labor and delivery, and the health of the baby at birth are documented, including the birth weight and APGAR scores, if available. In addition, any difficulties with feeding, breathing, jaundice, or other medical problems in the early neonatal period must be documented.

The past medical history in children includes documentation of all acute illnesses. Chronic illnesses and the medications that have been prescribed are listed, as well as the use of any herbal products and home remedies. If the child's chart is available, all encounter forms are reviewed to determine the reason for the visits, resultant medical diagnoses, and outcomes of previous treatments.

Complementary Care: Commonly used herbal preparations

Herb	Use	Concerns
Aloe vera	Minor skin wounds and irritations.	No known side effects for topical applications.
Bilberry	The tea form is used for the treatment of diarrhea.	Can affect clotting time by decreasing platelet aggregation.
Cayenne pepper	Relief of pain associated with tonsillitis (capsule form) and sore muscles (ointment).	Ointment may cause burning sensation when used topically.
Chamomile	Pain associated with colic, teething, and stomach aches.	Hypersensitivity reaction. Contraindicated in those allergic to daisies, marigolds or ragweed.
Echinacea	Symptoms of the common cold and mild infections.	Do not use for autoimmune disorders, diabetes, AIDS, HIV. Use for short-term illnesses only.
Fennel	Colic, stomach spasms, and cough associated with respiratory infections.	May have a laxative effect.
Feverfew	Migraines.	Not safe for children younger than 2 years of age. Administration of NSAIDs inhibits effect of feverfew.
Licorice	The oral form treats cough; the topical form is used in the treatment of eczema.	Safe for children if taken for short-term illness. Contraindicated in diabetes, hypertension, liver and kidney disease.
Nettle	Asthma and allergy symptoms.	May increase blood sugar.
St. John's Wort	Mild depression.	May cause photosensitivity; many herb-drug interactions.
Tea Tree Oil	The topical form is used as an antibacterial.	Use restricted to topical application.
Valerian	Mild to moderate insomnia.	May potentiate sedative effects of barbiturates, anesthetics, and CNS depressants. May cause GI upset.

Adapted from Bascom, A. (2002). *Incorporating herbal medicine into clinical practice*. Philadelphia: F.A. Davis.

where research and practice meet: Use of Herbal Products

The use of herbal products and home remedies is common (Lanski, Greenwald, Perkins, & Simon 2003). Often, however, parents do not divulge herbal product use for their children in encounters with health care providers. Likewise, Woolf, Gardiner, Whelan, Alpert, and Dvorkin (2005) found that only 42% of pediatric nurses and physicians surveyed felt confident initiating the topic of herbal product use with parents. In addition, only 7% felt that the use of herbs was appropriate as adjunct therapy for the hospitalized child, even if some herbs form the basis of approved pharmaceuticals: Digoxin (Lanoxin), for example, comes from the foxglove plant. It is important, however, to ask about the use of herbal products to avoid inadvertent drug interactions.

Immunizations

Common childhood diseases the child may have had, as well as any immunizations received, are documented, and the chart is reviewed before the interview to determine if the immunizations are current. Maintaining current immunization status protects the child and family against preventable communicable diseases. The Centers for Disease Control and Prevention (CDC) reviews and updates the immunization schedule regularly, so it is important for the nurse to be aware of and follow the most current guidelines (CDC, 2007). The following Web site provides the most current child immunization schedules: <http://www.cdc.gov/vaccines>.

DEVELOPMENTAL MILESTONES

A good foundation in growth and development is a necessity for the nurse working in a pediatric setting. Developmental assessment is important to determine if a child's development is within the normal range. It is also useful in identifying children at risk. Developmental milestones can be assessed using the Denver II Screening Test in children from birth to 6 years of age (Denver Developmental Materials, 1990). The Denver II assesses personal-social, fine motor-adaptive, gross motor, and language skills (Frankenburg, Dobbs, Archer, Shapiro, & Bresnick, 1992). The nurse also documents the child's behaviors during administration of the test, including compliance during testing, interest in surroundings, fearfulness, and a subjective measure of the child's attention span. After the test has been administered, the parents may be asked if the child's performance was characteristic of his normal behaviors. Referral is needed when the child has "failed" the test with two or more delays, if there is no improvement in areas of concern 3 months after the initial screen, or if the child is determined to be "untestable" at two consecutive screenings.

Administering the 125-item test requires training. Information on training sessions and testing materials can be obtained through the following link: <http://www.denverii.com/DenverII.html>.

Due to the training process involved and the time required to administer the Denver II, a more focused and concise assessment can be employed instead. Table 21-1 provides a synopsis of the various age groups' gross and fine motor skills and sensory development. Language and play are also listed.

Table 21-1 Developmental Milestones

Age	Gross Motor	Fine Motor	Sensory/Language/Play
Newborn: Birth–1 Month	<p><i>Birth–1 month</i></p> <p>Reflexes present</p> <p>Absence of head control, but can momentarily hold the head in midline</p> <p>Head lag when the newborn is pulled from a lying to a sitting position</p> <p>Assumes flexed position</p> <p>When supine assumes tonic neck flex position</p> <p>Kicks legs and waves arms</p> <p>Rounded back when sitting</p> <p>Rolls over accidentally</p>	<p><i>Birth–1 month</i></p> <p>Hands predominately closed</p> <p>Strong grasp reflex</p>	<p><i>Birth–1 month</i></p> <p>Touch: First sense to develop</p> <p>Smell: Recognizes mother and has a taste preference for sweets</p> <p>Hearing well developed: Becomes quiet when hears a familiar voice</p> <p>Limited visual acuity 20/100, fascinated with faces, follows moving objects, contrasting colors (black and white)</p> <p>Language: Cries and smiles during sleep</p> <p>Play: Interaction with parents and caregivers</p>
Infant: 1–2 Months	<p><i>1–2 months</i></p> <p>Less head lag when pulled to sitting position</p> <p>When prone can slightly lift head off of floor</p> <p>Improved head control, turns and lifts head from side to side when prone</p>	<p><i>1–2 months</i></p> <p>Holds hands open</p> <p>Grasp reflex absent</p> <p>Can pull at clothes and blanket, bats at objects</p>	<p><i>1–2 months</i></p> <p>When supine follows dangling toys</p> <p>Visually searches for sounds</p> <p>Turns head to sound</p> <p>Language: Coos, has social smile</p> <p>Play: Interaction with parents and caregivers, through gross and fine motor skills and senses</p>
Infant: 3–6 Months	<p><i>3–6 months</i></p> <p>Can hold head more erect when sitting, still some bobbing, by 6 months sturdy head control</p> <p>Only slight head lag, by 6 months no head lag</p> <p>Raises head to 45°–90° off of floor</p> <p>In sitting position (tripod) back is straight and balances head well, sits alone by 8 months</p> <p>When held in a standing position can bear some weight, by 8 months readily bears weight</p> <p>Rolls from back to side and then abdomen to back</p> <p>When supine puts feet to mouth</p> <p>Begins to creep on hands and knees</p>	<p><i>3–6 months</i></p> <p>Plays with toes</p> <p>Clutches own hands, inspects and plays with hands</p> <p>Pulls blanket over face</p> <p>Rakes objects</p> <p>Grasps objects with both hands (palmer grasp)</p> <p>Shakes rattle and holds bottle</p> <p>Eventually able to put objects in container and bang them together</p> <p>Carries objects to mouth</p> <p>Transfers objects from hand to hand</p> <p>Reaches and bangs toys on table</p> <p>Likes mirror images</p>	<p><i>3–6 months</i></p> <p>Follows object 180°</p> <p>Good vision</p> <p>Locates sound by turning head</p> <p>Beginning eye–hand coordination</p> <p>Pursues dropped object visually</p> <p>Sees small objects</p> <p>Responds to name</p> <p>Language: Coos and babbles</p> <p>Play: Interaction with parents and caregivers, through gross and fine motor skills and senses</p>
Infant: 9–12 Months	<p><i>9–12 months</i></p> <p>Creeps on hands and knees</p> <p>Pulls self to standing position</p> <p>Stands while holding onto furniture and begins to cruise</p> <p>Stands alone</p> <p>Changes from prone to sitting position</p> <p>Can reach backwards while sitting</p> <p>Can sit down from standing position alone</p> <p>Begins to walk holding hand and then independently, takes first step</p>	<p><i>9–12 months</i></p> <p>Uses pincer grasp</p> <p>Hand dominance now evident</p> <p>Releases and rescues an object</p> <p>When sitting, purposely reaches around back to retrieve object</p> <p>Can randomly turn pages in a book</p> <p>Can make a simple mark on paper</p> <p>Waves bye-bye and plays pat-a-cake</p> <p>Begins to feed self finger foods</p>	<p><i>9–12 months</i></p> <p>Increasing depth perception</p> <p>Moves toward sound</p> <p>Thoroughly explores and experiences objects</p> <p>Points to simple objects</p> <p>Language: Says “mama” and “dada.”</p> <p>Play: solitary play (play alone), and continued interaction with parents and caregivers, through gross and fine motor skills and senses</p>

Table 21-1 Developmental Milestones—cont'd

Age	Gross Motor	Fine Motor	Sensory/Language/Play
Toddler: 1–3 Years	<p>Stands without support</p> <p>Walks independently</p> <p>Creeps upstairs</p> <p>Pulls toys while walking</p> <p>Runs with wide stance</p> <p>Jumps in place with both feet</p> <p>Climbs</p> <p>Begins to stand on one foot momentarily</p> <p>Can walk up and down stairs with alternate feet</p>	<p>Holds a pencil or a large crayon</p> <p>Makes artwork that is more representative of the object</p> <p>Copies a circle</p> <p>Knows colors</p> <p>Feeds self with a spoon and drinks from a cup</p> <p>Constantly throws objects on floor</p> <p>Builds tower of 3–4 cubes eventually building tower of 7–8 cubes</p> <p>Screws/unscrews</p> <p>Turns pages in a book one page at a time</p> <p>Turn knobs</p> <p>Removes shoes and socks, learns to undress self</p>	<p>Well developed vision</p> <p>Can identify geometric objects</p> <p>Intense interest in book's pictures</p> <p>Distinguishes food preferences based on senses</p> <p>Language: Single words and simple phrases, "I do" or "Want drink." By 15 months knows 15 words.</p> <p>Play: Parallel play (play along side another child)</p>
Early childhood (preschooler): 3–6 Years	<p>Dresses self</p> <p>Throws and catches ball</p> <p>Pedals tricycle</p> <p>Kicks ball forward</p> <p>Stands on one foot for 5–10 seconds</p> <p>Skips and hops on one foot</p> <p>Walks down steps with alternate feet</p> <p>Jumps from bottom step</p> <p>Balances on alternate feet with eyes closed</p>	<p>Moves around in a more balanced fashion</p> <p>Builds tower of 9–10 cubes</p> <p>Draws stick figure with 6 parts</p> <p>Uses scissors to cut outline of picture</p> <p>Copies and traces geometric patterns</p> <p>Ties shoe laces</p> <p>Uses fork, spoon and knife with supervision</p> <p>Colors, prints letters</p> <p>Mostly independent toileting</p>	<p>Well developed senses</p> <p>Preferences based on the use of senses</p> <p>Language: Vocabulary has increased, from 1500 to 2000 words, eventually speaks in complete sentences</p> <p>Play: Cooperative play (play with peers), make believe, dramatic play</p>
School-age: 6–12 Years	<p>Gradual increase in dexterity and becomes limber</p> <p>Improves coordination and balance, rhythm</p> <p>Climbs, bikes, skips, jumps rope and swings</p> <p>Learns to swim, dance, do somersaults and skate</p>	<p>Good eye–hand coordination</p> <p>Balance improves</p> <p>Can sew, draw, make arts and crafts, build models, play video games</p> <p>Prints and writes</p> <p>Likes activities that promote dexterity such as playing a musical instrument</p>	<p>20/20 Visual acuity</p> <p>Color discrimination fully developed</p> <p>Mature sense of smell</p> <p>Hearing deficits may be discovered as language develops</p> <p>Language: Accelerated, vocabulary expands to 8000–15,000 words</p> <p>Play: Cooperative play (play with peers), solitary activities and active play (e.g., dance or karate)</p>

Table 21-1 Developmental Milestones—cont'd

Age	Gross Motor	Fine Motor	Sensory/Language/Play
Adolescence: 12–19 Years	<p>Begin to develop endurance</p> <p>Speed and coordination</p> <p>Focuses skills on interest area</p>	<p>Manipulates complicated objects</p> <p>High skill level playing video games and computer</p> <p>Good finger dexterity for writing and other intricate tasks</p> <p>Precise eye–hand coordination</p>	<p>Increased concentration so can follow complicated instructions</p> <p>Senses tied into body image</p> <p>Develops adult preferences based on senses</p> <p>Language: Continues to develop and refine with increased vocabulary up to 50,000 words. Improved communication skills</p> <p>'Play": Peer groups, team sports, solitary time, school or community activities, dating</p>

Patterns of Daily Activities

SLEEP

The nurse must determine both the number of hours and the quality of sleep the child receives each night. Sleep requirements change as the child grows and each child's sleep requirements are different. Newborns sleep about 16 or 17 hours a day, typically in stretches of 2 to 3 hours at a time. Babies are typically able to sleep through the night by age 6 months (<http://www.mayoclinic.com/>). Children also differ in their ability to sleep. Some can sleep anywhere under any conditions while others suffer sleepless nights if there is even the slightest change in their normal routine. Naps may be a part of a child's life up to the preschool years. Children may experience nightmares or night terrors that can disrupt sleep. Nightmares may reflect the struggles children experience during the day, or the fears a child has regarding separation, impulses, or conflicts. Night terrors occur during the first few hours of sleep. Nightmares and night terrors can be frightening experiences for a child; a child can recount her nightmares. However, with night terrors the child has no recollection.

NUTRITION

The questions a nurse asks regarding nutrition are based on the child's age. If the infant is breastfed, information is gathered as to how often and for how long the child is fed at each feeding, and how many wet diapers are changed in the course of one day. With sufficient breast milk intake, the infant will have six or more wet diapers and gain weight. Newborns often lose 10% of their birth weight. This weight loss is usually by the 12th day of life (Wright & Parkinson, 2004).

For the infant who is receiving formula, information is gathered as to the type of formula, the amount taken at each feeding, and the number of feedings per day. It is also important to note if and when juices or solid foods have been started, and whether supplements or vitamins have been prescribed.

When assessing children and adolescents, a 24-hour recall elicits the food items eaten in a typical day and reflects sociocultural trends. The nurse can document

the amount and type of milk, juices, and all other liquids. In addition, the nurse must document food allergies for all children. Analysis of the food intake is compared to the foods suggested in the Food Guide Pyramid for Young Children. (Go to <http://www.mypyramid.gov/kids/index.html>.)

PLAY, ACTIVITIES, AND SCHOOLWORK

Patterns of play and children's activities reflect the interests of the child, the family financial circumstances, and work schedules of the parents, environmental safety, and the availability of after-school activities. Throughout infancy, learning takes place in the context of sensory stimulation. The parent can provide insight into whether there is sufficient stimulation in the immediate environment to help the child learn. For example, talking and singing adds auditory stimulation. Holding, cuddling, and consoling the infant provides the tactile sensory stimulation for developing a sense of trust and facilitates the bonding process.

As the child matures, continued supervision of the child's activities is needed to encourage social competence and healthy habits. Information is gathered about the daily routine of the child, the contact the child has with playmates, older siblings, and adults, and whether the child has an opportunity to develop gross and fine motor skills or has attended community programs such as Head Start. For school age children, additional information is gathered regarding achievement with schoolwork, special education needs, extracurricular activities, and interaction with peers.

A good understanding of the patterns of daily activities allows the nurse to make suggestions for a healthy lifestyle to the parent or child, alert the primary care provider of potential problems, and provide anticipatory guidance as appropriate to the situation.

REVIEW OF SYSTEMS

Much like the physical examination, the review of systems is best conducted with a "head-to-toe" approach, starting with a general question regarding each body system. It can also be conducted by asking questions during the physical

Nursing Care Plan Imbalanced Nutrition

Nursing Diagnosis: Imbalanced Nutrition: Less Than Body Requirements related to inadequate intake

Measurable Short-term Goal: Child will ingest adequate nutrients

Measurable Long-term Goal: Child will demonstrate appropriate growth for age on normal curve

NOC Outcomes:

- Appetite (1014) Desire to eat when ill or receiving treatment
- Nutritional Status (1004) Extent to which nutrients are available to meet metabolic needs

NIC Interventions:

- Nutrition Therapy (1120)
- Nutritional Monitoring (1160)
- Nutrition Management (1100)

Nursing Interventions:

1. Monitor weight daily on same scale and at same time during hospitalization and at every encounter in community-based care.
RATIONALE: Monitoring assists in early identification and correction of nutritional deficiencies to prevent complications from malnutrition.
2. Provide favorite high-protein, high-calorie, nutritious foods and drinks in small frequent meals (specify for child).
RATIONALE: Child is more likely to eat familiar foods and small frequent meals may be better tolerated during illness.
3. Ensure that mealtime is pleasant and uninterrupted. Be sure to schedule treatment and procedures at times other than feeding time. Do not mix medications in food offered during mealtimes.
RATIONALE: Child may refuse to eat essential foods if they have been associated with unpleasant activities, smells, or tastes.
4. Encourage additional nutritious, high-calorie snacks as tolerated by child (e.g., milkshakes, string cheese)
RATIONALE: Supplemental nutrition may provide the additional calories and nutrients via the preferred oral route.
5. Initiate oro- or nasogastric supplementation as appropriate
RATIONALE: The ill child may be unable to ingest adequate calories and nutrients orally.

examination. The review of systems includes the following areas:

- General: usual weight, change in weight, weakness, fatigue, fever or allergies
- Skin: rashes, pruritus, turgor, changes in color, indications of injury, acne, changes in nails or hair
- Head, Eyes, Ears, Nose, Throat (HEENT): injury to head, headaches, dizziness; eye infections, itching or watering eyes, behaviors indicating change in visual acuity, use of glasses, date of last eye exam; ear infections, behaviors indicating change in hearing; nose bleeds, colds, hay fever, sinus infections; sore throats, tonsils, dentition, caries
- Neck: neck pain, enlarged lymph glands, neck range of motion
- Chest: respiratory infections, asthma, chronic cough, wheezing, shortness of breath, breast changes
- Cardiovascular: heart murmur, palpitations, date of last blood work
- Gastrointestinal: regurgitation, vomiting, changes in bowel habits, constipation, diarrhea, food intolerance, abdominal pain, changes in appetite or eating pattern
- Genitourinary: *General*—dysuria, urgency, odor to urine, date of last urinalysis, signs of puberty, urethral or vaginal discharge, presence of lesions, sexual habits, contraceptive use, and symptoms or history of sexually transmitted infections; *males*—changes in groin/scrotum/glans, presence of circumcision; *females*—

menarche, date of last menstrual period, dysmenorrhea, and date of last Pap smear (if appropriate)

- Musculoskeletal: injuries, fractures, weakness, clumsiness, gait, muscle pains
- Neurological: seizures, tics, psychiatric diseases, anxiety, depression
- Endocrine: history or symptoms of thyroid disease or diabetes or diseases that affect normal growth.

Nursing Insight— Family dynamics

Family dynamics are assessed by observing the behaviors between the child and his parent.

Questions to consider:

- During a health care visit, does the parent or caregiver seem sufficiently concerned about the problem? Or, does the parent or caregiver seem overly concerned about the problem?
- Does the parent or caregiver have the information that a responsible parent would know regarding the child's illness, past medical history and immunizations? Is the parent or caregiver a reliable historian?
- Is the parent or caregiver providing comfort to the child if the child is frightened?
- Does the parent or caregiver appear angry about being in the office?
- Is the parent or caregiver aware of the needs of the child?
- Does the child look well cared for?

Now Can You— Discuss the health history for the child?

1. State the major components of a thorough health history for the child?
2. Ask salient questions about the child's health?

Health Assessment

When examining children, the approach to the physical assessment is based on the child's age, cognitive level, and degree of illness. Infants can be examined from head to toe without difficulty. Some children are fearful of any examiner and are uncooperative. Others seem to enjoy the experience as something new. As a guideline, an exam starts with the least invasive actions and concludes with the most distressful actions. For example, it is easier to examine the posterior lung fields with the caregiver holding the child on her lap early in the exam while leaving the examination of the ears and mouth for the end of the exam (see Chapter 18 for assessment of the newborn).

ANTHROPOMETRIC MEASUREMENTS

Before the physical assessment, vital signs and growth measurements of length, weight, head circumference, and skinfold thickness are taken and recorded. Growth charts from the National Center for Health Statistics (NCHS) were revised in 2000 to include body mass index-for-age (BMI-for-age) (see Chapter 18). These growth charts can be found at <http://www.cdc.gov/nchs/about/major/nhanes/growthcharts/charts.htm>.

Length

Length is measured in the infant while he is lying supine on a measuring tray or board. If a measuring board is not available, the nurse holds the head in midline while an assistant holds the hips and knees extended flat on a paper-covered table. Points are marked at the top of the head and the heels of the feet, the child is moved, and the distance between markings is measured. For the older child a stadiometer is used to obtain a standing height. The child removes his shoes and stands with his back to the stadiometer, with the back of the heels and shoulders touching the wall.

Weight

The weight of an infant is measured using an infant scale lined with a thin paper cover. After the scale setting is balanced, the infant's clothing is removed and the child is weighed in either a supine or sitting position. The nurse protects the child from an accidental fall by placing a hand over the infant without direct contact. Older children are weighed on a standing scale. The same scales should be used to measure height and weight at each visit.

Body Mass Index

Once weight and height are assessed, body mass index (BMI) can be calculated. The BMI is used to assess total body fat and nutritional status. In children, the BMI is represented as a percentile, allowing a comparison to other children of the same age and gender.

diagnostic tools Body Mass Index (BMI)

A BMI-for-age plotted below the 5th percentile indicates a child who is underweight; a BMI-for-age between the 5th and 85th percentile is considered a healthy weight; children with a BMI-for-age between the 85th and 95th percentile are considered at risk for obesity; and those with a BMI-for-age >95% are considered obese.

assessment tools Body Mass Index (BMI)

The BMI-for-age is calculated by dividing the weight in kilograms by the meter height squared. However, since most health care providers obtain height in centimeters, an alternative calculation is to divide the weight in kilograms by the centimeter height squared multiplied by 10,000. For example, the BMI for an 8-year-old boy who weighs 26 kg with a height of 135 cm is calculated as follows: $26 \text{ divided by } 135^2 (18,225) \times 10,000 = 14.26$. A BMI of 14.26 plots on the growth chart between the 10th and 25th percentile, which is a healthy weight. The nurse can help the family calculate their child's BMI by accessing the CDC Web site. This Web site has a BMI Percentile Calculator for the Child and the Teen: <http://apps.nccd.cdc.gov/dnpabmi/Calculator.aspx>.

Head Circumference

For children 2 years of age and younger, head circumference measurements are done at routine well-child visits. The head's largest circumference is measured by placing the tape over the lower forehead, above the pinna of the ears, and over the occipital prominence (Fig. 21-1). This measurement is recorded in centimeters and displayed as a percentile. As with weight and height, evidence of growth within the percentiles remains consistent over time, with normal values according to age and gender reflecting normal development. When there is a deviation, either below or above the percentile from the previous visit, it may signify a potential problem. The nurse informs the primary care provider of these findings.

Skinfold Thickness Measurements

Skinfold thickness measurements indicate the degree of adipose tissue or body fat. In addition to calculating and plotting the BMI once yearly, as recommended by the American Academy of Pediatrics (AAP, 2003), skinfold thickness measurements can add to the objective assessment of obesity in children and adolescents who are at risk. The nurse might measure the degree of skinfold thickness in the tricep or abdominal areas. The average of two consecutive readings is used as the skinfold thickness measurement. The reliability of the skin fold measurement is entirely dependent on correct measurement technique.

Figure 21-1 Measuring head circumference.

VITAL SIGNS

Temperature

Vital signs consist of temperature, pulse, respirations, and blood pressure (Table 21-2). Due to the toxic nature of the chemical, mercury thermometers should not be used in assessing temperature. A variety of digital and tympanic thermometers are available. The route used for assessing temperature depends on the age and developmental level of the child. Newborn temperature is assessed via the axillary route. The tip of a digital thermometer is placed in the axilla with the arm held against the side of the body until the temperature registers. Rectal temperatures are not routinely measured. If a rectal temperature is desired, caution is taken not to insert the thermometer more than ½ inch. In older children, tympanic membrane temperatures are obtained (Fig. 21-2). Since temperatures register within seconds, this route is a convenient one in pediatrics. The route used is charted when recording the temperature (see Appendices A and B).

Pulse

Assessing the pulse in newborns and children requires concentration. The heart rate is variable and changes with illness. The pulse is counted for a full minute while the infant or child is quiet. The most accurate pulse in children of all ages is the apical pulse, and it is also the one assessed prior to giving many medications. With an uncooperative infant, the femoral arteries are palpated in the inguinal area, or the brachial arteries in the antecubital fossa.

Respirations

Respirations are to be counted for one full minute and can be assessed accurately only when the infant or child is not crying. A good time to count them is when a child is sleeping or resting quietly in a parent's arms. If possible, it is wise to start the vital sign assessment with respirations. There is a great deal of variability in the respiratory rate in children. Infants and young children are diaphragmatic breathers. The nurse can visually count the number of respirations by observing the abdomen as the child breathes.

Blood Pressure

Blood pressures are measured during well-child visits or routine physicals beginning when the child reaches 3 years of age. Readings are especially important for children with cardiac, pulmonary or kidney disease, dehydration, or complaints of dizziness, regardless of age. Selection of the cuff size is an important consideration. A good rule of thumb is to use a cuff with a bladder width that is approximately

40% of the arm circumference. With this approximation, an accurate radial blood pressure can be assessed (Clark et al., 2002). Electronic blood pressure devices with varying cuff sizes are also available.

PHYSICAL ASSESSMENT

General Impression

As the nurse meets the child and the parents and engages in conversation with them, an impression begins to take form. This subjective feeling about the child encompasses many areas of assessment. As the nurse conducts the health history and performs the physical assessment, additional notions regarding the child and family develop. Not only is the uniqueness of the child portrayed, but a reflection of the family life that the child is a part of also becomes evident.

Take note of the behaviors of the child as he interacts with his parents. How does the child react to questions? What is the child's speech like? Is the child quiet, pleasant, talkative, uninterested or angry? For the younger child, does the child listen to parents, interact in a meaningful way, or engage in age-appropriate behavior?

Hygiene and nutritional status are also examined. Is the child clean and appropriately dressed for the season? Body size, skin color, eyes, and the condition of the hair are observed for evidence of a good overall nutritional state.

Skin Assessment

The skin is assessed for color, turgor, and lesions. Skin color reflects ethnicity, diet, disease, and injury. Variations in tone are due to genetic composition. Carotenemia, a benign yellowing of the skin due to excessive carotene in the blood, may be present in the child with a diet high in yellow and orange vegetables. Pallor may indicate anemia, cyanosis may indicate a compromised cardiorespiratory state, and yellowing of the skin and sclerae may indicate a dysfunction of the liver. Petechial lesions may be indicative of an infectious process or a blood disorder. Ecchymotic lesions may also indicate a blood disorder or be a tell-tale sign of past accidental or non-accidental injuries.

The nurse can assess the child's skin for evidence of dehydration by grasping a small area of skin and pulling

Table 21-2 Average Range for Pediatric Vital Signs

Age Group	HR	RR	BP Systolic	BP Diastolic
Infant	80–150	25–55	65–100	45–65
Toddler	70–110	20–30	90–105	55–70
Preschooler	65–110	20–25	95–110	60–75
School-age	60–95	14–22	100–120	60–75
Adolescent	55–85	12–18	110–125	65–85

Figure 21-2 Taking tympanic temperature.

up. Once released, the skin should quickly return to its normal position. Skin that remains in the “tenting” position for several seconds indicates absence or presence of skin turgor and inadequate hydration.

If a rash is present or if jaundice is suspected, the nurse determines if the skin blanches or turns pale. The nurse applies pressure to the skin with the thumbs about 1 to 2 inches apart. This presses the normal pink and darker colors out. In the presence of jaundice, there is a yellowish underlying color. Petechial lesions do not blanch, which may indicate a serious bacterial infection in an ill child. The primary health care provider should be notified immediately.

The skin examination concludes with the inspection and documentation of the texture of the hair and the condition of the scalp, palms, and nails. Cradle cap is most common in newborns and is identified by thick, crusty scales over the scalp. The older child is monitored for lice or ticks.

Normal nails are pink and convex, with white edges extending over the end of the fingers. In children with cardiac disease, nails are examined for evidence of clubbing. Nail biting is a nervous habit that is evidenced by very short nails without the normal white edges.

The palms are examined for the normal flexion creases. Normally there are three creases. In a small section of the population, the two horizontal creases fuse to form a single horizontal palmar crease. This is a common finding in many genetic disorders, particularly Down syndrome. If this palmar crease is evident on only one hand, the child may have no genetic disorders.

Ethnocultural Considerations—Skin assessment

In light-skinned individuals, the sclera is white. In darker-skinned individuals, the sclera can be slightly yellow with small black marks. This is a normal finding.

Head Assessment

The head is observed for symmetry and shape. Beyond the newborn period, head shape abnormalities in the infant may be due to craniosynostosis, a premature fusing of one or more of the cranial sutures, or from gravitational influences caused by the infant’s head being kept in the same position for an extended period of time. An odd head shape can

Figure 21-3 Anterior and posterior fontanel.

develop due to the malleability of the skull bones. The supine sleep position has greatly reduced the incidence of sudden infant death syndrome (SIDS). However, infants who are placed in the recommended supine position for sleep are at increased risk for deformational posterior plagiocephaly, or flattening, of the occiput (Nield & Kamat, 2006). Head repositioning techniques, especially during play times, may be useful when the first signs of plagiocephaly occur (Persing, James, Swanson, & Kattwinkel, 2003).

The skull is palpated to evaluate fontanel, sutures, contusions, or other swellings. Fontanel are fibrous-membrane-covered areas where two or more skull bones converge. Although there are six fontanel, the two most commonly evaluated are the posterior and anterior fontanel. The posterior fontanel closes within 1 to 3 months after birth, while the diamond-shaped anterior fontanel remains open until 12 to 18 months of age.

The anterior fontanel is the most significant fontanel for evaluation (Fig. 21-3). The average width is 2.1 cm (Kreisler & Richter, 2003). A larger fontanel or one with a delayed closure may signify an infant with hypothyroidism, Down syndrome, achondroplasia (congenital dwarfism) or increased intracranial pressure. Assess the fontanel when the infant is held in a sitting position. Depression of the fontanel may be indicative of dehydration, fullness of the fontanel a potential sign of increased intracranial pressure.

The face is examined for general appearance and the comparison of features to those of the parents. Unusual features are noted, such as a micrognathia (shortened chin), low-set ears, flattened nasal bridge, enlarged or protruding tongue, allergic shiners (dark, under-eye rings) or a wide and flattened philtrum (the vertical groove from the bottom of the nose to the upper lip).

Neck Assessment

Lymph nodes of the head and neck are palpated systematically, starting at the preauricular area, proceeding to the postauricular area, and then to the occipital nodes (Fig. 21-4). Next, the tonsillar nodes at the angle of the mandible are examined, followed by the submandibular and submental nodes under the chin, the cervical chain of lymph nodes, and finally the supraclavicular area. Size, shape, mobility and tenderness are documented. It is

Figure 21-4 Lymph nodes of the head and neck.

common for young children to have palpable, painless, movable nodes up to 1 cm in diameter. Pain upon palpation may be indicative of an upper airway infection. The trachea is palpated for midline placement and masses. A lateral deviation of the trachea may be due to a mass or a collapsed lung. The thyroid gland is examined for enlargement, nodules, and goiters.

Eye Assessment

Observation of the eyes includes assessment of symmetry, shape, and placement in relation to the nose. In addition, the nurse can assess for symmetry and size of the pupils and their response to light. The conjunctiva and lids are observed for conjunctivitis, styes, or chalazions (small discrete swellings of the upper lid that develop when a meibomian oil gland becomes blocked). The sclerae are inspected for color. The nurse notes erythema, swelling, or discharge from the eye. Documentation of the presence of discharge includes type (watery, purulent), color, amount, and associated symptoms. Treatment depends on the cause, which may be bacterial, viral, or an allergen.

assessment tools Visual Acuity

Visual screening for children can begin at the age of 2 ½ years. There are a variety of charts that will assist in the assessment of visual acuity. Visual acuity for each eye is assessed by occluding the contralateral eye with a plastic paddle. With all charts the objects, letters and numbers decrease in size. The Allen chart requires the child to identify common objects; the “tumbling E” requires the child to identify in which direction each E is facing; and the Snellen charts require the child to identify letters or numbers.

To ensure optimal eye health in children, testing for ocular alignment and visual acuity is essential (Bickley & Szilagyi, 2007). Assessment of visual acuity depends on the age of the child. Infants begin to use a steady gaze to regard faces or objects with interesting patterns. The nurse observes for and documents this finding during the physical exam. Any difference in visual acuity between one eye and the other is abnormal and should be referred. In addition, children are referred for further evaluation if they have a visual acuity reading of less than 20/50 or after failing a second screening.

TESTING FOR OCULAR ALIGNMENT. A common method for assessing ocular alignment is the Hirschberg corneal light reflex test, in which a light is shone directly into the child’s eyes and note is taken of the position of the corneal light reflection in both eyes. The reflection should fall in the same location on the cornea of each eye. Displacement of the corneal light reflection in one eye is indicative of strabismus.

The second screening test is the cover–uncover test, in which the child is asked to focus on a distant object across the room. The nurse covers the first eye while watching the second eye for any movement. The cover is then removed from the first eye, which is observed for any movement. If no movement is detected, ocular alignment is intact. The examination is repeated on the opposite eye.

The red reflex is tested by viewing the pupil through an ophthalmoscope from a distance of ten inches. If the pupil appears red, the finding is normal. A white retinal reflex may indicate cataracts, retinoblastoma, or chorioretinitis.

TESTING FOR COLOR BLINDNESS. Children should be screened at least once during the school-age years for the ability to discriminate between red, yellow, and green. A common method for detecting color blindness is the use of the Ishihara pseudochromatic charts. Each chart consists of a field of colored dots, each with a number in the center of the colored field; the inability to identify these numbers indicates color blindness.

Ear Assessment

The external ears are examined for size, shape, placement, pain, and presence of drainage from the ear canal. The pinna of the ear should be above the imaginary horizontal line drawn from the medial and lateral canthi toward the occiput. Low-set ears may indicate a congenital anomaly such as Down syndrome. To assess for pain, the nurse moves the pinna of the ear up and down. If the child complains of pain when pressure is applied to the tragus, the canal is examined for evidence of otitis externa. Cerumen (ear wax) may be seen on the external ear or in the external canal with an otoscope. Purulent drainage may indicate a foreign body in the external ear canal or a ruptured tympanic membrane. Any clear drainage noted from the ear, particularly after head trauma or with cranial infections, should be reported to the health care provider immediately as this fluid may indicate a cerebrospinal fluid leak.

“What to say” — Use of a small cotton swab to clean the ear

The nurse can instruct parents on the use of a small cotton swab to clean the ear. A small cotton swab should be used to clean only the external ear, and not the ear canal. When a small cotton swab is used in the ear canal, the cerumen is pushed back into the canal where it cannot be moved out by the mechanical action of the tiny ear hairs. Cerumen tends to dry, harden, and become difficult to remove over time. Impacted cerumen in the ear canal may lead to hearing deficits.

When an otoscope is used, the canal should be positioned for the optimal viewing of the tympanic membrane and canal. As a general rule, the pinna is pulled down and back for children younger than 3 years, and up and back for older children. The child is positioned to prevent injury or discomfort. With the parent's help to gently restrain the child from moving, the otoscopic examination can take place either with the child either sitting on the parent's lap or in the supine position. The nurse understands that holding the otoscope upside down allows the nurse the use of one hand to help hold the child's head and the other to position the stem of the otoscope against the child's head for more stability. The tympanic membrane is examined for the presence of normal anatomical landmarks (Fig. 21-5).

Visual loss of these landmarks may be due to erythema, fullness behind the tympanic membrane, inflammation, purulent exudate, or fluid. Due to the anatomic structure of their ears, infants and young children are prone to developing otitis media. The eustachian tubes are shorter and more horizontally positioned, enabling viruses and bacteria to travel to the middle ear. Infants who are breastfed, do not attend daycare, and are fed in an upright position have decreased rates of otitis media.

HEARING SCREENING.

In the older cooperative child, a tuning fork is utilized to assess bone and air conduction of sound. The Weber test involves striking the tines of the tuning fork and immediately placing the handle of the tuning fork midline on top of the child's head. The nurse asks the child in which ear he hears the sound best. If hearing is normal, sound is heard equally in both ears. Sound heard in one ear better than the other indicates a conductive hearing loss.

The Rinne test assesses both air and bone conduction of sound. Bone conduction is tested by placing the handle of the vibrating tuning fork on the mastoid process behind the ear. The child informs the nurse when he no longer can hear the sound of the vibrating tuning fork and the nurse immediately moves the tines forward to within 1 to 2 inches of the auditory meatus. The child should hear the air-conducted sound of the vibrating tines twice as long as he heard the bone-conducted sound.

Figure 21-5 Tympanic membrane landmarks.

Tympanometry assesses the status of the middle ear. The nurse places a probe into the ear canal. The amount of sound that is reflected by the tympanic membrane is measured along with the pressure in the canal. The tympanogram delineates the movement of the eardrum as stiffness, floppiness, or normal eardrum movement.

Early detection of hearing loss is important to prevent delayed hearing, speech, and language development (Box 21-1). Hearing loss may affect both the academic success and psychosocial development of the child. Since hearing loss in childhood is associated with middle ear disease, it is recommended that children with positive results from office screening exams be referred to an audiologist for further evaluation and treatment.

Nursing Insight— Screening techniques for children

Screening tests require cooperation of the child. Hearing screening should be performed before any injections, vaccines, or laboratory work. With testing, the nurse assesses for frequency (pitch) and the decibel level (loudness). Frequency is defined as the number of vibrations a sound creates per second. As the frequency increases, the pitch of the sound also increases. The frequency range is 250–6000. For a normal finding, the child should hear at all frequencies at the 20-dB range.

Conditioned play audiometry (CPA) is a common test for children older than 3 years. In this test, the child is asked to engage in a play-oriented activity, like placing a colorful block in a box each time a sound is heard. The child is subjected to sounds of different frequencies that a child with normal hearing could hear.

A conventional audiogram assesses hearing acuity by asking the child to raise her hand or press a button each time a sound is heard. The child must be able to understand the language spoken, be able to follow directions, pay attention, and wait to listen to the sounds.

Optimizing Outcomes— Hearing screening

Children should be screened for hearing loss as needed. A hearing impairment may interfere with normal psychosocial development, communication among friends, and educational pursuits. The best outcome to detect hearing loss includes periodic screenings because of the increased potential for hearing loss due to overexposure to high levels of noise associated with yard work, listening to music at concerts and via earphones, and through chronic ear infections, ototoxic drugs, head injuries, including abuse, or diseases.

Box 21-1 Risk Factors for Hearing Loss in Preschoolers

- Family history of childhood hearing loss.
- Parental concerns regarding hearing, speech, or language development.
- Prior infections with meningitis, mumps or otitis media.
- Head trauma.

Nose/Sinus Assessment

The nasal mucosa is inspected for color and inflammation. Pale, boggy mucosa is a typical finding in a child with allergic rhinitis. The nasal mucosa appears erythematous with upper respiratory infections. Any bleeding of the mucosal lining is noted. Purulent discharge from the nose may indicate a viral or bacterial condition. Purulent discharge occurring in one nostril is suggestive of a foreign object in the other nostril. The septum is inspected for the midline position. Maxillary sinuses are detected via x-ray exam by age 4, with other sinuses are radiologically evident by age six (Bickley & Szilagyi, 2007). These areas are palpated for tenderness, using the thumbs of both hands and holding the child's head.

Throat/Mouth Assessment

The examination of the throat and mouth is saved for last in younger, less cooperative children. The nurse may ask the child to see “all of the tongue.” Eliciting the sound “eeehh” flattens the tongue better than “aaahh” and visualization of the posterior pharynx is possible without the use of the tongue blade. The palate, uvula, tonsils, and mucous membranes are observed and assessed for color, exudate, and odor. The lips are observed for shape, symmetry, color, dryness, fissures at the corners of the mouth indicative of B₂ (riboflavin) deficiency, and clefts.

The teeth are inspected for number present, condition, color, alignment, and caries. Tooth eruptions occur at varying rates. Generally, when counting teeth on visual examination, the nurse can expect one tooth per month after 6 months of age until all 20 deciduous teeth are in place. The gingival tissue is inspected for color and condition. The gingival tissue is the same color as the surrounding mucous membranes and should not be hypertrophied or show evidence of bleeding.

Chest Assessment

The nurse inspects the chest for size, shape, symmetry, respiratory effort, and breast development. In infants, the anteroposterior diameter is fairly equal to the lateral diameter. By 2 years of age, the lateral diameter is greater than the anteroposterior diameter. Equal anteroposterior and lateral diameter after the age of 2 years may indicate chronic lung disease. A chest that is larger on the left than on the right may indicate an enlarged heart or a collapsed right lung. Pectus carinatum (pigeon chest) and pectus excavatum (funnel chest) are abnormal chest shapes caused by sternal deviations. Pectus carinatum is a protrusion of the sternum. Pectus excavatum is a depression of the lower portion of the sternum.

Nursing Insight—Retractions

With any increased work of breathing, retractions are observed. When the trachea or the smaller airways of the lungs experience air flow restriction, the pressure within the chest is reduced. As a result, the intercostal muscles are drawn inward in an attempt to assist in breathing. This drawing

inward is visible as intercostal retractions. Retractions may also be seen in the substernal, subcostal, and suprasternal notch regions.

Normal breast development begins in girls between 10 and 14 years of age. Boys also undergo breast changes and many show evidence of breast development. For the female, the breast development is documented using the Tanner Staging Guidelines.

Breast enlargement in the neonate is normal, and is a result of maternal hormones. This enlargement subsides over the first 30 days of life. Breast assessment is important at every well-child visit for early detection of precocious puberty. Girls must be taught breast self-exam when breast tissue begins to develop.

Lung Assessment

Lung sounds are best auscultated with the child in a sitting position. The nurse instructs the child to take slow deep breaths through an open mouth. Using a stethoscope with an appropriately sized pediatric diaphragm, the nurse systematically auscultates the five lobes of the lungs, anteriorly and posteriorly, beginning with the apices and then moving side to side to compare bilateral lung sounds. In an infant, auscultation of lung sounds is best done early in the exam, while the child is quiet.

Direct observation of breathing can also indicate inadequate oxygenation. For instance, a child with tachypnea (rapid respiratory rate, 80 to 120 breaths/minute), shallow breathing, and use of accessory muscles means respiratory distress. On the other hand, the child with slow breathing means the child does not have the energy for adequate oxygenation. Quiet breath sounds with an increased work of breathing means that air is not entering into the lung fields. An alteration in depth hyperpnea (too deep) is associated with fever and hypopnea (too shallow) is associated with central nervous system depression.

The child's posture can also indicate adequate or inadequate oxygenation. The child in respiratory distress sits in a tripod position sitting upright, leaning forward on outstretched arms with the jaw thrust forward. This particular position helps maximize opening up the airway and use of accessory muscles of respiration. Because a child with respiratory difficulties is often anxious, it is important to allow him to assume the position of comfort, which is usually the position that is easiest for the child to breathe.

Nursing Insight—Lung Assessment

The nurse will more accurately assess the lungs by creating a quiet environment, placing the child in the best position for auscultation, warming the diaphragm of the stethoscope before auscultation, placing the stethoscope on the child's bare skin, and comparing bilateral breath sounds.

BREATH SOUNDS. Normal breath sounds can be classified as bronchial, bronchovesicular, or vesicular. Adventitious sounds of these three classifications are described as

crackles, wheezes, and rhonchi, respectively. Bronchial breath sounds are loud, high-pitched, and heard only over the trachea. The inspiratory and expiratory sounds are equal in length. Bronchovesicular breath sounds are of intermediate intensity and pitch, with equal inspiratory and expiratory phases. These sounds are best heard between the scapulae and over the mainstem bronchi. If bronchial or bronchovesicular sounds are heard elsewhere, it is indicative of an area of consolidation. Vesicular breath sounds are heard throughout the lung fields. These soft and low-pitched sounds have a longer inspiratory phase than an expiratory one. Decreased or absent breath sounds indicate a serious condition such as asthma, atelectasis, emphysema, pneumothorax, or acute respiratory distress syndrome (ARDS).

clinical alert

Important respiratory signals

The nurse must recognize that normal breath sounds are equal bilaterally in intensity, rhythm, and pitch. The following respiratory signals may indicate that a respiratory condition is present in a child:

- Noisy breathing or snoring (air passing through a narrowed upper airway) may indicate nasal polyps, foreign body obstruction, choanal obstruction, hypertrophied adenoid tissue or obesity.
- Grunting is caused by the glottis closing at the end of expiration and may suggest respiratory distress or pneumonia.
- Nasal flaring (intermittent outward movement of the nostrils) happens on inspiration and is a form of accessory muscle use found in a variety of conditions such as respiratory distress syndrome (Venes, 2009).
- Coughing (a forceful expiratory effort) is a normal process that clears the throat, but can indicate an infection, asthma, lung disease, or sinusitis.
- Stridor (a high-pitched, harsh sound occurring during inspiration) results from air moving through a narrowed trachea and larynx and can indicate croup (Venes, 2009).
- Wheezing (a musical noise) results from air moving through mucus or fluids in a narrowed lower airway that is associated with asthma.
- Hoarseness is a rough quality in the child's voice and can mean that the airway is inflamed.
- Crackles is a fine, high-pitched sound heard on inspiration or expiration produced by air passing over retained airway secretions or the sudden opening of collapsed airways found in several respiratory conditions (Venes, 2009).
- Rhonchi is a low-pitched wheezing, snoring, or squeaking sound indicating a partial airway obstruction. Mucus or other secretions in the airway, bronchial hyperactivity, or tumors that occlude respiratory passages can cause the airway obstruction (Venes, 2009).
- Color changes in the skin (pallor, mottling, and cyanosis) are significant respiratory signals and usually indicate cardiac involvement.
- Chest pain is caused by alteration in chest structures, nonpulmonary involvement, or a variety of respiratory conditions.
- Clubbing (excessive growth of the soft tissues at the ends of the fingers or toes) is usually associated with chronic hypoxia and pulmonary disease.

critical nursing action Adventitious Lung Sounds

A 3-year-old child is brought into the clinic with a chief complaint of recent coughing. The mother states that the child has no fever or cold symptoms, but began to cough that day. The nurse auscultates all lung fields and hears wheezing and localized rhonchi on the left side, but normal vesicular sounds on the right side. The nurse must notify the health care provider immediately for further evaluation and treatment.

Cardiac Assessment

The chest is inspected for symmetry and pulsations and all peripheral pulses are palpated (Table 21-3). In slim children, pulsations from the heart may be visible. The nurse begins palpation with the carotid pulse, making note of any distended neck veins, and continues with the brachial and radial pulses. Capillary refill is assessed as well as changes in the fingernails, e.g., clubbing of the fingers is noted. Peripheral edema and cyanosis are assessed during palpation of the femoral, popliteal, posterior tibial, and dorsalis pedis pulses.

Continued palpation of the chest can identify the presence of thrills, which are a consequence of blood flowing rapidly from high pressure to low pressure. The rough vibrating sensations are felt by placing the palm of the hand over the chest. Some ventricular septal defects result in thrills at the lower left sternal border. Pulmonary stenosis may cause a thrill at the upper left sternal border, whereas aortic stenosis is frequently palpable in the suprasternal notch.

Nursing Insight— Point of Maximum Impulse (PMI)

The point of maximal impulse (PMI), or area of most intense pulsation, and the point of apical impulse, or the impulse corresponding to the apex of the heart, are usually located in the same area of the chest. Generally, the apical impulse is found just lateral of the left midclavicular line (MCL) and fourth intercostal space (ICS) in children younger than 7 years. For children older than 7 years, it is found in the fifth ICS. The stethoscope is placed over this area for auscultation of the apical pulse.

Auscultation begins with the diaphragm of the stethoscope and further evaluation of the heart sounds is done with the bell of the stethoscope (Fig. 21-6). To assess for the first heart sound (S_1 —the “lub” sound), the nurse begins at the fourth or fifth *left* ICS at the MCL. The first heart sound reflects the closure of the mitral and tricuspid valves and signifies the beginning of ventricular contraction or systole. The second heart sound (S_2 —the “dub” sound) reflects the closure of the pulmonary and aortic valves and signifies the beginning of atrial contraction or diastole. The nurse hears “lub dub.”

During inspiration, the S_2 sound may be audible as a split sound as the pulmonary valve closes slightly later than the aortic valve. This physiological splitting is heard as a “lub-dub” and is within the context of normal. If splitting is also heard during expiration, this is suggestive of pulmonary valve pathology.

Two other heart sounds may be heard during the cardiac cycle. The S_3 and S_4 heart sounds are both heard in diastole. A physiological S_3 is heard frequently in children and young adults. It is heard best at the apex in a left lateral lying position by listening for the sound in early diastole

Table 21-3 Cardiac Assessment Techniques

Assessment Technique	What to Look for	Normal Findings	Abnormal Findings	Rationale
Inspection	Skin color, shape and symmetry of chest, clubbing	Pink, symmetrical chest	Pallor, cyanosis, asymmetry of chest shape and movement, hyperdynamic precordium	Poor cardiac output. Deoxygenated circulating blood, Ventricular failure or hypertrophy, tachycardia
Palpation	Skin and body temperature, moisture, chest movement, point of maximal impulse (PMI)	Warm, dry, symmetrical movement, PMI at 4th or 5th ICS at midclavicular line	Cold extremities, dry flaky skin, diaphoresis. Thrills or heaves.	Poor circulation, heart failure, ventricular hypertrophy
Percussion	Heart shape and size	Normal size and shape for age and weight	Enlarged heart, axis deviation	Heart failure and hypertrophy
Auscultation	Murmurs, other sounds	No murmurs, innocent murmurs. Quiet precordium	Murmurs, clicks, rubs, snaps.	Structural defects, increased workload of heart and volume overload

© Judith M. Marshall (2006).

right after the S₂. It is called a ventricular gallop and, due to the cadence of the rhythm, sounds like the word “Kentucky.” Although an S₃ is most likely a finding not associated with heart disease, the finding should be documented and reported. S₄, heard in late diastole, is heard only in children who have congenital heart disease such as pulmonary hypertension and pulmonic stenosis. It is never a normal finding and must be reported to the primary health care provider. The sound is sometimes compared to the word “Tennessee.”

Murmurs are attributed to turbulent blood flow within the vessels. The nurse assesses for intensity, location, radiation, timing, and quality. Innocent murmurs are systolic, musical, or vibratory and of low intensity. The Still’s murmur is the most common murmur and is located over the mid or lower left sternal border. This murmur may be heard in well children, those with fever, after exercise, or in children with anemia when cardiac output is increased. A venous hum is a continuous soft, hollow sound that disappears when the child is supine. Diastolic murmurs usually indicate pathology.

Abdominal Assessment

The child should lie quietly in the supine position. The assessment begins with an inspection of the abdomen

and its contour, which may be flat, round, protuberant, or scaphoid (shaped like a boat). Visible peristalsis may be noted in a thin child, and should be documented and reported. The umbilicus and inguinal areas are inspected for bulging, and note is made of any scars, rashes, and lesions or piercings.

The abdomen is divided into four quadrants: right upper quadrant (RUQ), left upper quadrant (LUQ), right lower quadrant (RLQ), and left lower quadrant (LLQ) (Fig. 21-7). The terms epigastric, umbilical, periumbilical, and suprapubic can also be used to describe symptoms and physical findings that are specific to these areas. The nurse must listen for up to 1 minute before determining the absence of bowel sounds in any one quadrant.

After inspection, the abdomen is auscultated in all four quadrants to assess for bowel motility. These high-pitched sounds occur every 5 to 10 seconds, so it is important for the nurse to allow enough time to adequately assess frequency and character of the bowel sounds. The absence of bowel sounds or high-pitched tinkles in the presence of abdominal distention and/or peritoneal signs suggest an acute abdominal condition. A child who is experiencing signs of a bowel obstruction has absent bowel sounds below the obstruction.

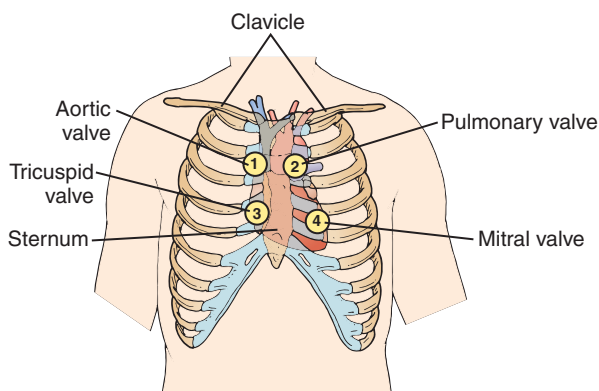

Figure 21-6 Four points of cardiac auscultation.

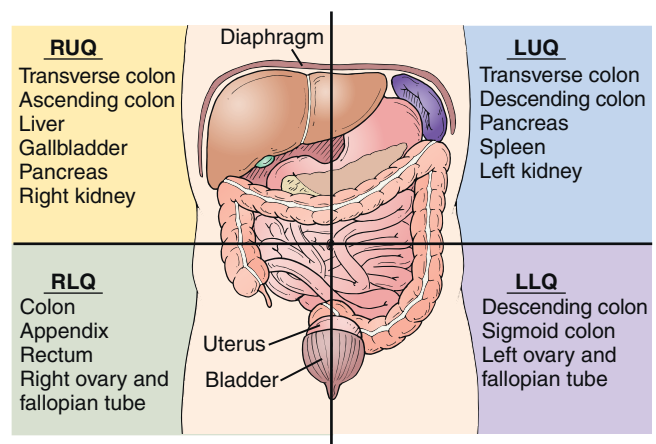

Figure 21-7 Abdomen divided into quadrants and organs in each quadrant.

Palpation of the abdomen occurs last so as not to disrupt bowel sounds. Palpation is divided into light palpation and deep palpation. Light palpation assists in identifying abdominal tenderness. Deep palpation is useful when assessing for the liver, kidneys, spleen, inguinal lymph nodes, and abnormal masses. If a mass is encountered, it is reported, noting its location, size, shape, consistency, and tenderness. Throughout the abdominal assessment, the nurse observes for changes in facial expression, guarding, and tensing of the abdominal muscles.

Nursing Insight— Palpation of the abdomen

To minimize the sensation of tickling during palpation of the abdomen the nurse may palpate through a layer of light clothing or place the child's hand on top of the nurse's hand while palpating. To relax the abdominal muscles, bend the child's knees until feet are flat on the exam table. Palpate any tender or painful areas last. The suprapubic area may feel tender if the child's bladder is full. Consider having the child empty their bladder before the abdominal assessment.

Genitourinary and Perineal Assessment

Both males and females are assessed for Tanner staging of hair growth, evidence of normal development for the age of the child, signs of sexual abuse, and precocious puberty (Table 21-4).

FEMALE GENITALIA. The femoral nodes should be palpated. Enlarged nodes may indicate the presence of a sexually transmitted infection or something as simple as an inflamed hair follicle after shaving. The external genitalia of the female (the labia minora, labia majora, clitoris, vaginal opening, and urinary meatus) are examined for the presence of lesions, discharge, and irritation. The nurse must be able to visualize the vaginal and urethral openings. Occasionally the labia minora are fused due to adhesions, making this assessment difficult to impossible; this finding must be

reported to the primary health care provider for further evaluation and separation of the labia minora. A malodorous vaginal discharge may indicate the presence of a foreign body, especially in young children, or an infection. In the neonate, the labia majora is often under developed and does not cover the labia minora. This is even more pronounced in the premature. Vaginal exams in young children need to be completed by trained examiners. The American Academy of Pediatrics recommends the first annual pelvic exam between the ages of 18 and 21 or when the girl becomes sexually active, regardless of age (AAP, 2007).

MALE GENITALIA. The penis is inspected for size, presence of foreskin, placement of the urinary meatus, and signs of inflammation and infections. The penis should be straight, the glans clean and smooth, and the slit-shaped urinary meatus near the end of the glans.

Nursing Insight— Uncircumcised Males

The foreskin of uncircumcised males should not be forcibly retracted until after 1 year of age. After 1 year of age, genital retraction and subsequently replacing the foreskin to its neutral position is possible.

Palpate the penis for masses and nodules. Inspect the scrotum for size, shape, symmetry, and presence of testicles. An enlarged scrotum should be transilluminated to assess for hydrocele versus a possible hernia. The nurse places a penlight under the scrotum; the scrotum will exhibit a red glow with a hydrocele, but not with a hernia. The testicles are palpated for size and shape. Testicles are roughly the same size and smooth in contour. A testicle that is hard or in which a nodule is palpated must be reported to the primary health care provider to further rule out a tumor. The nurse must also report if one or both testicles have not descended. Males are instructed in testicular self-examination by the age of 14 years. Testicular cancer, while rare, is the most common cancer in men age 15 to 35 years (Nemours Foundation, 2007).

Table 21-4 Tanner Staging of Development of Secondary Sex Characteristics

Sex Characteristics	Scoring				
	1	2	3	4	5
Breast Development in Females	Slight to no elevation of papilla	Breast buds appear; areolar widening with slight elevation	Entire breast enlarged with no protrusion of the papilla or nipple	Enlargement of the entire breast with formation of secondary mound of areola and papilla	Mature breast with protrusion of nipple only. No protrusion of the papilla
Pubic Hair Development in Females	None	Sparse, lightly pigmented, straight along border of labia	Darker and increasing amount on labia and pubis. Distribution in typical female inverted triangle	Coarse, thicker, curly. Increasing amount, less than adult.	Adult female triangle with extension of hair onto medial thighs
Pubic Hair and Genital Development in Males	No pubic hair. Preadolescent genitalia	Scant, long, slightly pigmented pubic hair. Slight enlargement of scrotum and testes; scrotum reddens and becomes more textured	Pubic hair darker, starting to curl and extends across pubis. Scrotum and testes continue to enlarge. Penis becomes longer and slightly wider	Pubic hair is coarse, curly, less quantity than adult. Scrotum is darker; penis increases in length and breadth. Glans is broader.	Adult distribution of pubic hair with extension to medial thighs; genitalia adult in size and shape

Adapted from Tanner, J.M. (1962). *Growth at adolescence* (2nd ed.). Oxford: Blackwell Scientific.

ANAL EXAMINATION. The anus is not routinely examined in children unless indicated by abdominal, bowel, rectal, or stool abnormalities. If an anal examination is indicated, the child is placed in a side-lying position with the knees flexed. The area is examined for anal placement, lesions, trauma, irritation, fissures, bleeding, leakage of stool, and hemorrhoids, as well as general cleanliness. Tone can be assessed by lightly touching the anus and observing for the anal reflex. If a digital exam is necessary, educate the child about the procedure in an age-appropriate manner, provide distraction during the procedure, and ask the child to “push down like he is trying to poop” to help relax the anal sphincter.

Musculoskeletal Assessment

Much of the musculoskeletal exam can be done while observing the child enter and move about the exam room. The child is observed for range of motion, symmetry of movement, general alignment, and any deformities. Each joint is palpated for range of motion and the presence of any presence of any, erythema, or swelling.

The child’s muscles are assessed for strength of movement. For upper extremity strength, the child is asked to hold both arms out to the sides and then out to the front. The child is asked to hold these positions as the nurse applies downward pressure to both arms. The symmetry of strength in both hands can be assessed by having the child squeeze the nurse’s index fingers. The strength of the legs can be tested by asking the child who is lying supine to raise his legs while the nurse applies downward pressure on the legs. Screening for scoliosis is usually done at age 14. A scolometer can be used to assess for the condition as well as noting if the back appears straight and the hips are even.

Neurological Assessment

Mental status can be assessed by observing the infant interact with the parent, or by asking the older child to answer questions and listening for clear speech in the responses. This can be assessed in the course of a normal interview. Most of the assessment of motor functioning is done during the skeletal examination. In addition, the child can be asked to hop, skip, or jump to assess symmetry of movement. The nurse might suggest a game such as ‘hop on one foot.’ Sensory testing is done if there is a question regarding sensory functioning.

Cerebellar function is checked by observing the child’s posture and gait or by using the finger-to-nose test. Young children perceive this test as a game and readily cooperate. The Romberg test assesses cerebellar functioning; the child stands with eyes closed and arms outstretched and is assessed for the ability to stand without swaying.

The child is also assessed for persistence of primitive reflexes, which normally disappear during infancy. Babinski, Moro, palmar, plantar, and tonic neck reflexes are a few that are seen in the neonate but that disappear over time. Persistence of these reflexes may indicate cerebral dysfunction. Deep-tendon reflexes (DTRs) are elicited using the reflex hammer. DTRs are difficult to elicit in some children and a distraction may be needed while testing reflexes.

Cranial nerve assessment is an integral part of the physical examination and may be completed throughout the exam or as a separate part of the exam (Table 21-5). For instance, the nurse can assess the muscles for facial expression during the interview. The nurse also examines

Table 21-5 Cranial Nerve Testing

Cranial Nerve	How to Test
I. Olfactory	Ask the child to close both eyes and have the child identify smells. Rarely done during a routine examination.
II. Optic	Perform vision screen for test of visual acuity and color vision, test for peripheral vision, and examine the optic disc with the ophthalmoscope.
III. Oculomotor	Ask the child to follow an object through the six cardinal positions of gaze. Assess for pupillary response and drooping of upper lids.
IV. Trochlear	CN III, IV, and VI are tested together.
V. Trigeminal	Observe child chewing on a cracker. With eyes closed, gently stroke different areas of the face with a cotton ball to assess sensory function.
VI. Abducens	CN III, IV, and VI are tested together.
VII. Facial	Observe child’s facial expressions during the interview and exam. May need to ask child to frown and then smile.
VIII. Acoustic	Cause a loud sound and assess if child turns to the sound.
IX. Glossopharyngeal	Stimulate gag reflex.
X. Vagus	Assess uvula in midline. Assess ability to swallow by asking child to do so.
XI. Accessory	As the nurse provides resistance, ask child to shrug shoulders and turn head side to side.
XII. Hypoglossal	Observe infant sucking on a bottle. Ask child to stick out the tongue. Listen for clarity of speech.

the pharynx, tongue, and muscles of mastication during the examination of the mouth. The nurse understands that abnormal results of the cranial nerve exam may indicate a brain injury, infection, or compression of a particular nerve.

Now Can You—Discuss the importance of a health assessment for a child?

1. State the major components of a health assessment for the child?
2. Describe alterations in a health assessment for the child?

ROUTINE HEALTH SCREENING

Children are screened for lead poisoning and iron-deficient anemia during well-child care visits. Children with a positive family history for acquired cardiac disease or hypercholesterolemia may be screened for elevated cholesterol levels. High-risk children are screened for tuberculosis.

Lead Poisoning Screening

Routine screening for lead poisoning occurs during the latter part of infancy. The incidence of lead poisoning has

decreased with the removal of sources of lead in gasoline, lead paint, and water supplies. However, lead can be found in tap water and in some folk medicines. Visit <http://www.cdc.gov/nceh/lead/publications/books/plpyc/chapter3.htm#top> for more information on the prevention of lead poisoning in children.

Ethnocultural Considerations— Lead exposure in folk medicines

Folk medicines used by Indian, Middle Eastern, West Asian, and Hispanic cultures may contain high levels of lead. During a health assessment interview, inquire as to the use of Greta, Azarcon (coral, luiga, maria luisa, or rueda), Ghasard, or Ba-baw-san.

Across Care Settings: Decreasing exposure to lead

Nurses can promote decreased lead exposure in tap water by encouraging parents to contact the water authority to determine the lead content in the water. The EPA states that 15 parts per billion is acceptable. If mixing formula from powder or concentrate, advise parents to flush water from the system by running the tap for 1–2 minutes before using the water. Most of the lead comes from the corrosion of older pipes that leach into the water supply after sitting in the pipes for several hours.

Iron-Deficiency Anemia Screening

Iron-deficiency anemia is screened in children by hemoglobin and hematocrit measurements. Since children are at risk for anemia in infancy, screening is done in the latter stage of infancy. However, the incidence of iron-deficiency anemia is declining with an overall prevalence of 7% in children 1 to 2 years of age. The U.S. Preventive Services Task Force (USPSTF) has determined that there is insufficient evidence to recommend for or against routine screening for iron deficiency anemia in asymptomatic children 6 to 12 months of age. Continued screening of high-risk children is recommended (USPSTF, 2006).

Cholesterol Screening

Children from families with hypercholesterolemia are candidates for cholesterol screening. For children with cholesterol level greater than or equal to 200, weight loss is recommended (Newman & Garber, 2003). Further, the discontinuance of saturated fat from the diet of a child may decrease the cholesterol. A child should not be placed on a weight reduction diet without proper guidance from a health care professional.

Tuberculosis Screening

Tuberculosis (TB) screening is recommended for children at high risk; those who are foreign-born; those who travel to or have household visitors from a country with a high prevalence of TB; and those in contact with people who are homeless, incarcerated, infected with HIV, or are

intravenous drug users. Other risk factors include living with a household member who has an active case of TB, a chronic condition such as diabetes or renal failure, or who is immunocompromised. Tuberculin skin testing (TST) for latent TB infection is administered to children who have one or more risk factors (Reznik & Ozuah, 2006).

General Care Measures for the Child in the Hospital or Clinic Setting

The child who requires general care in the hospital or clinic setting may be admitted for testing or treatment of an illness or disease. Parents may wish to provide much of the care their child needs in regard to bathing and feeding. These measures are comforting to the child and parent and reduce anxiety in both. The nurse is responsible for these activities in addition to the child's safety. General care measures include: bathing, feeding, rest and safety, infection control, and fever reducing measures. The nurse also provides emotional and spiritual support as needed.

BATHING

Family home practices and preferences for bathing are assessed on admission of the child. Bathing of infants can be accomplished at the bedside using a portable tub. For infants younger than 6 months or for those who have head lag, the nurse supports the head and neck with one hand while using the other hand to wash. If a tub bath is contraindicated, a bed bath can be given. Precautions are taken to control the water temperature so that it does not exceed 100°F (37.8°C), and to quickly cover areas of the body after washing. The parent may welcome the respite from caring for the child or may wish to continue bathing the child in the hospital. Toddlers and preschoolers may enjoy a bath in a larger tub. Although they can wash some body areas without supervision, most children need reminders or prompting to wash. A child is never left alone while tub bathing. Older children may be able to shower and groom themselves with little assistance. Privacy is valued by the older child. A child who is feeling ill or who has tubes, drains, or dressings may be unable to ambulate to the bathroom for washing or to immerse herself in water. A sponge bath is appropriate in this case.

Shampooing hair during the bath may be part of daily care for children. Again, the nurse can assess family preferences and practices. Shampoo basins can be used at the bedside to wash hair. African-American children or those with braiding or dreadlocks require special care. Braids are left in place for several weeks and care of the hair and scalp is individualized for each child. Parents may be asked for instructions in hair care.

The nurse can use bath time to observe parent–child interaction and to assess the child. Language skills and social skills can also be assessed during the bath. The skin is assessed for lesions, rashes, turgor, color, and circulatory integrity. Muscle tone is easily assessed along with adequate respiratory status. This can also be a time for the child to become acquainted with the nurse as a caring, supportive person.

critical nursing action Key Actions in Caring for the Child Confined to Bed

The child confined to bed is at risk for skin breakdown. The nurse should do the following:

- Keep the skin clean and dry.
- Assess nutritional status for adequate protein.
- Use the draw sheet for position changes.
- Assess skin for irritated areas.
- Assess for pressure ulcers by looking for the “red flush” (the first sign of tissue compromise and ischemia).

FEEDING

Basic knowledge of nutritional requirements is essential when working with children. Formula-fed infants require no more than 24 to 32 ounces of iron-fortified formula daily. For infants who have a gastrointestinal disturbance, pulmonary failure, or are in congestive heart failure, it may be difficult to ingest the required amount of calories without tiring and gavage feedings may be necessary.

For the older child, assess preferences by taking a diet history and asking about routines at mealtimes. Children are often prescribed an “as tolerated” diet and they are able to select foods that appeal to them. It is best to gently encourage the intake of wholesome and nutritious foods and snacks. Foods ingested are also important for their fluid content (e.g., gelatin and ice pops). Parents can be encouraged to bring in favorite foods from home. Cultural preferences may make a difference in whether or not a child eats while hospitalized. Foods and caloric intake should be appropriate for age and developmental level (Table 21-6).

Nursing Insight— Encouraging adequate food and fluid intake

- Offer small portions at frequent intervals.
- Host a “tea party” using medicine cups filled with the child’s favorite drink.
- Make food into fun shapes (trace a smile face with a spread on a sandwich; use a cookie cutter to make different shapes for sandwiches).
- Offer incentives of more time doing a favored activity.
- Offer two choices (“Would you like to use a straw or a colored cup for your drink?”). This allows autonomy.

Text rights not available.

REST

Hospitalization disrupts a child’s normal daily routine as well as their sleep pattern. The pediatric nurse can assess normal sleep patterns, including information on both nighttime hours of sleep and daytime naps. Most pediatric units allow parents to “sleep-in.” This provides both the parent and child with comfort and creates an environment with decreased levels of unfamiliarity and anxiety. The nurse understands that children up to the age of 5 may take an afternoon nap. If the child’s condition allows, uninterrupted naptimes should be included in the plan of care.

SAFETY MEASURES

Safety measures instituted on a pediatric unit are based on the developmental level of each child to protect him from harm. Safety measures include keeping toxic materials out of reach, identifying children with name bands, and knowing the whereabouts of children on the unit. The nurse must also provide a safe environment in the hospital room and in the transport of children from their room to other departments in the hospital.

clinical alert

Keeping children safe in the home or hospital

In the home, parents must think like a child thinks. Suggest that parents get down on the floor in their home to see what their child sees (e.g., electrical plugs and outlets, tablecloths ready to be pulled, hot coffee mugs on the edge of the table).

In the hospital, toxic and nontoxic materials should be stored in a locked utility room, on the top shelf of a cabinet, or in another location where children do not have ready access. Utility rooms, kitchens, medication carts, treatment rooms, and supply rooms are locked, denying access to children. Play areas should be locked unless the child is accompanied by an adult.

The nurse verifies the child’s identity by checking the name band before any treatment or medication is administered. Name bands can be removed by the child easily or they may inadvertently fall off leaving the nurse with no means to verify a child’s identity. If a child is found without a name band, the child’s name must be verified and a new name band applied to an extremity. The nurse cannot depend on all children to correctly identify themselves. Younger children may answer to any name or may not answer at all. When a name band is not on a child’s extremity, medications or treatments are administered only after a parent or nurse has identified the child and the name band has been replaced.

The nurse is responsible for keeping children safe on the pediatric unit. Many pediatric units have alarms and restricted access at stairways, elevators, and the entrance to the unit. The nurse can review with the older child the places she is allowed to go and the activities she can engage in while a patient on the unit. Limits must be set and enforced. To prevent child abduction, pediatric personnel need to be vigilant about visitors.

In the child’s room, safety features are used on high chairs and strollers, and beds are kept in the locked position with the height of the bed in the lowest position. Crib

side rails are elevated when the child is in the bed. Bubble tops may be needed to prevent a child from climbing over the rails. Check the room for any small articles that may be left behind in a bed, such as syringe covers and alcohol wipes. All items must be removed from the bed.

Safety concerns regarding the transport of children are based on their developmental level. Infants can be carried short distances in the room or on the unit. For longer transports to other areas of the hospital, bassinets, cribs, strollers, wheelchairs, or special vehicles are used (e.g., wagon with raised sides). The wagon can be painted in bright colors, and some have plastic bubble tops in the shape of small automobiles. Children enjoy this type of transport. It is important to check that restraint devices like a seat belt in a stroller are securely fastened and that the child is not left unattended during transport.

INFECTION CONTROL MEASURES

Transmission of infection requires three essential elements: an offending microorganism, a susceptible host, and a method of transmission to infect the host. The offending microorganism can be brought into the hospital setting with the ill child or can be part of the new environment. Main routes of transmission include contact, droplet, airborne, common vehicle, and vector borne. Fundamental isolation precautions include handwashing and gloving, the appropriate placement of a patient, and the use of barrier gear to protect the caregiver and prevent further transmission of infection.

The Healthcare Infection Control Practices Advisory Committee (HICPAC, 2008) lists two tiers of isolation precautions. The first tier is “standard precautions” that integrate the features of universal precautions designed to reduce the risk of transmission of blood borne pathogens. The second tier is “transmission-based precautions” that are intended to prevent the transmission of pathogens from those with infectious diseases. Transmission-based precautions include airborne, droplet, and contact precautions (Schulster et al., 2004). When caring for children in a hospitalized setting, the specific guidelines from the CDC should be followed for procedures related to precautions (Schulster et al., 2004).

clinical alert

Hand washing

The nurse knows that hand washing is essential prior to patient care. Hand washing removes microorganisms and can minimize infection to the patient. Meticulous hand washing also allows antimicrobial products to be effective against the transmission of infection.

The experience of isolation for a child can be perceived in negative ways. In the preschool years, when magical thinking is the predominant manner of processing information, the child may perceive the situation as a punishment for some previous thought or action. Koller, David, Goldie, Gearing, and Selkirk (2006) found that children placed in isolation because of the SARS (severe acute respiratory syndrome) outbreak in Canada experienced emotional upheaval. The authors recommended that nurses be aware of the difficult situation that existed and continue to provide family-centered care.

Once the precautions are in place, and the child and family are coping with the restrictions, children may need diversional activities. Child life specialists can assist in the selection of age-appropriate games and toys. Once a toy is brought into a precaution room, it must be cleaned before other children can play with the toy. Visitors need not be restricted from the room but they do need specific instructions on how to protect themselves and the patient. Guidelines are placed on the door with step-by-step instructions on what is required prior to entering the room. Hand washing before and after leaving the room is essential.

FEVER-REDUCING MEASURES

Fever (a temperature greater than 100.4°F [38.0°C]) accompanies many childhood illnesses. A fever is a natural and beneficial response to the invasion of an offending organism and can help “kill” the virus or bacteria. If a child with a fever is very uncomfortable and irritable his fever may be treated with antipyretics or by using environmental measures. Antipyretics work to lower the set point at the thermoregulatory center in the hypothalamus. Antipyretic drugs commonly administered to children include acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs).

clinical alert

Aspirin (Salicylates)

Aspirin (Salicylates) is not given due to the correlation between the use of aspirin and the development of Reye’s syndrome in children with viral infections.

Acetaminophen (Children’s Tylenol) is available in suppository, liquid, and capsule form. It can be given every 4 hours with no more than five doses in a 24-hour period; there is little risk of hepatic toxicity. Ibuprofen (Children’s Advil), a common NSAID, is given to children as a fever-reducing measure. This drug is given every 6 hours and may be an advantage when rest is crucial or when administering medications to the child is a challenging task. Dyspepsia and nausea are common side effects of ibuprofen. The medication, taken as a chewable tablet, caplet, or liquid, can be given with food or after meals if gastrointestinal (GI) upset occurs. The child should be monitored for GI bleeding. Dosing for ibuprofen is dependent on the

medication: Dosage Recommendations for Acetaminophen (Children’s Tylenol)

Acetaminophen (a-seet-a-min-oh-fen)

Age:	Dosage (mg):
0–3 months	40
4–11 months	80
12–23 months	120
2–3 years	160
4–5 years	240
6–8 years	320
9–10 years	400
11 years	480

Data from Deglin, J.H., & Vallerand, A.H. (2009). *Davis’s drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

temperature of the child. A fever below 102.6°F (39.2°C) warrants a dose of 5 mg/kg of body weight. If a child's temperature is over 102.6°F (39.2°C), the dose is increased to 10 mg/kg of body weight. The efficacy of antipyretic medication is assessed by retaking the child's temperature one hour after administration.

Environmental measures can be effective in reducing fevers in children. Measures that do not cause shivering are essential. Shivering produces heat, which is counterproductive in reducing fever. Cooling measures, such as reducing room temperature, applying cool compresses to the skin, and wearing a light layer of clothing, are effective alone or when administered 1 hour after an antipyretic is given.

A cooling blanket, which has coils through which a refrigerated solution circulates, may be necessary to control hyperthermia. The cooling blanket is placed on the bed, covered with a sheet, connected, and set to a temperature of 98.6°F (37°C). The temperature is decreased according to the child's response to cooling. Rectal temperature must be monitored every 15 minutes while the child is on the machine, and the child must be assessed for shivering. Cooling blankets are only used in circumstances warranting an immediate drop of a very high fever.

EMOTIONAL AND SPIRITUAL SUPPORT

Parents may be in need of emotional and spiritual support when a child is hospitalized. It is important for the nurse to be “in the moment” with parents and other family members. Conveying a caring attitude and listening closely to what the parent is really saying is important in making a connection with them. The relationship that the nurse creates with parents and family members is basic to healing and is an expression of spirituality (Dossey, Keegan, Guzzetta, & Kolkmeier, 2005).

The nurse helps family members by listening to their concerns, clarifying any misconceptions, and helping the family develop coping strategies to decrease stress and optimize functioning. Coping resources include both the strength from within and the support from resources in the community.

Collaboration in Caring—Spiritual care

The parents and child may find comfort in talking with a priest, monk, chaplain, deacon, rabbi, imam, or other trusted person with religious ties. Spiritual care may come from a particular faith community that has shared beliefs and values. At times when parents ask “why is this happening to my child?” it may be beneficial for the nurse to arrange a meeting with people from their faith community to discuss the parents' concerns and issues.

Common Procedures for the Child in the Hospital or Clinic Setting

EXPLAINING PROCEDURES

As a child develops cognitively, his understanding of the world changes. To an adolescent, a venipuncture may be an annoyance, but to a toddler, it may be a frightening

experience that is stressful not only to the child but to the parent as well. Developmental characteristics dictate how to approach the child and what to say to the child. What the nurse conveys to the patient and the parents can diminish the anxiety and fearfulness associated with common procedures.

critical nursing action Preparing an Infant for a Procedure

- Describe the procedure to the parents, explaining what will happen and how long it will take. Encourage the parent to stop you at any point if there is a question.
- Remind parents that infants often cry for reasons other than discomfort, but be honest about any discomfort the infant may experience with the procedure.
- Identify what restraints may be used and give an explanation as to why they are needed.
- Allow parents to decide whether they would like to be present for the procedure. Parents may prefer to leave the room and return immediately following the procedure to comfort their child.

critical nursing action Preparing a Toddler for a Procedure

- Describe the procedure to the parents, explaining what will happen and how long it will take.
- Use play to demonstrate the procedure to the toddler; encourage him to demonstrate/practice with a doll or teddy bear.
- Use simple, concrete language to describe the procedure and how it might feel to the toddler. Limit preparation to 5–10 minutes due to the short attention span of the toddler.
- Identify what restraints may be used and give an explanation as to why they are needed.
- Allow parents to decide whether they would like to be present for the procedure. Parents may prefer to leave the room and return immediately after the procedure to comfort their child. Allow the parents to stroke their child or speak soothingly to their child if they remain in the room.

critical nursing action Preparing a Preschooler for a Procedure

Explain the procedure in terminology the child can understand. *Begin* preparation immediately prior to the procedure so the child will not worry for hours or days. *Use* play to demonstrate the procedure to the child; encourage her to demonstrate/practice with a doll or teddy bear.

Set limits for the child so she is aware of expectations. For example, tell her she can yell and scream as much as she wants, but must hold very still. *Give* legitimate choices to the child whenever possible. *Allow* parents to decide whether they would like to be present for the procedure. Parents may prefer to leave the room and return immediately after the procedure to comfort their child. Allow the parents to stroke their child or speak soothingly to their child if they remain in the room. *Use* distraction techniques such as deep breathing, singing, or squeezing a parent or nurse's hand.

Nursing Insight—Distraction

A distraction kit is a set of materials that help divert the child's attention to a more pleasant experience than the painful experience.

- Appropriate for any age
- Use before, during and after procedure
- Can also suggest holding someone's hand really tight, say 'ouch' really loud, count to 10 or count backwards, sing a song, pretend to be somewhere else.

Environment:

- Use designated treatment rooms when possible.
- Child's inpatient room should be kept as a 'safe area' whenever possible.
- Optimal lighting for a procedure should be sufficiently bright and focused on safety, but otherwise without glare.

Preparations:

- Parent: Relieve parental anxiety so they can help prepare and reassure the child/youth. Provide an explanation of what they will see and hear.
- Patient: Relieve patient anxiety. Use simple explanations that are developmentally appropriate to explain how, why, where and when.

Source: Stollery Children's Hospital, Edmonton, Alberta, Canada.

critical nursing action Preparing a School-Age Child for a Procedure

Explain the procedure in terminology that the child can understand. Children in this stage of development have a good concept of time, so preparation can begin in advance of the procedure.

For the younger school-age child, *use play to demonstrate* the procedure and if possible have the child demonstrate on and practice positioning with a doll or teddy bear. *Allow* the child to touch and explore equipment to be used in the procedure, and involve the child in simple tasks during the procedure when possible. *Set limits* for the child so she is aware of expectations. For example, tell her she can yell and scream as much as she wants, but must hold very still. Give legitimate choices to the child whenever possible. *Allow* parents and the child to decide together whether parents will be present for the procedure. Some school-age children may be modest about exposing body parts in front of family members. Allow the parents to stroke their child or speak soothingly to their child if they remain in the room. *Teach* the child techniques such as deep breathing, counting, reciting a silly rhyme, or anything else that might help distract and relax the child during the procedure.

critical nursing action Preparing an Adolescent for a Procedure

Describe the procedure, explaining exactly what will happen and how long it will take.

Encourage the adolescent to stop you at any point if she has a question. *Be honest.* *Describe* potential risks and pain associated with the procedure, but don't dwell on it. *Allow* the adolescent to take as active a role as possible in the procedure. Practicing positioning or demonstrating the equipment prior to the procedure will help give the adolescent

a sense of control. Provide a peer video of the procedure if possible. *Allow* the adolescent to make decisions such as when the procedure should take place, if possible. Allow the adolescent the option of having a parent present. *Offer* tips for distraction such as deep breathing, relaxation, counting, or squeezing an object or parent's hand.

critical nursing action Before, During, and After a Procedure

Before:

1. Think through the procedure in advance and anticipate problems.
2. Gather all equipment and check to make sure it functions properly.
3. Establish trust. Get to know the child first.
4. Through the use of play, allow the child to "perform" the procedure on her doll, teddy bear, or other appropriate surrogate.
5. Offer a coping strategy such as guided imagery or relaxation breathing.
6. Give the child realistic choices.
7. Be sure informed consent is signed.
8. Wash hands.
9. Let the child know that it is "OK" to cry.

During:

1. Whenever possible, all treatments need to be scheduled away from the child's bed or "safe area."
2. Expect the child to do well.
3. Talk to the child and ask how he is doing.
4. Keep the child informed as to the progress of the procedure.
5. Use distraction techniques such as pop-up picture books, bubbles, "shutting off the pain switch," or other techniques that have been practiced before the procedure.
6. When appropriate, give the child some control by allowing him to make some of the decisions.
7. Involve the parent to provide comfort to the child, if the parent is able. Sometimes a parent's presence at the procedure may not be beneficial for the child.

After:

1. Praise the child for completing the procedure.
2. Provide an opportunity for the child to verbalize feelings.
3. If the parents were not involved in the procedure, comment on a positive aspect involving the child during the procedure. "Jill was able to help out and keep still when she was asked to do so! She did a great job!"
4. Give a reward (stickers, small toy, previously agreed-upon reward negotiated with parents).
5. Document the child's response to procedure and outcomes.

“What to say” — Using developmentally appropriate words

For children with beginning language skills, use simple terms that are familiar to the child, such as "go potty," "owie," and "boo boo." For the concrete thinker who takes what is said literally, do not use words that may frighten the child (e.g., "dye in your vein," "shot in the arm," "cut out the tonsils," and "take your temperature"). Instead, use "special medicine in your vein," "special medicine in your arm," "make your tonsils better," "check to see if your temperature is working." For all children, be honest and they will learn to trust you.

INFORMED CONSENT

Informed consent involves providing the patient with the necessary knowledge to make a decision regarding health care. Informed consent implies that the person understands the benefits and risks of treatment or the refusal of treatment. The person must also be legally able to give consent by virtue of his age. In most of the United States and Canadian provinces, the age of majority is 18. An exception is made for the adolescent younger than 18 who is married, a parent, self-supporting, or a member of the military (Feldman-Winter & McAbee, 2002). Informed consent can be obtained from these emancipated minors. In some jurisdictions, the age of consent varies for girls aged 14 years and older for contraception advice and gynecological procedures. For most children, the parent or legal guardian is the person who gives consent for their care.

Written informed consent is required before diagnostic procedures, medical treatments, or surgical procedures. It is also required prior to immunizations or any treatment with inherent risks.

Be sure to— Obtain written consent before a procedure

Informed consent must be obtained before a procedure is performed. It is the physician's responsibility to explain the procedure and the risks and benefits of treatment. In addition, alternatives to the prescribed treatment should be discussed. When signed by the emancipated minor or parent, an informed consent is a legal document denoting that the emancipated minor or parent understands the nature of the procedure, risks, and benefits. The nurse serves as a witness to the signature.

nursing diagnoses The Child Undergoing Procedures or Surgery

- Anxiety related to the procedure
- Pain related to break in skin integrity
- Knowledge Deficit related to unfamiliarity of procedure
- Interrupted Family Process related to demand of surgery
- Risk for Fluid Volume Deficit related to NPO status, nausea, vomiting, or bleeding

where research and practice meet: Informed consent

For children who are part of a research study, consent needs to be obtained (Lee, Haven, Sato, Hoffman, & Leuthner, 2006). Assent seeks to obtain the child's agreement to participate in the study and assurance that he understands all the material presented to him regarding the study. Depending on the age of the child, the material is presented in terms that the child can comprehend. Assent implies that sufficient education about the project, the process, and the consequences have been explained fully and that the child is sharing in the decision-making process.

INTRAVENOUS LINES

Children may require intravenous therapy for treatment of dehydration. In the hospital, children may require intravenous therapy for fluid maintenance or replacement, before diagnostic testing, blood product replacement, or medication administration or preoperatively. Intravenous fluids may be administered through a peripheral line, a central venous access, or a peripherally inserted central catheter.

A peripheral line with a normal saline lock is used to keep the vein open (KVO) for the possibility of future intravenous therapy, or for the child who requires intermittent medication administration. The tubing is capped at the end with an injection cap that allows for multiple punctures. Once the medication is disconnected from this tubing, and the line flushed, the child can ambulate unencumbered by the IV pole and tubing. The hospital's protocol for flushing the peripheral intermittent infusion device is followed. The normal saline lock is secured to prevent accidental dislodgement. For the younger child who has a normal saline lock inserted in the dorsum of the hand, a cover with cling wrap may be necessary to prevent the child from manipulating or pulling out the normal saline lock (Fig. 21-8).

Children with a condition necessitating long-term intravenous access are candidates for central venous access devices. The intravenous catheter is inserted into a large vein such as the vena cava, subclavian, jugular, or femoral vein. Broviac, Hickman, and Groshong catheters are used for access. These catheters are multilumen and accommodate more than one intravenous therapy. After insertion, a chest x-ray exam is done to confirm proper positioning of the catheter. With a central venous access device, the child is not subjected to multiple intravenous "sticks." It is easily accessed for medication and fluid administration as well as blood draws, without the pain associated with further needle punctures.

The peripherally inserted central catheter line (PICC line) can be left in place for up to 4 months. It is inserted above the antecubital fossa into the median, cephalic or basilic vein and threaded into the superior vena cava. PICC lines are most often used for long-term antibiotic and analgesic therapy (Fig. 21-9). These lines may also be threaded just to the head of the clavicle. This is considered a midline placement and is often used for antibiotic therapy. The hospital's protocol for PICC line flushing and dressing changes over the insertion site is followed.

A vascular access port is another central venous access device that is implanted under the skin and is used for

Figure 21-8 Normal saline lock.

Figure 21-9 PICC line.

long-term fluid or medication administration. The Infus-A-Port or Port-A-Cath is not visible and no dressing is required (Fig. 21-10). Although the child may be restricted from contact sports, he can swim or shower without restrictions. To access this device, the nurse palpates for placement, cleanses the area, and uses the Huber needle to puncture the port's central diaphragm.

clinical alert

Risk of infection

With any procedure where the skin barrier is compromised, adhere to sterile techniques for dressing changes over IV sites and to monitor for signs and symptoms of infection: change in temperature, erythema, edema, pain at IV site, and tenderness on palpation.

Figure 21-10 Infus-a-port.

Table 21-7 Calculation of Daily Maintenance Fluid Requirements

Child's Weight	Daily Maintenance Fluid Requirement
0–10 kg	100 mL/kilogram of body weight
11–20 kg	1000 mL + 50 ml/kilogram for each kg >10
>20 kg	1500 mL + 20 ml/kilogram for each kg >20
Example:	
A child weighs 48 kg. For the first 20 kg the child needs 1500 mL. For the next 28 kg, the child needs 20 mL/kg. So,	
$1500 \text{ mL} + (28 \text{ kg} \times 20 \text{ mL}) = 1500 \text{ mL} + 560 \text{ mL} = 2060 \text{ mL/day}$	

MEASURING INTAKE AND OUTPUT

The pediatric nurse carefully assesses the intake and output in children, especially those with vomiting, diarrhea, fever, nasogastric suctioning, draining wounds, and burns; presurgical patients; and children with cardiac, renal, or respiratory illnesses. Calculation of daily maintenance fluid requirements is described in Table 21-7. The nurse measures intake for the breastfed infant by recording “breast-fed” (or by weighing the infant before and after the feeding and recording the increase in weight as ounces or milliliters consumed) on the intake sheet. For infants with congestive failure or a respiratory illness like bronchiolitis, the nurse also asks about the length of time the feeding took to complete. Expending too much energy in feeding may be deleterious to the child’s health. Gavage feedings may be necessary for the child in congestive failure. Intravenous fluids may be required for the child struggling to breathe with a dyspneic respiratory condition.

For the child who wears diapers, the diaper can be weighed before and after use to determine urinary output. Diapers are weighed on a gram scale and output is determined by subtracting the weight of a dry diaper from the weight of a wet one. Each gram is equal to about one milliliter; therefore the difference is the amount of urine output in milliliters. The method used to measure normal urinary output is 1 to 2 mL/kg per hour.

X-RAY EXAMS

Children require x-ray exams for diagnostic purposes. They are also essential when checking for the placement of a chest tube, central line, or a feeding tube. For the younger child needing an x-ray exam the nurse may be asked to help position the child for an optimal view. A lead apron is worn to protect against unnecessary exposure to radiation. Pregnant women should not assist since fetal tissue is especially sensitive to damage by x-rays.

SPECIMEN COLLECTION

Urine Sample Collection

To collect a urine sample, children may require either catheterization or a clean-catch specimen. A catheterized specimen is obtained using sterile technique. Bladder catheterization can be a traumatic experience for both the child and the parents. Distraction techniques can be helpful in decreasing anxiety and fear. A lubricant with 2% lidocaine is used to eliminate the discomfort of catheterization. If a clean-catch specimen is requested, the nurse places a urine collection bag around the perineal area after cleaning the perineum and surrounding skin (Fig. 21-11). The infant is diapered and the bag monitored for urinary output. The urine must be removed from the bag and sent to the lab within 30 minutes of voiding.

Figure 21-11 Urine collection bag.

Stool Sample Collection

Stool samples are frequently obtained for ova and parasites (O & P), to determine the causative agent for a diarrheal condition, or to check for the presence of occult blood. If the child is toilet-trained, he can use the potty chair or the toilet with a collection hat under the seat. In a non-potty trained child, stool from the diaper is collected. Samples are transferred into a collection cup using tongue blades. O&P samples are sent to the lab as soon as possible. When lab services are not provided 24 hours a day, the sample should be refrigerated as soon as possible.

Blood Sample Collection

Having blood drawn can be a traumatic event. Preparation and support during the procedure will alleviate some of the fear and pain associated with venipuncture. Trauma can be alleviated by using distraction techniques with the child prior to the venipuncture. Application of EMLA cream, a topical analgesic containing lidocaine and prilocaine, anesthetizes the skin before any painful procedure. The cream is applied to the site, covered with a transparent dressing for one hour, and removed prior to the venipuncture.

Throat Culture Collection

A rapid strep test or a throat culture can be used to diagnose group A streptococci as the cause of sore throat. If the rapid strep test is positive, an antibiotic is prescribed. If the rapid strep test is negative, a culture to grow the bacteria is done to confirm the results. A throat culture is more accurate than the rapid strep test, but it may take several days to obtain results. Most children do not tolerate throat cultures very well. For younger children it may be helpful to place the child on the parent's lap facing forward, and have the parent place one arm across the child's chest and over his arms, and one hand on the child's forehead. The child is now sufficiently restrained to obtain a specimen safely. The nurse uses a tongue blade to push the tongue downward and swabs the posterior pharynx with two sterile cotton-tipped applicators.

clinical alert

Epiglottitis

One caveat exists regarding throat cultures. Throat examinations and cultures should not be performed on a child who has suddenly

developed a high fever; is drooling; has severe sore throat, hoarseness, stridor; and sits in a tripod position. This history indicates the possibility of epiglottitis. Eliciting the gag reflex, as happens with a throat culture, in this child may cause the inflamed epiglottis to completely obstruct the airway.

Cerebrospinal Fluid Collection

A lumbar puncture (LP) is a necessary procedure to rule out sepsis or meningitis. It can also be scheduled as a procedure for children undergoing treatment for cancer. The nurse prepares the child for a LP by telling the family and the child the reason for the procedure, showing them how to help out with positioning, and teaching some distraction methods. Practicing the position required for the procedure can be helpful. An hour before the lumbar puncture, EMLA cream can be applied to the skin at the designated site. This makes the procedure less painful. With the lumbar puncture, a needle is inserted into the subarachnoid space at the level of L4 or L5 to withdraw cerebrospinal fluid (CSF) for analysis. An infant is seated upright with the head bent forward. An older child must lie on his side with the head flexed, hips and knees flexed, and the back arched while being firmly held to make sure he does not move. CSF samples are sent for culture, glucose, red blood cells, and protein.

After CSF test, vital signs are taken. The child is encouraged to lie flat for 1 hour and drink fluids. The child may complain of a headache or pain at the site of the lumbar puncture. Neurological signs are observed for any changes. Complications such as nerve trauma, infection, bleeding, or pressure effects are rare.

Enteral Tube Feedings

When a child is unable to take adequate nutrition by mouth, an alternate feeding method is used to maintain and promote growth in the child. The type of feeding method selected depends on the child's medical condition. Children can be nourished through an oro- or nasogastric feeding tube or a gastrostomy tube. Feedings may be administered as a bolus or a continuous infusion. Bolus feedings are given at relatively the same rate as an oral feeding would normally be taken and are the preferred method to deliver formula in children who cannot tolerate oral feedings. Formula given as a continuous infusion is placed on a feeding pump and regulated to be administered over a predetermined number of hours. Continuous infusions are often preferred in children with serious cardiac defects to decrease the workload of the heart while providing enteral nutrition. To allow underweight infants

Labs: Analysis of Cerebrospinal Fluid					
	Pressure (mm Hg)	Protein (mg/dL)	RBCs	Glucose (mg/dL)	WBCs
Infant	<200	20–170	None	34–119	0–30
Child	<200	5–40	None	60–80	0–20

RBCs = Red blood cells, WBCs = White blood cells.

Procedure 21-1 Inserting an Oro- or Nasogastric Tube

Purpose

To maintain the child's nutrition using a feeding tube that is passed through the mouth or nares and into the stomach

Equipment

- Oro- or nasogastric tube
- Tap water or a water soluble lubricant
- Syringe
- pH indicator paper

Steps

1. Wash hands and don gloves
2. Determine tube length required by measuring from the nose to the earlobe and to the midway point between the end of the xiphoid process and the umbilicus.

RATIONALE: Proper measurement determines the distance that the catheter is inserted.

3. Note the measurement by finding the manufacturer's black mark on the appropriately sized feeding tube.
4. Lubricate the tube with tap water or a water-soluble lubricant. Follow manufacturer guidelines.

RATIONALE: Lubrication eases catheter insertion.

5. Using the dominant hand, gently direct the tube toward the back of the throat or, if using the nose, toward the occiput.
6. Aspirate stomach contents.

RATIONALE: Indicates proper placement.

7. Check for proper placement using the method following the institution's policy:
 - a. Use pH indicator paper for assessment of gastric aspirate.
 - d. Inject a small amount of air into the tube while auscultating over the stomach; the nurse should hear a "swoosh" as the air enters the stomach.
 - c. Obtain an x-ray film to verify placement. This method is not practical for every feeding, but is often used after initial placement of the oro- or nasogastric feeding tube when used for continuous feeding.

RATIONALE: Indicates proper placement.

Clinical Alert There are some risks with an oro- or nasogastric tube. The liquid from the feeding or medication may enter the lungs and possibility cause pneumonia. In addition, the feeding tubes may cause the child discomfort. The tube can also become plugged, causing pain, nausea, or vomiting.

Teach Parents

It is important to teach parents about artificial nutrition and hydration as well as the function of the oro- or nasogastric tube. Parents can be encouraged to report displacement of the tube, noted distress in the child and tube placement if necessary.

Documentation

6/18/10 1300 Nasogastric tube inserted in left nostril without difficulty. Placement of the tube confirmed. Nasogastric tube secured.

-D. Naccarini, RN

or children to gain weight, a continuous feeding may be given during hours of sleep to boost calorie intake without interfering with a normal daily feeding/eating schedule.

OROGASTRIC AND NASOGASTRIC FEEDING TUBES. For newborn infants requiring gavage feedings (a feeding done using a tube that is passed through the nares and into the stomach; the food is in liquid form, usually at room temperature), the orogastric route is preferred because newborns are obligate nose breathers. The tube is inserted and then removed at the end of the bolus feed. If the tube is to be left in place, the nasogastric route should be considered. Nasogastric tube feedings are preferred over total parenteral nutrition since they preserve the stomach's mucosa, allow the digestive process to continue, and are cost-effective (Procedure 21-1).

Nursing Insight— Psychosocial needs of the infant receiving gavage feedings

The time taken to administer a gavage feeding can be used in the same way as in a regular feeding. Place the infant comfortably in the mother's arms with the head elevated. Provide the infant with a pacifier to help simulate an actual feeding.

Non-nutritive sucking has been shown to increase weight gain and decrease crying, and to allow for the normal muscular development of the mouth and tongue.

Once placement of the tube is confirmed and the child is in position, the nurse administers a bolus feeding of room-temperature formula via gravity through an appropriately sized syringe attached to the feeding tube. The formula-filled syringe is held less than 12 inches above the infant. When the feeding is complete, the tubing is flushed with tap water to prevent clogging of the lumen, the syringe is removed, and the feeding port capped. To decrease the chance of regurgitation, the infant is burped after the bolus is infused. Follow hospital guidelines for nasogastric gavage feedings. The nurse must remember that the amount of water should be only the amount required to successfully flush the length of tubing, excess water may result in over feeding.

GASTROSTOMY FEEDING TUBES. When a child requires enteral tube feedings over a longer period of time, such as those with oral feeding aversions or neurological dysfunction, a gastrostomy tube (GT) is an alternative to the nasogastric tube. A GT is inserted through the abdominal

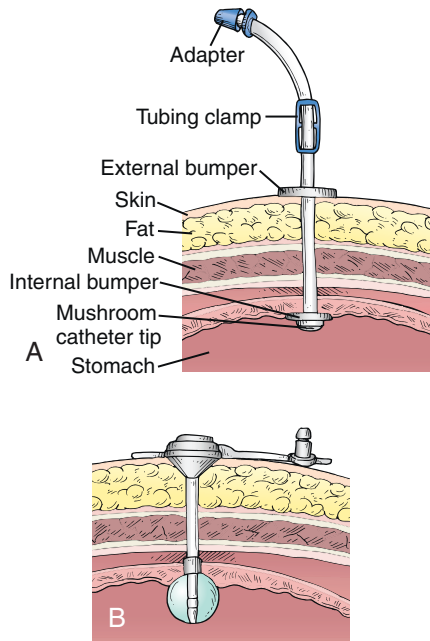

Figure 21-12 Gastrostomy tubes. A. PEG. B. Mic-Key.

wall into the stomach. The GT is secured internally and externally with a variety of bumpers depending on the manufacturer of the GT. Some physicians also secure the GT in place with external sutures for the first 7 to 10 days postoperatively.

After the initial insertion, the GT is left open to gravity drainage for 12 to 24 hours and the wound site observed for signs of infection. Stoma care and assessment are important nursing interventions due to the potential for leakage of gastric secretions onto the peristomal skin. Guidelines for feeding the child through a gastrostomy tube are similar to nasogastric tube feedings. Two of the many types of gastrostomy tubes available are shown in Figure 21-12.

clinical alert

Gastrostomy tubes

A gastrostomy tube may move into the duodenum and cause an obstruction as it occludes the pyloric sphincter. Mark the tube with indelible ink to make it is easy to observe for migration. The nurse must report any vomiting, abdominal distention, or evidence of bile drainage as aspirate.

Ostomies

An ostomy is a surgical opening from either the small or large bowel to the surface of the abdomen to allow for fecal elimination (Fig. 21-13). An ostomy may be needed for a variety of reasons, including trauma, obstruction, disease, and infection. It may be needed on a temporary basis to allow the bowel sufficient time to heal, or permanently when the child's condition does not allow for ostomy reversal.

For infants and toddlers, the parent assumes all responsibility for the care of the ostomy. The nurse assists the parents by clarifying misconceptions, addressing concerns about caring for the child with an ostomy, and providing teaching guidelines regarding ostomy care. It is necessary

Figure 21-13 Child with an ostomy.

for the nurse to feel comfortable discussing difficult issues with the child. If the child is unable or unwilling to verbalize his feelings, the nurse may attempt to engage the child through the use of play or art by bringing crayons and paper to the child's room and giving the child time to process the current events in his life. The child may be able to express himself through art or play more readily than through words. A Child Life Specialist may provide additional ways for the child to communicate his "stories" about how the ostomy is affecting his everyday life. Nurses must be aware of community resources and refer the parents and child to appropriate support groups. Through participation in support groups, the parents and child will be able to talk with others who face the same issues and have struggled with similar concerns.

Older children must be encouraged to become independent in the care of their ostomy. A school-aged child needs to learn all aspects of ostomy care, including removal and reapplication of the ostomy appliance and peristomal skin care. The child must be aware of the signs and symptoms of potential complications to report to the school nurse or parents. Nurses and parents must be aware of the special needs of all adolescents (peer group and self-acceptance, sexuality, and depression) and how those needs may be further affected in the presence of an ostomy. When the child is in the school setting, there should be an arrangement made with the school nurse to allow for adequate time and privacy for maintenance of the ostomy and for storage of ostomy supplies.

RESTRAINING THE CHILD

Physical Restraint

Restraining a child may be a necessary intervention to ensure a child's safety during a procedure or to prevent injury to an operative site. Parents as well as the child need to be informed as to why a restraint is necessary. Once the restraint is applied, the child must be checked and documentation made as to the condition of the skin and circulation of the affected extremity. The extremity is checked every 15 minutes for 1 hour after initial application and then every 1 to 2 hours to ensure the child's safety.

Be sure to— Use of restraints

The Joint Commission has specific information about restraint and seclusion <http://www.jointcommission.org/>

critical nursing action Care of the Child in Restraints

1. Remove restraints every 2 hours to assess skin and provide range of motion to the affected extremity.
2. Provide supervised time with restraints off, if appropriate, to allow the child to engage in activities of daily living (toileting, feeding, reading a book, watching TV, etc.).
3. Encourage games and activities that promote growth and development.
4. Reapply restraints.
5. Document condition of skin, nursing care given with restraints off, removal and reapplication of restraints.
6. Teach parents how to remove and reapply restraints.

Common types of restraints used for children are the elbow restraint and the mummy restraint. The elbow restraint prevents the child from flexing the elbow, therefore preventing the child's hands from reaching the head. They prevent the child from pulling out an intravenous (IV) line in a scalp vein or other peripheral line. If the child is recovering from cleft lip repair, the elbow restraint prevents the child from touching the incision area. Most children tolerate this type of restraint without problems related to skin integrity or circulatory compromise.

The mummy restraint temporarily immobilizes an infant or small child for an examination or procedure that involves the head, neck, or throat. This is ideal to keep the child safe during venipuncture, throat examination, insertion of a nasogastric tube, or administration of ophthalmic, otic, or oral medications. The mummy restraint is much like swaddling an infant. It is a total body restraint.

Pharmacological Restraint

In addition to physical restraints, pharmacological restraints can be administered to children during diagnostic and therapeutic procedures. Sedation of children is administered to allow the safe completion of a procedure. Chloral hydrate (Aquachloral) is a nonbarbiturate sedative-hypnotic drug commonly used in children to produce sedation. The drug decreases anxiety and induces sleep without respiratory depression or suppression of the cough reflex.

Whether hospitalized, in a clinic, or in the home, a child may experience pain related to an acute injury, medical or surgical condition, or disability. A child's pain may be either acute or chronic. All pain is not the same for all people. The skill of the nurse lies in helping the child to convey the kind and intensity of the pain he is experiencing and then determining the best way to manage pain (pharmacological and nonpharmacological).

The Child in Pain

Whether hospitalized, in a clinic, or in the home, a child may experience pain related to an acute injury, medical or surgical condition, or disability. A child's pain may be either acute or chronic. All pain is not the same for all people. The skill of the nurse lies in helping the child to convey the kind and intensity of the pain he is experiencing and then determining the best way to manage pain (pharmacological and nonpharmacological).

Nursing Insight— The definition of pain

A key point to remember is: *pain is whatever the child says it is.* What one person experiences as mild pain, another may experience as severe pain. With the use of pediatric pain scales, most children are able to communicate their level of pain very clearly. The important thing is for the nurse to listen to the child rather than prejudice what the child should feel.

PAIN ASSESSMENT AND MANAGEMENT

Ongoing assessment is essential for the child experiencing pain. Proper pain assessment requires identification of the type of pain the child is experiencing, the origins of either physiological or psychological pain, and the behavioral patterns associated with the pain. Pain assessment tools are invaluable for obtaining a child's perception and, for the younger or disabled child as well as the parent's view of pain levels. There are several statistically reliable pain scales available for use with children of different ages and stages of cognitive development. The most commonly used pain scales are the numeric scale, the Wong Faces Scale, and the FLACC pain scale (Fig. 21-14 and Table 21-8).

The nurse should familiarize the child and family with an appropriate pain scale during hospitalization or a clinic visit, when the child is injured or ill, or for a medical procedure or surgery. The nurse understands that it is important to use the same pain scale according to age, developmental stage, and cognitive function level. In addition to the pain scales, the nurse asks about intensity, duration, and location of the pain; the effects of movement on

medication: Chloral Hydrate (Aquachloral)— Points to Remember

Chloral Hydrate klor-al hye-drate

- As a sedative, administer 25 mg/kg per day PO up to 500 mg per single dose.
- As a hypnotic, administer 50 mg/kg per day PO up to 1 g per single dose.
- Administer 1 hour before the procedure.
- Peak time is 1–3 hours.
- Duration of action is 4–8 hours.
- Provide juice, ginger ale, or water for administration of liquid chloral hydrate
- Monitor for dizziness, confusion, and delirium.

Table 21-8 FLACC Pain Scale

Categories	Scoring		
	0	1	2
Face	No particular expression or smile; disinterested	Occasional grimace or frown; withdrawn	Frequent to constant frown, clenched jaw, quivering chin
Legs	Normal position or relaxed	Uneasy, restless, tense	Kicking, or legs drawn up
Activity	Lying quietly, normal position, moves easily	Squirming, shifting back and forth, tense	Arched, rigid, or jerking
Cry	No cry (awake or asleep)	Moans or whimpers, occasional complaint	Crying steadily, screams or sobs, frequent complaints
Consolability	Content, relaxed	Reassured by occasional touching, hugging, or talking to. Distractible.	Difficult to console or comfort.

Each of the 5 categories—(F) Face; (L) Legs; (A) Activity; (C) Cry; (C) Consolability—is scored from 0 to 2, which results in a total score between 0 and 10.

the severity of pain; any aggravating and alleviating factors; and, if appropriate, previous interventions that alleviated the pain. It is useful to know what experiences the child has had with pain, including previous surgeries, illnesses, or congenital conditions. A child's ability to manage pain is sometimes related to the child's position in the family or his experience of illnesses in other close family members. Pain has many descriptors: mild, moderate, severe, chronic, stabbing, burning, pricking, aching, throbbing, or dull. Pain is also expressed nonverbally with facial expressions, guarding, and muscle tension.

Mild pain is a slight discomfort. Its management may include minor analgesics along with comfort measures or distraction. However, engaging in a distraction does not mean that the child has no pain. It is simply a coping mechanism that diverts a child's attention from the pain for a finite period of time. Pharmacological intervention for mild pain starts with analgesics such as acetaminophen (Tylenol) or ibuprofen (Advil, Motrin), and is administered on a scheduled or as-needed basis.

Although moderate pain may also be relieved by using distraction, the child experiences much stronger unpleasant sensations. Using a child's vivid imagination is very effective in pain management, as long as it is used in conjunction with regularly timed analgesic administration, including milder opioids such as codeine in varying combinations of acetaminophen (Children's Tylenol).

Severe pain causes pallor, sweating, piloerection (elevation of the hair above the skin), dilated pupils, increased respiration and blood pressure, and muscle tension. However, if pain has been prolonged then the child's body may have become accustomed to it, in which case marked increases in vital signs may not be noted. Again, that does not mean that the child is not experiencing pain. When brief, intense pain subsides, the child's body may respond with a lower BP or pulse rate.

Management of severe pain, often associated with surgical interventions, usually calls for strong analgesics like morphine (Astramorph). The maximum allowable dosage may be started in the recovery room and followed by regular dosing, within the allowable limit for the specific child, to ensure adequate pain coverage.

Acute pain occurs 24 to 48 hours after trauma or surgery. It is initially experienced as severe pain, and gradually

subsides over time. With orthopedic trauma, a short period of auto-anesthesia can occur that belies the extent of the injury. As narcotics do not relieve all of the pain following surgery, they can be accompanied with some success by comfort measures, such as holding a hand or encouraging the child "to send his pain to you by squeezing your hand tightly."

Chronic pain in children is any pain lasting more than 3 months. It can result in fear of re-injury, anorexia, weight loss, changes in sleep patterns, guarded movements, a rigid facial expression, and an overall diminishment of the child's joy of living. Management of chronic pain involves careful observation of which pain relief measures work best for a particular child. Decreasing pain to acceptable levels allows the child to carry on with as many age-appropriate activities as possible given the circumstances of his illness or condition. Table 21-9 shows a comparison of acute and chronic pain.

Clinical Alert

Naloxone (Narcan)

When giving morphine sulfate (Astramorph), be sure to have the opioid antagonist Naloxone (Narcan) available. Narcan completely blocks the effects of opioids including CNS effects and respiratory depression. The dose for children is 5–10 mcg/kg (0.01 mg/kg).

Data from Deglin, J.H., & Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

medication: Morphine Sulfate (Astramorph)

Morphine mor-fee-n

Morphine sulfate (Astramorph) is an opioid analgesic. It is frequently used for children with chronic pain. It can be given PO, IV, IM, epidurally, or via a patient-controlled analgesia pump (PCA). For children <50 kg (22.7 lbs.) the dose is:

- 0.3 mg/kg PO every 3–4 hours, or
- 0.1 mg/kg IV or IM every 3–4 hours.

Data from Deglin, J.H., & Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

Table 21-9 Characteristics of Acute and Chronic Pain

Acute Pain	Chronic Pain	Chronic Cancer Pain
Identifiable cause	Cause hard to find	Usually identifiable cause
Short duration	Lasts longer than three months	Duration varies
Sudden onset	Begins gradually and persists	Onset varies
Well defined	May or may not be well defined	May or may not be well defined
Limited	Unlimited	Unlimited
Decreases with healing	Persists beyond healing time	May persist beyond healing
Reversible	Exhausting and useless	Exhausting and useless
Objective signs and symptoms	Objective signs absent	Objective signs absent
Anxiety	Depression and fatigue	Depression, fatigue, and anxiety

Nursing Insight— *Myths about pain management*

- Children do not feel pain with the same intensity as adults.
- Neonates do not feel pain because their nervous systems are not mature.
- Children cannot tell where they hurt.
- Children will tell you if they are really having pain.
- Children become accustomed to pain.
- Narcotic analgesics are dangerous for children because they become addicted or go into respiratory distress.
- If children can be distracted, they are not in pain.
- If children say they are in pain, but do not look in pain, they do not need to be medicated.
- Being in pain for only a little while is not that bad.
- After children have undergone surgery they should not be given analgesia until they can vocalize pain, because they received enough anesthetic to “cover” their pain.
- The best way to give analgesics is intramuscularly.
- Children with neurological impairments do not feel pain as much as other children.
- Children, especially boys, should learn to tolerate pain; they will make better, stronger adults.

Children react to pain and its management in individual ways that also correspond to their developmental level (Table 21-10). Responses to analgesia, time, route, and dose are documented to enable nurses across all shifts to provide a continuum of care for the child.

Now Can You— **Discuss important aspects for the care of the child in the hospital or clinic setting?**

1. Discuss general care measures for the child in the hospital or clinic setting.
2. Discuss the important aspects of preparing the infant and child for a procedure.
3. Describe developmentally appropriate assessments of pain in children?

The Child with Disabilities

Disabilities may be congenital or develop from illness, injury, or disease progression. Regardless of the cause, families of children with disabilities are beset with emotional upset and confusion about the reality of not having the child they expected (i.e., one without a disability). In addition, the family is often distressed about the child's pain and her experiences with surgery, treatments, procedures, and repeated clinic appointments. The child is apt to have ongoing physical, occupational, or speech therapy, and parents often need to perform physically painful procedures at home in order to promote their child's development. Other ongoing treatments and procedures include respiratory therapy, gavage feedings, medication administration, using assistive devices, planning special diets, taking care of elimination needs, and implementing special techniques to maintain the musculoskeletal system.

EMOTIONAL CONCERNS

Raising a child with a disability is distressing due to the disruption of the normal routine, the conveyance of continuous “bad news” or prognostics, the reconfirmation of future emotional and physical concerns, and the awareness of financial implications the diagnosis and treatment provoke. These financial concerns include medical care that is not covered by insurance or government-sponsored health care programs, as well as expenses incurred for child care or respite care. Often, a parent is required to stop working and become a full-time caregiver resulting in further economic distress.

Across Care Settings: Insurance for children

The nurse can teach the family about how to obtain health insurance for their child. Health insurance provided to children through state and national programs is free or low-cost. The costs are different depending on the state and the family's income. When there are charges for health care the charges are minimal. Children who have health insurance generally have better health throughout their childhood. Benefits of insurance for children include: (1) receiving

Table 21-10 Pain Management Strategies

Age (Guideline Only)	Concerns/Reactions	Distraction	Environment	Parental Involvement	Preparation	Positions	Post Procedure Comforting
Infant /Toddler (0–3 Years)	Separation anxiety Protest Despair Denial	Pacifier Swaddling Rocking Eye contact Music Picture books	Controlled lighting and noise. Use treatment room.	Encourage parental presence, provide guidance and if possible, comfort/cuddle baby during procedure.	Prepare parent: offer explanations of what they will see and hear. Develop a plan “who will do what”	Swaddle Cuddle	Soothe Swaddle Hold and rock Soft music Soothing voice
Preschool (3–6 Years)	Separation anxiety Concerns with body image Develops fantasies with illness and treatment Battle for control	Distraction kit Deep breathing Bubble blowing Counting Singing	Use treatment room Music Controlled lighting and noise	Encourage parental presence and provide guidance in encouraging participation during strategies	Medical play with relevant medical equipment and participation Pre-procedural teaching Reassurance of what child is to expect—focus on senses.	Lap Parent or staff may support patient or have other close physical contact Present patient with choices	Praise and reward (stickers) Medical play Play Stories
School Age (6–11 Years)	Has questions regarding body and illness Concerns of helplessness, passivity, and dependency Tend to be phobic and develop fears Anger	Deep breathing Hand squeezing Riddles/trivia Pretend games Talking Distraction kit	Use treatment room Music Controlled lighting and noise	Encourage parental presence and provide guidance Encourage parents to be part of the team	Simple medical terms to describe what will happen Allow appropriate play with medical equipment Explain reasons for various components of tests and allow appropriate participation by patient	Lap Parent may support patient or have other close physical contact Present patient with choices	Praise, reward (stickers) Play, medical play Stories Evaluate procedures and discuss suggestions for next time
Teens (12 and older)	Illness interferes with struggle for independence Illness is a major threat to developing self-image Very threatened by helplessness and loss of privacy Denial, withdrawal, anger, hostility, disappointment	Imagery Walkman Deep breathing Hand squeezing Talking Jokes Distraction kit	Use treatment room Music Controlled lighting and noise	Ask permission of patient for parental involvement Encourage parents to be part of the team	Clarify misconceptions and initiate discussions about the past experiences with procedures Allow appropriate participation by patient Pre-procedural teaching utilizing medical play	Present patient with choices Plan positioning with teen	Praise, reward (stickers) Play, medical play Stories, evaluate procedures and discuss suggestions for next time

needed immunizations that prevent disease, (2) receiving treatment for acute as well as recurring illnesses and (3) receiving preventative care to keep the child healthy.

The nurse can encourage the family to call 1-877 KIDS NOW (1-877-543-7669) or go to your state's program: <http://www.insurekidsnow.gov/states.asp>

It is important to note that children who are eligible for Medicaid cannot enroll in the state program because Medicaid provides comprehensive health benefits.

DEVELOPMENTAL CONCERNS

Many congenital problems are repaired surgically either shortly after birth or once the child is physically developed and strong enough to withstand the rigors of surgery. Parents and the child need constant support from health care personnel to sustain a loving environment for the child with a disability who may be undergoing the same growth and development changes as any other child of the same age. However, due to constant medical and surgical interventions, the child may demonstrate either signs of regression to more immature behaviors, or surprising evidence of what some call a “maturity beyond their years.” The latter has been observed in children with cancer who are faced with pain and/or body image disturbances, such as alopecia or extreme weight loss, and with their own mortality as they might understand it at their age.

PHYSICAL CONCERNS

The child with a disability undergoing surgery, especially at a younger age, may experience rapid fluid and electrolyte changes (see Chapter 32). These conditions may require intensive care procedures that are worrisome to parents and often painful for the children. Children with severe congenital heart problems (see Chapter 27) face a lifetime of corrective procedures to augment initial surgeries or pharmacological therapy that consume time, energy, and finances. In addition, both parents and child need to learn physical self-care techniques, such as diabetes or anticoagulation monitoring. Often, abnormalities affect several body systems so that visits must be made to several different medical specialists who may require multiple pharmacotherapeutic regimens. Throughout all this, families must learn to care for the physical needs of the child.

CAREGIVER FATIGUE

Caring for a child with a significant disability takes its toll on the entire family. Respite care agencies were developed in response to the needs of parents of extremely disabled children to give short-term relief from the 24-hour surveillance and care often required in cases of severe disability. As medical advancements have increased the life expectancy of disabled children, so too have the number of disabled children or premature births resulted in larger numbers of children and families requiring long-term medical care and social systems to support their needs.

Most disabilities in childhood result in multiple visits to clinics, hospitals, or rehabilitation centers, thus disrupting normal activity and sleep patterns. It requires much more energy for a disabled child to perform even the simplest task than it does for a healthy child. It has been estimated that a

severely disabled child needs to perform a simple task, such as getting into “puppy position” or standing independently for 15 seconds, 10,000 more times than a physically healthy child in order to accomplish it. These children have extra requirements for stamina, calories, vitamins, minerals, and protein in order to accomplish normal daily activities, let alone learning developmentally appropriate mental skills. These children also need additional sleep, but may have more trouble getting enough sleep if the demands of their care interfere with a normal sleep pattern. All of these factors contribute to caregiver fatigue.

RESILIENCY

Coping mechanisms give rise to resiliency in children and their families. Resiliency theory defines the protective factors in families, schools, and communities that exist in the lives of children. Four common attributes of resilient children include social competence, problem-solving skill, autonomy, and a sense of purpose and future. Nurses can help parents and children develop resiliency and positive self-esteem by fostering a mix of love and nurturing in the face of overwhelming stressors (DuHoux, 2004). Emotional security and maturity provide the foundation for resiliency (Box 21-2).

nursing diagnoses The Developing Child

- Family Processes, altered—related to health condition (specify), injury, violence
- Growth and Development, altered—related to trauma, hospitalization, congenital defects, prolonged pain, separation from family
- Injury, high risk for—related to lack of awareness of environmental hazards
- Pain, Chronic—related to effects of condition (specify)
- Poisoning, high risk for—related to age-specific environmental hazards
- Self-esteem, chronic low—related to disfigurement, separation, ineffective relationship with parents or peers
- Sleep Pattern Disturbance—related to pain, fear, desire to sleep with parents at night
- Social Isolation—related to physical handicap, hospitalization, terminal illness
- Violence, high risk for—related to verbal threats of physical assault, perceived threat to self-esteem

Family Teaching Guidelines... Caring for the Child with a Disability

How to: Care for the child with a disability

Topic: The nurse will improve the care of the family and a child with a disability

Essential information:

- ◆ Maintain a respectful attitude toward the parent and the child
- ◆ Listen carefully to the parent's concerns, realizing that parents often “know their child best”
- ◆ Evaluate how social and healthcare agencies can assist parents and the child to manage the disability—financial, medical, community services
- ◆ Assess the child's skills for coping with pain or fatigue
- ◆ Evaluate the need for respite care and reliable community resource providers

Box 21-2 Ways to Promote Resiliency

- Express love and gratitude
- Foster competency and positive attitudes
- Nurture positive emotions
- Encourage helping others
- Teach peace-building skills
- Reinforce positive behaviors
- Reduce stress

summary points

- ◆ When examining infants, children, and adolescents, the approach to the physical assessment will be based on the child's age, developmental and cognitive level, and, when ill, the extent of the illness.
- ◆ Vision and hearing screening are important ongoing assessments in children to promote normal psychosocial development, communication among friends, and academic success.
- ◆ Screening for lead poisoning, iron deficiency anemia, cholesterolemia, and tuberculosis are important assessments in the at-risk developing child.
- ◆ Explanations of procedures must be given at a developmentally appropriate level, avoiding words that may be unintentionally frightening.
- ◆ Regardless of a child's age, the nurse works to gain the trust of both the child and the family to help establish a therapeutic relationship.
- ◆ Children react to pain and its management in ways that correspond to their developmental level. Accurate pain assessment depends on the consistent use of an assessment tool both familiar to the child and parent.
- ◆ Disabled children expend a great deal of energy to perform the simple activities of daily life; therefore, children need age-appropriate care.
- ◆ Caring for the child with a physical or mental disability exacts its toll on the entire family. The pediatric nurse must be aware of all available resources within the community to assist the family in the care of the disabled child.

review questions**Multiple Choice**

1. When preparing a 4-year-old child for a procedure, the pediatric nurse must be aware of the child's developmental status. The nurse would best demonstrate this awareness by:
 - A. Demonstrating the procedure on the child's teddy bear
 - B. Providing a peer video of the procedure for the child to view
 - C. Explaining the procedure to the child the day before the actual procedure occurs
 - D. Discussing the procedure at length with the child
2. The 10-year-old child is receiving preoperative teaching prior to a tonsillectomy. The pediatric nurse should teach the child about the operation and use developmentally appropriate explanations such as:
 - A. "Don't worry; the doctor will cut your tonsils out while you are asleep."
 - B. "The shot that you will receive in your arm will only help the pain a little bit."
 - C. "Don't worry about the operation; it is really not a big deal."
 - D. "The doctor will give you special sleeping medicine before she operates."
3. There are many myths regarding children and pain levels. The pediatric nurse is aware that the following is true of pain management in pediatrics.
 - A. Children cannot tell where they hurt.
 - B. The child who is neurologically impaired does not feel pain.
 - C. Children should not receive narcotics because they will become addicts.
 - D. The use of special pain scales allows children to better express their level of pain.
4. The pediatric nurse utilizes the "head to toe" approach when conducting a physical assessment on an infant. The correct technique is demonstrated in which of the following sequences? Assessing the....
 - A. Heart rate, urine output, respiratory rate, and presence of bowel sounds.
 - B. Head circumference, lung sounds, presence of bowel sounds, urine output
 - C. Presence of eye drainage, abdominal pain, lung sounds, and urine output
 - D. Urine output, skin color, skin turgor, heart rate and bowel sounds.

Select All that Apply

5. A 24-month-old child comes to the clinic for a well-visit assessment. The pediatric nurse is orienting a new graduate nurse and begins the assessment. The assessment will include which of the following components?
 - A. Visual screening by having the child identify certain objects
 - B. Viewing the tympanic membrane by pulling the pinna down and back
 - C. Auscultation of bowel sounds in all 4 quadrants
 - D. Taking the child's vital signs.

Fill-in-the-Blank

6. The pediatric nurse is preparing to administer ibuprofen (Children's Motrin) to a 12-kg (26.4 lbs.) child with a fever of 103.6°F (39.8°C). The nurse understands that a child with this degree of temperature elevation can receive the medication at a dose calculated to 10 mg/kg of body weight. The nurse understands the importance of safe medication administration by giving _____.
7. The 2-month-old child who requires intermittent gavage feedings will have an _____ tube inserted because infants are obligatory _____. The infant should be positioned in the parent's arms with the _____ elevated.

8. The pediatric nurse is aware that the posterior fontanel closes at approximately ___ to ___ months of age and that the anterior fontanel remains open until approximately ___ to ___ months of age.

True or False

9. It is not necessary for the pediatric nurse to ask the parent questions related to the use of herbal products because this is not a common finding in pediatrics.
10. An accurate and effective way to assess the pediatric patient's respiratory rate is by counting the respirations while the child is sleeping and by observing the abdominal area.
11. According to the Centers for Disease Control and Prevention, handwashing is not necessary if the pediatric nurse is wearing gloves when providing care.
12. It is important for the pediatric nurse to incorporate developmental theory when working with children. The preschool-age child who is on isolation precautions will perceive isolation as a punishment for a previous thought or action because of the developmental stage of magical thinking.

CONCEPT MAP

Caring for the Family Across Care Settings

chapter 22

A Link in the Chain

Nurses assist in making the lives of children better.

Nurses work in hospitals, in intensive care units with alarms everywhere, in clinics with toys all around, in community settings or behind desks in offices.

Nurses assist in making the lives of children better.

Nurses help repair children's bodies when they are broken or not made just right.

Nurses help children smile when they are receiving medication that might make them sicker before they become better.

Nurses deliver treatments to open up their airways, change dressings and deliver IV fluids.

Nurses assist in making the lives of children better.

Nurses must be creative and make medical situations fun rather than frightening.

Nurses cradle the children in their hearts and hands to help them feel secure and safe in a strange environment.

Nurses assist in making the lives of children better.

Nurses give of themselves by opening up their hearts to the families - letting them know that they genuinely care.

Nurses truly make a difference.

Nurses together are a long and strong chain that embraces many children.

Each nurse is an individual link in that chain.

—Megan Connelly, MSN, APRN, CCRN, CPNP-AC, Children's Hospital in Omaha, Nebraska

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Identify the effects of hospitalization on the child and his or her family.
- ◆ Discuss ways in which nurses can decrease the stress of hospitalization for the child and family.
- ◆ Discuss the concept of across care settings.
- ◆ Identify various community settings.
- ◆ Determine the nurse's role in assisting children and families in the various care settings.

moving toward evidence-based practice Dental Care

Kenny, G.M., McFeeters, J.R., & Yee, J.Y. (2005). Preventive dental care and unmet dental needs among low-income children. *American Journal of Public Health, 95*(8), 1360–1366.

The purpose of this study was to examine variations in the level of dental care and unmet dental needs among low-income children. Data for the study were drawn from the 2002 National Survey of American's Families (NSAF). The NSAF is a national household survey that provides information on more than 100,000 children and adults younger than the age of 65 in the

United States. Each survey respondent is allowed to provide data on up to two children regardless of the number of children residing in the household. The data must be from two categories: children 5 years of age or younger and/or children ages 6 through 17 years.

(continued)

moving toward evidence-based practice (continued)

The study addressed two primary issues: (1) unmet dental needs and (2) the number of preventive dental care visits during the previous 12-month period. The primary caregiver was also asked about delays or failures in seeking dental care, how many dental visits the child had experienced in the previous 12 months, and if the child had received preventive dental care during the previous year.

Some of the factors examined included:

- The child's health insurance status at the time of the survey
- The child's race/ethnicity
- The child's citizenship
- The parents' primary language
- The age of the child
- Whether or not the family was experiencing an economic hardship
- The highest education level attained by the parent
- Whether or not the child resided in a metropolitan area
- The family structure (number of parents living in the home)
- The number of children in the family
- The parents' employment status.

Data analysis revealed the following findings:

- 55.6% of the uninsured children from low-income families had not received a preventive dental visit *in the preceding 12 months*.

- 19.9% of families with private insurance and 24.3% of those with public insurance had not received a preventive dental visit *in the preceding 12 months*.
- 13.7% of the uninsured children had unmet dental needs.
- 12.9% of the insured children had unmet dental needs.
- 35.7% of low-income Hispanic children had received no dental care, as compared to 26.5% of low-income Caucasian children *in the last 12 months*.
- 54.5% of children who were not U.S. citizens had received no preventive dental care, compared to 26.8% of children who were U.S. citizens.
- 42.9% of the children of Spanish-speaking parents received no preventive care, as compared to 26.3% of those from English-speaking families.
- 7.1% of black children were found to have unmet dental needs as compared with 11.2% of Caucasian children.

Greater than one half of the children from low-income homes who had no dental health insurance did not receive preventive dental care visits. Similar findings occurred among families with private insurance but no dental benefits.

1. What might be considered as limitations to this study?
2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

Nursing care for mothers, families, and children has “matured from providing simple basic care to providing highly scientific and technological care both in the hospital and community settings. Currently, there is a body of knowledge that supports early diagnosis, disease prevention along with health promotion, shorter hospital stay, increased outpatient services, community health care, and a holistic approach. Advances in knowledge have supported a healthier lifestyle and longer life expectancy but have also contributed to the complexity of issues that nurses face in providing safe and competent nursing care to mothers, children, and families across care settings. Regardless of the positive or negative consequences of the complexity of issues, families are demanding better health care in more a humanized and compassionate environment.

Pediatric nurses today must find a balance between advanced scientific and technological care and humanized compassionate care. Now, pediatric nurses have an opportunity to guide child health care of the future by integrating attitudes of human caring, supporting a holistic perspective, and shifting nursing care from the popular curative view of health care to an attitude of health promotion, illness prevention and a more family centered care environment” (Ward, 2006, pp. 15–16).

Pediatric nursing occurs in multiple settings, including hospitals, clinics, home health settings, rehabilitation

centers, schools, and other supportive services. Because children and families have a variety of unique needs throughout the life cycle, the pediatric nurse must be knowledgeable and highly skilled in meeting them, which requires a broad base of knowledge about growth and development, family functioning, and environmental influences (Fig. 22-1). The concepts outlined in this chapter present innovative nursing care across care settings.

Across Care Settings

Currently there are myriad options for the delivery of nursing care ranging from the traditional hospital inpatient environment to the broader community setting. Pediatric nursing care for families is holistic, based on normal growth and development, emphasizing the optimization of preventative health and safety measures yielding positive health outcomes. Family-centered care across all settings, from community to acute care, is the underpinning for contemporary nursing and parallels today's trend for the child and family to obtain health care in diverse familiar settings in which they live, grow, play, work, or go to school.

Based on the many options available for children and families today there is need for an ongoing source of health care. A medical home provides comprehensive primary care services on an ongoing basis, in a manner encouraging

Figure 22-1 Pediatric nurse holding a child.

a positive relationship with the child, family, and the health care team. The concept of a medical home has gained attention, particularly in the care of children who have special needs, which comprise approximately 1 in 5 households (American Academy of Pediatrics, 2008). The care is provided in a manner that is family-centered, coordinated, culturally sensitive, and accessible (Alberg & Kerr, 2004). Quality of life can be improved for all children, especially those with special needs, with the collaboration of families, insurers, employers, government, medical educators, and other components of the health care system, through the care provided in a medical home.

critical nursing action Outcomes of a Medical Home and Coordinated Care

Children with special needs receive coordinated ongoing comprehensive care within a medical home based on these outcomes

- Families of children with special health care needs will have adequate private and/or public insurance to pay for the services needed.
- Children will be screened early and continuously for special health care needs and will have increased wellness.
- Services for children with special health care needs will be organized in a manner that fosters trust, considers the family's cultural and religious beliefs, and builds support for the child and family.
- Families of children with special needs will partner in decision making at all levels, and will be satisfied with the services they receive.
- All youth with special needs will receive the services necessary to make appropriate transitions to adult health care, work, and independence.

Families will have increased satisfaction with their health care. (The National Center for medical home initiatives for children with special needs, 2008)

Nursing Insight— Benefits of a medical home

- A child regularly sees the same primary care physician and staff.
- There is coordination of care for the child.
- There is an open exchange of information in an honest and respectful manner.
- There is support for finding resources and information related to all stages of growth and development and medical conditions.
- The family is connected to information and family support organizations.
- The medical home partnership promotes health and quality of life as the child grows and develops.

PRIMARY HEALTH CARE PROVIDER OR CLINIC SETTING

When a child becomes ill, pediatric nursing care traditionally takes place in a primary health care provider's office or clinic setting. The primary health care provider's office is a private medical office or clinic facility where diagnosis and treatment are offered, related to a variety of acute and chronic conditions (Wheeler, 2005). Health information is also provided and discussions are held with the family about how to take care of the child at home, providing well childhood check-ups and administering scheduled immunizations. It is important that caregivers understand the importance of accessing a primary health care provider to receive comprehensive care and education about their child's condition. The pediatric nurse in this setting can recommend additional community resources for the family (Fig. 22-2). Advantages for this type of care include a reasonable cost of care, continuity of care by remaining in a medical home, and the fact that the child remains in the care of the family. Because it is generally episodic and short-term care, it can decrease the risk of exposure that the child may have to other infectious or communicable conditions.

Figure 22-2 The nurse provides community resources to parents.

Family Teaching Guidelines... Teaching Tips for Families

How To: The nurse can tell the family to bring a list of questions or concerns to discuss when visiting the primary care physician's office (WebMD, 2008).

ESSENTIAL INFORMATION

- ◆ Bring a list of any allergies that the child has along with medications the child is currently taking.
- ◆ Be ready to share information as to how the child is growing and changing. Keep track of the child's developmental progress.
- ◆ Inquire about resources including community organizations that may provide assistance.
- ◆ Ask about how to receive care after normal business hours or emergency care.
- ◆ Request to meet the health team members who will be working with the child (a nurse, a referral coordinator, or a medical assistant).

THE HOSPITALIZED CHILD

Hospitalization is required when the child becomes ill and the level of care requires more in-depth treatment than can be provided by a primary health care provider in the office or clinic. When a child enters the hospital, it may be an entirely new experience where both the child and family are exposed to an unfamiliar medical environment. The hospital may be a specialty hospital located in a separate building especially designed for children or may be part of a general care hospital.

Collaboration in Caring— Types of hospitals

Hospitals: Acute care settings that provide many health care services, such as emergency care, specialized in-patient care, surgery, critical care, diagnostic tests and treatments, therapies, patient education, and other specialized services.

Children's Hospital: A specialty pediatric hospital that is specially designed and managed specifically for children that provides various health care services, such as emergency care, specialized in-patient care, surgery, critical care, diagnostic tests and treatments, patient education, and other specialized services where physicians, nurses, child life specialists, other health care providers, and employees are specially trained to work with children.

Day Hospital: A specialized hospital that serves children who require medical treatments such as blood transfusions, chemotherapy, steroid pulse therapy, intravenous hydration, intravenous antibiotic therapy, immunoglobulin therapy, or Remicade infusions.

Ambulatory Surgery Centers: A surgical center is where children receive minimal surgical treatment, recover from the procedure, and are discharged soon after the surgery.

Children are more vulnerable to the stress of hospitalization because they do not have a full range of coping mechanisms such as highly developed problem-solving

skills. The child and family are also introduced to an entirely new group of people, and are exposed to uncomfortable or painful treatments and procedures, to other cultures and languages, and to many new and difficult stressors (Leininger, 1988). The pediatric nurse must provide skilled, safe, and competent care and be supportive in their adaptation to this unfamiliar and potentially frightening environment (Gurwitsch, Kees, Becker, Schreiber, Pfefferbaum, & Diamond, 2004).

In a family-centered care environment, it is essential that the pediatric nurse understands that the family is the primary caregiver and decision maker in the care of their child. It is paramount that pediatric nurses have access to and provide education about the child's condition, diagnostic testing, and procedures and, lastly, provide important discharge and teaching instructions. The nurse must also provide emotional support and take extra time to communicate effectively and therapeutically with the child and family. An important role of the pediatric nurse is to support and care for the child and family so that the child may function at the highest level possible. The nurse is committed to nurturing the child's development; supporting the child's need for family, recognizing that the child has a unique perception of the world; and respecting the child's and family's individual rights, thoughts, and feelings. The child reacts to hospitalization in a manner that reflects the wide range of development and differences of the age group. To provide effective pediatric nursing care to the child, the nurse must be keenly aware of all of these issues and seek to understand and incorporate these and the developmental level into the plan for provision of care.

When caring for children and their families in hospitals, nurses must use evidence-based theory and provide care that takes into account the effects of hospitalization and separation on the child and family (Hopia, Tomlinson, Paavilainen, & Astedt-Kurki, 2005). Typically, healthy children have a single and brief encounter when hospitalized. The stressors are real, but not as pronounced as for children who have chronic illnesses. Some of the issues experienced during hospitalization include separation from the child's parents and family, fear of the unfamiliar, and sometimes events that are painful or disturbing. Children who have chronic illness and have repeated experiences with hospitalization often experience stress over loss over the routine or regimen related to the child's condition, trying to maintain activities of daily living that are often more complex (e.g., feeding and mobility), multiple personnel with whom to communicate, and attempting to maintain a routine family life during repeated hospital stays.

Based on age and developmental milestones, the effects of separation can be more or less profound. Specifically, infants 6 months of age and younger have not developed a clear and selective attachment to their parents. For this reason, hospitalization may not cause severe direct psychological trauma to the infant. As long as the infant has contact with a nurturing caretaker, such as a nurse, he or she may not experience adverse effects. Long-term absence can also affect the parents. They may withdraw and become less attached to their infant.

A toddler's reactions to separation may become more intense and emotional (e.g., biting, kicking, crying, and hitting). In addition, any disruptions in routines may cause stress for the toddler that then may contribute to the

continuation of naughty behavior. Another reaction to this stress may be that regression occurs in their bowel and bladder control and the toddler who was once potty trained may revert to diapers for a short period. Older children also may exhibit negative responses to hospitalization through the display of negative behavior and verbal expressions of anger or sadness. They begin to associate certain health care providers with specific treatments or procedures that cause stress, such as a laboratory technician drawing their blood or a nurse giving an intramuscular injection.

Regardless of age or separation from family, a child who is hospitalized will exhibit three stages: protest, despair, and detachment. The *protest phase* begins when the child realizes his or her parent is leaving or that he or she is separated from them, even if for a brief period. Depending on the child's age, the child could cry, cling, and act aggressively. This is then followed by the *despair phase* in which the child seems to withdraw from the environment and becomes very apathetic. If the parent does not return, the child begins to show renewed interest in his or her surroundings and begins to form new relationships with others. During this formation of new relationships, the child begins detaching his or her feeling from their parents. Sometimes, in this *detachment phase*, health care providers see this as a good sign of the child's adjustment; however, it is really an important clue for intervention. These children have simply repressed their pain at the sense loss of their about their parents' absence. This may help explain why children sometimes show disinterest on the return of their parents, as a way of acting out their anger. It is encouraging to note that this process is reversible but potentially may leave permanent emotional scars if the parents are away for an extended length of time. Detachment is the final phase, when the child has begun to internalize the stressor and seems outwardly happy, although the stressors are still present.

Now Can You— Describe the effects of hospitalization on a child?

1. Describe how family-centered care impacts hospitalization?
2. Discuss developmental differences related to reactions to hospitalization?
3. Describe protest, despair, and detachment in relation to hospitalization?

Ways to Decrease the Stress of Hospitalization

Family visitation and the family-centered care have dramatically helped children and families cope with the stress of a hospitalized child. Despite the availability of parental rooming in, the parent may also be coping with other children at home or the need to work, which could lead to separation from the child, even though family visitation is encouraged. It is important to remember that the ill child depends on his parents as the primary source of coping and comfort. To help a child of any age adapt to the stress of hospitalization, the pediatric nurse can suggest rooming-in to the parents, where they stay in the room both during the day and through the night (Table 22-1).

The nurse can also use creativity in helping the child to gain control over the environment by encouraging the

child to bring something from home to familiarize the room and make it personal. They might also encourage the child to draw a picture or design that can be hung up in the hospital room or give him or her a choice to watch a movie or select a game that he or she would like to play.

Therapeutic Play. Therapeutic play otherwise known as play therapy or medical play has been shown to help to ease the stress of hospitalization and provide children with a means for dealing with their concerns and feelings.

Nursing Insight— Therapeutic play

Therapeutic play is the use of play as therapy to help children who have had or will have a stressful experience. Therapeutic play may decrease the child's fear and anxiety. It also may help to correct misconceptions the child may have about being in the hospital. There are two types of play techniques: directed and nondirected. Directed therapeutic play is guided by an adult who facilitates the play, including determination of the goals. In nondirected therapeutic play, the child is in control of the activity, although an adult may select the materials. Both types of play allow the child to demonstrate his or her emotions regarding the hospitalized experience.

Often, a child life therapist may be available to assist with therapeutic play and offer age appropriate toys or distraction such as music or games. Therapeutic play also may help the child to cope with, and master, stressful experiences (Fig. 22-3). Pediatric nurses are encouraged to incorporate the use of therapeutic play in their everyday care of the child. By using play techniques and activities in all settings, including the emergency and outpatient departments, children benefit even if it means only that they are able to watch other children at play.

Therapeutic play happens when a child is preparing to receive an injection. The nurse or child life therapist encourages the child to play with equipment such as a needle-less syringe filled with water, a doll, and alcohol prep pad. After the injection, the nurse can then provide a bandage and a sticker for a reward. Another example is an older child simulating the medical procedure (administering IV antibiotics), a therapeutic play technique that the nurse uses is

Figure 22-3 Child life specialist playing with child.

Table 22-1 Erikson's Developmental Tasks and What May Happen During Hospitalization

Age	Developmental Task	What May Happen During Hospitalization	The Nurse Can
Infant	Trust vs. mistrust	Separation anxiety Stranger anxiety Disruption in normal routine	Encourage consistency among caregivers. Encourage the parents to stay with the infant. Encourage bonding. Allow the infant's home routine whenever possible. Comfort the infant; rock, hold, cuddle, swaddle. Encourage parents to bring familiar toys/blanket from home. Communicate with parents.
Toddler	Autonomy vs. shame and doubt	Regression Separation anxiety Negative behavior Increase in tantrums Fearfulness	Encourage consistency among caregivers. Encourage the parents to stay with the toddler. Allow the child's home routine whenever possible. Encourage parents to bring familiar toys/blanket from home. Communicate with parents. Allow the child to participate in care whenever possible. Use therapeutic play. Offer praise. Ensure a safe environment.
Preschool	Initiative vs. guilt	Play restrictions Fearfulness Thinks that hospitalization is a punishment	Encourage consistency among caregivers. Encourage the parents to stay with the preschool child. Allow the child's home routine whenever possible. Encourage parents to bring familiar toys from home. Communicate with parents. Allow the child to participate in care whenever possible. Use therapeutic play. Offer praise. Ensure a safe environment. Encourage use of the playroom and interaction with other children. Explain a procedure, treatment and/or surgery in simple terms. Allow the child to ask questions. Encourage realistic choices whenever possible.
School Age	Industry vs. inferiority	Play restrictions Questions identity Increased need or attention Regression Fear of bodily mutilation	Encourage the parents to stay with the school age child. Allow the child's home routine whenever possible. Encourage parents to bring familiar toys from home. Communicate with parents. Allow the child to participate in care whenever possible. Use therapeutic play. Offer praise. Ensure a safe environment. Encourage use of the playroom and interaction with other children. Explain a procedure, treatment and/or surgery in simple terms. Allow the child to ask questions. Encourage realistic choices whenever possible. Encourage the child to verbalize feelings. Alleviate fears about changes in body image. Respect the child's privacy.

Table 22-1 Erikson’s Developmental Tasks and What May Happen During Hospitalization—cont’d

Age	Developmental Task	What May Happen During Hospitalization	The Nurse Can
Adolescent	Identity vs. role confusion	Concerns about body image Separation from peers Loss of independence Decrease in socialization	Encourage visits or contact from peers. Explain a procedure, treatment and/or surgery in understandable terms. Be honest. Allow the teen to ask questions. Encourage realistic choices whenever possible. Encourage the teen to verbalize feelings. Alleviate fears about changes in body image. Respect the teen’s privacy. Encourage parent’s involvement in care. Recognize the teen’s tendency to reject authority.

to discuss the process with the child, clarifying what is going to happen and allowing him or her to release anxiety and decrease fears of the imminent situation.

GUIDED IMAGERY. Another way to help a child cope with the stress of hospitalization is the use of guided imagery.

The child may be still somewhat hesitant after the role modeling but may eventually drink the medicine. The nurse then offers praise and allows the child to select a colorful sticker.

 **Complementary Care: Guided imagery**

- Guided imagery is a relaxation technique that aims to ease stress and to promote a sense of peace and harmony during a difficult time.
- Guided imagery can be used by persons of all ages.
- Guided imagery encompasses the power of the mind, to help heal the body, while maintaining a relaxed state including all of the body’s senses (touch, smell, sound, sight and visual). (Tusek, 2008)

Effects of a Hospitalized Child on Parents

Parenting an ill child can be stressful and demanding on both the child and the parent. During the period of illness, the child can begin to recover, become gradually sicker, or suddenly begin to exhibit behaviors that give the parents cause for great concern. Symptoms such as withdrawal, lack of activity, or irritability in performing basic functions may be a signal that the child’s condition is worsening. During these times, continued parenting of a hospitalized child has many dimensions, such as interpreting the child’s behaviors, teaching the child new skills or how to perform basic functions again, helping a child understand the words and language of health care providers, and offering support during frightening experiences. Hospitalization has been demonstrated to be equally stressful for the parent as for the child. Parents may describe themselves as feeling incapable due to their loss of control over the situation and their inability to be able to protect their child. Some observed behaviors by parents include anxiety, denial and withdrawal, guilt and fear (including concerns by the parents that they may have had a causal effect on their child’s illness). There are ways that the nurse can help parents cope with the stressful situation during a child’s hospitalization.

ROLE MODELING. Role modeling is another way to decrease the stress of hospitalization and refers to a process by which the child learns certain behaviors by observing the behavior of others. Role modeling can help to decrease fears and anxieties as well as teach coping skills. Role models can be the people who are involved in the child’s life, such as parents, grandparents, siblings, or teachers. Role models can also come from videotapes, movies, or even their peers. Role models who are similar in age, sex, race, and attitudes are more likely to be imitated as well as models who have a caring demeanor (Watson, 1996). For example, a child might view a video about another child and his or her experience preparing for hospitalization and surgery. Viewing how the child in the video prepares for surgery may help the child who is facing surgery to find ways to cope with the anxiety and stress of the procedure.

The pediatric nurse has a critical role in assisting parents in adapting to the child’s hospitalization. The plan of care for the hospitalized child begins with the admission process when the pediatric nurse includes the parents in a conversation about important information about the child while at the same time offering support. The planning stage, with parental involvement, includes setting goals and objectives that are used to evaluate overall care. The plan of care also includes home routines, preferences, developmental needs, and identification of special needs.

 **critical nursing action** The Nurse Role Models for the Child

The pediatric nurse says “I am going to give you medicine that will help you get better.” The nurse may need to role model by pretending to drink the medicine, encouraging the child to take the medicine.

Parents with a hospitalized child often need to debrief and tell their story about the events that led to their child’s hospitalization. Nursing assessment of parental needs,

Nursing Care Plan The Hospitalized Child

Nursing Diagnosis: Anxiety related to unfamiliar environment and procedures

Measurable Short-term Goal: The child will experience decreased feelings of apprehension and anxiety.

Measurable Long-term Goal: The child will not experience unavoidable anxiety during hospitalization.

NOC Outcomes:

Anxiety Level (1211) Severity of manifested apprehension, tension, or uneasiness arising from an unidentifiable source

Anxiety Self-Control (1402) Personal actions to eliminate or reduce feelings of apprehension, tension, or uneasiness arising from an unidentifiable source

NIC Interventions:

Anxiety Reduction (5820)

Security Enhancement (5380)

Calming Technique (5880)

Nursing Interventions:

1. Approach the child and parent(s) in a calm and reassuring manner, providing teaching and anticipatory guidance as appropriate.

RATIONALE: Feelings of anxiety or apprehension in the care, given are easily transmitted to the patient and family. Knowledge reduces fear of the unknown.

2. Encourage the family to stay overnight, bring the child's favorite toys or security objects, and maintain routines as appropriate.

RATIONALE: Familiarity enhances the child's feeling of safety in a strange environment.

3. Provide a pacifier for an infant or rock, hold, or comfort an older child as needed.

RATIONALE: Comfort measures will vary by age, culture, and individual preference.

4. Perform any invasive or painful procedures in a place other than the patient's room.

RATIONALE: The patient's room should become and remain a safe place where the child is able to relax.

5. Encourage the family, and the child, if age-appropriate, to participate in care activities such as bathing, feeding, medication administration, or help with dressing changes.

RATIONALE: Reduces unnecessary anxiety from having a stranger perform tasks. An older child will feel less anxiety if allowed some control over how things are done

knowledge, concerns, expectations, and coping abilities is imperative to direct nursing actions that ease parental role stress. Parental stressors include sights and sounds of the hospital, changes in the child's behavior or appearance, changes in the parental role, unknown outcome, financial concerns, guilt or anger over the situation, and frustration about the function of the entire family (Fig. 22-4). Seeking parental advice about the best way to approach their child, acknowledging parental need for involvement, and anticipating stressful events are integral to appropriately caring for the child in a family-centered manner. The communication between the pediatric nurse and family members must be genuine and the plan of care must include resources available in the hospital as well as the community.

- Perform ongoing assessment to ensure that the nurse fully understands any changes in the plan of care for the child.
- Observe for the need for crisis intervention, should the child's condition deteriorate or change.
- Encourage the parents to participate in the child's care, while being supportive of the child and family.

Nursing Insight— Nursing interventions to help parents cope with the child's hospitalization

Parents suggest that nurses may perform common interventions to help them cope with their child's hospitalization.

- Before admission, if possible, visit the hospital to see where the child will be staying.
- Encourage constant and open communication with the health care team.
- Encourage visitation of parents, friends, and family members. The number of visitors may be limited depending on the child's condition.

Figure 22-4 Parents at the bedside of a child in the hospital.

“What to say” — Developing a plan of care

Admission to the hospital is a critical period for both the child and parents. The nurse can ease the experience by including the parents in the plan of care. The nurse can request information from the parents about the child's personal routine as well as the child's perception of hospitalization.

- What are your child's daily routines related to eating, elimination, sleeping, bathing, and play?
- Who are the important people in your child's life?
- Does your child have a favorite toy or attachment object?
- Has your child had previous hospitalizations?
- What has your child been told about hospitalization?
- Does your child have any fears that the staff should know about?
- Have there been any recent changes or problems in your child's life?
- How does your child usually react to pain or when frightened?

The nurse must recognize the parent's concerns, including possible guilt, fear, or other anxieties about the child's hospitalization. The pediatric nurse plans care ensuring the promotion of trust by the child and parents through prompt attention to the child's needs. The nurse provides opportunities for the child and family to participate in care and by including parental preferences and home schedules so that care is provided in a familiar and consistent manner. The nurse can also provide positive reinforcement for the parents that may help alleviate some stress. Finally, the nurse ensures an ongoing evaluation of the plan of care is necessary in order to make needed adaptations and modifications.

TWENTY-FOUR-HOUR OBSERVATION UNIT

A short-stay hospitalization experience is also known as 24-hour observation. A 24-hour observation occurs when a child becomes suddenly ill and will most likely recover quickly. The child may need a shortened hospital stay for observation and specifically for treatments such as rehydration, aerosol treatment for acute asthma, or medication for an allergic reaction. At the conclusion of the 24-hour period the child is reassessed and it is then determined whether continued hospitalization is needed or whether the child can be discharged home. The pediatric nurse provides acute nursing care and then quickly begins to prepare the child and family for discharge. As a part of discharge process, the nurse explains specific medical orders as well as when to notify the primary health care provider with any questions, concerns, or change in condition.

AMBULATORY SURGERY CENTER

An ambulatory surgery center is a place where children receive minimal surgical treatment, recover from the procedure, and then are discharged home soon after the

surgery. This type of experience minimizes the separation between child and family and can be emotionally less stressful. Although the surgery is usually minor, it is essential to teach the family about the surgery entails and ways to care for the child at home. Some of the recovery takes place in the surgery center, but the longer recovery process continues at home. At home, parents need to be informed about the exact recovery process along with how care for the child and when the child can resume normal daily activity. The nurse assesses the family's knowledge in order to determine their ability to care for the child independently at home or if additional support is needed.

critical nursing action Caring for the Child at Home After Minor Surgery

Nurses can teach parents how to care for their child at home after minor surgery:

- Taking the child's axillary temperature
- Assessing the child's level of consciousness
- When to begin giving the child liquids
- When to offer liquids based on type of surgery, prescribed diet, and age
- When to offer solid food based on type of surgery, prescribed diet, and age
- What type of activity is expected or should be encouraged
- What are the actions and side effects of medications
- What are the signs and symptoms of infection
- What are signs of poor airway exchange
- How to use assistive devices and medical equipment and perform home treatments
- How to contact a nurse, pharmacist, health care professional, or community agency
- When to call the doctor

CRITICAL CARE UNIT

When critical care of the child is required, the child is admitted to the critical care unit, usually through the emergency department or the operating room. A child who becomes very ill on a medical-surgical floor is transferred into a pediatric critical care unit (Hohenhaus, 2005). After delivery, a newborn who requires intensive care is transferred to a neonatal intensive care unit. Other types of critical care units where children might receive care include cardiac, surgical, or psychiatric critical care units. In any of these units, the child is extremely ill and receives specialized care, medication, intravenous fluid, respiratory, or ventilator support (Fig. 22-5).

clinical alert

Common problems of critical illness

Common problems of critical illness are shock, acute respiratory failure, chronic respiratory failure, infection, sepsis, renal failure, neurological conditions, bleeding and clotting disorders, or multiorgan dysfunction.

Figure 22-5 Child in critical care unit.

Nursing interventions for the illness is complex and ongoing. In this type of setting, the pediatric nurse usually cares for just one or two patients at a time in order to meet the multifaceted health care and emotional support needs of the child and family.

EMERGENCY DEPARTMENT

Emergency care is provided in a hospital or health care facility that provides quick treatment for children who have become suddenly ill or experienced a severe injury. Emergency departments are open 24 hours per day and 7 days per week. Children who arrive in the emergency department first receive a rapid screening or triage assessment to establish the nature and severity of their presenting illness. If the illness or injury is severe, the child is treated in an urgent manner and all necessary procedures, treatments, and tests are preformed immediately. The emergency department may have several areas of treatment, including a general and minor care area; a resuscitation room; or specialty areas for specific populations such as children, women, or persons requiring mental health care.

Usually, children who have a minor illness such as an ear infection are sent to a less acute area, sometimes termed non-urgent. In some hospitals there is a “fast track” system where less urgent children are quickly assessed, treated by a physician, and then discharged home. Sometimes after the child receives an initial assessment and treatment, he or she is admitted to a hospital depending on the diagnosis and subsequent treatment.

Community Settings

Children have special health care needs where families, nurses, and other health care providers collaborate to create a family-centered plan of care. Today children are apt to receive the majority of their health care in a community setting. Community settings are on the front line of prevention and early detection and these settings may be located in neighborhood clinics, schools, shopping malls, or health care centers.

Collaboration in Caring— *Caring for children in the community: Where they live, play, and go to school*

There are many places in the community where children and their families can access health care:

Community Centers: A community-based center where the pediatric nurse provides health screening and education; emphasizing health promotion and disease prevention

Preventative Medicine Center: A community-based center that provides a comprehensive menu of pediatric testing, diagnosis, and treatment related to acute and chronic conditions

Home Health Care: Health care services provided by nurses and other health care professionals in the child’s home

Medical Home: An ongoing source of health care providing primary care services that is both ongoing and comprehensive

Mobile Health Care Units: A portable van that visits neighborhoods, schools, and other community locations where children can obtain screening, diagnosis, and treatment related to a variety of medical conditions, receive immunizations, and receive well childhood check-ups or basic care

Primary Physician’s Office: A medical facility that provides diagnosis and treatment related to a variety of acute and chronic conditions as well as education, dissemination of information, well childhood check-ups, and administration of immunizations.

Rehabilitation Services: Services that can be provided in a community-based center or hospital where children can receive occupational, physical, audiology, and/or speech therapy.

School Setting: Schools offer basic nursing care for minor acute conditions, disease management, and teaching about health promotion and disease prevention, as well as play a role in advocacy, screening, and counseling services.

State Health Program: Each state works with its federal and local partners to help children remain healthy and safe. The programs and services help prevent illness and injury, promote healthy places to live and work, provide education to help people make good health decisions, and ensure that states are prepared for emergencies or natural disasters (National Center for Injury Prevention and Control, 2008).

The Department of Health and Human Services: The United States government’s principal agency for protecting the health of all Americans and providing essential human services, especially for those who are least able to help themselves (U.S. Department of Health and Human Services Health Resources and Services Administration, Maternal and Child Health Bureau, 2008).

In the care of children and families, the focus for health care is early identification, assessment, and referral. Community settings often provide primary care along with health screening and surveillance. Health screening means to test or examine children for the presence a disease, illness, chronic condition, developmental delays, or mental health issue. Health screening plays an important role in the early diagnosis and management of selected illnesses or conditions and the initiation treatment which

can then prolong and improve lives (The National Academy Press, 2008). **Health surveillance** is the continuous observation related to tracking health conditions and risk behaviors. Nurses, physicians, and other health care professionals gather ongoing information about disease incidence, demographics of an illness, and implementation of policies that may prevent further spread of diseases.

Collaboration in Caring— *The nurse's role in health screening and surveillance*

The nurse has a key role in health screening and surveillance:

- Pay attention to voiced parental concerns.
- Ask questions about the child's growth and development.
- Observe the child's mental, physical, and spiritual state (not just a diagnosed condition).
- Note any risk factors that may be present.
- Document specific observations and findings.
- Provide community resources and make appropriate referrals.
- Track disease incidence and demographics of illnesses.
- Implement policies that may prevent further spread of diseases.
- Initiate follow-up care for any concerns and conditions.

CLINICS

When a child comes to a community setting such as a clinic to receive health care services, her symptoms are noted and she may undergo a physical assessment by a primary health care provider or nurse practitioner to diagnose the condition. In the community setting, children can receive treatment for the condition and may experience diagnostic testing such as x-ray exam or blood sampling. In a small town or rural area only one community clinic might be available. In a large urban area there can be many specialty sites. Clinics can also be housed in an acute care setting such as a hospital.

Across Care Settings: Clinics

In a community, there can be one general care clinic or many types of specialty clinics:

Allergy & Asthma Clinic: A clinic for children that provides comprehensive services for diagnosis and treatment of allergy and asthmatic conditions

Audiological Clinic: A clinic for children where they are assessed for auditory conditions, may receive newborn hearing screenings, obtain treatment for otitis media, or receive hearing aids

Cardiology Clinic: A clinic for children that provides comprehensive services for diagnosis and treatment of congenital and acquired heart conditions

Dermatology Clinic: A comprehensive clinic for the evaluation of children with conditions related to acute, chronic, or genetic integumentary conditions

Diabetes Clinic: A consultation and management clinic for children who are diagnosed and are living with diabetes

Eating Disorders Clinic: A consultation clinic employed by physicians, psychologists, dietitians, and social workers

that is specifically designed for children with eating disorders, such as anorexia nervosa or bulimia

Endocrinology Clinic: A clinic for children that provides comprehensive services for diagnosis and treatment of endocrine and metabolic conditions

Gastroenterology—Nutrition Clinic: A clinic for children that provides comprehensive services for diagnosis and treatment of gastrointestinal, nutritional, and liver conditions

Genetic Clinic: A clinic for children that provides comprehensive services for diagnosis and treatment of inborn errors of metabolism and biochemical genetic conditions along with genetic counseling of patients and prenatal testing

Immunology Clinic: A clinic for children that provides comprehensive services for diagnosis and treatment of children with unusual infections, primary immune deficiencies, or complement deficiencies

Infectious Disease Clinic: A clinic for children that provides comprehensive services for diagnosis and treatment of acute infections or chronic infections

Neurology Clinic: A clinic for children with neurological conditions such as spina bifida, cerebral palsy, or autism who require comprehensive care and treatment

Oncology Clinic: A clinic for children that provides comprehensive services for diagnosis and treatment of cancer

Ophthalmology Clinic: A clinic for children that provides comprehensive services for diagnosis and treatment of ophthalmologic conditions

Orthopedics: A clinic for children that provides comprehensive services for diagnosis and treatment of acute and chronic musculoskeletal and bone conditions

Pulmonary/Cystic Fibrosis Clinic: A clinic for children that provides comprehensive services for diagnosis and treatment for acute and chronic respiratory conditions

Rheumatology Clinic: A clinic for children that provides comprehensive services for diagnosis and treatment of arthritis, lupus, and inflammatory conditions

Urology Clinic: A clinic for children that provides comprehensive services for diagnosis and treatment of acute, chronic, and congenital genitourinary conditions

SPECIALTY CAMPS

Specialty camps are a recreational, educational, and supportive resource where children can play, learn how to care for and cope with their condition, and meet other children who share the same medical condition (e.g., Asthma Camp, Arthritis Camp, Diabetes Camp, Ventilator Assistive Camp). In specialty camps, activities are planned that help children alleviate stress, interact with their peers, achieve mastery over planned activities, and provide a diversion from the challenges of coping with their illness or condition.

CHURCHES, SYNAGOGUES, MOSQUES

Faith communities can offer a wide variety of health-related services including teaching about health promotion and disease prevention, administration of immunizations and flu shots, provision of sick-day care, as well as daycare, preschool, and after-school care programs. In addition, prenatal classes including newborn care and information about normal growth and development may be taught in the faith community setting (Walker-Brown, 2005).

Nursing Insight— *Maternal and Child Health Bureau*

This U.S. Department of Health and Human Services Web site offers information about equal access for all to quality health care in a supportive, culturally competent, family and community setting (U.S. Department of Health and Human Services Health Resources and Services Administration, Maternal and Child Health Bureau, 2008).

After a child has received the needed health care, parents may wonder how to continue to care for their child and his or her special needs. Families must be given information about follow-up care especially related to rehabilitation. Follow-up care can help ensure that the child returns to normal functioning, learns to adapt to his or her condition, or reaches the highest most realistic level of health.

“What to say” — *When a family asks about follow-up care*

When a family asks about follow-up care related to rehabilitation services for the child, the pediatric nurse responds by saying:

Rehabilitation services generally happen in a hospital or community center where the child can begin to recuperate and receive physical, occupational, audiology, or speech assessment and therapy. Other health care professionals will assist the child in working toward the achievement of optimal function and the relief of pain. The ultimate goal is to assist the child’s physical recovery and reentry into the community, home, and school. A social worker may also be involved in the child’s care to assess the capacities of the family’s ability to cope with the impact of the condition and situation. A social worker can also offer a broad range of community services and may serve as emotional support to referrals for community resources.

CARE IN SCHOOL SETTINGS

Care in school settings is provided by nurses who specialize in the prevention of illness, help children with special health care needs, and assists in the early identification of health concerns for children. The National Association of School Nurses (NASN)’s purpose is to advance the delivery of professional school health services to promote optimal health and learning in students. School nursing is a speciality practice that helps children maintain good health practices, along with academic success. School nurse’s role is to facilitate normal development; promote health and safety and intervene with actual and potential health problems. The school nurse also provides case management services and collaborates with others professionals to maintain the family unit, instill self management skills as well as promote self advocacy (National Association of School Nurses, 2008).

School nurses also focus on supporting the families of these children by working with children who do not have access to primary care, are uninsured, or are homeless (Meadows-Oliver, 2003). Nurses in the school settings can

be an advocate for children and encourage parents to immunize the child as well as keep track of immunizations.

The school health nurse also plays a leadership role in the support of a coordinated school health initiative. There are eight potential areas in which the school health nurse may be involved:

- Provide the experience and resources in health education including developing health information and health programs
- Provide activities and health information including increasing the awareness and education of staff and faculty of the school and keep accurate health records
- Assess the health of students and providing access to health care
- Counsel and advise staff in the early identification of psychological or social issues
- Providing health education about nutrition, encourage healthy eating and snacking behaviors, and review and improve offerings of school menus
- Work with students and physical education teachers to encourage physical activity including students who may have special health care needs
- Report and intervene when there are hazardous situations within the school, including crisis intervention
- Provide leadership and collaborative partnerships with community agencies to meet the health care needs of children and their families.

Nursing Insight— *School nurses are the link between health and education*

- Provide education on health related topics such as nutrition.
- Assist special needs children with their unique needs.
- Help families access health care.
- Complete important screenings such as vision, hearing, and scoliosis.
- Offer counseling, primary health care services, and emergency care.
- Ensure communicable disease control by tracking immunizations and tuberculin skin test.
- Work with teachers in the identification of children at high health risk.
- Supply information for community referral and follow-up.
- Serve as advocates for children through medical case management, child abuse recognition, and crisis intervention/triage.
- Assist in the creation of community-wide disaster plans.
- Use individualized care plans and individualized family service plans.

summary points

- ◆ Family-centered care across all settings, from community to acute care settings, is the underpinning for contemporary nursing and parallels today’s trend for the child and family to obtain health care in diverse familiar settings in which they live, grow, play, work, or go to school.
- ◆ Pediatric nursing occurs in multiple settings, including hospitals, clinic settings, home health settings, rehabilitation centers, schools, and other supportive services.

- ◆ Hospitalization can occur when the child becomes ill and his or her care requires more in-depth treatment than can be provided by a primary health care provider in the office or clinic.
- ◆ The pediatric nurse must possess a broad base of knowledge about growth and development, family functioning, and environmental influences in order to care for children and their families across care settings.

review questions

Multiple Choice

1. During a well baby visit, the pediatric nurse initiates teaching related to health promotion and prevention of illness. Which of the following suggestions should the nurse include in the teaching session?
 - A. “Call the pediatrician if the baby has a temperature of 99°F (37.2°C).”
 - B. “If you smoke be sure to blow the smoke away from the baby’s face.”
 - C. “Call the pediatrician if you notice a change in the baby’s activity level or feedings.”
 - D. “We want to watch the baby’s weight gain, so feed the baby when she cries.”
2. The pediatric nurse utilizes Erikson’s developmental model to help the 2-year-old master the stage of autonomy. Which of the following will help the toddler to accomplish this task?
 - A. Allow the child to dress herself as much as possible.
 - B. Tell the parents to keep the child in view at all times.
 - C. Suggest colored mobiles be placed above the bed.
 - D. Instruct the parents to rock the child once a day.

Select all that apply

3. Nurses have a responsibility to educate families about the information found in *Healthy People 2010*. Which of the following are included as leading health indicators?
 - A. Reducing or eliminating various indigenous cases of vaccine-preventable diseases.
 - B. Reducing the proportion of adolescents who are overweight.
 - C. Decreasing the proportion of adolescents who participate in daily school physical education.
 - D. Reducing the proportion of adolescents with *Chlamydia* infections.

Fill-in-the-Blank

4. In order to provide effective pediatric nursing care to a child, the nurse must incorporate the child’s _____ into the plan of care.
5. Pediatric nurses utilize _____ to help decrease the stress and fear of hospitalization.
6. Providing culturally competent care means that a pediatric nurse can integrate the family’s cultural elements to enhance communication and work effectively with one another.

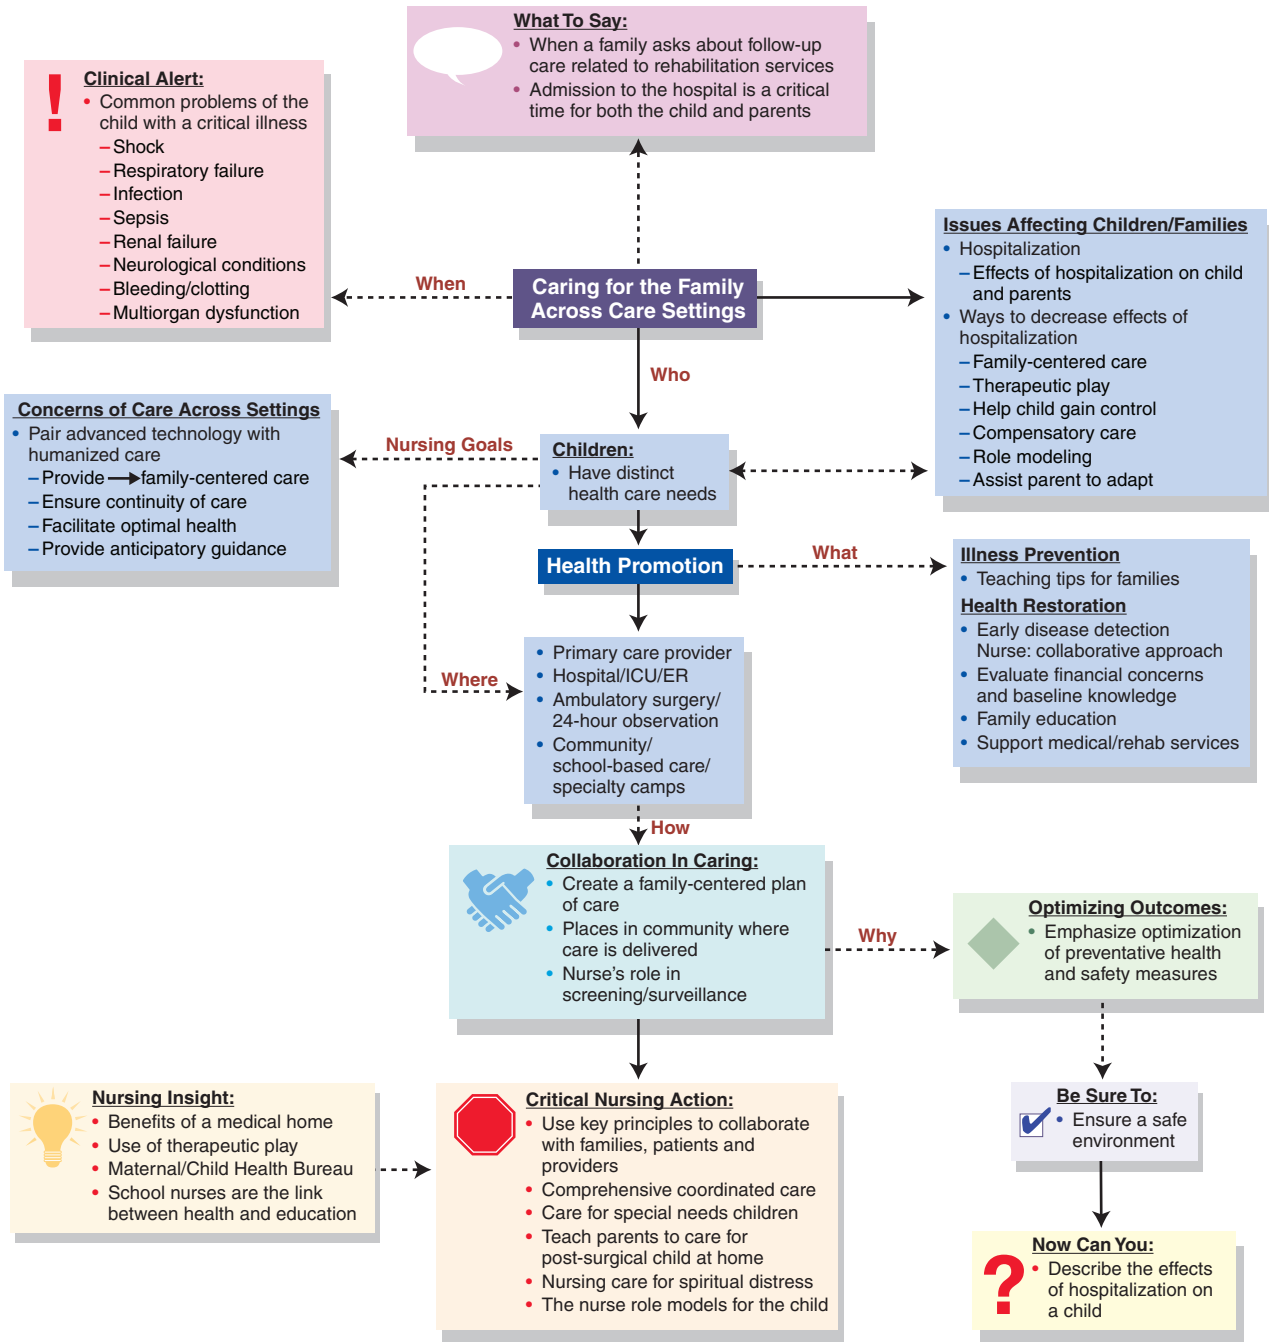

7. Effective parenting children can help meet children’s physical, emotional, and spiritual needs.

Ongoing Care of the Child in the Hospital and in the Community

Caring for the Child with a Psychosocial or Cognitive Condition

The thing most people want is genuine understanding. If you can understand the feelings and moods of another person you have something to offer.

—Paul Brock

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Explain the importance of integrating aspects of developmental psychopathology, and intergenerational transmission of vulnerability and resilience to form a framework to understand how to promote children’s cognitive and psychosocial health.
- ◆ Explore intervention options for children with cognitive and psychosocial problems/disorders.
- ◆ Describe the influence of ethnicity and culture on the promotion of children’s cognitive and psychosocial health.
- ◆ Examine the incidence of the various cognitive and psychosocial problems/disorders.
- ◆ Relate how developmentally sensitive approaches are used in identification of disorders and strengths used to devise a care plan.
- ◆ Describe criteria for referring children for mental health evaluation or psychological testing.

moving toward evidence-based practice Childhood Depression and Alcohol Use

Wu, P., Bird, H.R., Liu, X., Fan, B., Fuller, C., Shen, S., Durate, C.S., & Canino, G.J. (2006). Childhood depressive symptoms and early onset of alcohol use. *Pediatrics*, 118(5), 1907–1915.

The purpose of this study was to examine the relationship between depressive symptoms and the early onset of alcohol use in children and adolescents.

The investigation was based on data from a longitudinal study of psychopathology in 2491 children and early adolescents, ages 5–13 years. A subsample of 1119 children ages 10–13 years who reported never having used alcohol at the initiation of the study also completed the baseline and follow-up interviews. All of the children in the study had a Puerto Rican background.

Data collection included several types of measurements:

A structured interview was conducted with both parents and children. The interview included assessing the children for affective disorders, anxiety disorders, disruptive behavior disorders, and substance abuse and dependence disorders using the Diagnostic Interview Schedule for Children (DISC-IV) and based on the criteria identified in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. (DSM-IV).

For study purposes, alcohol use was defined as “drinking a full can or bottle of beer, a glass of wine or wine cooler, a shot of liquor, or a mixed drink with liquor in it.”

Depressive symptoms were considered positive if reported by either the parent or child. The numbers of depressive symptoms were measured in categories: <2 (low level depressive symptoms); 2–9 (medium-level depressive symptoms); and >10 (high-level depressive symptoms). Parents were asked about the presence of emotional, alcohol, or drug problems in either parent.

Parents completed a “parental monitoring” Likert-type scale that consisted of nine questions. The purpose of the tool was to determine how often the parent monitored the child’s television watching, video game playing, and other activities in or outside of the home. A high score indicated a high level of parental monitoring.

The parents’ use of discipline was measured through an interview that consisted of six items regarding the use of physical

(continued)

moving toward evidence-based practice (continued)

and verbal abuse, various forms of punishments and the withholding of affection.

Maternal warmth and support was evaluated using a 13-item Likert-type scale. A high score indicated a close maternal–child relationship.

A four-item tool that related to parental behaviors including hitting, beating, or badly hurting the child was used to assess physical abuse. A positive response to any of the four questions was considered to be consistent with physical abuse.

Measured socioeconomic factors included the age of the child, gender, highest level of parental education, and family structure/composition (i.e., the number of parent figures).

Data analysis revealed the following findings:

- One hundred and ten (9.8%) of children who had not used alcohol at the time of the initial interview reported the use of alcohol at the first follow-up.
- The rates of alcohol use varied according to the level of depression: at the baseline interview, those with <1 depressive symptoms reported an alcohol use rate of 4.1%; those with 2–9 depressive symptoms reported an alcohol use rate of 10.2%; and those with >10 symptoms reported an alcohol use rate of 14.1%.
- Sociodemographic factors revealed that the age of the child was positively associated with the timing of the onset of alcohol use and that parental education made little difference in the child’s use of alcohol.
- No association was found between alcohol use and the child’s gender or whether the child lived in a single-parent home.

- Parent psychopathology and child physical abuse were positively associated with alcohol use in the child.
- No association was found between alcohol use and a close maternal relationship or the level of parental discipline.
- Sensation seeking, exposure to violence, and antisocial behaviors were identified as risk factors for child alcohol use.
- No relationship was found between the child’s alcohol use and church attendance or the presence of stressful life events.

Children with high-level depressive symptoms and medium-level depressive symptoms were more likely to use alcohol than those with low-level symptoms. Children with fewer than two depressive symptoms were less likely to begin drinking than those with two or more depressive symptoms.

An early onset of alcohol use may be impacted by early life depressive symptoms. In addition, the presence of parent psychopathology, exposure to violence, and antisocial behaviors were also found to be significant risk factors for the early onset of alcohol use in children.

1. What might be considered as limitations to this study?
2. How is this information useful to clinical nursing practice?

Introduction

Understanding the normal neurological, cognitive, and emotional development of children is important in determining if they are functioning within their appropriate developmental level. For example, developmentally expected anxiety in infants and young children may suddenly arise as a fear of strangers or in response to separation from caregivers. This typically occurs between 7 to 12 months and peaks between 9 to 18 months, but decreases for most children by age 2 1/2 (Zero to Three, 2005a). Also, a child may have an inherent anxious temperament and may be inhibited when encountering new situations, people, or objects and may respond to these with fear and withdrawal. Likewise, nurses should note that normal behaviors for young children (imaginary friends, concrete thinking, etc.) are interpreted differently when displayed in adults (as signs of schizophrenia). Awareness of language development is important in determining learning disabilities, developmental disabilities, or autism.

Most children do not develop cognitive or psychosocial disorders. However, it is important for the nurse to have a good history of developmental milestones, including language development, sensory perception, emotion regulation, motor skills, attention, and memory (Denham, 2006; Heffelfinger & Mrakotsky, 2006).

Developmental Psychopathology

This chapter uses a framework based on developmental psychopathology, which draws on multiple theoretical models and literature across scientific disciplines, to help explain the interaction between normality and pathology at various stages of child and adolescent development.

Developmental psychopathology is an actual discipline that evolved from the contribution of multiple fields of study with the goal to provide understanding between psychopathology and normal adaptation (Cicchetti & Posner, 2005). It combines developmental, biological, and social theories to track deviations from developmental norms as they relate to psychological pathologies. This reflects an understanding that adaptive and maladaptive (mental illness) patterns can occur in infancy, childhood, or adolescence. In addition, and most importantly, it is thought that individuals with psychopathologies have the ability to function in an adaptive way. It is expected through the use of this framework that the nurse will gain understanding into individual patterns of cognitive and psychosocial child/adolescent health. Understanding of developmental psychopathology may aid in the prevention and early intervention of mental illness (maladaptive patterns).

Vulnerability and Resilience

Vulnerability and resilience are important topics in the care of children. The intergenerational transmission model is based on the premise that vulnerability toward maladjustment or resilience in the face of adversity may be passed on from one generation to the next. It is important that the nurse working with children and their families have a good understanding of the key concepts of intergenerational transmission of vulnerability and resilience. Vulnerability is defined as “a predispositional factor, or set of factors, that makes a disorder state possible” (Ingram & Luxton, 2005, p. 34). Children with resilience show positive adaptation despite significant life adversity (Cicchetti, 2003).

Optimizing Outcomes— Understanding resilience in the face of vulnerability

It is important to keep in mind that not all offspring of parents with mental health issues go on to develop mental health-related problems themselves. In fact, the children of parents or caregivers with mental health issues who do not exhibit any maladjustment or symptoms of mental health problems during childhood are known to be resilient children (Hammen, 2003). Researchers in this area of study found that much can be learned about mental health well-being from these children. The best outcome gained from this knowledge can be used to prevent and promote good mental health for all children.

Culture, Diversity, and Health Disparities

The anthropological model of culture, ethnicity, and race disputes beliefs that culture and race are innate (Smedley & Smedley, 2005). Within an anthropological framework, culture and race are learned behaviors. This dynamic view can be used to illustrate the value of how culture and diversity influence children’s and families’ cognitive and psychosocial health. Culture is considered to be an external and acquired phenomenon. It is the complex set of beliefs and attributes passed on within a group. Ethnicity refers to groups of people who share similar cultural characteristics (i.e., common language, religion, food, and

where research and practice meet: Is Mental Illness Passed Along to Children?

In a study of 166 low-income and racially diverse adolescent children of mentally ill mothers, Mowbray et al. (2004) discovered that the majority of children (30.1%) were actually socially and academically proficient, whereas, 15.1% of the children showed anxiety and depression with poor social and academic competence. In addition, 27.1% of the children were delinquent and peer-oriented, and 4.8% were classified as isolated nonconformists. Of the total children, 22.3% were in the middle of these groups (Mowbray et al., 2004). The intergenerational transmission of vulnerability and resilience model is important to consider while the nurse conducts assessment, formulates a nursing diagnosis, devises preventive interventions or plan of care for the child or family, and finally executes evaluation.

beliefs about health). Race is used to describe categories of people, mostly based on physical characteristics (e.g., skin color, shape of nose).

Another issue that deserves a great deal of attention from the nursing community involves health disparities. There is vast information research indicating that health care disparities in racial and ethnic minorities are widespread compared to those in non-minorities, and barriers such as mistrust, fear, and discrimination stand in the way of optimal mental health outcomes in ethnically diverse families (Heffernan, 2004). For instance, the nurse must recognize that new immigrants may be concerned with learning the language and getting and keeping a job, and may focus only on their children’s basic health care needs (e.g., vaccines, treatment for ear infection) and may not at all attend to children’s cognitive and psychosocial health needs. It is important that the nurse do a thorough assessment of health care needs, including cognitive and psychosocial wellbeing.

Given the magnitude of mental health disparities in children and adolescents, nurses at all levels of practice along with other health care providers must become better prepared to implement strategies designed to reduce health care disparities. In particular, nurses are well positioned to take a leadership role in the movement toward abating and eliminating health care disparities (Heffernan, 2004).

Nursing Insight— Understanding mental health disparities in children

In contrast to younger children, adolescents have the necessary cognitive and social structures to be able to perceive discrimination. In a study with Latino children and adolescents, researchers found that adolescents who perceived severe discrimination had poorer mental health outcomes compared with their peers (Szalacha et al., 2003). This indicates that children’s perceptions about how they are treated make an important difference in their own mental health outcomes. It is therefore important for the nurse to assess children’s perceptions of how they are viewed by others, including health care professionals.

Ethnocultural Considerations— Promoting understanding of culture in diverse families

It is important that nurses gain an in-depth understanding regarding the culture of various people; acquire sensitivity and empathy in working with diverse families (e.g., give up preconceived notions or generalizations about particular ethnic or racial groups); and attain skills in relationship building with children, adolescents, and parents/caregivers of various ethnic and racial backgrounds. It is recommended that nurses working with children and families of diverse socioeconomic backgrounds take an approach of listening, providing as much positive feedback as possible for what families are doing well and keep resilience-promoting strategies in mind. Using anticipatory guidance, nurses working with children and their families may be most effective suggesting alternative ways of handling a specific cognitive or psychosocial-related concern.

In this way, nurses can provide health and psychoeducation in a nonthreatening way to help families decide what works best for them.

There is also a flawed belief that poverty predisposes children and families to mental illness. Although it needs to be studied more thoroughly, there is evidence suggesting that poverty by itself does not cause mental health problems in children and families (Rutter, 2003). Strategies outlined above for nurses to decrease health care disparities also apply in working with families who may be poor, disenfranchised, affected by substance abuse, family violence, and child maltreatment.

Barriers to Child and Adolescent Mental Health

There are a number of barriers to the diagnosis and treatment of children's cognitive and psychosocial health. A brief overview is provided here to help the nurse gain an understanding of the issues in order to intervene to minimize these barriers. Though there are increasing efforts to educate the public, the *stigma* of mental illness continues to be a major barrier to accessing mental health services for children and their families (Hinshaw, 2006). The health care community and the lay public have long been skeptical about whether young children, in particular, experience clinically significant mental health disorders, such as depression. There is a prominent belief that childhood is a "sacred" happy time free of problems. Health care providers have also had a role in perpetuating barriers by minimizing or dismissing parents' or caregivers' concerns. Parents may be told that the child is simply going through a stage that will pass, when there are indeed grounds for concern (e.g., early signs of autism spectrum disorder). It is important for the nurse to understand that this type of thinking may lead to several issues for children, adolescents, and their families such as: (1) not getting screened on a timely basis for disordered behaviors and emotional difficulties that often can be attenuated or resolved if early intervention is sought in a timely fashion; (2) having a sense of shame for the family if a child or adolescent is eventually diagnosed with a mental health problem that might have been prevented or attenuated earlier; and (3) inability to receive adequate mental health or psychosocial treatment when indicated because of lack of resources (Hinshaw, 2005).

where research and practice meet: Injury Control Research Centers (ICRC)

The Department of Health and Human Services Center for Disease Control and Prevention; Injury Control Research Centers (ICRC) serves to conduct research about injury control in the areas of prevention, acute care, and rehabilitation. In addition, the ICRC serve as training and public information centers. This valuable research can help nurses to understand violent behaviors in youth today (U.S. Department of Health and Human Services, Centers for Disease Control and Prevention, 2008).

Psychopathology in Children

Children and adolescents are not immune to mental and emotional illnesses. Mental illness in children and adolescents may be confusing and frightening for children and families. The disorders can be quite devastating, particularly if they are not detected and treated.

ANXIETY

Anxiety disorders are among the most common psychiatric complaints in children. While children commonly experience transient anxieties at various developmental points, clinically significant anxiety must be recognized as a problem. It is important to distinguish between developmentally expected anxiety, anxious temperament, and symptoms of a disorder. The following diagnostic categories related to anxiety disorders have been identified in the *Diagnostic and Statistical Manual (DSM-IV-TR)*: separation anxiety disorder (SAD), generalized anxiety disorder (GAD), specific phobia, panic disorder, social phobia, selective mutism, posttraumatic stress disorder, and obsessive-compulsive disorder (OCD) (American Psychiatric Association [APA], 2000). In separation anxiety disorder, children experience overwhelming fear of becoming separated from or losing a caregiver (Fig. 23-1). The nurse understands that some degree of separation anxiety is normal at various stages of development and during transitions, but if the anxiety is severe and excessively disruptive, and if it persists for longer than 4 weeks, the child should be evaluated by a mental health professional. In GAD, children experience excessive worry about everything, including peer relationships, social acceptance, and pleasing others. Specific phobia refers to unrelenting fear of certain objects or situations (i.e., spiders, storms, snakes, water). These may be difficult to evaluate because

Figure 23-1 This child is displaying signs of separation anxiety.

at each developmental stage children and adolescents have various expected fears. Panic disorder usually begins in adolescence but may start earlier. Symptoms of a panic attack might include palpitations, sweating, shaking, nausea, dizziness, fear of dying, tingling sensations, chills, or hot flushes. Selective mutism refers to a child's enduring refusal to speak in certain situations. This refusal interferes with the child's functioning and development and is not due to physiological or deficit of knowledge. Posttraumatic stress disorder occurs in response to a perceived or actual threat to one's life or safety. There is a clear precipitant and a reaction is generally understandable. The response may persist for weeks, months, or years and is accompanied by panic symptoms. In obsessive-compulsive disorder (OCD), the child experiences sometimes debilitating recurrent worries or thoughts (obsessions) and repetitive actions or thoughts that to bind the anxious thoughts (compulsions).

It is estimated that 13% of children between the ages of 9 and 17 suffer with some type of anxiety disorder (Substance Abuse and Mental Health Services Administration [SAMHSA], n.d.). Nearly 50% of children with anxiety disorders have at least one other psychiatric disorder (SAMSHA, n.d.).

Signs and Symptoms

It is important for the nurse to understand normal developmental anxiety. This understanding provides a baseline from which to judge the occurrence of clinically significant distress. Anxiety is an important factor in motivation and alertness. Worries and fears are a part of every developmental stage, even throughout adulthood. An occasional bout of feeling nervous accompanied by sweating, nausea, diarrhea, worry, and/or tearfulness is well within normal limits. But when the anxiety does not abate or it gets worse with time, it may be indicative of an anxiety disorder. The nurse should question a child's or adolescent's level of anxiety if it does not respond to reassurance or closeness with a safe person or if it interferes with functioning.

Anxiety often presents in the form of somatic complaints like stomachaches and restlessness (Ginzburg, Riddle, & Davies, 2006). The school nurse can recognize anxiety problems when a child persistently presents with symptoms that do not have a recognizable physical cause.

Children or adolescents with clinically diagnosable anxiety disorders may suffer from persistent worry, unfounded fears, separation difficulties, sleep problems, or obsessions or compulsions (Cleveland Clinic, 2007). Anxious children may also resist going to school or staying there after arriving. They may avoid play time, even with good friends, and not be able to explain why.

Diagnosis

As with any emotional or psychiatric difficulty, a complete physical, psychosocial and family history helps reveal genetic, biological, and familial contributors to anxiety.

Nursing Care

There are specific interventions that a nurse may do to help prevent anxiety disorders from occurring or to

lessen their impact on children. Simply paying attention to any signs of anxiety (SAMSHA, n.d.) is the first step in recognizing clinically significant symptoms. The nurse should refer a child to a mental health professional if the child's anxiety interferes with normal functioning or if it persists regardless of attempts to reassure the child. The nurse can provide health teaching related to what makes the child anxious or worried and how to cope with such worries. Teaching may involve teaching relaxation and deep breathing as well as problem-solving techniques (Tomb & Hunter, 2004). Young people are more likely to respond to someone who takes the time to listen and care.

Current Western culture is filled with scary images, whether in the form of games, movies, television, or actual events in the news. It is important for the nurse to understand and to help parents think about how and when to protect children from the influx of information that might be overwhelming.

There are several evidence-based therapies provided by qualified advanced practice clinicians. The pediatric nurse can be aware of some of these therapies in order to assist parents in finding a referral. The Coping Cat program is designed for children ages 7 to 13 with anxiety disorders and the CAT program is for adolescents (Kendall, Aschenbrand, & Hudson, 2003). Both of these cognitive-behavioral programs are designed to help the child develop skills to cope with anxiety, as well as techniques to decrease fears through systematic exposure to the feared object. These programs are intended to be used with children and adolescents who have SAD, GAD, and social phobia.

The FRIENDS program was designed for the parents as well as their children with anxiety disorders (Barrett & Shortt, 2003). It is similar to the Coping Cat in that it uses cognitive-behavioral techniques to help children and their families cope with anxiety. FRIENDS is an acronym for **F**eeling worried? **R**elax and feel good. **I**nnner thoughts. **E**xplore plans. **N**ice work so reward yourself. **D**on't forget to practice. **S**tay calm, you know how to cope. This program has proved to be useful in reducing the risk of development of anxiety disorders in children (Barrett, Farrell, Ollendick, & Dadds, 2006), but has proven less useful when used to prevent depression (Spence & Shortt, 2007).

Complementary Care: Mindful breathing

Mindfulness means paying attention in the present moment. Paying attention to one's breathing may be a way of coping with anxiety. The teaching works best before an anxiety episode.

The nurse teaches slow breathing by telling the child to (Fig. 23-2):

- Consciously direct your attention to your breathing.
- Breathe in slowly, paying attention as the air enters nose and mouth and filling your lungs.
- Breathe out slowly, paying attention as the air leaves your body.
- Allow your mind to follow the breath in and out.
- Imagine yourself in a rubber raft riding the gentle waves of your breath.

Figure 23-2 The nurse teaches the child how to reduce anxiety with slow breathing.

POSTTRAUMATIC STRESS DISORDER

Posttraumatic stress disorder (PTSD) is an anxiety disorder that occurs in response to a real or perceived trauma or threat to one's life or safety. PTSD in young children has been the subject of great debate at professional meetings because not all children who have endured trauma present with a neat and simple set of symptoms (Scheeringa, 2006).

It is known that the types of events that are experienced by young children as traumatic are similar to those of older children, adolescents, adults, and elderly (e.g., automobile crashes, natural disasters, war, witnessing brutal deaths) (Scheeringa, 2006). Other types of trauma, like physical or sexual abuse, or witnessing of domestic violence can be devastating for the child and can cause PTSD that persists even into adulthood if not treated.

Children who endure trauma often exhibit additional symptomatology to that of PTSD and frequently may suffer from comorbid disorders such as depression, conduct disorders, and other anxiety disorders as well as physical disorders. While the current DSM-IV-TR (APA, 2000) criteria are not developmentally sensitive for young children, they are used by most clinicians to help develop a diagnosis. Many children do not experience all of the criteria required to meet the DSM diagnosis, but children can still suffer greatly with the anxiety resulting from the original trauma.

Nursing Insight— *Posttraumatic stress disorder in adolescence*

Adolescence is a time of experimentation and of a sense of invincibility. For those reasons, adolescents may be more likely to be in a position to experience traumatic events, thus being exposed to the possibility of PTSD. In a survey of American adolescents, researchers found that 23% had been both a victim and witness a traumatic event (i.e., assault) and more than 20% had symptoms that met criteria for PTSD (Commission on Adolescent Anxiety Disorders, 2005).

Signs and Symptoms

After a trauma, a child with PTSD exhibits symptoms within each of the following sets of reactions:

- Re-experiencing the trauma, perhaps in the form of a flashback (intense “remembering” of the event while feeling as if it were happening at the present moment), nightmares, or sensations.
- Avoidance of anything that could trigger the memories, through dissociation (a sense of being detached emotionally, mentally, and perhaps even physically) or avoiding places or events reminiscent of the trauma.
- Physiological symptoms of anxious arousal (insomnia, startle response, sense of panic) (Commission on Adolescent Anxiety Disorders, 2005).

The hallmark symptoms of PTSD in children are nightmares, flashbacks, dissociative experiences, psychological and/or physiological distress at reminders of the traumatic event, irritability, anger, hypervigilance, new fears and anxieties and many other symptoms that may interfere with adjustment and daily functioning (Scheeringa, 2006).

Diagnosis

A complete history reveals a traumatic event(s) that may help diagnosis PTSD. Diagnosis is based on the symptoms and reaction(s) to the event.

Nursing Care

Many children who endure posttraumatic distress may not be brought into a health care facility for clinical intervention. A significant number of seriously traumatized children enter treatment through the court system after having experienced abuse or serious loss within the family of origin (Osofsky, 2004). The nurse may come in contact with these children in primary care or in school or other settings.

In the community, the nurse can be instrumental in educating parents about the symptoms and helping the family and child by making referrals for appropriate services. The nurse can reinforce that it is important to provide a secure base for the child, one that includes family or caregiver's willingness to be available to and comfort the child without judgment.

Be aware of resources available that might provide play therapy for young children and their parents (Van Horn & Lieberman, 2006) or cognitive behavioral therapies (CBTs) for older children. The nurse can also teach the family that pharmacotherapy with selective serotonin reuptake inhibitors (SSRIs) has also been known to be effective in adolescents (Commission on Adolescent Anxiety Disorders, 2005).

Implementing nursing care similar to that given with any anxious child may help to allay fears. During an acute panic episode when the child is re-experiencing the triggering event or feels completely out of control, the nurse must remain with him, talk soothingly, and reassure the child that the nurse is providing personal safety.

Mood Disorders

Similar to adult psychiatric disorders, pediatric mood disorders may take the form of major depression (serious, time-limited depression), dysthymic disorder (longer-term, less

intense depression), or bipolar disorder (consisting of mood swings between depression and mania). These disorders are sometimes more difficult to diagnose in children and adolescents than in adults because of developmental phases and the lack of language and cognitive skills to describe symptoms and experiences. Health care providers may also not have adequate knowledge about prior symptoms.

DEPRESSION

Infants born of mothers who have been significantly depressed or stressed during pregnancy can exhibit depressive symptoms (listlessness, failure to attach, irritability) (Commission on Adolescent Depression & Bipolar Disorder, 2005). Likewise, infants who are unable to attach securely or who are listless or irritable may be difficult for the mother to care for and show attachment. This behavior can perpetuate disengaged attachment and depression in the infant. Some studies have indicated that children as young as 3 years old are capable of experiencing depressive disorders (Luby et al., 2003, 2006). These depressions may be related to environmental factors combined with genetic and biological factors.

Depressive symptoms are estimated to occur in 10% to 15% of children and adolescents. Untreated depression in a young person often increases the likelihood of recurrent depression or bipolar illness later in life. For this reason it is important to recognize and treat depression early on (SAMHSA, n.d.).

Signs and Symptoms

Five key features must be present and persistent for most days during a period of 2 weeks for the diagnosis of a major depressive disorder in children and adolescents. The nurse must remember that children can have just a few of these depressive symptoms that will interfere with optimal functioning. This list of symptoms was compiled based on several diagnostic classification publications to reflect a developmentally sensitive criterion (APA, 2000; Greenspan, 2005; Zero to Three, 2005b):

- Persistent sad or irritable mood—by subjective report (e.g., sad or empty) or observed by others (e.g., appears tearful). This mood is different from the child's baseline emotional and behavioral state, and is unrelated to events that may cause temporary distress or sadness (e.g., getting a time-out).
- Loss of interest in activities once enjoyed (anhedonia)—reported by child or observed by others.
- Significant change in appetite or body weight—weight loss or gain reflected by more than a 5% change in body weight.
- Difficulty sleeping or oversleeping—insomnia or hypersomnia (excessive sleep).
- Physical agitation or slowing—observed by others and the child's subjective report of being restless or “slowed down.”
- Fatigue or loss of energy.
- Feelings of worthlessness or excessive/inappropriate guilt.
- Decreased ability to think or concentrate or to make decisions as self-reported or observed by others, and in younger children this sign may appear as difficulty

in solving problems, responding to caregivers or sustaining attention. An example is a drop in grades and/or school performance.

- Recurrent thoughts of death or suicide with or without a suicide plan, and in younger children consistent engagement in activities or play that involve themes of death and suicide.

Depression in infants may include:

- Listlessness without physical cause
- Failure to respond to caregiver

The nurse understands that symptoms in the infant and very young child mirror the symptoms of attachment disorders and failure to thrive.

Diagnosis

Diagnosis is based on the exhibited depressive symptoms.

Nursing Care

The most important aspect of helping a depressed child is to ensure safety. It is recommended that any nurse working with a child who is depressed understand how to deal with the potential suicide ideation or intent.

Since depression often goes unrecognized in children or adolescents, the nurse can be instrumental in determining its presence. Pediatric and school nurses are in a position to observe changes in a child's behavior and demeanor as well as grades. Developing a trusting relationship with a child and asking about feelings or thoughts may provide evidence of underlying depression and provide the child with a first step in feeling better. Nurses should talk with the parent(s) or caregiver(s) of a child about suspected depression and suggest referral to a counselor for evaluation and treatment.

BIPOLAR DISORDER

Bipolar disorder (BPD), also known as manic–depression, is a mood disorder that is evidenced by significant mood swings (from depression to mania). It is thought that childhood or adolescent onset bipolar disorder may have an extended early course and may respond less

medication: Somatic Therapies for Depression

Serotonin Selective Reuptake Inhibitors (SSRIs):

Open-label studies suggest that fluoxetine (Prozac) is an effective medication in the treatment of pediatric major depression and dysthymia in patients with and without co-occurring mental health disorders (Findling, Feeny, Stansbrey, Delorto-Bedoya, & Demeter, 2001). This type of medication has been used in children as young as 8 years old (National Institute of Mental Health [NIMH], 2001). Other SSRIs are used off-label (meaning use other than specifically approved for by the Food & Drug Administration [FDA]) such as sertraline (Zoloft), paroxetine (Paxil), citalopram (Celexa), escitalopram (Lexipro), or fluvoxamine (Luvox) have also been prescribed by some clinicians (NIMH, 2001).

NOTE: Recent evidence that SSRIs can contribute to suicide ideation in adolescents and children have left many parents and physicians leery of using this medication to treat depression in young people.

Nursing Care Plan Depressed Child

Nursing Diagnosis: Self-Esteem: Situational Low related to cognitive and perceptual distortions

Measurable Short-term Goal: Child will use positive talk to interrupt negative thinking about self.

Measurable Long-term Goal: Child will demonstrate increased self-esteem by accepting positive feedback from others

NOC Outcome:

Self-Esteem (1205) Personal judgment of self-worth

NIC Interventions:

Self-Esteem Enhancement (5400)

Active Listening (4920)

Nursing Interventions:

1. Listen actively to child, displaying interest without judgment or responding too quickly.
RATIONALE: Active listening shows attention to the message and respect for the child's thinking and perceptions.
2. Monitor and help the child to identify statements reflecting perceived self-worth.
RATIONALE: Provides information about distorted or negative perceptions.
3. Assist the child to examine perceptions of self reflected in negative "self-talk" and turn these into positive statements of self-worth.
RATIONALE: Allows replacement of negative self-evaluations with positive statements that enhance self-esteem.
4. Encourage the child to identify personal strengths and accept valid positive responses from others.
RATIONALE: Helps the child develop positive self-esteem.
5. Assist child to set realistic goals to enhance self-esteem, providing appropriate praise or rewards for progress.
RATIONALE: Positive reinforcement supports progress in meeting realistic personal goals.

favorably to treatment. Children and adolescents with bipolar disorder may have coexisting mental health disorders as well (e.g., attention-deficit/hyperactivity disorder, oppositional defiant disorder, conduct disorder, anxiety disorder, and substance abuse) (Kowatch et al., 2005).

There are three recognized types of bipolar disorder. Bipolar disorder I (BD-I) is defined by the presence of depressive and manic episodes. Bipolar disorder II (BD-II) is characterized by episodes of hypomania (a lesser degree of mania) and depression. Bipolar disorder not otherwise specified (BD-NOS) is commonly the diagnosis given to children when the DSM-IV-TR (APA, 2000) criteria for BD-I and II are not specifically met but who show symptoms of bipolar illness.

There are little definitive data related to incidence of BD-I since many of the studies done to date have not used standardized criteria to explain the onset of symptoms. The overall lifetime pervasiveness of BD beginning between 15 and 17 is 1.3%. Typically the disorder is diagnosed in early adulthood. While BD was originally thought to be relatively rare in children, more research efforts are aimed at identifying and understanding this disorder.

Signs and Symptoms

Since BPD is a combination of major depression and mania, the nurse must be aware of symptoms associated with BPD. Both manic and depressive symptoms, as described by the National Institute of Mental Health (2000) are listed.

Nursing Insight—Bipolar disorder

Mania

Severe changes in mood—either extremely irritable or overly silly and elated
Overly inflated self-esteem; grandiosity
Increased energy
Decreased need for sleep—able to go with very little or no sleep for days without tiring
Increased talking—talks too much, too fast; changes topics too quickly; cannot be interrupted
Distractibility—attention moves constantly from one thing to the next
Hypersexuality—increased sexual thoughts, feelings, or behaviors; use of explicit sexual language
Increased goal-directed activity or physical agitation
Disregard of risk—excessive involvement in risky behaviors or activities

Depression

Persistent sad or irritable mood
Loss of interest in activities once enjoyed
Significant change in appetite or body weight
Difficulty sleeping or oversleeping
Physical agitation or slowing
Loss of energy
Feelings of worthlessness or inappropriate guilt
Difficulty concentrating
Recurrent thoughts of death or suicide

Source: NIMH (2000). *Child & adolescent bipolar disorder: An update from the National Institute of Mental Health.* (NIH Publication Number: 00-4778). Retrieved from <http://www.nimh.nih.gov/publication/index.cfm>

Although young children do not have distinct episodes of mania, children may have severe mood dysregulation with multiple, intense, prolonged mood swings each day (Kowatch et al., 2005). Also, children are more likely to display irritability or destructiveness than adults who display euphoria.

Diagnosis

Diagnosis is based on a thorough history and physical as well as the identification of the significant mood swings (from depression to mania). Often family members or significant others can describe the behavior that may help lead to a diagnosis.

Nursing Care

It is important for the nurse to recognize that if a child is in an acutely manic state, the child is struggling against an internal force and is not being a “bad child.” The nurse can teach the family and the child, as well as model the following therapeutic parenting techniques presented by the Child and Adolescent Bipolar Foundation (CABF, 2008):

- Practice and teach relaxation techniques
- Use firm restraint holds to control rages
- Prioritize battles and let go of less important matters
- Reduce stress in the home
- Use good listening and communication skills
- Use music and sound, lighting, water, and massage to assist the child with waking, falling asleep, and relaxation
- Become an advocate for stress reduction and other accommodations at school
- Help the child anticipate and avoid, or prepare for stressful situations by developing coping strategies beforehand
- Engage the child’s creativity through activities that express and channel gifts and strengths
- Provide routines, structure and freedom within limits
- Remove objects from the home (or lock them in a safe place) that could be used to harm self or others during a rage, especially guns
- Keep medications in a locked cabinet or box

It is also important to note that a person should be present to care for a child experiencing a depressed phase of bipolar disorder. Just in case the diagnosis of bipolar disorder is missed, and an antidepressant is prescribed, the nurse understands that an antidepressant could trigger mania. It is important to fully assess history of symptoms and to teach the family what to watch for in terms of the child’s reaction to the medication(s). The

nurse can have the family visit the following Web site for more information about bipolar disorder: <http://www.bpkids.org>, a parent-led organization that provides supportive information for children, caregivers, and families.

Now Can You—Differentiate between depression and bipolar disorder?

1. Describe the signs and symptoms of depression and bipolar disorder?
2. Describe nursing care for the child with depression or bipolar disorder?

SUICIDE

Suicide represents a devastating consequence resulting from any number of psychiatric difficulties. What was relatively rare before the mid-1950s has now become an alarmingly frequent occurrence. Barrio (2007) summarized potential factors that might influence a child or adolescent to consider or attempt suicide: (1) certain psychiatric disorders that may be related to a sense of helplessness (depression, substance abuse, anxiety disorders, or aggressive disorders); (2) a history of family or friend having attempted or actually committed suicide; (3) personal or familial biological factors (related to depression and/or impulsivity); (4) environmental factors, such as accessibility of a means (guns, poison, etc.), or lack of connection or supervision; previous suicide attempts; and/or (5) disenfranchised status (sexual orientation, minority status).

According to the National Center for Health Statistics, suicide is the third leading cause of death in young people 10 to 24 years of age, which in 2004 translated into the following statistics: 1.3 children (ages 10 to 14) per 100,000, 8.2 adolescents (ages 15 to 19) per 100,000, and 12.5 young adults (ages 20 to 24) per 100,000. Younger children more often resorted to suffocation as a method to kill themselves while older children tended to use firearms or poison. There were gender differences that identified males as four times more likely in their adolescents and six times more likely in early adulthood to succeed at suicide than females (Centers for Disease Control and Prevention [CDC], n.d.). This difference may be due to the choice of method (males tend to chose more lethal means).

Signs and Symptoms

The nurse should suspect suicide potential when faced with any of the following in the child or adolescent:

- Symptoms of depression or other mental illness
- Alienation or withdrawal from friendships or relationships
- Personality changes
- Decline in schoolwork
- Giving away personal possessions that were once prized
- Preoccupation with death in writing or drawings
- References to dying or no longer being around
- Access to a method of suicide (e.g., medications, weapons)

medication: Valproate (Depakote)

The nurse needs to be aware that most medications used for the treatment of bipolar disorder have not been studied specifically with children. Lithium carbonate (Eskalith, Lithobid) has been the most common treatment. It is a mood stabilizer that calms the manic symptoms.

Diagnosis

Nursing Insight— Assessing the child for suicide risk

If the nurse is concerned that a child or adolescent might be suicidal, the nurse must ask the child about suicidal thoughts or behaviors. This information may help to save the child's life.

- “Have you thought about doing something to hurt yourself or take your life?”
- “Do you ever wish you were not alive?”
- “What would you do if you were to hurt yourself?”

When a child or adolescent gives information that indicates risk for suicidal behavior, the nurse must take steps to keep the child or adolescent safe and make a referral for immediate mental health evaluation.

Nursing Care

The school nurse is in a position to recognize children or adolescents who might be suicidal. This care involves awareness of the signs of suicide ideation and the risk factors that may precede suicide ideation. The nurse must ask about suicide ideation. The nurse can discern: Does the child have a plan? Is that plan possible (i.e., is the means to self-harm accessible)? Has the child attempted suicide before? Foremost, if any of these factors are present, the nurse must refer the child (and family) to a mental health professional that can assess the level of risk. The child or adolescent may need immediate hospitalization to remain safe.

If danger is not imminent, the nurse can assist the child or adolescent and the family in identifying and further developing the protective factors available to them. The nurse can identify family strengths and resources available in the community (crisis or suicide hot lines, counseling, inpatient treatment facilities) to help protect the child. The nurse can also talk with the family about other measures that can be implemented to keep their child safe (e.g., remove all guns or other weapons from the home, ridding cupboards of poisons, locking medicines away, monitor the child closely).

Specific psychotherapeutic approaches like cognitive behavior therapy (CBT) or dialectical behavior therapy (DBT) focuses on helping the child and adolescent develop skills for coping with emotional intensity and impulsivity (Katz, Cox, Gunasekara, & Miller, 2004). Both types of therapy are performed by specifically educated clinicians, but the nurse, particularly in the hospital, can be supportive. Pharmacological treatments include medications to treat the underlying psychiatric difficulty (Table 23-1).

In the community, the nurse can raise awareness about the programs that seek to prevent suicidal behavior in adolescents. There are some school-based programs that target students who are at-risk for dropping out of school and assist the child or adolescent to remain involved in school. Once a child or adolescent has dropped out of school, economic and social changes also might play a role in suicidal thoughts. In addition, the child or adolescent may be more susceptible to feelings of hopelessness and isolation.

clinical alert

Suicidal behavior related to antidepressant therapy

In 2006, the Food and Drug Administration (FDA) requested that pharmaceutical companies manufacturing SSRIs add a “black box” warning to the packaging. This warning is related to an apparent rise in suicide in children and adolescents recently prescribed an SSRI for depression. Subsequent studies discussed by Goodman, Murphy, & Storch (2007) related that the increased incidence of suicide ideation and attempt was not universal, nor was it related only to those diagnosed with depression, but also in children taking SSRIs for other disorders. The evidence is controversial because other studies have shown antidepressants to be very effective in decreasing the suicide risk by effectively dealing with the underlying causes. Several factors have been proposed to explain the occurrence of suicidal ideation in children treated with these medications. (1) The prescription may be an inadequate dose and therefore the depression is not treated. (2) An energizing phenomenon, which describes a situation in which the depressive symptoms related to energy decrease before the mood symptoms, may occur, thus making it more possible for the depressed individual to have the energy to attempt suicide. (3) The emergence of an activation syndrome may be related to a toxic reaction to the medication. (4) Motor restlessness related to akathisia (motor restlessness that may appear as a side effect of antipsychotic medication) may occur. (5) A shift from depression to mania in a not-yet-diagnosed bipolar child may occur. (6) Idiosyncratic reactions (perhaps related to gene-drug reactions) may occur (Goodman et al., 2007).

SCHIZOPHRENIA

Schizophrenia is a serious chronic mental health disorder that is thought to be the result of abnormalities in neurodevelopmental processes that occur early (prenatal, infancy, early childhood) as well as later (late childhood and adolescence) in life (Bearden, Meyer, Loewy, Nien-dam, & Cannon, 2006). The disorder typically begins in late adolescence or early adulthood, but it is possible for children as young as 5 or 6 to exhibit signs. Researchers have found that the age at onset of schizophrenia plays an important role in the course and outcome of illness. The earlier the onset of symptoms occur, the greater the impairment (Bearden et al., 2006). Although schizophrenia is a chronic mental illness, early recognition and treatment can vastly improve the outcome for the child. Untreated, schizophrenia can be devastating for the individual and the family.

Schizophrenia is rarer in children younger than pre-adolescence. About 1% of the world's population (adult, adolescent, and child) is identified with a diagnosis of schizophrenia (Nicholson & Rapoport, 1999, cited in NIMH, 2001). Further complicating the diagnosis is that early symptoms are similar to those of pervasive developmental disorders such as autism. In some cases, it is thought that a pervasive developmental disorder is a precursor of schizophrenia.

Signs and Symptoms

The nurse knows that discerning the signs and symptoms of schizophrenia begins with a mental health interview that includes a comprehensive developmental and family history. Schizophrenia typically has a gradual onset, is difficult to identify in young children, and may

Table 23-1 Pharmacological Treatments for Psychological Difficulties		
Category	Medications	Uses
Antianxiety	Beta blockers	Anxiety
	Propranolol (Inderal)	
	Alpha blockers	
	Clonidine (Catapres)	
Antidepressants	Selective serotonin uptake inhibitors (SSRIs)	Depression
	Fluoxetine (Prozac)	Anxiety
	Sertraline (Zoloft)	OCD
	Paroxetine (Paxil)	Elective mutism
	Citalopram (Celexa)	
	Escitalopram (Lexapro)	
	Fluvoxamine (Luvox)	
	Tricyclics	Enuresis
	Imipramine (Tofranil)	Autism
	Clomipramine (Anafranil)	
	Other	
Bupropion (Wellbutrin)		
Venlafaxine		
Mood Stabilizer	Lithium carbonate	Bipolar disorder
	(Lithobid, Lithane, or Eskalith)	Mania
		ODD
		ADHD
Anticonvulsants	Valproate (Depakote)	Bipolar disorder
		Mania
Antipsychotics	Traditional	Autism
	Haloperidol (Haldol)	Psychosis
	Atypical	Tourette’s syndrome
	Risperidone (Risperdal)	Behavioral problems related to other psychiatric disorders (conduct disorder, ADHD, MR)
	Olanzapine (Zyprexa)	
	Quetiapine (Seroquel)	
	Ziprasidone (Geodon)	
Aripiprazole (Abilify)		
Stimulants	Methylphenidate (Ritalin and Concerta)	ADHD
	Dextroamphetamine (Dexedrine and Adderall)	
Nonstimulants	Atomoxetine (Strattera)	ADHD

be indistinguishable from other disorders. The nurse understands that it is important to recognize early signs and symptoms and begin treatment as early as possible (Commission on Adolescent Schizophrenia, 2005).

There are two types of symptoms in the presentation of schizophrenia. Positive symptoms are those that are generally seen after observing and listening to the parent or the child. These symptoms include hallucinations (hearing voices, seeing things, experiencing strange sensations), delusions (false beliefs, i.e., beliefs that the radio is sending special messages), and disorganized speech and behavior (APA, 2000). Negative symptoms are less obvious. These symptoms include a decrease or “flattening” of affect (visible expression of mood), speech, and motivation (APA, 2000).

Diagnosis

A diagnosis of schizophrenia is based on a mental health interview that includes a comprehensive developmental and family history. If the child has had a gradual onset of the signs and symptoms this condition may be suspected. Before the actual evidence of diagnostic symptoms there is often a prodromal (period marked by a shifting in personality) and the emergence of “odd” behaviors (i.e., withdrawal, obsessions, aloofness), thoughts (distractibility), or emotions (lability, anxiety).

Diagnosis may be confirmed by the presence of initial and subsequent psychoses such as hallucinations, delusions, disorganized thinking and speech, lack of motivation and interest in life, and aberrant emotional expressions (Bearden et al., 2006).

Nursing Care

Early treatment for schizophrenia usually involves pharmacological agents (e.g., atypical antipsychotics), adolescent and family psychoeducation, and brief psychotherapy aimed at increasing level of functioning. Treatment is usually divided into the acute and maintenance phase. To obtain the best outcome, the adolescent and family should always stay in treatment (Commission on Adolescent Schizophrenia, 2005). Acute treatment for active psychosis (hallucinations, delusions, fearfulness, acting out) consists of maintaining the safety of the child and others. It is frightening to lose sight of reality. The child may act out against misperceived threats and injure self or others. The majority of treatment at this point is pharmacological adjustment. The nurse uses therapeutic communication to convey a sense of security to the child and family. It is also important to approach the child in a calm and reassuring manner. If the symptoms are severe the child may be hospitalized.

The schizophrenic child will always need to take medications to control symptoms. Pharmacological treatment involves the use of antipsychotic medications such as Risperidone (Risperdal), Olanzapine (Zyprexa), and quetiapine fumarate (Seroquel). Other forms of care for the child include group training in social skill acquisition (as most schizophrenic children have inadequate social skills) and cognitive behavioral therapy (CBT). Nursing care also includes educating the child and family about the importance of taking the medications and related side effects. Families of children with schizophrenia, like those with any chronic difficult illness, may need ongoing support. There are organizations that offer support and advocacy for families of the mentally ill. One such

organization is the National Alliance for the Mentally Ill (NAMI; www.nami.org) that provides parents and families with important information. The nurse is in an ideal position to help identify children and adolescents with early prodromal signs and refer for further evaluation, family psychoeducation, and other interventions such as understanding the importance of medication.

AUTISM SPECTRUM DISORDERS

Autism spectrum disorder (ASD) can be first diagnosed in infancy or childhood. The DSM-IV-TR defines autism spectrum disorder as a continuum of disorders that involve limitations in social relatedness, verbal and nonverbal communication, and the range of interests and behaviors (APA, 2000). There are five specific autism spectrum diagnoses. Pervasive developmental disorder (PDD) is the term used by DSM-IV-TR and is synonymous with autism spectrum disorders. The five pervasive developmental disorders include autistic disorder (serious deficits in the development of social and communication skills accompanied by significant repetitive behaviors), Asperger's disorder (a milder form of autistic disorder), Rett's disorder (a rare disorder that predominantly affects girls; development is normal until around 6 to 18 months when autistic symptoms appear), childhood disintegrative disorder (a rare disorder in which the child usually develops normally until age 2 before developing symptoms of autism; predominantly affects boys), and pervasive developmental disorder not otherwise specified (a disorder in which either autism or Asperger's is suspected but the diagnostic criteria are not fully met) (APA, 2000; Ozonoff, Rogers, & Hendren, 2003).

Signs and Symptoms

Three clusters of symptoms characterize autism spectrum disorder (ASD). The first symptom cluster involves qualitative impairment in social reciprocity which means the child is unable to engage in socially appropriate communication. This impairment is marked by poor eye contact, lack of interest in other people, and failure to interact appropriately with others.

The second symptom cluster is characterized by communication impairment. The child either uses no language at all, or exhibits deviant speech with errors in tone, prosody, pitch, grammar, or pragmatics. Errors in pragmatics, such as difficulty taking turns in conversation, are particularly common in higher functioning individuals.

Restrictive and repetitive behaviors, interests, or activities characterize the third symptom cluster. Specifically, restrictive interests are narrow in focus, overly intense, and/or unusual. An example might include experiencing sensory qualities of objects in unusual ways (e.g., sniffing objects or playing with toys in unusual ways). Another example of unusual interests would be a preoccupation with the parts of a toy rather than enjoying the toy. Restrictive behavior is characterized by unreasonable insistence on sameness or following familiar routines in a very rigid or extreme way.

Repetitive behavior is a common symptom that is displayed by children with autism spectrum disorder through repetitive motor mannerisms such as hand flapping or spinning or rocking, these movements are called stereotypies or tics (sudden uncontrollable movement or vocalization).

Nursing Insight— Autism spectrum disorders

The reported number of children with autism spectrum disorders has increased since the early 1990s. Whether there is a true increase in prevalence or whether past rates were underreported is a matter of debate. The factors involved in understanding the potential increase in prevalence include that the true prevalence rates 10 or 20 years ago are difficult to ascertain retrospectively; changes in diagnostic criteria, e.g., the concept of autism is now viewed as a spectrum of disorders; a heightened public awareness of autism; and increased media coverage of affected children and families. Also relevant is that in 1991, the US Department of Education added autism as a category for special education services. It is speculated that this change led to increases in the number of children classified as autistic, because a diagnosis would allow children to take part in available educational services (Yeargin-Allsopp et al., 2003). The CDC estimates that 1 in 166 children are diagnosed with an autism spectrum disorder (CDC, 2004).

critical nursing action Understanding Autism Spectrum Disorder

The “First Signs” program uses the acronym Autism A.L.A.R.M. to highlight important clinical guidelines:

Autism is prevalent (Wiseman, 2006):

- 1 out of 6 children are diagnosed with a developmental disorder and/or behavioral problem.
- 1 in 166 children are diagnosed with an autism spectrum disorder.
- Developmental disorders have subtle signs and may be easily missed.

Listen to patients:

- Early signs of autism are often present before 18 months.
- Parents usually do have concerns that something is wrong.
- Parents generally do give accurate and quality information.
- When parents do not spontaneously raise concern, ask if they have any concerns.

Act early:

- Make screening and surveillance an important part of your practice (as endorsed by the AAP).
- Know the subtle differences between typical and atypical development.
- Learn to recognize red flags.
- Improve the quality of life for children and their families through early and appropriate intervention.

Refer:

- To Early Intervention or a local school program (do not wait for a diagnosis).
- To an autism specialist, or team of specialists, immediately for a definitive diagnosis.
- To audiology and rule out a hearing impairment.
- To local community resources for help and family support.

Monitor:

- Schedule a follow-up appointment to discuss concerns more thoroughly.
- Look for other features known to be associated with autism.
- Educate parents and provide them with up-to-date information.
- Advocate for families with local early intervention programs, schools, respite care agencies, and insurance companies.
- Continue surveillance and watch for additional or late signs of autism and/or other developmental disorders.

Diagnosis

In 2003, a partnership between the American Pediatric Association and the Center for Disease Control created a program called First Signs. This widely disseminated public awareness campaign was designed to increase pediatric primary care provider and parental awareness about the signs and symptoms of autism. Based on this awareness, a thorough developmental history can be conducted that can lead to an early diagnosis.

Nursing Care

Nurses who work in primary care settings can provide care for children with autism. Awareness of the need for early intervention is important because of the substantial cortical plasticity (the ability of tissues to grow during early brain development). There are many successful non-medical treatments for children with autism. One of the most important interventions involves early language development. Ozonoff et al. noted that “language functioning is the strongest predictor of outcome in autism and very limited language at age five is a powerful indicator of severe handicap in adulthood” (2003, p. 134). Poor functional communication skills also contribute significantly to the problematic behaviors that some autistic children display (e.g., poor frustration tolerance and aggression toward self or others). Equally important are interventions that address social competence. The nurse can teach parents that social skills training and acquisition groups provide the child with an opportunity to learn and practice appropriate social relatedness.

Using the actions suggested in the mnemonic A.L.A.R.M., the nurse can assist the child and family in coping with this disorder. Children with autistic spectrum disorders respond best to structure and predictability. Learning and social interactions should be approached systematically and gradually, allowing the child to develop comfort with the concepts (Wiseman, 2006). As with the schizophrenic child, it is important to stay aware of the child’s physical boundaries and reluctance to be touched by others.

Psychosocial and Cognitive Disorders

REACTIVE ATTACHMENT DISORDER

Reactive attachment disorder (RAD) mirrors the information on attachment theory. It is important to note that developmental research in attachment is vast and growing but that clinical research regarding attachment disorders is just beginning to emerge and there is much yet to be learned about assessment, prevention, and treatment (Stafford & Zeanah, 2006). There are few if any statistics citing the incidence of RAD. It is reportedly a rare disorder (APA, 2000). Adoptive and foster parents are most frequently faced with attachment difficulties in children placed after the first 11 months of life.

There are two types of RAD: emotionally withdrawn/inhibited and indiscriminately social/disinhibited. The inhibited RAD children usually lack the ability to seek and accept comfort, and to respond to or show affection. These children may have problems with emotion regulation evidenced by withdrawal, avoidance, and “frozen watchfulness” (APA, 2000).

The disinhibited RAD children usually show more ability to interact with caregivers but seek comfort and affection from strangers indiscriminately (APA, 2000). This describes the child who arbitrarily wanders off with any stranger, not even thinking to turn back to ensure that the caregiver is near.

Nursing Insight— Understanding reactive attachment disorder

The nurse must first understand how the attachment system works. Basically, the goal of the attachment system is designed “to ensure survival of offspring by promoting mutual proximity of infants and caregivers, thereby providing protection from danger” (Stafford & Zeanah, 2006, p. 231). Another role of the attachment system is to help with regulation of developing emotion in the infant and child (Stafford & Zeanah, 2006). The attachment system works in conjunction with other systems that include affiliate, exploratory, and wariness (temperament) systems.

Signs and Symptoms

Infants and children diagnosed with attachment disorders have usually endured neglect or maltreatment or have experienced severe trauma. Many of these children have been institutionalized during the first year of life when the ability to connect with another is forming. The main sign/symptom is children who experience difficulties attaching or bonding (even to a parent).

Diagnosis

There are currently no established tools to use to make a diagnosis of RAD, but a thorough clinical interview and observation is essential in identifying behaviors that suggest a diagnosis of attachment disorder (Stafford & Zeanah, 2006). Infants typically exhibit attachment patterns around 9 to 12 months of age. The pediatric nurse can aid in the diagnostic process by observing how the child interacts around parents and strangers.

The medical diagnosis of RAD as per DSM-IV-TR (APA, 2000) requires that marked disturbances and developmentally inappropriate social relatedness symptoms start before the age of 5 and must be evident in most situations.

Nursing Care

Since attachment disorders in infants and children result from the lack of opportunity to experience a caring relationship, this opportunity should be offered as a first step

where research and practice meet: Patterns of Attachment

Through the Strange Situation procedure (Ainsworth, Blehar, Waters, & Wall, 1978) researchers are able to assess the infant's or children organizational patterns of attachment during low- and high-stress episodes involving a caregiver. The patterns are divided into three categories of strategies: secure organized, insecure organized (avoidant, resistant, dependent), and insecure not organized (disorganized, controlling, defended/coercive, unclassified) (Stafford & Zeanah, 2006).

in treatment. Developing trust through meeting the child's basic needs or responding to cries or tantrums or listlessness with patience and consistency is exceptionally important. A child with RAD has no true concept about which basic needs will be met.

When a caring person is available to the infant or child that person should receive support and education from professionals. Nurses can work with all types of families such as foster care families, families with children adopted from institutions, and children in other situations to help the family with RAD. It is important to let the families know that while the children need loving and nurturing, they may rebuff the care that is offered. Nurses can also identify barriers to intervention that might include parental mental health needs, substance abuse, family violence, and trauma. They can then mobilize the appropriate resources to involve children and families into recovery. Child–parent psychotherapy is a respected intervention that should be considered and nurses can connect families with these services (Van Horn & Lieberman, 2006).

clinical alert

Dangerous “attachment therapies”

Nurses should know that there is a group of therapies to avoid for children with attachment disorders because of coercive techniques employed, and in fact these therapies have been dangerous as there have been child deaths related to treatment. These therapies are usually known as “attachment therapy,” “holding therapy,” “rage reduction,” and “rebirth” (Barth, Crea, John, Thoburn, & Quinton, 2005; Stafford & Zeanah, 2006).

FAILURE TO THRIVE

Failure to thrive (FTT) is not a diagnosis but a description of a condition that usually happens early in life when the infant does not meet age-appropriate weight gain (Locklin, 2005). It is known that FTT infants do not obtain or are unable to take in enough nutrition to adequately meet standard growth and weight expectations.

Certain situations from a mental health perspective are related to the development of FTT. Families in vulnerable situations (e.g., poverty, young and/or single parent, mentally ill or substance-abusing parents), or those in which child abuse or neglect exist, are at risk for FTT.

Bassali and Benjamin (2007) reported that in the 1980s, 1% to 5% of the admissions to tertiary care for children younger than 1 year were related to FTT and 10% of outpatient visits were related to FTT. This condition is more common in underdeveloped countries where poverty and hunger are more rampant. Poverty is by far the greatest determinant in FTT (Block & Krebs, 2006).

Signs and Symptoms

Assessment of the signs and symptoms of failure to thrive is accomplished by tracking the growth rate of the infant or child to determine if an actual lack of adequate progression exists. Physical examination and evaluation of the child's developmental status is also important, since lack of sufficient nutrition on an ongoing basis will affect the child's cognitive and emotional development. Beyond that, it is important to develop an understanding of the underlying cause(s).

Historically, health care providers distinguished FTT according to organic (medical conditions or illnesses that would affect the child's ability to take in or use nutrition) versus nonorganic (related to abuse, neglect, or attachment difficulties) classifications. In recent years, however, these distinctions have been less useful as many children with FTT exhibit symptoms of both causes (Block & Krebs, 2006). As a result, there is much less emphasis on attributing FTT to a problematic infant-caregiver relationship or maternal deprivation (Locklin, 2005). Still, psychosocial factors cannot be ruled out without assessing the family situation as well as potential physiological causes.

Diagnosis

Infants that have weights below the 3rd percentile or are two standard deviations below the mean for their gestational age on standardized growth charts are commonly diagnosed with FTT (Locklin, 2005) (Fig. 23-3).

Nursing Insight— Failure to thrive

During a nursing assessment the nurse can discern:

- How does the caretaker interact with the child?
- Are there signs of abuse or neglect?
- Does the caretaker understand appropriate feeding amounts and routines?
- Does the caretaker mistakenly believe that a healthy adult diet (i.e., lower fat) is also healthy for an infant?

Nursing Care

A comprehensive history and physical examination are vital in identifying the source of the problem and developing a plan of care. There are sometimes challenging cases of FTT that require specialized intervention by developmental pediatric or mental health care providers. Nurses can help identify these cases and provide education regarding feeding practices and the importance of support for caregivers and families. The nurse can also provide support and reassurance to new mothers and caregivers who are struggling with FTT infants and young children. While nursing care must address the physiological needs

Figure 23-3 Failure to thrive.

of the child, it must also encompass the emotional needs. If the nurse suspects neglect or abuse, steps must be taken to the appropriate child protection agency.

nursing diagnoses Failure to Thrive

- Imbalanced Nutrition: less than body requirements related to inability to ingest or digest food or absorb nutrients because of biological or psychological factors
- Delayed Growth and Development related to inadequate caretaking, environmental and stimulation deficiencies, or physical/psychosocial conditions
- Risk for Impaired Parenting related to unmet social and emotional needs of parental caregivers, ineffective role modeling, insufficient knowledge or crisis

ATTENTION-DEFICIT/HYPERACTIVITY DISORDER

Attention-deficit/hyperactivity disorder (ADHD) is familiar to parents, school teachers, and others who know the child. Images of the overactive, talkative child “bouncing off the walls,” and always in trouble are likely portrayed. ADHD is one of the most publicized and perhaps overdiagnosed psychiatric conditions of childhood. A child can have attention-deficit disorder with or without hyperactivity. The category of ADHD without hyperactivity typically has symptoms of distractibility. While ADHD without hyperactivity garners much less attention than ADHD with hyperactivity, it can cause just as much difficulty in the life of the child and the family.

The CDC indicated that a total of 4 million children between the ages of 3 and 17 have been diagnosed with ADHD. This comprises 6.5% of the children of the number of U.S. children born since the diagnosis of ADHD has been used.

Signs and Symptoms

Symptoms of ADHD may include hyperactivity, impulsivity, distractibility, and inattention. Although ADHD is most often diagnosed in early school-age children, symptoms can be seen in much younger children. Children with these symptoms often have difficulty with school performance as well as social and peer interaction. While poor school performance is usually the driving factor in seeking help for children with these symptoms, difficulty with peer groups and family relationships are just as evident. Many children with ADHD also have comorbid conditions such as depression, anxiety, oppositional defiant disorder, and learning disabilities.

Diagnosis

Evaluations for ADHD are conducted by advanced practice nurses, physicians, and other health care providers. For appropriate assessment of ADHD, the child must first meet the diagnostic criteria outlined in the DSM-IV-TR (APA, 2000) (Table 23-2).

When the criterion is met, the final diagnosis requires evidence of the child's behavior in a variety of settings, such as classroom, during homework, or playtime. Evidence is obtained by asking parents, teachers, and other caregivers to complete rating scales about behavior. Additional information needed includes the age at onset of symptoms, duration of symptoms, and degree of impaired functioning.

Table 23-2 Characteristics of Attention Deficit Hyperactivity Disorder

Developmentally inappropriate or maladaptive symptoms consisting of either inattentive symptoms (1st column), hyperactive or impulsive symptoms (2nd column), or a combination (both columns).

Inattention	Hyperactivity or Impulsivity
Distractibility	Excessive energy and activity
Inability to complete projects	Restlessness
Easily bored	Overactivity
Disorganized	Inability to sit still or stay in one place for long
Inattentiveness	Excessive talking
Avoidance of detailed tasks	Poor boundaries—interrupts or intrudes
Forgetfulness	Difficulty delaying

Nursing Care

The nurse understands that ADHD is evaluated by using a variety of rating scales. Specific rating scales are the DuPaul ADHD Rating Scale, the Connors Parent/Teacher Rating Scale and the Child Behavior Checklist (teacher, parent versions) (Achenbach, 2001; Achenbach & Rescorla, 2000) have been validated as useful in diagnosing ADHD. Each of these rating scales asks caregiver or teacher rate the child's behavior (e.g., behavior occurs extremely often, often, sometimes, rarely or never). A school nurse may be trained to perform observations of the child while in class to assist in the information gathering. These scales in combination with a clinical family interview provide the examiner with valuable information to determine a diagnosis. A thorough clinical interview with the child is also important in determining the appropriate diagnosis and treatment.

The most effective treatment for ADHD is a combination of pharmacological and psychosocial interventions. Using both modalities allows for the control or abatement of symptomatic behavior by the medication while at the same time working on changing maladaptive behavior patterns through therapy with the child and family. When recommending psychosocial intervention, clinicians must keep in mind the developmental level of the child and family. Also, from a developmental psychopathology perspective it is important to inform the family that early intervention works best and that the child and family may have periods of adaptive and maladaptive behavior.

PHARMACOLOGICAL INTERVENTION. Stimulants are the most commonly used medication for this condition. Ritalin and other forms of methylphenidate, Adderall (amphetamine salts), and atomoxetine (Strattera), a nonstimulant medication, are commonly used in this condition. The FDA recently approved a transdermal methylphenidate patch for children 6 years and older. This patch was designed for children who were unable to swallow any tablets or capsules.

PSYCHOSOCIAL INTERVENTION. The nurse recognizes that children often respond to therapeutic approaches that include behavioral therapy, rewards (sticker charts), as well

as positive versus negative reinforcement (used as often as possible when child demonstrates acceptable behavior). School nurses are in a position of supporting teaching and other staff in the use of behavioral charts. Pediatric nurses in the community can offer support to parents and families in ongoing use of behavior modification.

Some families may resist medications. Other families may put all of their faith into medications, thus not following through with the entire treatment plan. It is important for the nurse to help the family make use of all of the treatment options available to them and to participate actively with their health provider(s) in developing a plan for their child.

OPPOSITIONAL DEFIANT DISORDER AND CONDUCT DISORDER

Antisocial behavior is at the core of disordered behavior that can often explode into clinical disorders most often known as oppositional defiant disorder (ODD) and conduct disorder (CD).

ODD and CD have multifactorial and complex etiologies. Studies have identified a number of biological and psychosocial factors that may be associated with the development of CD and ODD in children and adolescents. Among the biological factors is temperament, hormonal changes (especially in adolescence), neurotransmitter dysfunction, and prenatal toxin exposures (e.g., fetal alcohol exposure). Psychosocial factors include less competence in problem-solving skills, less ability to take on another's viewpoint, family or parental history of depression, antisocial personality, and criminal behavior, disruptions in family functioning (e.g., parental conflict, parenting practices), peer group rejection, and lower-socioeconomic background. Specifically, there is evidence showing that parental hostile attributions and parental harsh discipline styles may lead to child behavioral problems (Dishion & Patterson, 2006).

Signs and Symptoms

There is evidence indicating that early childhood problem behaviors may include noncompliance, oppositional behavior, and temper tantrums. Sometimes it can be difficult to distinguish between normative and problematic behavior in young children. It is important that the nurse become familiar with normal development stages and not to overpathologize negative behavior during childhood (Wakschlag & Danis, 2004).

In middle childhood, children may show overt (e.g., hitting) and covert (e.g., saying mean things about a friend) antisocial behavior (experienced by others as aversive, disruptive and unpleasant), and relational aggression (aggression toward people who have a relationship with the child). It may be less clear about what behavior problems demonstrated in middle childhood may be grouped into either ODD or CD.

Later in adolescence, behavior may include delinquency, substance abuse, and high-risk sexual behavior. The set of behavior problems typically exhibited in early childhood are often identified as oppositional defiant disorder (ODD). Finally, behaviors observed later in adolescence are often identified as CD (Dishion & Patterson, 2006).

where research and practice meet: **Oppositional Defiant and Conduct Disorder**

Disruptive, aggressive, and antisocial behaviors in children are often the type of behaviors that lead families to seek help for psychosocial-related problems. These behaviors are often difficult to tolerate by parents, family members, peers, teachers, and others. The nurse will encounter families with children exhibiting these behaviors. There are a number of preventive intervention studies that show promise for clinical application.

One such study is the Family Check-UP (FCU), a randomized trial of parental management strategies used in the context of increasing young children's autonomy. The FCU also addresses other familial issues including parental depression, housing and daycare needs, and feedback sessions using motivational interviewing approach. These management strategies were administered to the families of young children (enrolled when children were 17–27 months old) and showed promising results. The findings included decreased Child Behavior Check List [CBCL] Destructive Scale scores for 3-year-old boys and improved maternal engagement when children were 2 years of age (Shaw, Dishion, Supplee, Gardner, & Arnds, 2006).

Diagnosis

Improvement in self-report measures (Achenbach & Rescorla, 2000), and better criteria in the DSM-IV-TR as well as the help of other tools (Greenspan, 2005), has made it easier for clinicians to diagnose behavior disorders.

What is less well known is the difference between ODD and CD. It is important to note that many children who meet the criteria for ODD or CD often have comorbid mental health problems and may also function poorly in interpersonal relationships with peers and caregivers (Dishion & Patterson, 2006).

Nursing Care

Early assessment of these conditions is important, using multimethod and multi-informant approaches that include: self-report scales (e.g., CBCL), child interview, parent interview, physical assessment, observation of child–parent interaction, and thorough family assessment (e.g., history of exposure to violence in the family and community).

When working with children and adolescents who exhibit ODD or CD, it is important for the nurse to be aware and manage personal feelings that may be aroused by the patient and family. The nurse can educate the family about the family-based prevention and intervention programs.

Nursing Insight— Prevention and intervention programs using a family-based approach for oppositional defiant disorder and conduct disorder

The Nurse–Family Partnership (Olds, 2002): Incorporates nurse home visits by specially trained nurses to low-income first-time families and their support systems. The nurse helps the family learn about preventive prenatal and postnatal health and offers support in maintaining optimum health. (Another resource is www.nursefamilypartnership.org).

The Incredible Years program (Baydar, Reid, & Webster-Stratton, 2003): This program was developed by Carolyn Webster-Stratton, a pediatric nurse practitioner as well as a clinical psychologist. The program is an evidence-based intervention program designed to help parents and young children (ages 3–10) who have or are at-risk to develop aggressive, disobedient, hyperactive and inattentive behaviors.

The Family Check-UP (FCU) (Dishion & Kavanagh, 2003; Shaw, Dishion, Supplee, Gardner, & Arnds, 2006): This intervention program assesses families to identify those with children at risk for substance abuse or antisocial behavior. These families are then offered support and therapeutic and case management services to decrease the risk factors.

Evidence-based programs have been found to be effective across various socio-demographic and ethnic samples in the United States and northern European countries (Webster-Stratton, Reid, & Hammond, 2004). Some of the programs have also been implemented from a preventive perspective with at risk preschool and school-age families (Baydar et al., 2003). Although it takes special training, the programs are comprehensive and intensive. The programs are valuable for nurses to learn about in order to help families find proper resources.

The nurse can also help parents learn some basic behavioral techniques. For example, the nurse can teach the parent about the value of ignoring annoying behaviors exhibited by the child. If the behaviors do not present safety issues, ignoring the behavior can be one of the best ways of extinguishing it because the child does not garner the desired attention. The nurse can tell the parent that it is also important to offer positive verbal feedback when behaviors are within acceptable limits.

Nursing Insight— Youth violence: Fact sheet

The Youth Violence: Fact Sheet at <http://www.cdc.gov/ncipc/factsheets/yvfacts.htm> offers a comprehensive resource about the problem of violence (compiled and referenced from research and refereed articles). The nurse can access this information to be used as an educational tool when talking to youth and families about violence. Examples of fact sheet topics are the following:

- Occurrence
- Consequences
- Groups at Risk
- Risk Factors
- Individual Risk Factors
- Family Risk Factors
- Peer/School Risk Factors
- Community Risk Factors
- Protective Factors
- Individual Protective Factors
- Family Protective Factors
- Peer/School Protective Factors

Nursing care for this condition also includes educating the family about medications. It is important that the child and family understand the action, potential side effects, and additional information about prescribed medications. Children with ODD or CD may be prescribed

medications from a number of categories such as stimulants for ADHD symptoms; antipsychotics for behavior regulation; mood stabilizers for regulation of high and low mood presentations; as well as antianxiety agents.

Nurses who work with families that have children with ODD or CD must be mindful of the stress that these disorders have on the whole family. It may be exhausting for parents to cope with the defiant behaviors. Siblings may be put at risk simply spending time with the misbehaved child. Respite care (short-term care) can give the family a “rest” from the child who has the disorder. Encouraging family members to take care of personal needs as well as the child’s may be useful in helping them to find balance in daily living.

nursing diagnoses Oppositional Defiant Disorder and Conduct Disorder

- Ineffective coping related to personal vulnerability
- Impaired social interaction related to hostile, negative, and defiant behavior
- Chronic low self-esteem related to difficulties with positive social interactions
- Compromised family functioning related to inadequate information and family disorganization

Tic Disorders

A tic is a sudden seemingly uncontrollable movement or vocalization. Many children in the elementary school age group experience motor tics (facial or bodily twitches or shrugs) that are mild and eventually spontaneously resolve. Generally, tics are manageable when the child concentrates on controlling them, but they become worse when the child is under stress. Vocal (phonic) tics are characterized by bursts of yelling out words, grunts, and throat-clearing (APA, 2000). Tics are more common in boys than in girls.

TOURETTE’S SYNDROME

There are a number of tic disorders, including Tourette’s syndrome, which is a motor and vocal tic disorder that may have a chronic motor or sometimes transient tic (APA, 2000). Specifically, Tourette’s syndrome most often includes chronic motor and phonic tics that vary in frequency, intensity, and complexity (Spessot & Peterson, 2006). Children may not initially know they exhibit tics but over time become aware of the behavior. By adolescence most children have become aware of the

premonitory urge (warning signal) (Spessot & Peterson, 2006). Tics occur more frequently in children than in adults. The incidence is estimated to be 5 to 30 per 10,000. The tic can begin as early as 2 years of age and can last throughout the lifetime with asymptomatic periods (APA, 2000).

Signs and Symptoms

Children with Tourette’s syndrome often exhibit symptoms of other disorders, similar to obsessive–compulsive disorder (APA, 2000; Leckman et al., 2006; Snider & Swedo, 2003), autism spectrum disorders (Canitano & Vivanti, 2007), and ADHD (Leckman et al., 2006). Many of the symptoms are similar. Children with co-existing disorders are more likely to suffer depression, low self-esteem, negative peer acceptance, and poor school performance than those with tics alone (Leckman et al., 2006).

Diagnosis

diagnostic tools Tourette’s Syndrome

The nurse can help the family recognize certain features of Tourette’s syndrome to assist in the diagnosis of the condition:

- The child may have both multiple motor and one or more vocal tics present at some time but not necessarily concurrently.
- The tics occur several times a day
- The tics occur almost every day or intermittently throughout a period of more than 1 year.
- The onset of tics is before age 18 years.
- The disturbance is not due to the direct physiological effects of a substance or a general medical condition.

(Canitano & Vivanti, 2007).

Nursing Care

The nurse working with a child with Tourette’s syndrome must recognize the impact the disorder has on the child’s functioning and social relationships. The child becomes self-conscious and worried that he will blurt out words or utterances at inopportune times. The child may also be shunned or laughed at by peers who do not understand the behavior. The nurse can help the parents watch for signs that the child is being bullied by peers or siblings. In addition, the nurse can help teachers understand that the child cannot control the tics. Robertson et al. (1999, cited in Leckman et al., 2006) referenced two interesting features of Tourette’s: (1) suggestible, meaning talking about tics can trigger the tic, (2) suppressible, meaning that if the child is told to stop the tic or can focus on the tic, the tic might be stopped momentarily.

Tic disorders do not often cause impairment of daily living. In fact, many of the manifestations are actually mild. Nursing interventions are predominantly geared toward helping the child and family cope with the disorder. Tourette’s and other tics can create stress for the child as the child may experience a low self-esteem. The nurse can also help the family watch for signs of coexisting disorders such as ADHD or OCD. Behavioral skills training and stress management can be helpful in teaching the child to recognize the warning signs and to better decrease stressful situations that might lead to tic episodes. Pharmacological interventions include the use of haloperidol (Haldol) or clonidine (Catapres).

where research and practice meet: Parenting Patterns

In a study, Dishion and Patterson (2006) differentiated the parenting patterns in families with children who exhibit antisocial and disruptive behavior from those of families whose children do not show these behavior problems. It was found that proactive parenting (engaging children in positive and joint activities, use of verbal cues that promote positive behavior in children) distracted children from misbehavior.

Maltreatment of Children

Child maltreatment is considered to be any action or failure to act by a person that endangers a child's physical or emotional health and development. A person is abusive if he or she fails to nurture the child, physically injures the child, or relates sexually to the child (U.S. Department of Health and Human Services [USDHHS], 2007). Child abuse may include physical, sexual, emotional abuse, and neglect.

Child physical abuse may result in injury inflicted by beating, pushing, kicking, pinching, burning, or choking. Physical abuse includes shaken baby syndrome, which manifests as symptoms related to head trauma as a result of forceful shaking of the infant or young child.

Child sexual abuse involves any sexually related act, usually between a child and an adult (related or not) that can include fondling, forced, or assented oral sex or intercourse, sodomy, exposing children to adult sexual behavior (showing pornography to children), and exploiting through child pornography or prostitution.

Child emotional abuse includes any behavior, attitude, or failure to act that disrupts children's socio-emotional development and mental health. Some examples include shaming or humiliating (ascribing derogatory labels to the child, "you are worthless"), intimidating (threatening and frightening).

Child neglect involves failure to provide emotional and physical care as well as opportunity for education. Neglect is most common but also the most difficult to identify.

Other types of abuse include Munchausen-by-proxy syndrome (a person, usually the mother, deliberately makes the child sick) as well as the electronic sexual luring (enticing via computer) of children.

Nursing Insight— Incidence of child maltreatment

Statistics gathered routinely by the U.S. Department of Health and Human Services (DHHS) track the incidence of child maltreatment and give a breakdown of the incidence of the various types of maltreatment. In 2005, it was estimated that of the 899,000 U.S. (including Puerto Rico and the District of Columbia) children abused, 62.8% were neglected, 16.6% were physically abused, 9.3% had been sexually abused, and 7.1% were emotionally abused (DHHS, 2007). Of these children, 1460 children died related to their abuse or neglect (1.96 children per 100,000). These statistics reflect only the cases that were reported and does not address those children subjected to other forms of domestic violence (parents abusing parents or elders). It also does not address the numbers of children and adolescents who are lured into online abuse experiences. Unfortunately, those responsible for maltreatment of children in the U.S. (perpetrators) are most often parents (79.4%). Other offenders include relatives (6.8%) or unrelated caregivers (10.1%) (DHHS, 2007).

Signs and Symptoms

Children from any family can exhibit any signs and symptoms of abuse, but there are certain children who are in a more vulnerable position. Child rearing can be difficult in normal circumstances, but additional stressors can

contribute to child maltreatment. Children with disabilities or with difficult temperamental characteristics may be abused by frustrated or unprepared parents. Children of very young parents or young single mothers who live in poverty or in situations that are stressful may be more apt to abuse a child. Parents who suffer from mental or chronic physical illness may not have adequate resources available to deal with parenting. Other parents who have extremely stringent ideas of discipline may use harsh punishment. The signs and symptoms of abuse are multifaceted (Table 23-3).

Diagnosis

Abuse may be difficult to diagnosis. However, the health care provider can pay close attention to circumstances where the child is exposed to situations where there is excessive stress, marital conflict, parental substance abuse and psychopathology, intergenerational history of abuse, beliefs that children need to be "toughened up," and in families who experience hardships. Diagnosis of physical, sexual, or emotional abuse or neglect may take time, and a thorough family history, physical examination, and developmental assessment are necessary for diagnosis.

Nursing Care

The nurse can be instrumental in the care of children who have experienced any type of abuse including family education, support, referral, and initiatives to help abate and ultimately stop child abuse (Lieberman & Van Horn, 2005).

Educating parents about what to expect from parenthood and from child rearing may help the parents understand how to cope with some of the difficult times related to raising a child. Helping the parents develop resources for support such as babysitters, family members, community sites, and health care resources may help them find ways to cope with parenting. In addition, the nurse can provide parents with information regarding "normal" stages of growth and development which may help the parents to avoid pressuring the child to develop faster than physiologically able. It may also be helpful to discuss with parents ways to discipline the child that does not involve physical or verbal aggression.

The nurse can educate children and adolescents about the body and personal boundaries. The community nurse is sometimes the first person who recognizes abuse or the person with whom a child is comfortable sharing information. The nurse understands that it is important to develop a safe and trusting relationship with children.

It is also important that the nurse understands what steps to take in reporting maltreatment in children as well as implementing steps toward prevention and intervention. Efforts to stop abuse against children should include the following measures: decrease unintended pregnancies, stop the use of alcohol or drugs during pregnancy, decrease the use of drugs or alcohol by new parents, improve availability of and access to health care across the spectrum of the family's life, and help parents and caregivers learn about nonviolent parenting and discipline. The nurse can also be involved politically and educationally to promote these efforts.

Health care professionals cite several reasons for underreporting suspected child abuse. For instance, despite the availability of education and training regarding how to

Table 23-3 Physical, Sexual, Emotional Abuse and Neglect

Type of Abuse	Tactics of Abuse	Possible Signs and Symptoms in the Child	
Physical: Bodily injury caused by intentional or unintentional physical aggression.	Beating, hitting, slapping, poisoning, kicking, pinching, biting, shoving, choking, pulling hair, burning	Suspicious bruises, welts, or burns	
		Unexplained fractures or dislocations	
		New and healing or healed lacerations or abrasions	
	Excessive corporal punishment	Wariness of adults or caregivers	
		Fearful of going home	
		Acting out with aggression	
Shaken baby syndrome	Retinal hemorrhages		
	CNS injury		
Munchausen by proxy		Prolonged or recurrent illnesses or injuries that cannot be explained	
		Sexual: Sexual acts involving an adult and a child.	Penetration, incest, rape, oral sex, sodomy, fondling
			Violations of bodily privacy
			Exposing children to adult sexuality
			Commercial exploitation
Sexual exploitation (prostitution or pornography)			
Emotional: Attitude, behavior, or failure to act that interferes with a child's mental health or social development.	Intimidation, belittling, shaming, lack of affection and warmth, habitual blaming, ignoring or rejection, extreme punishment, exposure to violence, child exploitation, child abduction	Inappropriate or precocious interest in or knowledge of sexuality	
		Poor peer relationships	
		Sudden changes in behavior (regressive, acting out, sexual)	
Neglect: Pattern of failing to meet basic needs.	Physical, educational, emotional	Running away from home or substance abuse	
		Rapidly declining school performance	
		Suicide attempts	
		Apathy, depression	
		Hostility	
		Difficulty concentrating	
		Clothing unsuited to the weather	
		Poor hygiene	
		Hunger	
		Lack of supervision	

report cases of child abuse and neglect, many professionals feel ill equipped to handle the situation once a case is identified. Contrary to current belief, professionals who report child abuse are not revealed to the family in question unless the caller chooses to disclose this information. Also, while all reports are taken seriously, not all reports result in the removal of the child from the home. Every reports is investigated but any action may or not be taken depending on the assessment (Childhelp National Child Abuse Hotline, n.d.). It is also important to note that the nurse is required to report any suspicion of child abuse or neglect.

Be sure to— Report cases of child abuse

To report suspected child abuse, the nurse can call the local enforcement agency and/or follow the clinical setting's guidelines for reporting abuse. All U.S. states have mandatory reporting guidelines for professionally licensed health care workers/providers. It can be a difficult experience to report child abuse because of possible consequences to the child, family, and professional. It is important to remember that all allegations of child abuse must

first be investigated before confirmed. After documented confirmation the child will be placed in a safe environment free of abuse.

National Hotline in USA: 1-800-4-A-Child

See also Vieth, Bottoms, & Perona (2006).

Substance Use and Abuse

Substance abuse refers to the repeated use of illicit substances (drugs or alcohol or inhalants) despite the negative consequences (APA, 2000). Substance dependence/addiction refers to the physiological and/or emotional reliance on that substance (APA, 2000). The incidence of substance abuse by young people has waxed and waned over the decades, but its significance cannot be ignored. It is known that 80% of deaths in adolescents involve accidents, homicides and suicides and in many of these cases drugs and alcohol are involved (Mayes & Suchman, 2006).

Clearly, the problem of alcohol and drug use and abuse in children and adolescents is a grave concern. Youth in the United States are exposed to drug or alcohol abuse at significant rates. It is estimated that 8.2% of U.S. children, age 12 and older used an illicit substance (SAMHSA, 2003).

Nursing Insight— Substance use and abuse

The literature and research is vast regarding drug and alcohol abuse and risk factors. An interesting body of literature involves studies examining biological and genetic factors, especially related to alcohol abuse (Mayes & Suchman, 2006). In studies of twins and family behaviors, researchers found evidence suggesting that both genetic predisposition and behavior were important in adolescents' initial use of marijuana (Mayes & Suchman, 2006). These data seem to suggest that there may be an important link between genetic and environmental circumstances (Mayes & Suchman, 2006).

Young people may abuse any of the substances abused by adults. The major factors determining which substances are used are availability and cost. Some of the more common substances of abuse for children and adolescents include alcohol, tobacco, marijuana, cocaine, ecstasy (MDMA), methamphetamine, other forms of stimulants, prescription medications (the child's own prescription, or medications stolen from a family member), and inhalants (e.g., glue, gasoline, white-out). It is essential that nurses not be naive about the possibility of substance abuse.

Signs and Symptoms

Signs and symptoms of a child who is using and abusing may be surprisingly similar to those of depression and/or suicide. In fact, psychiatric disorders and the possibility of suicide ideation go hand in hand with the abuse of or addiction to illicit substances. The American Academy of Child & Adolescent Psychiatry (AACAP, n.d.) published a list online of some of the warning signs that a young person might be abusing alcohol or drugs:

- Physical: fatigue, repeated health complaints, red and glazed eyes, and a lasting cough
- Emotional: personality change, sudden mood changes, irritability, irresponsible behavior, low self-esteem, poor judgment, depression, and a general lack of interest
- Family: starting arguments, breaking rules, or withdrawing from the family
- School: decreased interest, negative attitude, drop in grades, many absences, truancy, and discipline problems
- Social problems: new friends who are less interested in standard home and school activities, problems with the law, and changes to less conventional styles of dress and music

Diagnosis

Diagnosis of substance use and abuse is based on the physical, emotional and social factors exhibited by the child. A thorough family history is essential along with information about the child's physical and emotional health.

Nursing Care

Initial nursing care involves the use of screening tools to assess drug and alcohol use in children. The nurse is in an ideal position to identify adolescents at-risk for substance

abuse, especially if there is a strong family and genetic history of abuse. Two tools that can be used in the identification of substance abuse are the CRAFFT (Knight, Sherritt, Shrier, Harris, & Chang, 2002) and the CAGE (Ewing, 1984). Both of these tools use simple acronyms to assist in the evaluation of drinking or drug use.

After a thorough assessment is done the nurse can help the child and family find community resources that may help conquer the substance abuse problem. Research indicates that nearly 80% of adolescents with substance abuse receive treatment (Commission on Adolescent Substance and Alcohol Abuse, 2005). There are many different types of treatment, but the most promising appears to be a family-based approach, as it shows the best outcomes for reduction in substance abuse in adolescents (Commission on Adolescent Substance and Alcohol Abuse, 2005). Family treatment means that the entire family receives psychoeducation regarding substance abuse.

Eating Disorders

Eating disorders that are mostly apparent in adolescence are classified into four categories that include anorexia nervosa (purging or withholding), bulimia nervosa (binging and purging), binge eating disorder (binging without purging), and eating disorder not otherwise specified (EDNOC) (APA, 2000; Commission on Adolescent Eating Disorders, 2005). Eating disorders most often affect females but adolescent males are also known to suffer from these illnesses. Eating disorders are mostly a phenomenon of Westernized society and thus it is thought that Western media plays a role in these problems (Commission on Adolescent Eating Disorders, 2005).

From a developmental psychopathology perspective, there are a number of risk factors that may cause the adolescent to develop an eating disorder. The physiological factors include hormonal and physical changes associated with puberty in conjunction with temperamental factors. In addition, possible genetic factors might contribute to the development of eating disorders (Steiner et al., 2003). Certain experiences can act protect the adolescent from eating disorders, including participation in high school sports that focus on the sport rather than on pursuit of thinness (Steiner et al., 2003) as well as supportive families and peer groups.

The prevalence data found in community samples reports rates of 0.3% to 0.58% in female and 2% in male children and adolescents 11 to 20 years old (Commission on Adolescent Eating Disorders, 2005). These data provide limited information for several reasons. The research has ignored populations that have well documented incidences of eating disorders (e.g., children of ethnic minorities in Westernized countries and generally in children of non-Westernized society). Also, studies have not used uniform tools to measure the disorders.

Signs and Symptoms

In general, adolescents with eating disorders (anorexia or bulimia nervosa) have an inordinate concern with body image and body weight. Adolescents with eating disorders are often hiding behaviors related to food and caloric intake from others. It is also not unusual for these adolescents to have other co-occurring or resultant mental

health and family psychosocial problems (e.g., depression, anxiety, and family discord) as well.

Adolescents with anorexia nervosa usually lose up to 85% of ideal body weight by either restricting food or caloric intake or by consuming caloric intake but then purging by vomiting or vigorous physical activity (Commission on Adolescent Eating Disorders, 2005). These behaviors can result in physical symptoms including amenorrhea, weakness, or fatigue that interfere with general health and well-being. In some cases, symptoms may result in a life-threatening situation and even death.

clinical alert

Anorexia nervosa

Anorexia nervosa can become a life-threatening problem or cause death because of severe weight loss that can result in electrolyte imbalance and hemodynamic instability.

Diagnosis

The diagnosis of anorexia nervosa or bulimia can be challenging and based on both physical and emotional signs and symptoms. Adolescents with this disorder are below their ideal body weight and are often preoccupied with food. During an interview, the adolescent may express that he or she refuses to eat or consumes very large amounts of calories and then purges by self-induced vomiting or using laxatives or other means (Commission on Adolescent Eating Disorders, 2005).

Nursing Care

The nurse can communicate to the family that treatment of anorexia nervosa and bulimia involves contacting a physician to address the physical symptoms based on the dangerously low body weight. In some instances, adolescents may require hospitalization to correct electrolyte imbalance and homodynamic stability. Because this condition has both physical and psychological implications, nurses caring for children with anorexia nervosa must have the appropriate education and training. Often, once the child's physical health has been stabilized the child is admitted to a psychological unit or directed to outpatient psychological care.

Antidepressant and antipsychotic medications have yielded some promising results. Research shows that antidepressant medication in combination with cognitive behavior therapy has been effective in the treatment of adolescents with bulimia nervosa (Commission on Adolescent Eating Disorders, 2005). The nurse can provide support to the adolescent and family.

Along with physical and mental care, adolescents with bulimia nervosa may need dental care for repair of dental erosion and cavities that result from vomiting.

The nurse may be in the best position to identify early cases of eating disorders and refer for preventive individual and family treatment. The nurse has to keep in mind that the assessment needs to be conducted within a growth and developmental perspective and that intervention should be considered within a family-based approach. When making referrals for treatment, it is important to consider the skill level of the treatment clinician and often a team approach with expertise in this area of health and mental health

work best. For guidelines and further information, the nurse should consult the American Academy of Pediatrics: Committee on Adolescence Identifying and Treating Eating Disorders <http://aappolicy.aappublications.org/cgi/reprint/pediatrics;111/1/204.pdf>.

Obesity

The definition of obesity in children and adolescents has been debated a great deal by professionals in the field. Recently researchers and care providers have agreed upon certain criteria. Youth are considered overweight if they reach a body mass index (BMI) above the 85th percentile and obese when the BMI is above the 95th percentile. These definitions take into account the child's or adolescent's age and gender (Anderson & Butcher, 2006).

While obesity is not technically classified as an eating disorder, the psychological factors involved are significant. Being overweight or obese deserves the collaborative attention of pediatric primary care providers, nurses, nutritionists, educators, mental health specialists, public health researchers and clinicians, policy makers, parents and children, and others (Anderson & Butcher, 2006; Caprio, 2006).

Daniels (2006) describes many of the physiological problems that go along with obesity including hypertension, diabetes, sleep disorders related to breathing difficulties, and increased risk for cardiovascular disease. In addition to the physiological problems encountered, children who are overweight or obese may be teased or bullied by peers, leading to difficulties with self-esteem and social development.

Obesity in children and adolescents is widespread and is considered to be an important US and International public health problem. In the United States, 17% of children between the ages of 2 and 19 are obese. The breakdown of these statistics shows that 13.9% of 2- to 5-year-olds, 19% of 6- to 11-year-olds, and 17% of teens between 12 and 19 years old fall rate above the 95th percentile for weight related to their height. These statistics show a dramatic increase since the late 1980s and early 1990s (Ogden et al., 2006). Childhood obesity is of epidemic proportions.

Signs and Symptoms

The nurse understands that it is important to identify obesity as early as possible in the child. The nurse can begin with a comprehensive individual and family history (diabetes, dyslipidemia, cardiovascular disease) and physical assessment as well examining a set of laboratory tests (e.g., metabolic profile). The height, weight, and body mass index (BMI) should be assessed and plotted on the charts identified by the CDC (Caprio, 2006).

Currently there is research assessing the possible link between the environment (physical space available for children to be physically active) and obesity (Epstein, 2003). The link between environment and obesity is not yet conclusive (Sallis & Glanz, 2006).

Golan and Crow (2004) present information about the obesogenic factors present in Western society. **Obesogenic** refers to the role that environment plays in the development of obesity (Pearce, Blakely, Witten, & Bartie, 2007; Swindburn & Egger, 2004). Certain factors found in modern Western lifestyles contribute to eating disorders in general, including the availability of high-density, high-caloric energy foods, decreased physical activity, inactivity,

media (constant barrage of food commercials targeting children), and the glorification of thinness and diets (Golan & Crow, 2004).

It is also important to assess individual and family attitudes and practices related to food and weight. Parents who are fearful that their child will become fat may inadvertently over restrict food to the point that the child hoards food or uses it for comfort. On the other hand, parents who do not understand or cannot afford a healthy diet may reinforce poor dietary habits.

Ethnocultural Considerations—Disparities in childhood obesity

Despite the fact that African American and Latino children and adolescents have higher prevalence rates of obesity compared to white children and adolescents, researchers have found that African American and Latino children receive much less attention related to obesity. It is also known that African American and Latino are also more likely to develop obesity-related problems, such as type 2 diabetes (Caprio, 2006).

Children in low-income families also experience higher levels of obesity. Access to high-quality, low-fat foods is limited, as is often the education of the parents in providing such foods. Lower-income families often have less access to programs than more privileged families have (Kumanyika & Grier, 2006).

Nurses and especially nurses of African American and Latino backgrounds are well positioned to close the gap and help eliminate these disparities by becoming involved or taking leadership roles in programs that identify and involve these youngsters and their families in interventions.

Diagnosis

Diagnosis of obesity is based on an excess of fat in proportion to lean body mass. Basically, the child is considered obese when his or her weight is greater than what is considered healthy for his or her height (BMI above the 95th percentile).

Nursing Care

An important role of the nurse is assessing the risk factors and early onset of obesity (family history, sedentary lifestyle, availability of healthy nutritional resources) in order to begin preventive teaching efforts. The nurse can communicate to families that the Women Infants and Children (WIC) program educates families and provides food packages to underprivileged families. In addition, clinic nurses have the opportunity to help new parents learn healthful attitudes about food and feeding. The nurse can use the information from *Healthy People 2010* obesity prevention to guide family teaching.

Improving the activity level of children and adolescents should be included in teaching. The nurse can be instrumental when working with school programs to offer adequate physical education along with academics. Nurses can also encourage parents to monitor their child's nutrition and activity levels, particularly passive entertainment (computer, television, or video games).

The nurse should also be aware that dieting is not suggested for young people. In fact, in the long run restrictive eating often contributes to boomerang overweight or to other eating problems. Nevertheless, focusing on healthy eating

habits that can last throughout the lifetime is essential. It is important to empathize with the child who expresses dissatisfaction with his or her weight and provide education and guidance related to healthful eating and exercise.

Across Care Settings: Prevention of childhood obesity in schools

The school environment is a good community site to begin implementing prevention of obesity programs because it is the place where most children spend most of their waking hours. The nurse can help ensure that the school provides healthy meals; replaces soda machines with water; promotes and improves physical activity, and provides education about nutrition, physical activity, and acceptable weight (Story, Kaphingst, & French, 2006). The nurse can become involved in school-based programs by providing health education that is known to promote healthy eating, physical activity, and well-being. The nurse can also become involved at other levels, including as a parent, researcher, and advocate for change in school policy.

Sleep Disorders

Sleep and lack of sleep is a complex issue. Reports of sleep problems in children are often identified by the parents or caregivers because children do not usually complain of sleep issues (Kryger, 2005). The child's sleep problem is an issue that can affect the entire family. Often, the nurse encounters sleep-deprived parents based on the child's sleeping difficulties.

During the nursing assessment, the nurse discovers that a variety of daytime difficulties can contribute to sleeplessness at night. These difficulties include the child taking long naps during the day, excessive caffeine consumption, worry and stress, or childhood illness. In addition, parents may communicate that teachers complain about the child's irritability or hyperactivity or about the child falling asleep during class. There are few studies about childhood sleeping patterns that include infants, children, and adolescents but the existing evidence provides some understanding into this important area of study (Owens & Mindell, 2005).

It is estimated that about 25% of all children experience sleeping issues during childhood and the degree of problems varies from mild to severe difficulties with falling asleep or staying asleep. Studies of childhood sleep disturbances, using mostly caregiver-reported data, suggest that 6% to 50% of preschool- and school-age children have sleeping problems (Owens & Mindell, 2005).

Signs and Symptoms

It is thought that the problem of sleep disorders stems from an interaction between neurodevelopment and behavior (Sheldon, 2005). Temperamental tendency for being awake at night, developmental issues, the quality of the child's health, and the way parents or caregivers manage the child sleep routines are all thought to play important roles in the outcome of sleep related difficulties. Signs and symptoms of a child having a sleep disorder might include sleepwalking, difficulties getting to sleep or staying asleep, nightmares, excessive daytime sleepiness, or irregularity of sleep routine (Owens & Mindell, 2005).

Family Teaching Guidelines... Sleep Hygiene

Shelton (2005), a pediatric sleep medicine specialist, recommends the following sleep hygiene guidelines for children:

- ◆ Provide a quiet, dark, and comfortable environment or bedroom.
- ◆ Set a strict bedtime and awake routine that remains consistent on a daily basis.
- ◆ Avoid long daytime naps.
- ◆ Allow a long space of time between day time nap and bedtime.
- ◆ Provide a healthy snack before bedtime so the child is not hungry.
- ◆ Avoid substances such as caffeine, chocolate, and medications that contain alcohol or other foods/beverages that are stimulating to children.
- ◆ Cut down on fluids before bedtime so that a full bladder or wetness does not interrupt sleep.
- ◆ Avoid a high level of activity and television viewing before bedtime and replace it with quiet activities (e.g., reading books).
- ◆ Encourage children to fall asleep without the parent/caregiver in the room.

Diagnosis

Sleep disorders can be diagnosed based on a positive answer by the caregiver to one or more of these questions:

- Is it hard for your child to fall asleep?
- Is it hard for your child to stay asleep though the night?
- Does your child wake up feeling tired?
- Is your child sleepy during the day?

Nursing Care

The nurse must listen carefully to the parents' concerns about the child's sleeping issues. The nurse knows that it is important to discover this problem early, understand the causes of sleep disturbances, as well as to implement prevention and intervention strategies. Sheldon (2005) found that children who slept longer had higher intelligence test scores and performed better in school.

The nurse can perform a thorough physical assessment of the child. Certain health conditions can interfere with sleeping, including cow's milk allergies, otitis media, neurological disorders, attention-deficit/hyperactivity disorder (ADHD), and some chronic illnesses.

It is also important that the nurse conduct a thorough assessment of the child's sleeping patterns and how these patterns influence the child's well-being and family functioning. A comprehensive assessment also includes development and behavior history. Sometimes diagnostic data conducted in a sleep laboratory can help confer a sleep-related diagnosis. The electroencephalogram (EEG) is a diagnostic test that provides important data about stages of sleep as well as the integrity and development of the central nervous system (Sheldon, 2005).

The nurse can help the family by providing support while listening without passing judgment and then provide information on sleep hygiene.

“What to say” — Bathing before bedtime is not recommended

Did you know that a bath before bedtime is no longer considered to have a calming effect? The literature says that a bath before bedtime can have the opposite effect as it stimulates the child and therefore it is not recommended (Sheldon, 2005). The most important principles that nurses can suggest to parents are that there be a consistent bedtime and standard routines (Sheldon, 2005). The nurse can ask parents to describe the bedtime routines and help parents create good sleep hygiene habits for the child. Medications such as hypnotics may be prescribed for children, but it is thought that over time medications do not improve sleeping patterns in otherwise healthy children (Sheldon, 2005).

case study Sleeping Issues

Paul is 4 years old, and according to his mother he has had sleeping difficulties since he was born. He voices many fears, makes demands, and sometimes has tantrums at bedtime. He says he is afraid of the dark even though he has a night light in his room. Paul complains of being hungry as soon as he lies down in bed. Unless his mother stays in the room with Paul until he falls asleep, he does not stop crying and often becomes upset for no apparent reason. Paul takes an afternoon nap until 5:00 P.M. Now that the family is expecting a new baby they wish to have Paul's sleeping difficulties under control. He has a bedtime of 8:00 P.M. but he does not get to sleep until 11:00 P.M. or midnight unless he has not napped during the day.

critical thinking questions

1. Name the priority nursing diagnosis related to this situation.
2. Discuss the importance of parental education and specific sleep hygiene techniques that the nurse can teach.

- ◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

Now Can You— Discuss sleep disorders?

1. Explain how a nurse would assess a child who complains of sleep disorders.
2. How can sleep disorders be diagnosed?
3. Explain sleep hygiene.

Developmental Conditions

DEVELOPMENTAL DISABILITIES

Children and adolescents who are diagnosed with developmental disabilities are affected by the disparities in health care (Fisher, 2004). Goals related to developmental disabilities have been included in the *Healthy People 2010* initiative as a step toward reducing those disparities. Developmental

disabilities is a term that encompasses a number of disorders, including Down syndrome (DS), fragile X syndrome, and fetal alcohol spectrum disorders (FASD). Developmental disabilities may also co-occur with a variety of physical symptoms (seizures, sensory impairments, speech and language problems, and cerebral palsy).

A number of factors that cause genetic conditions, such as Down syndrome or fragile X syndrome, result when abnormal genes are inherited from parents or when there are errors in genetic combinations. Metabolic conditions such as phenylketonuria (PKU) can lead to developmental disabilities if not recognized and treated early. Pregnancy-related problems include alcohol ingestion or viral infection such as rubella. In addition, trauma or asphyxia during the birth process can lead to inadequate oxygen availability and may cause developmental disabilities. Certain illnesses or events that may occur during childhood or adolescence (e.g., whooping cough, measles or meningitis, extreme malnutrition, lack of medical care or exposure to toxins like lead or mercury, as well as head trauma) can contribute to the development of developmental disabilities (National Information Center for Children and Youth with Disabilities [NICHCY], 2004).

As many as 3 out of every 100 people in the United States have developmental disabilities (The Arc, 2001, revised 2004). More than one half million children ages 6 to 21 have developmental disabilities and require special educational services in school.

Nursing Insight—Fragile X syndrome

Fragile X syndrome (FXS) is the most common cause of developmental disabilities. It is caused by “an expansion mutation in the fragile X gene (*FMR1*) located on the X chromosome” (Wattendorf & Muenke, 2005, p. 111). FXS is known to affect 1 in 4000 male and 1 in 6000–8000 female children. This genetic disorder is typically not tested for unless there is a family history of developmental disabilities or dysmorphic physical features (e.g., elongated face, large ears, and macroorchidism in boys) associated with the disorder. It is estimated that about 25% of children with FXS also meet the criteria for autism spectrum disorder (ASD) as these children show difficulties with relatedness, play, and communication and demonstrate repetitive behaviors. It can be difficult to distinguish between infants who have FXS and infants with other disorders as the physical features are not known to be the best marker of diagnosis. There is new research attempting to look at how best to differentiate these infants from others early on. A group of researchers have sought to examine early sensory-motor patterns through videotape analysis of infants with FXS vs. ASD in retrospective type of research (Baranek et al., 2005). It is imperative that early identification of the disorder be made and that early intervention with the child and family begin so there is the best opportunity to maximize positive outcomes for the child and family. The nurse has an important role to help identify the disorder and then provide family education, support, and connecting families with appropriate special education and health services.

Signs and Symptoms

Three criteria must be present for the diagnosis of developmental disabilities to be made: (1) an intelligence

quotient (IQ) score significantly below average (i.e., below 70—average score is 100); (2) limitations in functions of daily life, such as communication, social situations, and school activities (APA, 2000; CDC, 2005b); and (3) onset before the age of 18.

There are four levels of developmental disabilities:

- Mild: IQ between 55 and 69; person generally able to live independently; by far the largest group of developmentally disabled children
- Moderate: IQ between 40 and 54; person able to function semi-independently with help
- Severe: IQ between 25 and 39; person generally requires institutionalization or very close monitoring
- Profound: IQ below 25; person requires total care

The incidence of each type of developmental disability decreases with the severity of the difficulty.

Diagnosis

Diagnosis of developmental disabilities is based on IQ and on the signs and symptoms seen during infancy based on the baby’s physical characteristics (facial features, head circumference) or significant delays in reaching developmental milestones.

Official diagnosis of developmental disabilities is performed by a qualified clinician or a collaborative team of clinicians. These clinicians assess developmental progress at various stages of development as well as perform intelligence and achievement testing. With a confirmed diagnosis of developmental disabilities, the nurse can assess the level of functioning of the child and the family and determine their current level of need. The nurse can communicate to parents that using standardized tests can further suggest a diagnosis.

Nursing Care

Nursing assessment for developmental disabilities should entail prenatal history, birth history, and developmental progress. Each of these assessment categories provides the nurse and family with valuable information.

The nurse understands that there is not one portrait of a developmental disabled child. Some mildly disabled children may not appear “different.” The nurse must remember that each type of disability has unique needs.

An important aspect of nursing care is communication. The nurse can communicate to families that the most preventable forms of developmental disabilities are related to prenatal nutrition and abstinence from alcohol (CDC, n.d.). Genetic counseling may also be helpful, particularly in families where the parents are older or where there is history of fragile X. Promoting good prenatal care as well as encouraging parents to have their children immunized (CDC, n.d.), and enforcing safe practices when bike-riding or playing may help prevent developmental disabilities.

Another focus of nursing care is educational and directed toward building life skills for the child based on the degree of disability. The goal is for the child or adolescent to develop the greatest level of functioning and skills possible to maintain daily living. The nurse can encourage the family to use physical therapy, speech and language therapy, and special educational opportunities. The nurse can teach the family about community resources such as the Special Olympics or schools for therapeutic horseback

riding instruction. Group activities can build both motor and learning skills as well as provide socialization.

For eligible school-aged children (including preschoolers), special education and related services are available most often through the public school system. The school teacher, nurse, and parents work together to develop an Individualized Education Plan (IEP). This plan addresses the child's unique needs and provides the services to meet the needs of each child.

DOWN SYNDROME

Down syndrome (DS) is the most common and readily identifiable chromosomal abnormality associated with developmental disabilities. During cell development, the fetus receives 47 chromosomes instead of the normal 46. The extra chromosome changes the development of the body and the brain.

Down syndrome affects approximately 1 in every 800 live births in the United States each year. Although a woman of any age can have a child with Down syndrome, the chances increase for women older than 35 years of age.

Signs and Symptoms

The most common physical characteristics of DS are poor muscle tone, slanting eyes with folds of skin at inner corners (epicanthal folds), hyperflexibility, short, broad hands with a single crease across the palm of one or both hands, broad feet with increased space between the first and second toes, flat bridge of the nose, short, low-set ears, short neck with extra folds of skin, small head, small oral cavity and airway, and short, high-pitched cries in infancy.

In addition to distinct physical appearance, children with DS frequently have health-related issues. Approximately one third of babies with DS have heart defects, which can be surgically corrected, while some have gastrointestinal anomalies that require surgery. Visual and hearing problems are also common, along with speech difficulty, as are sleep-related issues often due to sleep apnea. Assessment of sleep issues should be conducted usually beginning with asking the caregiver if the child snores and has pauses in breathing during sleep. If that is the case, then further evaluation is needed and it begins with sleep studies that include electroencephalography (EEG). Children with DS are also prone to hypothyroidism and should be evaluated yearly. While this condition is potentially serious, proper diagnosis through an x-ray exam at age 3 can prevent serious injury.

Diagnosis

The diagnosis of DS is usually made from a chromosomal blood test shortly after birth. In addition, just as intelligence varies in the normal population, there is a wide variation in the DS population as well regarding cognitive abilities, behavior, and developmental progress.

Nursing Care

Nursing care of a child with DS is similar to that of any developmental disorder. The nurse must be sensitive to the needs of parents who have learned the newborn has the disorder. Helping parents cope and providing them with resources is an important nursing intervention.

Early intervention with children who have DS has become much more sophisticated. Early intervention

serves to provide the best possible individualized care to children with DS so these individuals can make the most of personal capabilities. Nursing care should be geared to the special physical, developmental, and emotional needs of each child. The nurse can coordinate programs designed to help children with DS. These programs offer speech therapy, cognitive and social skills, self-help skills, as well as occupational and physical therapies that may improve gross and fine motor development. The nurse is also in a good position to help families cope emotionally with living with a child with disability.

Collaboration in Caring— Raising public awareness

The nurse has a responsibility to raise public awareness and acceptance about children with Down syndrome. Children with DS can be included in mainstream educational curriculum and society. The parent, nurse, school personnel, and other individuals in the community can develop an Individualized Education Plan (IEP). The nurse can also communicate to the family and public sector that the National Information Center for Children and Youth with Disabilities at www.nichcy.org is a good resource. The nurse can help the child with DS throughout the lifespan as the child grows into adulthood. Through improved public acceptance and increased community resources more opportunities for persons with disabilities to live and work independently in the community is possible.

FETAL ALCOHOL SPECTRUM DISORDER

The teratogenic effects (causing abnormal development of the embryo) of alcohol have long been recognized. Warnings against drinking while pregnant are carried on all alcoholic beverages. Still, fetal alcohol spectrum disorder (FASD) is a common disorder with a range of physical and neurodevelopmental problems that are known to be completely preventable. The term FASD is more commonly used now than fetal alcohol syndrome (FAS) to describe the effects on infants and children caused by maternal alcohol intake during pregnancy (Caley, Kramer, & Robinson, 2005). FASD describes a spectrum of alcohol-related disorders that includes FAS, alcohol-related neurodevelopmental disorder (ARND), alcohol-related birth defects (ARBD), and fetal alcohol effects (FAE).

Epidemiological studies report that the prevalence of FASD is 1 to 1.5 per 1000 live births, but alcohol-related neurodevelopmental disorders (ARND) (i.e., associated problems that do not fully meet the criteria for FASD), are six to eight times more common than FASD (Klug & Burd, 2003). FASD results from maternal consumption of alcohol during pregnancy. Data show that alcohol intake at any time of pregnancy can be harmful.

Signs and Symptoms

Nurses working in the nursery or in the neonatal intensive care may be able to identify traits of FASD. Characteristics of FASD include facial dysmorphic features (e.g., epicanthal folds, flat mid-face, short nose, short eye openings, thin upper lip, under developed jaw, groove in upper lip), low birth weight, failure to thrive and microcephaly. Later on

developmental delays, hyperactive behavior, learning and attention difficulties, poor motor skills, and developmental disabilities are noted (Caley, Kramer, & Robinson, 2005).

Diagnosis

Early diagnosis is important, but often very difficult without definitive evidence of maternal alcohol ingestion. A diagnosis of FASD requires a good history, including information on maternal consumption of alcohol during pregnancy.

Nursing Care

The nurse can communicate to families that FASD and ARND are 100% preventable, and as such, it is important to develop prevention programs to reduce the rates of these disorders. It is known that prevention programs designed to prevent these disorders would save money that is currently being used to treat children with FASD (Klug & Burd, 2003). Nurses can provide information to families about the effects of alcohol on the fetus. School nurses especially can facilitate early education regarding alcohol consumption during pregnancy (Caley, Kramer, & Robinson, 2005). Since there are no guidelines about safe consumption rates for pregnant women, the public should know that the safe amount is no alcohol intake during pregnancy. Material can be obtained from National Institute on Alcohol Abuse and Alcoholism (NIAAA) Web site (www.science.education.nih.gov). In addition, nurses can help to identify cases of FASD and help families seek appropriate services.

Learning Disorders and Cognitive Impairment

The Interdisciplinary Council on Developmental and Learning Disorders—Diagnostic Manual for Infancy and Early Childhood (ICDL-DMIC) (Greenspan, 2005) prefers to label learning disorders as learning challenges. The nurse understands that a child may manifest challenges in more than one specific learning area, including math, reading, and organizing skills (Greenspan, 2005). It is known that early learning challenges are influenced by emotional and social competencies, auditory processing and language skills (memory, ability to retrieve), perceptual motor skills, motor planning (sequencing, visual memory), visual/spatial processing skills, and ability to modulate sensory information (Greenspan, 2005). The ability to learn involves many of these skills working together. Increased information about learning issues may help identify this condition early and initiate preventive interventions.

There are several disorders in this area including

- Reading Disorder (Dyslexia—significantly impaired ability to read; words or letters may be “mixed up” or distorted, making it impossible to recognize what others see)
- Arithmetic Disorder (Dyscalculia—significant inability to understand or recognize numbers or functions of numbers, or copy them correctly, or follow sequences)
- Writing Disorder (dysgraphia)
- Graphomotor Disorder related to poor fine motor skills)
- Disorder of Written Expression (related to significantly poor spelling, grammar, handwriting)
- Language Disorder (delays in or lack of ability to understand or express verbal communication)

It is estimated that nearly 5% of the children currently in the U.S. school system have a learning disorder. Overall population statistics point to prevalence between 2% and 10% (APA, 2000).

Signs and Symptoms

The nurse understands that a multi-dimensional approach is used to assess early learning patterns. The recommended areas for assessment include functional emotional developmental capacities, auditory processing and language, visuospatial capacities, and regulatory-sensory processing patterns (Greenspan, 2005). The Diagnostic Manual for Infancy and Early Childhood has a comprehensive section with details regarding each area of assessment and the interested reader is encouraged to consult this original source (Greenspan, 2005).

Diagnosis

Diagnosis is made through comprehensive assessments involving interviews and observation. Definitive testing is recommended before a learning disorder or challenge is diagnosed. The DSM-IV-TR identifies reading disorder, mathematics disorder, disorder of written expression, and learning disorder not otherwise specified. It also specifies that each disorder must be diagnosed as a result of standardized test administered on an individual basis (APA, 2000).

Nursing Care

Early identification of learning challenges should be conducted before a child is fully immersed in an academic environment so that early intervention can begin. Early identification and treatment gives the child the greatest potential for a good outcome (Greenspan, 2005). The nurse can communicate to the family that the child’s strengths should be incorporated as part of assessment, early prevention, and intervention. The nurse can fully inform the parents about their child’s rights and entitlements in the public school sector. Often, children who enter public education with a learning challenge or disability will have an IEP (Individualized Education Plan) that is revised every few months. School nurses can provide education and support to children and their families.

Elimination Disorders

ENURESIS

Most children have experienced toileting “accidents” based on waiting too long to use the bathroom or drinking too much liquid before going to bed. For the most part, these experiences, while embarrassing, are not overly concerning. Parental worries about toilet learning can often be allayed when the nurse instructs parents on the normal growth and development that makes toilet learning possible.

Enuresis refers to the occurrence of wetting clothing or the bed at least two times per week for at least 3 months, or that causes significant embarrassment or restriction of activities for the child, like not attending sleepovers or camp (APA, 2000). Children and adolescents can exhibit either diurnal (daytime), nocturnal (nighttime), or *both* types of enuresis. Primary enuresis is diagnosed in children who are at least 5 years of age and have not yet achieved toileting control. Secondary enuresis occurs in

children who have been successful in using the toilet for a significant period of time (6 to 12 months) and then become regularly incontinent.

Causes of enuresis range from physiological problems (urinary tract infections or diabetes) to anatomical problems (genitourinary malformations) to psychological problems (stress or trauma) or disturbances in the sleep cycle (American Academy of Child and Adolescent Psychiatry [AACAP], 2004).

Enuresis tends to run in families. Seventy-five percent of all children with enuresis have a first-degree relative who has also suffered from the disorder (APA, 2000).

Signs and Symptoms

The nurse performs a complete history when assessing the child with enuresis. This history will be helpful in the development of a differential diagnosis. First the diagnosing clinician (nurse practitioner or physician) rules out medical conditions, like urinary tract infections, structural problems, diabetes, or kidney disease. Since there is a familial pattern, understanding its presence in biological relatives is an important clue.

Diagnosis

In considering the child's toilet learning history, age of learning, and difficulties experienced, the nurse can help the family document the onset of the disorder and situations when "accidents" happen. The nurse can also assess recent and chronic stressors that may be affecting the child such as the birth of a sibling, divorce, or other family disruption that might contribute to regression and lead to a diagnosis.

Nursing Care

Initially, the nurse can recognize that it is important to understand parental attitudes about toilet training. Parents who expect their child to be potty trained before the child is physically or emotionally able may stymie their efforts by their insistence.

“What to say” — Toilet training

The nurse can communicate to parents that toilet training can begin when both the parents and child are ready. Parents are ready when they can devote about 3 months of time offering lessons and encouragement. The child is ready to be toilet trained when he or she can indicate that his or her diaper is soiled or wet or can communicate that he or she would like to use the toilet. The child can communicate this information at about 18–24 months of age. Other indicators that the child is ready include the child showing interest in other people using the bathroom or in underwear, noticing a small toilet in the bathroom, or even playing with the toilet paper. The nurse can remind parents that sometimes the child is not ready to be toilet trained until 2 ½ or 3 years of age (American Academy of Family Physicians [AAFP], 2006).

The nurse can also communicate to parents that treatment falls into two categories: behavioral and pharmacological. Behavioral treatments are common and effective. An example of a behavioral treatment is using the bell and pad method, in which a pad that is attached to an alarm is placed under the child at bedtime. If the child urinates, the alarm

rings. Other behavioral methods parents can easily employ are to make sure the child stops drinking liquids early in the evening and the child urinates before going to bed. The parent may also choose to awaken the child during the night to use the bathroom. In time, the problem generally resolves.

Early pharmacological treatments include the use of the tricyclic antidepressant, Imipramine (Tofranil). It is important to note that other tricyclics do not stop bedwetting. More recently, DDAVP (desmopressin), a vasopressin analog has been shown to work to decrease nighttime enuresis. This medication is administered either nasally or orally.

ENCOPRESIS

The DSM-IV-TR describes **encopresis** as the “repeated passage of feces into inappropriate places (e.g., clothing or floor)” (APA, 2000, p. 116). Encopresis can be primary (in children who have not become consistently continent by age 5) or secondary (children who have been continent and then become incontinent for a period of time). The child may present with either constipation with fecal incontinence due to overflow of feces, or without constipation.

Signs and Symptoms

Signs and symptoms of encopresis in the child can be observed or noted as the child may withhold the feces involuntarily due to constipation which may set into motion a cycle of fearfulness of the pain of defecation. The child may also suffer from encopresis related to psychological stressors. If the potty training period is difficult, or if the child uses a toilet that is too tall to get good enough leverage to force the feces out properly, defecation may become associated with pain.

Diagnosis

As with enuresis, children may be diagnosed when they exhibit regression in bowel habits when confronted with stressful situation.

Nursing Care

It is important for the nurse talk to the parents about the child's defecation patterns during a medical appointment. The nurse also understands that it is important to take a thorough history of bowel habits and toilet training. Monitoring the occurrence of constipation will give an indicator of the cause(s). It is also important to evaluate the child's dietary habits, focusing on the amount of fiber and liquids the child consumes. The nurse can also talk to the parents to determine any transitions that may be happening in the child's life such as moving, a new baby in the household, or loss of a caregiver.

where research and practice meet: Encopresis

There are few statistics available for encopresis. A study of 13,111 parents and children of various cultures in Amsterdam found that encopresis occurred in 4.1% of 5- to 6-year-olds, and 1.6% of 11- to 12-year-olds. Twenty-five percent of the children seen by pediatric gastroenterologists present with symptoms of encopresis or constipation. It is estimated that encopresis occurs six times more prominent in boys than in girls (kidshealth.org).

As with enuresis, it is important for the nurse to help the family understand healthy toilet training. Making defecation nonstressful and rewarding may help the child change the behavior. A child's potty is recommended to help the child position him- or herself to push stool out adequately. Nurses can also encourage families to provide a high-fiber diet for their child both for prevention and for intervention with constipation. Since family stress and change can contribute to encopresis, referral of the family for counseling may be in order.

summary points

- ◆ Developmental psychopathology is a discipline that evolved from the contribution from multiple fields of study with the goal of providing an understanding of psychopathology and normal adaptation.
- ◆ Vulnerability is defined as a predispositional factor, or set of factors, that makes a disordered state possible. Resilience is a dynamic developmental process reflecting evidence of positive adaptation despite significant life adversity.
- ◆ There is vast research indicating that health care disparities in racial and ethnic minorities are widespread compared to those in non-minorities, and barriers such as mistrust, fear, and discrimination stand in the way of optimal mental health outcomes in ethnically diverse families.
- ◆ Though there are increasing efforts to educate the public, the stigma of mental illness continues to be a major barrier to accessing mental health services for children and their families.
- ◆ Psychopathology in children includes conditions such as anxiety, depression, posttraumatic stress disorder, suicide, bipolar disorder, schizophrenia, and autism spectrum disorder.
- ◆ The most effective treatment for attention-deficit/hyperactivity disorder (ADHD) is a combination of pharmacological and nonpharmacological interventions. Using both modalities allows for the control or abatement of symptomatic behavior.
- ◆ Child maltreatment is considered to be any action or failure to act by a person that endangers a child's physical or emotional health and development. A person is abusive if the person fails to nurture the child, physically injures the child, or relates sexually to the child.
- ◆ The nurse is in an ideal position to identify adolescents at-risk for substance abuse, especially if there is a strong family and genetic history of abuse; referring for treatment as early as possible. Treatment might involve family psychoeducation regarding substance abuse.
- ◆ Anorexia nervosa can become a life-threatening problem or cause death because of severe weight loss that can result in electrolyte imbalance and hemodynamic instability.
- ◆ A number of factors can cause developmental disabilities: genetic conditions, such as Down syndrome or fragile X syndrome; metabolic conditions such as phenylketonuria

(PKU); or pregnancy-related problems, including alcohol ingestion or viral infections such as rubella.

- ◆ The nurse recognizes that it is important to take a complete nursing history when assessing the child with elimination disorders.

review questions

Multiple Choice

1. In the emergency room, a 10-year-child complains of dizziness, palpitations, sweating, and tingling sensations. The child's mother tells the nurse that recently her child has been talking about death. The pediatric nurse analyzes these behaviors as signs and/or symptoms related to what condition?
 - A. Selective mutism
 - B. Panic disorder
 - C. Posttraumatic stress disorder
 - D. Suicidal tendencies
2. A nurse working in the newborn nursery admits a newborn with facial dysmorphic features. What other clinical manifestations leads the nurse to believe that this neonate was born to a mother who consumed a large amount of alcohol during her pregnancy? (*Select all that apply.*)
 - A. Low birth weight
 - B. Hypoactive behavior
 - C. A high pitched cry
 - D. Microcephaly
3. When developing a nursing care plan for a 26-month-old toddler with inorganic failure to thrive, the pediatric nurse determines which diagnosis as the priority?
 - A. Imbalanced Nutrition Less than Body Requirements related to the inability to absorb nutrients
 - B. Delayed Growth and Development related to inadequate ingestion of nutrients
 - C. Risk for Impaired Parenting related to insufficient knowledge
 - D. Imbalanced Nutrition Less than Body Requirements related to vomiting and diarrhea.
4. An infant comes to the genetic clinic to be evaluated for Down syndrome. While performing a nursing assessment, the pediatric nurse documents several clinical manifestations that are suspicious of Down syndrome. Which of the following clinical manifestations are indicative of this genetic disorder? (*Select all that apply.*)
 - A. Epicanthal folds
 - B. Flattened nose
 - C. Short, low set ears
 - D. Short neck with extra skin folds

Fill-in-the-Blank

5. An infant born to a mother who consumes alcohol during her pregnancy is at risk for developing _____.
6. Researchers have found that the age at onset of schizophrenia plays an important role in the outcome of this condition. It is believed that the _____ the onset, the _____ the impairment.

True or False

7. The pediatric nurse is aware that while performing an adolescent assessment, he or she should not be fearful of asking the adolescent questions related to suicidal thoughts.
8. The pediatric nurse must keep in mind when working with children whose parents have mental health problems that these children will likely go on to develop mental health problems.
9. Attention-deficit/hyperactivity disorder is one of the most commonly recognized psychiatric childhood conditions.
10. The pediatric nurse working in a clinic must be able to identify appropriate developmental milestones in order to facilitate expected outcomes for the child.

chapter 24

Caring for the Child with a Respiratory Condition

When the breath wanders the mind also is unsteady. But when the breath is calmed the mind too will be still...

— Svatmarama

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Describe the anatomy and physiology of the respiratory system.
- ◆ Identify congenital respiratory conditions and structural anomalies in children that affect respiratory function.
- ◆ Explore upper and lower airway disorders in children.
- ◆ Examine infectious and noninfectious agents and allergens that affect children's respiratory health.
- ◆ Plan nursing care for children with respiratory conditions across care settings.

moving toward evidence-based practice Use of Antibiotics for Acute Otitis Media

Rovers, M., Glasziou, P., Appelman, C., Burke, P., McCormick, D., Damoiseaux, R., et al. (2006). Antibiotics for acute otitis media: A meta-analysis with individual patient data. *The Lancet*. 368 (9545), 1429–1435.

The study examined data from six randomized controlled trials that compared antibiotics with placebo or no treatment in 1643 children ages 0–12 years (mean age 3.4 years) with acute otitis media. All participants were assessed for pain and fever control. Forty-two percent had evidence of bulging tympanic membranes. Two of the trials used a low dose of antibiotics for the treatment regimen; one trial excluded children younger than 2 years of age, one trial included only nonsevere cases, and two trials excluded children determined to need immediate antibiotics.

Among children younger than 2 years of age diagnosed with bilateral, acute otitis media, 55% of the control group and 30% of the group taking antibiotics continued to have pain,

fever, or both at 3–7 days. The researchers concluded that treatment with antibiotics reduced both pain and fever at 3–7 days and is most beneficial in children younger than 2 years of age diagnosed with bilateral acute otitis media and otorrhea. Observation was recommended for older children with mild disease.

1. Based on the above synopsis do you believe it is justified to use observation with children younger than 2 years old who do not present with bilateral otitis media or otorrhea?
2. How is this information useful to clinical nursing practice?

See Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

Pediatric respiratory conditions can be very frightening for children and parents. Nurses equipped with the necessary knowledge and skills can be instrumental in providing the competent care needed for these conditions. Nurses are in a position to comfort a frightened child, reassure parental anxieties, and ensure timely nursing interventions.

Gas exchange is the main function of the respiratory system. Body cells need to consume oxygen and discharge carbon dioxide. Respiration is needed both internally at the cellular level and externally through breathing. To accomplish this, the respiratory system undergoes periods of development from the newborn period through late childhood. Major changes in the respiratory system occur immediately after birth and within the first 4 weeks of life. Other changes occur over the course of 12 years of life resulting in lengthening of the airways and expansion of the alveoli. This chapter describes the important differences in the anatomy and physiology of the respiratory system between the adult and the child, provides respiratory assessment in formation, discusses treatments and procedures, and explain a variety of respiratory conditions experienced in childhood.

A & P review The Respiratory System

The anatomy and physiology of the respiratory system in children differs from that of the adults in many ways. There are anatomical and physiological differences; the most obvious difference is size. Anatomically, the respiratory system consists of the upper respiratory tract, which comprises the nose, nasal cavity, sinuses pharynx, larynx, and trachea, and the lower respiratory tract, which includes the lungs, bronchi, bronchioles, and alveoli.

Ventilation (breathing) involves taking in oxygen through the nose and mouth and then delivering it to the lungs. The nose has cilia (small hair-like projections) and mucus-producing cells that line the nostrils to prevent small particles from entering the nasal cavity. Foreign matter entering the nasopharyngeal cavities are trapped in the mucus.

The oxygen passes from the pharynx to the larynx. To prevent any food or liquid from entering the larynx, the epiglottis closes over the opening of the larynx during swallowing. A cough reflex expels foreign bodies. From the larynx, air passes through the trachea which branches into the left and right bronchi. The bronchi divide into smaller branches called bronchioles. The bronchioles end in a cluster of air sacs called the acinus.

Individual air sacs called alveoli exchange oxygen and carbon dioxide. Oxygen exchange with the bloodstream occurs in the capillaries. Oxygen attaches to the red blood cells and is transported to the rest of the body. Carbon dioxide diffuses from the bloodstream into the alveolus where it is transported out of the body during exhalation. ♦

The Child's Respiratory System

The differences between adult and children's respiratory systems affect function and subsequent respiratory conditions. In infants, the nares are much smaller and more easily occluded than in adults. Until about 4 weeks of age,

infants are obligate nose breathers and do not open their mouths to breathe. Nasal patency is essential for inhalation and exhalation to occur in the infant.

The epiglottis in a younger (usually age 8 and under) child is longer and flaccid (floppy), making it more susceptible to swelling which may lead to airway occlusion. The epiglottis is small and does not close properly, and the larynx and the glottis are higher in the younger child's neck, which makes the child more prone to aspiration. The thyroid, cricoid, and tracheal cartilages are immature and are easily collapsible with flexion of the neck. There are fewer functional muscles in the neck and the increased amount of soft tissue make the younger child more susceptible to infection and edema.

The trachea in children is much shorter and narrower in diameter than in adults. To compare, the child's trachea is about 4 mm in diameter, about the diameter of a drinking straw (or as a general rule, the size of the infant or child's little finger) while the adult's trachea is about 20 mm in diameter. The child's trachea bifurcates (separates into two branches) at the third thoracic vertebra, while the adult's trachea bifurcates at the sixth thoracic vertebra. In addition to the higher level of bifurcation, the angle of the right bronchus (one of the two large branches of the trachea) is much sharper.

Because of the differences in the child's airway, the force needed for ventilation is greater. There is increased friction and resistance, making it more difficult to generate ventilation in the presence of airway edema that may result from hypersensitivity reactions or infectious process.

Lung tissue is also immature at birth and continues to grow and develop until about the age of 12. The alveoli also increase in number from 25 to 300 million during this time, along with the increasing size and functionality. The maturity of the alveoli enhances ventilation and respiration, thereby promoting more effective gas exchange.

Children younger than the age of 6 are abdominal breathers instead of thoracic breathers. The intercostal muscles are too weak to facilitate respiration, causing the child to rely on the use of the diaphragm for inspiration. As the diaphragm moves downward, negative pressure is created, expanding the alveoli and filling the lung with air. The downward movement of the diaphragm places pressure on the abdominal contents. With increased airway resistance, the weak musculature of the thorax is pulled inward, causing retractions, as if sucking on a collapsed straw.

clinical alert

Retractions

Retractions are a drawing back of the chest wall with inspiration and occur when the accessory muscles are used for breathing. In the chest, common sites for retractions include suprasternal, supraclavicular, intercostal, subcostal, and substernal.

Since the system is undergoing a process of development during childhood, the child is more prone to develop respiratory problems. In addition, the child does not have the immunity that adults have to many infectious agents. Respiratory infections are especially frequent during the years of growth. Because children are prone to respiratory illness, it is important for the nurse to know the normal

Table 24-1 Normal Values for Arterial Blood Gases

Component	Definition	Normal Values	Interpretation
pH	Acid–base status of the body	Preterm: 7.3–7.4	Acidosis <7.35
		Full term: 7.3–7.4	Alkalosis >7.45
		Children: 7.35–7.45	
Paco ₂	Pressure exerted by CO ₂ in blood	Newborn: 30–40 mm Hg	Acidosis >45 mm Hg
		Infant: 30–41 mm Hg	Alkalosis <35 mmHg
		Children: 35–45 mm Hg	
HCO ₃ ⁻	Buffers effect of acid in blood	Children >7 yr	Acidosis: 22 mEq/L
		20–22 mEq/L	Alkalosis: 26 mEq/L
Base excess	Status of bases in blood	Newborn: (–10) (–2) mEq/L	Acidosis more +
		Infant: (–7) (–1) mEq/L	Alkalosis more –
		Children: (–4) (+2) mEq/L	
		Thereafter: (–3) (+3) mEq/L	
Pao ₂	Pressure exerted by dissolved O ₂ in blood	Newborn: 60–90 mm Hg	Acidosis: <80 mm Hg
		Infant: 80–100 mm Hg	
		Children: 80–100 mm Hg	Alkalosis: >100 mm Hg

values for arterial blood gases in order to deliver effective care (Table 24-1). Pediatric nurses must consider these factors when caring for pediatric patients.

Congenital Respiratory Conditions and Structural Anomalies

There are a variety of congenital respiratory conditions and structural anomalies in children. It is essential that the nurse have a good understanding of the diagnosed condition along with an understanding of signs and symptoms and prescribed care.

CHOANAL ATRESIA

Choanal atresia is a congenital malformation of the nose in which there is blockage of the posterior side of the nose. It often is associated with bony abnormalities and may affect one side or both sides of the nose. A child with bilateral choanal atresia usually displays respiratory problems during development. Choanal atresia occurs in approximately one in 7000 live births (Haddad, 2004).

Signs and Symptoms

After 4 weeks of age, neonates have the ability to breathe through their mouths so that symptoms may not be apparent at birth. In unilateral cases, the neonate may be asymptomatic until signs of respiratory infection, nasal discharge, or persistent nasal obstruction occur. Children with bilateral choanal atresia may have difficulty with nasal breathing and make vigorous attempts to inspire, suck with their lips, and develop cyanosis. A newborn who is pink in color when crying, yet turns bluish when quiet should be suspected of having bilateral choanal atresia or another defect impeding the nasal airway.

The deformity of the nose may lead to involvement of other systems as the child grows, so the child may exhibit multiple problems. The child has a history of difficulty in breathing, and because of this may not eat properly. During feeding, the child may choke or regurgitate the formula or breast milk. The infant may have difficulty coordinating chewing, breathing and swallowing which may also cause regurgitation or aspiration. Weight gain may also be slow or poor. A child with this condition must be evaluated for cardiopulmonary and gastrointestinal involvement.

Diagnosis

Diagnosis of choanal atresia is established by the inability to pass a firm catheter through each nostril 3–4 cm into the nasopharynx. The diagnosis is confirmed by computerized tomography (CT) scan with intranasal contrast that shows narrowing of the posterior side of the nose.

Nursing Care

Immediate care of a child with choanal atresia includes inserting an oral airway and starting gavage feeding to prevent aspiration and malnutrition in later life. The child will have definitive repair which involves transnasal puncture and stenting, or through endoscopy, resection may be done. After any type of surgery, child may have recurrent stenosis necessitating dilatation, reoperation, or both.

Nurses caring for children with choanal atresia need to teach the parents to keep the child's nostrils clean by gently cleansing the rim of the nostrils with a warm soft cloth. A clean nasal area prevents dry mucus from accumulating in the child's nostrils to facilitate breathing. Since the child may have difficulty with feeding, aspiration precautions must be observed. The baby is fed in a semi-upright position with periods of rest to facilitate breathing. The nurse also instructs the mother to protect the child against respiratory infection by using good hand washing and

keeping the child warm and dry. The nurse must also communicate to parents to keep the child away from densely populated public places such as day cares, grocery stores, and malls. The nurse can encourage the parents to opt for early treatment, especially if the condition is bilateral.

ESOPHAGEAL ATRESIA AND TRACHEOESOPHAGEAL FISTULA

Esophageal atresia (EA) is failure of the esophagus to develop as a continuous passage, at times leading to a blind pouch. Tracheoesophageal fistula (TEF) is an abnormal communication between the trachea and the esophagus. This condition may lead to serious effects in ventilation. EA is the most frequent congenital anomaly of the esophagus, affecting about 1 in 4000 neonates. Of these, more than 90% have an associated tracheoesophageal fistula (Orenstein et al., 2004). In the neonate, EA is an emergency medical condition necessitating immediate action to protect the airway and respiratory system.

clinical alert

Checking the Mother's Obstetric History

When the nurse is caring for a newborn and observes the baby to be drooling excessively and/or having persistent choking spells and color change with feedings, it is important for the nurse to check the mother's obstetric history. If there is history of polyhydramnios, the nurse must report the observed symptoms to the baby's pediatrician at once. These symptoms are highly suspicious of esophageal atresia and tracheoesophageal fistula.

Nursing Insight— Variations of esophageal atresia with or without tracheoesophageal fistula

The nurse understands that there are different anatomical variations of EA with or without tracheoesophageal fistula:

- Esophageal atresia with distal tracheoesophageal fistula (87% of the cases)
- Isolated esophageal atresia
- Isolated tracheoesophageal fistula
- Esophageal atresia with proximal tracheoesophageal fistula
- Esophageal atresia with double tracheoesophageal fistula

This anomaly develops during fetal development when failure of separation takes place in the long tube in the neck when the tracheoesophageal groove fails to close. The esophagus and trachea are made up from the foregut in the 4- to 6-week-old embryo. The caudal part of the foregut forms a ventral diverticulum that develops into the trachea. The horizontal part of the trachea and esophagus fold then join together to form the septum that divides the foregut into ventral larynx and trachea, and dorsal part of the long tube called the esophagus. During this process of formation of the respiratory tract and passage for the food, the posterior deviation of the tracheoesophageal septum leads to failure of closure between the trachea and esophagus.

The exact cause of TEF is not known but approximately 17% to 70% children exhibit associated developmental anomalies, like chromosomal abnormalities, duodenal

atresia, and cardiovascular defects with TEFs (Sharma, 2006). The severity of the anomaly is analyzed on the basis of involvement of other organs. TEF can affect trachea alone or it may effect to the esophagus and other systems.

Signs and Symptoms

On assessment the nurse may observe frothing and bubbling at the mouth and nose, excessive drooling and salivation, episodes of coughing, cyanosis, and respiratory distress. With feeding, the symptoms may intensify and may lead to regurgitation, choking, and aspiration, so the infant should be NPO. In cases of isolated TEF, symptoms may occur later in life with the child having chronic respiratory problems and abdominal distension due to air building up in the stomach. Since EA and TEF have been associated with other congenital anomalies that occur in the musculoskeletal, gastrointestinal, cardiac, and genitourinary systems a thorough assessment by the nurse is necessary.

Diagnosis

If not diagnosed with prenatal sonogram, most neonates are diagnosed soon after birth or during infancy because TEF is life-threatening condition. A neonate is diagnosed on the basis of prenatal history of maternal polyhydramnios (excessive amniotic fluid). TEF may be confirmed by observing for an early onset of respiratory distress accompanied by signs and symptoms described earlier and possibly the inability to pass nasogastric or orogastric tube. Confirmatory diagnosis is made through radiography. A radio-opaque dye is administered to assess the extent of the anomaly. Chest films are taken to determine the patency of the esophagus or the presence and level of the blind pouch.

nursing diagnoses Esophageal Atresia with or without Tracheoesophageal Fistula

- Ineffective Airway Clearance related to excessive secretions
- Altered Nutrition: Less than Body Requirement related to inadequate ingestion of nutrients
- High Risk for Infection related to accumulation of secretion in the lungs
- Altered Family Processes related to frequent hospitalization/prolong sickness
- Impaired Family Social Interaction related to situational crisis
- High Risk of Aspiration related to excessive drooling and poor swallowing and inability to clear secretions

Nursing Care

Immediately after birth treatment is aimed at maintaining a patent airway and preventing aspiration of secretions. Although EA and TEF are surgical emergencies, discretion should be used about performing immediate surgical corrections. Highly compromised neonates such as those who are premature, those with concurrent congenital anomalies, and those who are in poor physical condition should not be operated on immediately. After life-sustaining measures are given, surgical corrections may come in stages that may be palliative in nature (i.e., gastrostomy and drainage of esophageal pouch). A child may be assisted with artificial ventilation in the beginning and could be weaned off the artificial ventilation as the condition improves. However, endotracheal intubation may be avoided because as it may worsen abdominal distention due to the connection between the trachea and esophagus.

critical nursing action Nursing Assessment

The nurse must use a complete nursing assessment to assess the child's condition. A complete nursing assessment includes watching for subtle changes in the child's color, respiration, behavior, heart rate, and general health. The nurse understands that subtle changes can occur before technology is able to recognize the changes. The nurse also understands the importance of using innate instincts when caring for the child; if the nurse senses impending crisis it is important to pay attention to this instinct and act accordingly (getting emergency equipment ready). It is also important to remember that the child has an uncanny ability to compensate. When the child is no longer able to compensate the child "crashes" and then may then have a poor probability of recovery.

Before surgical correction, the nurse understands that the neonate is not given oral feedings but instead intravenous fluids are given. The nurse positions the neonate at a 30-degree elevation to protect the trachea from secretions and the head turned to the side to prevent aspiration and drain secretions. Suctioning is done regularly and at frequent intervals. A nasogastric or orogastric tube with continuous suctioning is likely to be placed into the blind pouch, usually by the surgical team. Often antibiotic therapy is started because aspiration pneumonia is inevitable.

Immediately after the surgical correction, nurses must monitor vital signs at regular intervals. The site requiring correction is usually in the thoracic cavity, so the nurse should expect the baby to return with a chest tube, and possibly still be intubated with an ET tube. Infants with chest tubes are carefully handled to avoid dislodging of the tube. Suctioning of the oropharyngeal area is kept to a minimum to avoid disruption of the surgical repair.

Initially, nutrition is given parenterally. Oral feeding can be started when the child is both surgically and medically ready. It is also important to prevent infection therefore vigilant nursing care should be observed at all times.

After corrective surgery, the majority of the infants lead normal lives. If complications do occur, they are challenging, especially during infancy. Prognosis depends on the presence or absence of other associated anomalies.

CONGENITAL DIAPHRAGMATIC HERNIA

Congenital diaphragmatic hernia (CDH) is a life-threatening congenital abnormality characterized by a variable degree of pulmonary hypoplasia associated with a decrease in cross-sectional area of the pulmonary vasculature and dysfunction of the surfactant system. In the United States, CDH occurs in 1 of every 2000 to 4000 live births and accounts for 8% of all major congenital anomalies (Hekmatnia, 2003). Population-based studies report survival rates ranging from 25% to 60%. Infants with multiple anomalies have much lower survival rates than those with isolated defects (Steinhorn, 2004).

While CDH is frequently found among newborns, the child may exhibit signs and symptoms after the newborn period or even during adulthood. Prognosis is better with late presentations, with low or no mortality.

Closure of the posterolateral pleuroperitoneal canals during the 8th week of gestation causes separation of the developing thoracic and abdominal cavities. The failure of these canals to close causes the classical posterolateral

Family Teaching Guidelines... Esophageal Atresia with or without Tracheoesophageal Fistula

In many hospitals, the nurse takes responsibility in preparing parents for discharge and home management. There are several topics that the nurse must teach parents in order to care for the child who has a diagnosis of EA or TEF:

- ◆ In the case of tracheotomy, nurses must teach parents proper sterile technique of suctioning and how to handle the equipment appropriately.
- ◆ Ensure all emergency calling numbers are written down so emergency care could be provided in a serious situation.
- ◆ Ensure parents know how to identify respiratory distress.
- ◆ Ensure parents know feeding techniques for gastrostomy tube and how to handle tube plugging and dislodging.
- ◆ Instruct parents in performing CPR before the child goes home.
- ◆ Encourage parents to use different toys and games to promote stimulation during regular care (e.g., encourage mobilization or action play to help the child reach developmental milestones and divert the child's mind, which may help the child cope during the prolonged sickness). Mobilization can be as simple as holding or rocking while action play can be games, toy figures, or crafts.
- ◆ Involve other siblings in adapting the young child with EA or TEF. It is essential that the family help the child with EA or TEF learn socialization and interaction with others.
- ◆ Ensure the family knows how to operate equipment and knows proper maintenance of the equipment used at home.

diaphragmatic hernia where the herniation is through the foramen of Bochdalek. The effect on the diaphragm may be small, slit like, or include the entire hemidiaphragm. Both lungs are small, with the lung on the side of the defect more severely affected. There is a decrease in the number of alveoli and bronchial generations. The pulmonary vasculature is abnormal, with a decrease in volume and a marked increase in muscular mass in the arterioles. The pulmonary abnormalities may be due to the compression of the intrathoracic abdominal viscera although this is not the primary cause. Because lung hypoplasia, poor gas exchange and surfactant dysfunction, the whole pulmonary function is disrupted.

The three basic types of CDH are the posterolateral Bochdalek hernia (left sided) which occurs in utero at approximately 6 weeks of gestation. Left-sided Bochdalek hernia occurs in approximately 90% of the cases. It affects both the small and the large bowel, causing herniation of these organs that extends into the thoracic cavity. The anterior Morgagni hernia occurs in the anterior midline through the sternocostal hiatus of the diaphragm, with 90% of cases occurring on the right side; and the hiatus

hernia, a less common form in which the stomach hernia occurs through the esophageal hiatus.

Signs and Symptoms

Newborns with CDH usually have severe respiratory distress, typically developing within the first several minutes of life.

Diagnosis

The condition may be diagnosed during the prenatal period through ultrasonography. Features found in utero pointing to CDH include polyhydramnios, absent or intrathoracic stomach bubble, mediastinal and cardiac shift away from the side of the herniation. It is suggested that parents whose baby has been diagnosed with CDH prenatally be counseled to deliver their infant at an institution able to appropriately care for the mother and newborn, and have a realistic understanding about the severity of this diagnosis. Postnatally, children suspected with CDH or those with symptoms of respiratory distress require a chest x-ray exam after emergency stabilization measures are taken.

Nursing Care

While CDH was once considered a surgical emergency, today, a delayed surgical approach enables preoperative stabilization and decreases morbidity and mortality. The presence of pulmonary hypoplasia, pulmonary hypertension, and surfactant deficiency has negative effects on the neonate if early surgery is performed, especially if the neonate is premature.

The ideal time to repair a CDH is unknown. Some authors suggest that repair 24 hours after stabilization is ideal, but delays of up to 7 to 10 days are often well tolerated. Many surgeons now prefer to operate on these neonates when echocardiographic evidence for normal pulmonary artery pressures is maintained for at least 24 to 48 hours (Steinhorn, 2004).

Immediate medical management is aimed at stabilizing the patient, optimizing oxygenation, and preventing further trauma. First, an endotracheal intubation rather than mask ventilation is inserted to optimize oxygenation (Fig. 24-1). The nurse sees to it that the endotracheal tube is patent.

Then an orogastric or nasogastric tube connected to a continuous suction is inserted to prevent bowel distention

Figure 24-1 Child with an endotracheal tube.

Figure 24-2 Continuous pulse oxymetry is an important nursing intervention.

and avoid further lung compression. The administration of exogenous surfactant a few hours after delivery alleviates the existing surfactant deficiency. The use of extracorporeal membrane oxygenation (ECMO) may be recommended for full-term infants if ventilator and medical therapy do not maintain acceptable oxygenation and ventilation.

Nursing care requires skillful and cautious monitoring of oxygenation, blood pressure, and perfusion while maintaining the principle of minimal handling. Patients with CDH require a specially trained group of medical and nursing personnel both before and after surgery.

Before surgery, the child is cared for in an intensive care unit with close monitoring of the pulmonary and cardiac functions. Continuous pulse oxymetry is essential (Fig. 24-2). The nurse must perform orogastric or nasogastric suctioning (to prevent abdominal distention) at regular intervals if the child is not already on continuous suction. As much as possible, the child is turned on the affected side so that the unaffected lung may expand to the fullest.

clinical alert

Preoperative and postoperative suctioning

Preoperatively, any nasogastric or orogastric tube placement for suctioning must be done extremely carefully and gently, and progression stopped immediately if any resistance is met, as it is very easy to perforate the esophageal tissue of an infant with an anomaly.

Postoperative oral or nasal suctioning of the infant with EA, TEF, or CDH must also be done extremely carefully to avoid disruption of the repairs. Carefully measure the catheter and do not insert any further than the distance from the nares to the ear lobe.

Postoperatively, nursing care plays a vital role in the child's recovery. The nurse must perform vigilant assessments on all body systems to any detect complications or new problems. Because the child may have low blood counts and decrease in fluid volume the nurse must regulate plasma or blood transfusion and the intravenous infusions adequately. To maintain adequate nutrition, gavage feeding may be initiated by the second or third postoperative day. The nurse understands that gavage feedings must be administered slowly while watching the child closely

for any untoward manifestations such as aspiration. The child requires prolonged hospitalization, so the family must be informed about the lengthy hospital stay and the myriad of ongoing treatments. After the child has recovered, he may be discharged to the care of the parents. The nurse must emphasize to the family the need for frequent follow-up visits to ensure that no complications or problems are present.

RESPIRATORY DISTRESS SYNDROME

Respiratory distress syndrome (RDS) or hyaline membrane disease (HMD) are the terms used to refer to respiratory dysfunctions mostly among the preterm neonates related to the developmental delay in lung maturation. It occurs in 60% to 80% of infants less than 28 weeks of gestational age, in 15% to 30% of those between 32 and 36 weeks, in about 5% beyond 37 weeks, and rarely at term (Stoll & Kliegman, 2004). RDS is associated with infants of diabetic mothers, delivery before 37 weeks of gestation, deliveries by caesarean section, multifetal pregnancies, precipitous deliveries, asphyxia, cold stress, and a history of previously affected infants.

Decreased production and secretion of lung surfactant is the main cause of RDS. Surfactant is a surface-active phospholipid secreted by the alveolar epithelium. This substance reduces the surface tension of fluids that line the alveoli and respiratory passages, resulting in uniform expansion and maintenance of lung expansion at low intraalveolar pressure. Immature development of these functions produces consequences that seriously compromise respiratory efficiency. Adequate levels of surfactant are present after 35 weeks of gestation.

Deficiency in surfactant leads to unequal inflation of alveoli on inspiration and the collapse of the alveoli on end expiration. The neonate is unable to keep the lungs inflated and exerts extensive effort to re-expand the alveoli on each breath due to surfactant deficiency. This leads to atelectasis, increased pulmonary vascular resistance, hypoperfusion to the lung tissue, and consequently, hypoxemia, and hypercapnia. These series of events causes hypoventilation with increased PaCO_2 , decreased PaO_2 , and decreased pH. The combination of hypercapnia, hypoxia, and acidosis produces pulmonary arterial vasoconstriction, resulting in further alveolar hypoperfusion, impaired cellular metabolism, and consequently diminished production of surfactant. This vicious cycle continues unless prompt treatment is initiated.

Signs and Symptoms

The symptoms are apparent within a few minutes after birth although in larger premature neonates, the onset of symptoms may occur several hours later. Rapid, shallow, respiration with a rate of 60 breaths/min or greater should alert the nurse. Tachypnea (80 to 120 breaths/min), audible grunting, intercostal and subcostal **retractions**, nasal flaring, and cyanosis are accompanying symptoms. As the condition worsens, flaccidity and apnea occurs. Respiratory failure may occur with the rapid progression of the disease.

Diagnosis

Diagnosis of RDS is based on the signs and symptoms of this condition, x-ray exam of the chest, and blood gas

and acid base values. Radiographic findings include granular appearance of the lungs, bronchograms (dark streaks), and an air-filled esophagus. Laboratory findings are characterized by hypoxemia and variable metabolic acidosis.

Nursing Care

Most cases of RDS are self-limiting. Immediate establishment of oxygenation, ventilation, and supportive care are needed to prevent complications. Treatments of these neonates are best carried out in a specially staffed and equipped neonatal intensive care unit (NICU). Principles of supportive care in any preterm neonate should be adhered to, such as gentle handling and minimum disturbance, avoidance of hypothermia, and minimizing oxygen consumption. The nurse is advised to plan care appropriately so that these principles are followed.

The nurse understands that rescue therapy with surfactant is initiated as soon as possible in the first 24 hours of life. Administration of exogenous surfactant to neonates requiring 30% oxygen and mechanical ventilation dramatically improves survival and reduces the incidence of bronchopulmonary dysplasia. A physician who is qualified for neonatal resuscitation and respiratory management administers exogenous surfactant. The physician is supported by well-trained nurses and a respiratory therapist experienced in ventilatory management. Nursing responsibilities include assistance in the delivery of surfactant, collection and monitoring of arterial blood gases, conscientious monitoring of oxygenation with pulse oximetry, and reporting any adverse reactions to therapy.

Immediately after delivery, the neonate is placed in an incubator or a radiant warmer. The nurse ensures that the child's core body temperature is maintained at 97.9 to 98.6°F (36.6 to 37°C) through frequent monitoring. Nursing care also includes administering warm humidified oxygen at a concentration sufficient to keep arterial oxygen levels between 55 and 70 mm Hg (>90% saturation) to maintain normal tissue oxygenation while minimizing the risk of oxygen toxicity. Humidity of the air in the incubator is maintained at 30% to 60%.

When completing a respiratory assessment, if the child's PaO_2 cannot be maintained above 50 mm Hg at inspired oxygen concentration of 60% or greater, apply continuous positive airway pressure (CPAP) at a pressure of 6 to 10 cm H_2O via nasal prongs (Fig. 24-3). CPAP prevents collapse of surfactant-deficient alveoli and improves ventilation perfusion. Caring for children on CPAP requires advanced training and technical skills, so it is appropriate that nurses who are highly trained in neonatal intensive care handle children on CPAP.

Certain laboratory values such as oxygen and carbon dioxide tension and the pH of the arterial and capillary blood are monitored from time to time. Nurses must schedule laboratory testing at intervals that allow for maximum periods of rest for the child.

Nursing management for children with RDS also requires a vigilant nursing assessment and monitoring of vital signs. The nurse must accurately record and report significant changes in vital signs to the physician. Calories and fluids are provided intravenously; therefore, the nurse must monitor exact intake and output.

Figure 24-3 Child on continuous positive airway pressure.

clinical alert

Assisted mechanical ventilation

Neonates with severe RDS and those with complications require assisted mechanical ventilation.

case study Respiratory Distress Syndrome

Lara Smith, a 42-year-old primigravida with type 2 diabetes and in her 28th week of gestation, was admitted into the delivery room. She was complaining of lumbosacral pain 2 hours before admission. The labor and delivery nurse begins to monitor the progress of labor as well as provide emotional support since Lara appears to be quite anxious. The neonatal intensive care unit has been notified about a possible admission of a neonate at risk for respiratory distress syndrome.

critical thinking questions

1. What maternal conditions place the newborn at risk for respiratory distress syndrome?
2. What possible treatment can be given to Lara to prevent respiratory distress syndrome?

◆ See Suggested Answers to Case Studies in text on the Electronic Study Guide or DavisPlus.

BRONCHOPULMONARY DYSPLASIA

Bronchopulmonary dysplasia (BPD), also known as chronic lung disease (CLD), is a chronic obstructive disease of the lungs that occurs as a complication of prolonged oxygen therapy, especially in preterm infants who are on assisted ventilation. It was first described by Northway and associates in 1967 in a review of chest radiographs of preterm infants who were treated with positive pressure ventilation and oxygen for respiratory distress syndrome (Driscoll, 2003).

Immature lungs are one of the most important factors in the development of BPD; however, the mechanism by which this occurs is not yet completely understood. What is known about BPD is that it multiple factors are responsible. Available views on BPD suggest that it is a complex disorder resulting from more than solely lung injury related to oxygen toxicity and trauma from mechanical ventilation. Consistent pathological findings are decreased alveolarization, decreased septation, and minimal airway disease, all of which suggest arrest in lung development. Atelectasis, together with mechanical ventilation, induces increased lung volume and overdistention of the lungs, resulting in injury. The mechanically ventilated oxygen produces injury by producing free radicals that cannot be metabolized by the immature antioxidant system of the neonates. Several clinical factors including immaturity, infection, symptomatic patent ductus arteriosus (PDA) and malnutrition, contribute to the development of BPD.

Signs and Symptoms

Signs and symptoms of BPD include tachypnea, wheezing, rales, retractions, and episodes of cyanosis. Respiratory rates are increased by as much as 20 to 30 breaths/min from the regular rates based on age. There is prolonged exhalation and increased use of abdominal and accessory muscles. Due to the increase in abdominal pressure from high airway resistance and use of accessory muscles, umbilical and inguinal hernia may occur. Feeding, handling, and activity intolerance makes the infant prone to develop under nutrition leading to stunted growth and development.

Diagnosis

Neonates are diagnosed based on signs, symptoms, and radiographic findings. Radiographic examination shows thickened and fibrotic changes in the airways and alveoli.

Nursing Care

critical nursing action Assessing Respiratory Status

The nurse needs to assess the infant's respiratory status including increasing respiratory rate and decreasing oxygenation. The child who has a severe case of BPD may need recurrent hospitalization; therefore, the nurse must be able to provide emotional support to parents during these crucial moments.

The aim of management is to provide supportive care and minimize additional injury to the respiratory system by decreasing the workload of breathing and normalizing gas exchange, thus permitting improvements in growth and development. Infants with BPD who remain ventilator dependent for several weeks should be weaned gradually. An adjustment could be made to the small tidal volumes to prevent mechanical injury. In addition, a positive end-expiratory pressure (PEEP) of 6 to 7 cm H₂O may reduce the effects of atelectasis. A slightly prolonged inspiration duration of 0.5 to 0.6 seconds may improve lung function. Infants who can maintain their own breathing while weaning from the ventilator should be supplemented with oxygen therapy. Oxygen therapy should maintain arterial

Pao₂ above 50 to 55 mm Hg, since this level helps in adequate function of the tissues oxygenation and prevents pulmonary vascular resistance related to hypoxemia.

The nurse understands that wheezing is managed with bronchodilators. If the child responds to bronchodilators, the medication should be continued. Inhaled, Albuterol (Ventolin) increases air movement and improves the comfort of breathing. Corticosteroids may be administered to reduce inflammation and improve lung function. Different routes of medication administration such as intravenous or inhalation therapy are used according to the severity of the disease.

When caring for a child with BPD, the nurse uses pulse oximetry to monitor fluctuation in oxygen saturation. In addition, an arterial blood sample can be drawn to monitor hypoxemia in the tissue. As changes in the neonate's condition occur, the nurse anticipates that x-ray studies will help determine the respiratory status of the infant.

If an infant is placed on diuretics, careful replacement of calcium, chloride, and potassium must be ensured through regular electrolyte tests. Essential nursing care includes monitoring and maintaining fluid intake because infants with BPD are at high risk for developing pulmonary edema.

The nurse can ensure a proper nutritional plan to promote recovery, growth, and development. Caloric requirements increase to 150 kcal/kg per day in infants with BPD. If the infant can tolerate sucking, breast feeding is encouraged. If formula feeding is used, supplemental fortified formula should be given via nasogastric, orogastric, or gastrostomy tubes. The nurse can also observe the mother or both parents during feeding time to promote support and increase the mother's confidence in caring for the child.

critical nursing action Prevention of Respiratory Illnesses in Patients with BPD

The nurse should instruct all visitors to wash their hands before touching the neonate. The nurse should politely ask visitors with current respiratory infections to leave the room, explaining that the infant is at an increased risk for infection.

nursing diagnoses Bronchopulmonary Dysplasia

- Impaired Gas Exchange related to alveolar damage
- Ineffective Airway Clearance related to fatigue associated with poor oxygen to the tissues
- High Risk for Infection related to deformity in the lungs
- Altered Nutrition: Less than Body Requirements related to feeding difficulties and fatigue
- Fluid Volume Excess related to intestinal fluid edema
- Ineffective Family Coping related to chronic disease

CYSTIC FIBROSIS

Cystic fibrosis (CF) is an inherited autosomal-recessive disorder that causes the production of thick mucus that blocks exocrine glands and affects several body systems, including respiratory, gastrointestinal, and reproductive. CF is the most common cause of chronic respiratory

disease in children, and is accompanied by multiple, severe respiratory infections. The increased mucus production in the airways causes obstruction and stasis of fluid, providing a rich habitat for bacterial growth. In addition, the pancreatic ducts are often blocked by mucus, prohibiting the secretions of pancreatic enzymes necessary for the metabolism of food nutrients. In later childhood, the reproductive system is affected, as ovarian ducts and the vas deferens may be occluded, leading to infertility. There is also an increased loss of sodium, causing salt depletion in children with CF.

CF is most common in Caucasian individuals with fair skin, affecting approximately 30,000 children and adults in the United States. More than 10 million persons are carriers of the defective gene (Porth, 2005).

CF is transmitted as an autosomal-recessive trait, which means that the child can receive a defective gene from either parent. When both parents carry the defective gene, there is a 25% chance that the child will inherit one CF gene from each parent and manifest the disease. There is a 50% chance that the child will inherit one defective gene from each parent and just be a carrier of the disease. There is a 25% chance that the child will inherit only normal genes and be completely free of CF.

The CF genes have been found on chromosome 7, which encodes cystic fibrosis transmembrane conductor regulator (CFTR) protein. CFTR normally regulates the chloride channel and facilitates the activity of other chloride and sodium channels at the cell surface. Abnormal functions of CFTR cause a disruption of sodium ion transport across the exocrine and epithelial gland cells and make the cell walls impermeable to chloride ions (Porth, 2005). This causes an excess of sodium and chloride found in the sweat of children affected by CF. In addition, the loss of sodium and water from the airways increases the viscosity of the mucus and disrupts the ciliary mechanism (hair-like process) that is intended to clear the airways, predisposing the child to recurrent respiratory infections.

A similar transport defect occurs in the pancreatic and bile ducts. With inadequate excretion of pancreatic enzymes for food breakdown, children experience varying levels of protein and fat absorption. With reduced protein and fat absorption, there is weight loss and failure to thrive, requiring children's diets to be high in protein and calories. Fat is excreted in the stool, resulting in abnormal bowel patterns, including steatorrhea, diarrhea, and abdominal pain.

The mucus gland produces thin, free-flowing secretions, but in CF it produces thick mucus that accumulates and obstructs the different organs. In newborns, thick secretions may plug the small intestine and lead to failure in passing meconium (the first feces of a newborn infant, which is greenish black, odorless, and tarry) (Venes, 2009). In the gastrointestinal system thick secretions impair the digestive system and lead to malnutrition in childhood.

Signs and Symptoms

CF affects the different vital organs of the body, and children with the condition show a wide range of signs and symptoms. The severity of the symptoms varies from child to child. Since CF is a multisystem disease (failure of two or more organ systems), the symptoms are presented according to the body system affected.

The initial presentation of CF in the neonate appears in the gastrointestinal system. The newborn may have a meconium ileus, with meconium so thick that it causes obstruction and requires surgical removal. The infant may initially have bulky stools that are frothy and foul smelling. Prolapse of the rectum may also occur in infancy and childhood. Malnutrition, anemia, and growth failure persists despite normal caloric intake. Children with CF are usually thin and underweight. Of children diagnosed as having CF, 50% are classified in the less than the 10th percentile for height and weight. Protuberant abdomen, barrel chest, wasted buttocks, and thin extremities are common features in children with CF.

In the respiratory system, the child exhibits crackles, wheezes, and diminished breath sounds with a dry, nonproductive cough. There may be repeated bouts of pneumonia and bronchitis because thick secretions provide favorable flora for the bacteria to grow. In addition, the child has a history or recurrent attacks of infection and persistent cough. With increasing severity, difficulty in breathing, tachypnea, hypoxia, and cyanosis may occur. In advanced cases, the child may show emphysema and atelectasis as the airways become increasingly obstructed with secretions. Prolonged hypoxia in the child may lead to digital clubbing.

In the integumentary system, there is a persistent high concentration of sodium and chloride in sweat. The mother may report that the skin of her baby is always wet or salty when kissed. The child may show wrinkled skin because of dehydration or dry skin. Prolonged or untreated electrolyte imbalance may lead to a listless or inactive child. Mothers may report long sleep and nap times. The nurse may assess dehydration by looking at the mouth of a child (dry mouth, ulceration, or rash in the mouth).

Later, children with CF are potentially at greater risk of delayed development of secondary sex characteristics. The male's vas deferens may be occluded and the female's ovarian ducts may also be occluded, leading to infertility. In addition, due to pancreatic damage, there is also an increased risk of diabetes.

Diagnosis

The diagnosis of CF is based on the child's signs and symptoms, including a positive history of the disease in the family, absence of pancreatic enzymes, increase in the electrolyte concentration of sweat, and chronic pulmonary involvement. Chest x-ray films show patchy atelectasis and obstructive emphysema. A quantitative sweat chloride test is performed on sweat obtained by iontophoresis of pilocarpine. A chloride concentration of greater than 60 mEq/L is diagnostic of CF. The normal values of sweat chloride test are usually less than 40 mEq/L. In infants, a value greater than 40 mEq/L is highly suggestive of CF (Winkelsstein, 2005). Pancreatic dysfunction is also clinically apparent. Tests for direct documentation of enzyme secretion are invasive and are not routinely done for children. Pulmonary function tests are done in older children. These tests help to evaluate the progression of the disorder and provide direction for suitable treatment.

Nursing Care

The goal of treatment is to ensure respiratory function, enhance nutrition, promote growth and development, and encourage independence in an individual child and family.

Across Care Settings: Promoting respiratory function

To ensure respiratory function, a multidisciplinary approach should be taken. A physician, nurse, respiratory therapist, social worker, dietitian, and psychologist are the important professionals in the management of a child with CF.

The nurse understands that ensuring respiratory function in children entails controlling infection and improving aeration. These care measures are achieved via medicated aerosol therapy, chest physiotherapy (percussion and postural drainage), and antibiotic therapy (Fig. 24-4). Some children with CF may have a central venous access device for frequent antibiotic administration.

Most children with CF have a complete loss of pancreatic function and inadequate digestion of fats and protein; therefore, an important aspect of management is to replace the pancreatic enzymes. The nurse should remember that enzyme replacement is administered with meals and snacks so the digestive enzymes are mixed with food in the duodenum. Enzyme replacement should not exceed 2500 lipase units/kg per meal. The nurse must explore the best way of administering oral capsules with the family and the child.

Optimizing Outcomes— Nutrition

The best outcome for a child with CF is a well-balanced, high-protein, high-caloric diet. Pancreatic insufficiency results in malabsorption of fat-soluble vitamins (vitamins A, D, E, K). Daily vitamin supplementation is recommended. The nurse can also work closely with family to prevent infection as well as optimize nutrition and growth of a child.

Figure 24-4 Chest physiotherapy is performed to loosen and remove lung secretions. Percussion and vibration are used over the affected areas of the lungs.

Nursing Care Plan The Child with Cystic Fibrosis

Nursing Diagnosis: Risk for infection related to impaired body defense system

Measurable Short-term Goal: The child will remain free from symptoms of infection during hospitalization

Measurable Long-term Goal: The parents will implement measures to prevent infection

NOC Outcomes:

- Risk Control (1902) Personal actions to prevent, eliminate, or reduce modifiable health threats
- Immune Status (0702) Natural and acquired appropriately targeted resistance to internal and external antigens

NIC Interventions:

- Health Education (5510)
- Infection Protection (6550)
- Medication Management (2380)

Nursing Interventions:

1. Wash hands or use approved alcohol-based hand rubs, before and after providing care.
RATIONALE: Appropriate hand hygiene helps prevent infection outbreaks, reduces transmission of antimicrobial resistant organisms and reduces overall infection rates.
2. Monitor temperature every 4 hours. Report a single temperature greater than 101.3°F (38.5°C) or three temperatures greater than 100°F (38°C) in 24 hours to the care provider.
RATIONALE: Fever is often the first indication of infection.
3. Observe for and report additional signs of infection such as increased mucus production, persistent cough, tachypnea, difficulty breathing, or cyanosis.
RATIONALE: Increased mucus production in the airways causes obstruction and stasis of fluid, providing a rich habitat for bacterial growth. Early detection of infection allows for prompt and appropriate intervention.
4. Monitor and report laboratory values as ordered, such as complete blood count (CBC) with differential, serum protein, serum albumin, and cultures.
RATIONALE: Laboratory values are correlated with the child's history and physical examination to provide a global view of the patient's immune function and nutritional status.
5. Encourage fluid intake and a high-calorie balanced diet, emphasizing proteins, fatty acids, and vitamins.
RATIONALE: Nutrients benefiting the immune system include essential amino acids, linoleic acid, vitamin A, folic acid, vitamin B₆, vitamin B₁₂, vitamin C, vitamin E, Zn, Cu, Fe, and Se. Efficient immune function may be affected by deficiencies in one or more of these nutrients.
6. Instruct the child and parents on principles of medication management: prophylactic antibiotics, medicated aerosol therapy, chest physiotherapy (CPT), and deep breathing and cardiovascular exercise.
RATIONALE: Instruction empowers the child and family to manage care. Medicated aerosol therapy, CPT, and deep breathing exercises help reduce atelectasis and risk for infection and promote healing.
7. Encourage use of community resources such as the Cystic Fibrosis Foundation.
RATIONALE: The use of community resources may help support the family to find ways to prevent infection and increase the possibility of a positive adjustment to the condition.

The nurse must help the parents understand that caring for a child with CF can be challenging. There are sufficient resources and help lines that can assist parents. The nurse should use these existing resources and facilities to provide adequate health education to parents and older children.

nursing diagnoses Cystic Fibrosis

- Ineffective Airway Clearance related to thickened secretions
- Ineffective Breathing Patterns related to tracheobronchial obstructions
- Altered Nutrition: Less than Body Requirement related to inability to digest and/or loss of appetite
- Altered Growth and Development related to inadequate thickened of nutrients
- High Risk for Infection related to impaired body defense system
- Altered Family Processes related to frequent hospitalization/prolonged sickness

Across Care Settings: Caring for the child with cystic fibrosis at home

It is essential that the nurse teach parents how to care for their child at home. After the diagnosed and acute phase of illness, the family is prepared for home management and assists in promoting child growth and development with limitations.

- Teach the family about the nature of disease and prepare them to manage day-to-day minor complaints.
- Assist the family in arranging for the portable suction machine and about the proper technique suctioning at home.
- Instruct the family to do the respiratory therapy before a meal because chest physiotherapy may induce vomiting "of the thick tenacious mucus."

- Teach the family different techniques used for chest physiotherapy and postural drainage and coughing exercises based on their child's age. The child needs to be suctioned followed by chest physiotherapy and inhalation to liquefy the thick secretions.
- Teach the family about preferred meal plans, high-caloric diet, and mixing pancreatic enzyme with meal.
- Instruct the family to monitor the child's weight to ensure proper growth patterns.
- Teach the family how to administer medications properly.
- Inform the family how to access community resources and how to contact their home health nurse.

Be sure to— Use ethical considerations when conducting research involving children

In conditions such as CF, it is important for the pediatric nurse to conduct research for the advancement of knowledge. It is also important for the nurse to protect the children when doing research. Children are under the legal age limit and research requires the consent of the parent or legal guardian. Children are especially vulnerable due to their immaturity and inability to decide for themselves.

When conducting research in the pediatric setting, be sure to:

- Obtain written consent from the parents or legal guardians.
- Obtain written assent from mature children (generally age 12–13 and older).
- Use the ethical principles of beneficence, nonmaleficence, autonomy, veracity, justice, fidelity, and professional integrity.
- Review the institutional protocols carefully, ensuring that the highest standards of research are addressed.
- Secure clearance from the Institutional Review Board at the institution

Be sure to design the research so that:

- Children's rights are respected.
- Children are protected from harm and discomfort.
- Children's parents or legal guardians are provided the information necessary for them to give their informed consent.
- Children's rights to anonymity and confidentiality are ensured.

(Code of Federal Regulations Subpart A Sec. 46.102 (2005). *Basic HHS Policy for Protection of Human Research Subjects*. Office of Human Subjects Research. National Institute of Health: Bethesda, MD).

Now Can You— Describe congenital respiratory conditions and structural anomalies?

1. Identify the symptoms of the various congenital respiratory conditions and structural anomalies.
2. Prepare home care and management plans for children with congenital respiratory conditions and structural anomalies.

Upper Airway Disorders

SINUSITIS

Sinuses are hollow air spaces in the human body. In relation to the respiratory system, each sinus cavity has an opening into the nose for free exchange of air and mucus and is joined with the nasal passages by a continuous mucous membrane lining. The maxillary (behind the cheek) and ethmoid (between the eyes) sinuses are small but present at birth. The child's sinus cavities are not fully developed until 20 years of age, which makes the child vulnerable to sinus infection. Sinusitis is an infection of the sinus cavities.

Anything that causes a swelling in the nose such as an infection or an allergic reaction can affect the sinus causing problems. Normally, mucus collects in the sinuses and drains into the nasal passages. When children have a cold or an allergy attack, the sinuses become inflamed and drainage is difficult. In addition, air is trapped within the already blocked sinus along with pus or other secretions. This inflammation and accumulation of secretions can lead to congestion and infection. There is usually accompanying facial pain, headache and fever. If sinusitis persists for more than 3 months it is called chronic sinusitis.

Signs and Symptoms

The nurse can observe the following signs and symptoms in a child that is indicative of sinusitis:

- A cold lasting more than 10 to 14 days, sometimes with low-grade fever
- Thick yellow-green nasal discharge
- Postnasal drip leading to sore throat, cough, bad breath, nausea, and vomiting
- Headaches (usually not before age 6)
- Irritability and fatigue
- Swelling around the eyes

Diagnosis

When the child comes to the health care facility, diagnosis of acute sinusitis is determined by a physical examination with emphasis on the above listed symptoms. Sinus aspirate culture is the only accurate method of diagnosis but is not practical for routine use.

Nursing Insight— Diagnosing sinusitis

Sinusitis is difficult to diagnose in children because respiratory infections are more frequent during childhood.

Nursing Care

Medical management for bacterial sinusitis includes a prescription of antibiotics. An oral or nasal spray or drop decongestant also may be used to relieve congestion. The nurse can communicate to the parents that steam inhalation and use of saline nasal sprays can help relieve sinus discomfort. If the child shows symptoms of chronic sinusitis, the primary care provider initiates an intensive regimen of antibiotic therapy. Surgery is sometimes necessary to remove a physical obstruction. The nurse can teach the child and parents the importance of how to avoid sinusitis during a cold or allergy attack.

Complementary Care: Chiropractic care and chronic sinusitis

Complementary and alternative care has been increasingly used for children. A good knowledge and understanding of these approaches helps the pediatric nurse provide information about these therapies.

Chiropractors are one of the professional complementary care providers most often used for children. Chiropractors are licensed in all states and their professional fees are covered by third-party payers including Medicare and most leading insurance carriers. Chiropractors do not prescribe pharmaceuticals or perform surgery. Spinal manipulation is the principal therapeutic option. Spinal manipulation is a form of manual therapy that involves the movement of a joint beyond its usual end range of motion but not past its anatomic range of motion. Chiropractors engage in health promotion and treatments of pediatric conditions such as otitis media, asthma, allergic rhinitis, sinusitis, infantile colic, and enuresis. Initial visit to the chiropractic clinic lasts for about 45 minutes; follow-up visits are generally 15 to 20 minutes. Adverse effects from chiropractic adjustments are rare. Families who use this complementary therapy rarely abandon their mainstream pediatricians; as they are used as an adjunct therapy.

“What to say” — How to talk to parents about chiropractic therapy

Pediatric nurses are in a position to be asked by parents about chiropractic therapy. When asked, the nurse can provide parents with the basic knowledge in nontechnical terms. The nurse can speak in an open minded, nonjudgmental fashion, avoiding terms such as “unproven” or “unconventional.” The nurse can also elicit values, beliefs, and influences that led the parents to opt for the complementary therapy. When possible, the nurse can support the parents’ decisions and offer to obtain more information.

NASOPHARYNGITIS

Nasopharyngitis (the common cold) is a viral infection of the respiratory tract that involves the nose and throat. It occurs throughout the year but the highest incidence occurs during the early fall until the late spring and lasts for about 7 days. Young children have an average of six to seven colds per year but 10% to 15% of them have at least 12 infections per year. The incidence of illness decreases with age, with two to three illnesses per year by adulthood (Turner & Hayden, 2004).

Causative agents include rhinovirus in the early fall and late spring season, the respiratory syncytial virus (RSV) primarily in the winter and spring, and the parainfluenza virus in autumn. Adenovirus and coronavirus produce epidemics during the winter and spring. The common cold spreads easily from one person to another. Viruses causing the ailment are spread by small and large particle aerosols.

Signs and Symptoms

The common cold begins with dryness and stuffiness affecting the nasopharynx and is accompanied with increased

Family Teaching Guidelines... How to Avoid Sinusitis

HOW TO KEEP THE CHILD'S SINUSES CLEAR

- ◆ Use an oral decongestant or a nasal spray decongestant when initial signs and symptoms appear. Gently have the child blow the nose, blocking one nostril while blowing through the other one. It is also important to remember that a nasal spray decongestant can cause rebound swelling after 3 days of usage.
- ◆ Ensure that the child drinks plenty of fluids to keep nasal discharges thin.
- ◆ Apply heat via warm compresses or heating pad (on low heat) over the inflamed area.
- ◆ Use a cool mist humidifier in the same room or area occupied by the child.

ESSENTIAL INFORMATION

- ◆ Avoiding air travel during the symptomatic period is recommended. In the event that there is a need for the child to fly, a nasal spray decongestant may be used before airplane take-off to help prevent blockage of the sinuses and allowing mucus secretions to drain.
- ◆ Avoiding contact with known allergens is important.
- ◆ Using air conditioners to help to ensure even room temperature is helpful.
- ◆ Using electrostatic filters attached to heating and air conditioning equipment to help remove allergens from the air is necessary.

(Academy of Otolaryngology, Head and Neck Surgery, 2008).

medication: Erythromycin

Erythromycin (eh-rith-roe-mye-sin)

Indications:

IV, PO: Infections caused by susceptible organisms including upper and lower respiratory tract infections and otitis media

Action: Suppresses protein synthesis at the level of the 50S ribosome.

Therapeutic Effects: Bacteriostatic action against susceptible bacteria spectrum: streptococci, staphylococci, gram-positive bacilli

Pharmacokinetics:

ABSORPTION: Variable absorption from the duodenum after oral administration.

Contraindications and Precautions:

CONTRAINDICATED IN: Hypersensitivity

Adverse Reactions and Side Effects: Irritation

Route and Dosage:

CHILDREN PO: 30–50 mg/kg in divided doses q 6–8 hr.

NEONATES PO: 20–50 mg/kg per day divided q 6–12 hr.

Nursing Implications:

Inform parents of medication administration.

Prepare to administer around the clock.

Use calibrated measuring device for liquid preparations.

Do not crush or chew delayed-release capsules or tablets; swallow whole.

Data from Deglin, J.H., & Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

clear and watery nasal secretions and lacrimation (discharge of tears). At times the pharynx and larynx are also affected, which brings on sore throat and hoarseness. The child are complains of headache and general malaise.

Diagnosis

Diagnosis is based on the presenting symptoms. It is important to rule out other conditions that are possibly more harmful than the common cold. Routine laboratory examinations are not generally necessary in diagnosing a common cold. Pathogens associated with colds may be detected by culture, antigen detection, or serological methods. A specific etiological diagnosis is useful only when treatment with antiviral agents is being considered.

Nursing Care

The management of the common cold consists mainly of symptomatic treatment and good hand washing and cleaning of toys, tables, and other items used by the child to prevent the spread. Symptomatic treatment includes antipyretics and rest. Antihistamines help in drying up nasal secretions. They should be administered with caution as they dry up the bronchial secretions, which in turn may make the cough worse. Antihistamines can also cause dizziness and drowsiness. Decongestants are given to infants older than 6 months. They cause vasoconstriction and are usually given in the form of nasal drops. Antibiotics are not recommended for the dry hacking cough. Most cough mixtures contain alcohol so the medication needs to be administered with caution.

Nasopharyngitis causes discomfort especially for the infant. The nurse can elevate the head or crib, which helps with the child's drainage of secretions. Maintaining adequate fluid intake in the child is important because it prevents dehydration and keeps secretions thinned for easier expulsion. Fruit juices and gelatins may be offered to the child to increase their fluid intake. The nurse can communicate to the parents to avoid milk and milk products in excess, as this makes secretions thick and sticky. It may be helpful if nurses offer these fluids in tiny colorful cups or glasses with straw so they are more attractive for the child. The nurse can also stress the importance of rest. Children may be given play activities such as puzzle games, story books, crayons, and art materials to decrease boredom.

Because the hands are the primary vehicle for transmission of the cold virus the nurse should tell the family that hand washing must be strictly adhered to in order to prevent the spread of infection. The nurse must advise the parents that disposable wipes and tissue papers used for secretions should be disposed in sealed plastic bags.

The nurse, during health teachings, must reiterate the importance of good health as the major preventive measure for children not to catch cold. Prevention means that children are given adequate nutrition, rest, and sleep.

PHARYNGITIS

Pharyngitis is an inflammation of the pharynx that frequently results in sore throat. It occurs most commonly in winter and is spread by close contact. The incidence is high among children and declines in late adolescence and adulthood.

Pharyngitis can either be a short illness with no symptoms or could result in severe toxicity. In the case of the latter the causative agent is group A Beta-Hemolytic streptococci, which is also known as GABHS infection of the upper airway and may lead to acute rheumatic fever (ARF), scarlet fever, or acute glomerulonephritis (AGN). Colonization of the pharynx by GABHS may produce either asymptomatic or acute infection. The M protein is the major virulence factor of GABHS and facilitates resistance to phagocytosis by polymorphonuclear neutrophils. Type-specific immunity develops during infection and provides protective immunity to subsequent infection with that particular M serotype.

Signs and Symptoms

This illness in a child is abrupt and is accompanied by headache, fever, and abdominal pain. The tonsils and pharynx are inflamed, large, red, and often covered with yellow exudate (fluid released from the body). The anterior cervical lymph nodes are enlarged and tender and the child experiences pain on swallowing. Symptoms usually subside in 3 to 5 days unless superimposed by sinusitis, parapharyngeal, or peritonsillar abscess.

Diagnosis

Throat culture remains a good way to diagnose streptococcal pharyngitis (Fig. 24-5). A false-positive culture can occur if other organisms are misidentified as GABHS and children who are streptococcal carriers may have positive cultures. False-negative cultures are attributed to a variety of causes, including an inadequate throat swab specimen and a patient's covert use of antibiotics (Turner & Hayden, 2005). Diagnostic test kits with rapid identification of GABHS are available for use at the office or clinic settings. These rapid tests have high specificity. Therefore, a positive result generally does not need a throat culture confirmation. The throat culture does give information about susceptibility of the organism to specific antibiotics.

Nursing Care

Most untreated cases of streptococcal pharyngitis resolve in a few days. The objective of antibiotic therapy is to hasten clinical recovery and prevent acute rheumatic

Figure 24-5 Use a long, sterile cotton swab to swab a culture from the back of the child's throat.

fever. Antibiotics may be started immediately without culture. Oral penicillin is the prescribed treatment of choice. Oral penicillin is inexpensive and is given two or three times in a day for 10 days. Oral amoxicillin (Amoxil) is suitable for children since it is available as chewy tablets. A once daily 750-mg dose of amoxicillin (Amoxil) given orally for 10 days is as effective as 250 mg of penicillin given three times per day for 10 days (Turner & Hayden, 2004). Oral erythromycin (Erythrocin) is indicated in children allergic to penicillin.

The nurse instructs parents about administering oral penicillin and analgesics as prescribed. Emphasize bed rest especially during the acute phase of the illness. A cold or warm compress to the neck is helpful to relieve pain. If the child is old enough, warm saline gargles are offered to the child to soothe the painful throat. Food and fluids are given as tolerated because swallowing is painful. Cool and bland liquids are less painful to swallow than hot and solid foods. The child should not be forced to eat if there is intense pain on swallowing. Rather, foods that are high in nutrients and energy can be offered when the child can tolerate eating. Hand washing by the caregivers, both nurses and parents, should be done to prevent the spread of the infection.

For children who are cared for at home, it is important that the nurse instruct the parents to give the full dose of the antibiotic prescribed even though the child shows signs of improvement. This is a very important aspect in the management of pharyngitis to prevent valvular damage of the heart.

TONSILLITIS

Tonsillitis is an inflammation of the tonsils, which are two masses of lymphoid tissue located within the pharynx. Tonsils protect the respiratory and alimentary tracts from infection by inducing secretory immunity and regulating the production of secretory immunoglobulin. Tonsils normally enlarge progressively between 2 and 10 years of age and reduce progressively during preadolescence, which makes the tonsils of children larger than those of adults. Nearly all children in the United States experience at least one episode of tonsillitis.

Viruses and group A Beta-Hemolytic *Streptococcus* are the most common cause of infection in tonsillitis. Children who have been treated continually with antibiotics can become immunocompromised.

Signs and Symptoms

There are several types of tonsillitis: acute, recurrent, chronic, and peritonsillar abscess. The signs and symptoms differentiate the types of tonsillitis. The presenting symptoms in acute tonsillitis are fever and chills, foul breath, dry throat, dysphagia (difficulty in swallowing), referred otalgia (pain in the ears), headache, malaise (fatigue), muscular pains, and enlarged cervical nodes. Airway obstruction due to swelling causes the patient to breathe through the mouth. Symptoms usually resolve in 3 to 4 days; however, some patients may remain symptomatic for up to 2 weeks, even during therapy. Recurrent tonsillitis presents with multiple episodes of the illness in a year. Patients with chronic tonsillitis frequently present with halitosis, chronic sore throats, foreign body sensation, or a history of expelling foul tasting and smelly cheesy lumps. Severe throat pain, fever, drooling

foul breath, difficulty opening the mouth, and changes in voice quality are the symptoms of peritonsillar abscess. The inflammatory process brought about by the infectious process within these areas interferes with breathing, swallowing, and may cause partial deafness.

Diagnosis

Diagnosis is based on the presenting symptoms and inspection of the throat.

Nursing Care

Two treatment modalities are used for the management of tonsillitis: medical management and tonsillectomy. Medical management consists of antibiotics, antipyretics, and analgesics. Penicillin, erythromycin (Erythrocin), and amoxicillin (Amoxil) are the commonly prescribed antibiotics. Cephalosporins or clindamycin (Cleocin) are more effective for patients with chronic conditions.

Tonsillectomy (surgical removal of the tonsils) is used for recurrent or chronic tonsillitis. There are no criteria for the number of infections before tonsillectomy is carried out (Wetmore, 2004). The American Academy of Otolaryngology and Head and Neck Surgery (2008) suggests the occurrence of three or more treated infections per year as sufficient to necessitate a surgical intervention. Surgery is performed 6 weeks after an acute infection has been resolved.

Nursing care involves provision of comfort and reducing activities that may bring on bleeding. Vaporizers keep the mucous membrane moist during periods of mouth breathing. Warm saline gargles, throat lozenges, and antipyretics are given. A soft or liquid diet is preferred.

After the surgery, children are kept on their side to facilitate drainage of secretions. Coughing, clearing the throat, and blowing the nose are to be avoided. Secretions and vomitus are checked for fresh blood. Since the throat is very sore after surgery, the nurse can apply ice packs and an ice collar to provide relief. Food and fluids are offered when the child is alert: cool water, crushed ice, and flavored ice-pops are the initial foods to be given. However, red or brown colored fluids should not be given to be able to distinguish fresh or old blood. As the child begins to tolerate food, gelatin, cooked fruit, sherbet, soup, and mashed potatoes are offered. Foods to avoid include milk, ice cream, and pudding as they coat the mouth and throat and cause the child to clear the throat, which may cause bleeding.

Family Teaching Guidelines... Home Discharge Instructions Following a Tonsillectomy

The nurse can teach the parents to:

- ◆ Keep the child away from highly seasoned food and “sharp” foods (e.g., nacho chips) for a period of 2 weeks. The scab is most likely to be dislodged at 8–12 days.
- ◆ Have the child avoid gargling and vigorous tooth brushing.
- ◆ Instruct the child that he or she should not cough or clear the throat.
- ◆ Limit the child’s activities that may result in bleeding.

clinical alert

Signs of bleeding after tonsillectomy

When the nurse is caring for a post-tonsillectomy child, if the child is continuously swallowing, it is indicative of bleeding. Additional signs to be observed are restlessness, increased pulse rate, and pallor (late symptom).

CROUP OR LARYNGOTRACHEOBRONCHITIS

Croup is a generic term encompassing a heterogeneous group of illnesses affecting the larynx, trachea, and bronchi. Croup is described according to the main anatomical area affected. Epiglottitis, supraglottitis, laryngitis, laryngotracheobronchitis and bacterial tracheitis and encompass the croup syndrome.

Croup commonly affects children between 3 months and 5 years of age, most often at around 2 years of age. The incidence is higher in boys and it is most frequent during the winter months. The incidence of epiglottitis has dramatically decreased since the introduction of the Hib vaccine in the late 1980s.

Now Can You— Enhance communication?

1. What activities can the nurse perform to increase the child's communication and interaction with the nurses during illness and hospitalization?
2. How can the nurse enhance the children's feelings of control over their care?

where research and practice meet: Nurse–Child–Parent Interaction

In the pediatric setting, the nurses' interactions and communications with both the child and the parents are important components of nursing outcomes. It has been observed that the nurse tends to communicate with parents rather than with the child. This leaves the child an inactive or passive participant in his or her own care. Positive interactions and communication with patients and families who are experiencing crisis during illness and hospitalization are essential for the nurses to provide the highest quality of care.

Shin and White-Traut (2005) conducted a study to evaluate patterns of nurse–child–parent interaction and identify the characteristics of nurse–child and nurse–parent interaction in an inpatient pediatric unit. Eight triads of nurses, patients, and their mothers were videotaped for 4 hours each day over a 2-day period for 3 months as they interacted with each other. Data gathered were coded and analyzed via the Bales Interaction Process Analysis. The average time per interaction was 2 to 24 minutes. Interaction episodes consisted of nursing activities such as rounds, patient monitoring, and patient care. Nurses initiated the majority of the interactions between patients and mothers. Both positive and negative behaviors were more frequent between nurses and children whereas neutral behaviors were more common between nurses and mothers. Children remained passive participants in the interaction. Interaction strategies are needed to help children to learn how they can actively interact with their nurses. These strategies may contribute to the children feeling more in control in these interactions and in their care.

Viral agents, particularly the parainfluenza viruses 1, 2, and 3, which account for 75% of the cases, are the most common cause of croup (Knutson & Aring, 2004). *Streptococcus pyogenes*, *S. pneumoniae*, and *Staphylococcus aureus* are the common causes of epiglottitis while *Haemophilus influenzae*, *Staphylococcus aureus*, and *Corynebacterium diphtheriae* are involved in bacterial tracheitis.

Signs and Symptoms

The symptoms of croup can be explained in terms of the anatomic structure of the children. The subglottic region of the larynx is held within the rigid ring of the cricoid cartilage. In children with croup, viral infections cause this area to become inflamed and edematous. This condition leads to obstruction because children have a narrow larynx such that a decrease in airway diameter causes a decrease in airflow, leading to the symptoms of croup.

Hoarseness, a resonant cough described as barking or brassy accompanied by varying degrees of respiratory distress resulting from swelling or obstruction in the region of the larynx and inspiratory stridor, are the major symptoms of croup. Most children have mild symptoms of an upper respiratory tract infection such as rhinorrhea, cough, and low-grade fever for 1 to 3 days before the symptoms of croup become evident.

Nursing Insight— Acute epiglottitis or supraglottitis; a medical emergency

Acute epiglottitis or supraglottitis is a sudden, potentially lethal condition characterized by high fever, sore throat, dyspnea, and rapidly progressing respiratory obstruction. The nurse understands acute epiglottitis is considered a serious obstructive inflammatory condition, which requires immediate attention as this condition is a medical emergency. A common scenario is that the child goes to bed asymptomatic and awakens with complaints of sore throat and pain on swelling accompanied by a febrile state. The child typically assumes the tripod position: leaning forward and sitting upright with chin thrust, mouth open while bracing on the arms, and tongue protruding with drooling of saliva. The child is irritable and restless with a thick and muffled voice and there is a froglike croaking sound on inspiration. Suprasternal and substernal retractions may be visible. The nurse notes that the child breathes slowly, the throat is red and inflamed, and there is a distinctive large, cherry red edematous epiglottis.

Laryngitis is more common in older children. Viruses are also the usual causative agents. The principal complaint is hoarseness, which may be associated with other upper respiratory symptoms including coryza, sore throat, and nasal congestion and generalized symptoms such as malaise, fever, headache, myalgia, and malaise.

Laryngotracheobronchitis (LTB) is a viral infection of the glottic and supraglottic regions. Some clinicians use the term laryngotracheitis for the most common and most typical form of croup and reserve the term laryngotracheobronchitis for the more severe form. LTB is preceded by an upper respiratory tract infection and is characterized by onset of low-grade fever, inspiratory stridor (a high-pitched, harsh sound), barking cough, and hoarseness.

Bacterial tracheitis is an infection of the lining of the trachea but does not involve the epiglottis. Like epiglottitis, it is capable of causing life-threatening airway obstruction severe enough to cause respiratory arrest. It is considered a bacterial complication of a viral disease. It begins with an upper respiratory tract infection with croupy cough, stridor unaffected by position, toxicity, and high fever. The child does not have the dysphagia associated with epiglottitis. A major symptom of bacterial tracheitis is the production of thick purulent tracheal secretions, which brings about respiratory difficulties.

Diagnosis

Diagnosis of the croup syndrome is based on the signs and symptoms along with the history. Owing to the severity of the respiratory distress, immediate treatment takes priority over testing.

Nursing Care

The most important goals in the treatment of children with croup is maintaining the airway and providing adequate respiratory exchange.

Commonly, mild cases of croup are treated with cool mist. A high-humidity cool air vaporizer may be used at home in the child's room. In the hospital setting, oxygen hoods for infants and oxygen tents for toddlers are used. Cool mist is thought to moisten airway secretions to facilitate clearance, soothe inflamed mucosa, and provide comfort and reassurance to the child thereby lessening anxiety. Nebulized racemic epinephrine (MicroNefrin or Vaponefrin) (0.25 to 0.75 mL in 3 mL of a normal saline solution) or *l*-epinephrine (5 mL of 1:1000 solution) are equally effective to cause mucosal vasoconstriction and consequently decrease subglottic edema, thus relieving the symptoms. This treatment is indicated for those with moderate to severe stridor at rest or when stridor does not respond to cool mist. The nurse must observe the child after nebulization to assess the airway and side effects of the delivered medication.

Corticosteroids are also given to children to decrease the edema in the laryngeal mucosa through their anti-inflammatory action. Intramuscular dexamethasone (Decadron) and nebulized budesonide (Pulmicort) are widely used.

Antibiotics are not used in the management of croup since it primarily viral in nature. Symptoms which warrant hospitalization are: progressive stridor, severe stridor at rest, respiratory distress, hypoxia, cyanosis, and depressed mental status.

Epiglottitis and bacterial tracheitis are considered pediatric emergencies and may require artificial airways. The nurse must never assess the child's throat with a tongue blade, unless a respiratory therapist or medical doctor is present, because of the possibility of laryngeal spasm and emergent need of artificial airway; emergent intubation and tracheostomy may be necessary. Artificial airways usually improve the child's status. Antibiotic therapy is indicated for these two conditions. Combinations of ampicillin and sulbactam (Unasyn) are the drugs most often prescribed.

Monitoring the child's respiratory and cardiac system is a priority nursing care measure. Changes in condition are based on observations and assessment of the child's

response to therapy, including careful observation of the child's response to his or her surroundings (changes in level of consciousness).

Nursing diagnoses Upper Respiratory Disorders

- Risk for Ineffective Airway clearance related to excessive secretions, inflammation or obstruction in the airway,
- Risk for Ineffective Breathing Pattern related to tracheobronchial inflammation or obstruction
- Risk for Imbalanced Nutrition: Less than Body Requirements related to discomfort with swallowing
- Anxiety related to perceived threat of hospitalization, or to invasive procedures or changes in health status of the child
- Risk for Deficient Fluid Volume related to inadequate fluid intake or excessive losses through abdominal route
- Pain related to procedures or increased pressure in the middle ear (specific to otitis media)
- Disturbed Sensory Perception: Auditory related to inflammation and edema in the middle ear (specific to otitis media)
- Fatigue related to increased respiratory effort

OTITIS MEDIA/EXTERNA

External otitis, also known as otitis externa, is an inflammation, irritation, or inflammation of the outer ear and ear canal. Although it is popularly called swimmer's ear, it can occur in situations that do not involve swimming. It usually affects older children and teens whose ears are exposed to persistent excessive moisture. It occurs more often in warm climates and during summer.

External otitis is commonly caused by *Pseudomonas aeruginosa*. Fungal infections with *Candida* and *Aspergillus* may also be the causative agents. Excessive wetness as in swimming or bathing, dryness of the ear canal, lack of cerumen, presence of other skin pathology, digital trauma, and a foreign body make the skin of the ear canal vulnerable to infection.

Signs and Symptoms

The main symptom is ear pain, which is often severe. It is accentuated when the pinna of the ear is pulled or pressed. There can be itching and drainage of yellow to yellow-green secretions. On inspection, there is erythema and edema of the ear canal. Cerumen (wax) may become whitish instead of its usual yellow color. Severe cases may lead to hearing loss.

Diagnosis

Examination of the ear and the occurrence of the presenting symptoms including a positive history confirm the diagnosis. On otoscopy (the use of the otoscope in examining the ear), the eardrum appears red or there may be difficulty in visualizing the eardrum.

Nursing Care

Antibiotic ear drops are prescribed for a course of 7 to 10 days. Corticosteroids are also effective in treating most forms of external otitis. If the ear canal is swollen, a cotton wick is inserted into the ear canal so that the ear drops travel into the end of the canal. Analgesics are given to relieve pain.

During the course of treatment, the nurse can advise the child avoid wetting the ears. During bathing, shower caps or ear plugs with petroleum jelly may be used.

Nursing Insight— Preventing external otitis

Nurses can teach parents and older children ways to prevent infections. Children are advised to limit their stay in the water to less than an hour and ears should be completely dry before entering the water again. Shaking the head and judicious use of the corner of a towel can remove most excess water. The ear canal can also be dried with a small tuft of cotton. To keep the ear dry the parent can pull the auricle up and out to straighten the canal, then use a conventional hair dryer set on low or no heat held at a distance of 18 to 24 inches for 30 seconds, three times a day. Earplugs may be recommended by the physician. Children can also be advised to avoid swimming in dirty water and in public swimming pools that do not maintain good control of their chlorine and pH pool testing and treatment.

OTITIS MEDIA

Otitis media (OM) is basically an infection of the middle ear. It is one of the most prevalent conditions of early childhood. The incidence is highest among children between 6 months to 2 years. By 6 years of age, 75% of children have had one or more episodes of otitis media. In addition to the physical discomfort and economic costs related to otitis media, there is evidence that children with recurrent otitis media are at risk for both hearing loss and speech delay.

Otitis media presents in many forms: otitis media, acute otitis media (AOM), otitis media with effusion (OME), and chronic otitis media with effusion. Otitis media is an inflammation of the middle ear without reference to etiology or pathogenesis. Acute otitis media is inflammation of the middle ear space with the rapid onset of the signs and symptoms of acute infection such as fever and ear pain. Otitis media with effusion occurs when there is fluid in the middle ear space without symptoms of acute infection. Chronic otitis media with effusion is a persistent middle ear infection with discharge through a tympanic membrane perforation. An unresolved AOM that persists for more than 3 months leads to chronic otitis media.

The pathology of otitis media is better understood by reviewing the structure and functions of the Eustachian tube in children. The Eustachian tubes in children are shorter, wider, and more horizontal in infants than in adults. The Eustachian tube carries out three functions:

- Protection of the middle ear from nasopharyngeal secretions
- Drainage of secretions produced in the middle ear
- Ventilation of the middle ear to equalize air pressure within the middle ear with atmospheric pressure in the external ear canal and replenishment of oxygen that has been absorbed.

Because of this structure in children, drainage as a function is often impaired, which results in retention of secretions and air in the middle ear. The horizontal position also facilitates the movement of pathogens up the Eustachian tube from the pharynx into the middle ear.

Edema resulting from upper respiratory infection, allergic rhinitis, or hypertrophic adenoids interferes with the functions of the Eustachian tube.

Streptococcus pneumoniae, *Haemophilus influenzae*, and *Moraxella catarrhalis* are the three most common causes of infection in otitis media (Winklestein, 2005). Tobacco smoke as well as passive or second hand smoke aggravates the otitis media by impairing mucociliary function with subsequent congestion of soft nasopharyngeal tissues.

A direct link has been established between OM and infant feeding methods. Infants who have been breastfed have a lower incidence of OM than those who have been bottle fed. The number of episodes of OM decreases significantly with increased duration and exclusive breast feeding. Breast milk contains immunoglobulin A (IgA), which offers protection against allergies and viruses. Due to the position of the infant during breastfeeding there is less likelihood of reflux of milk in the ear, whereas during bottle feeding the chances of milk getting into the ear is increased.

The following factors lead to otitis media in children:

- The Eustachian tubes are short, wide, and straight and lie in a horizontal plane.
- The cartilage lining is undeveloped, making the tubes more distensible. The normally abundant pharyngeal lymphoid tissue readily obstructs the Eustachian tube openings in the nasopharynx.
- Immature humoral defense mechanisms increase the risk of infections.
- The lying down position of infants favors the pooling of fluid, such as formula, in the pharyngeal cavity.

Signs and Symptoms

The accumulation of fluids in the small space of the middle ear chamber results in pressure on surrounding structures, bringing about pain. Infants become irritable and express discomfort and pain by either holding and pulling on the affected ear or rolling their head from side to side. The child is febrile with a temperature as high as 104°F (40°C). Lymph gland enlargement may arise particularly in the post auricular and cervical lymph glands. Rhinorrhea, vomiting, and diarrhea may also be present. Loss of appetite is often present and chewing and sucking are known to aggravate the condition. In children with OME, exudate may accumulate and pressure increases, leading to tympanic membrane rupture. Often the child may not appear ill and only exhibits a feeling of fullness in the ear and a popping sensation during swallowing.

Diagnosis

Diagnosis is based on signs and symptoms as well as an otoscopic examination. An otoscopic examination reveals that in AOM the intact membrane appears bright red and bulging with no visible landmarks or light reflex. The usual landmarks of the bony prominences from the long and short processes of the malleus are obscured by the outwardly bulging membrane. In OME, otoscopic examination reveals a slightly injected, dull gray membrane, obscured landmarks, and a visible fluid level or meniscus behind the eardrum in air is present above the fluid.

Nursing Care

Antibiotics are used judiciously in the management of otitis because of the increasing resistance of the pathogens. Health education from the nurse is important if a decision is made to treat the condition with an antimicrobial agent. The full course of the antimicrobial therapy should be followed strictly. The nurse can tell the parents that if the child fails to respond to this initial antimicrobial management within 48 to 72 hours, another assessment must be done to confirm AOM and exclude other causes of illness or ineffective antibiotic response.

The American Academy of Pediatrics and the American Academy of published guidelines in the management of AOM in 2004 recommending that pain should be treated with either acetaminophen (Tylenol) or ibuprofen (Children's Advil). The cause of AOM has changed from primarily bacterial to primarily viral in recent years due to increasing administration of vaccines that decrease the incidence of bacterial infections, so withholding the use of antimicrobials is advised unless a bacterial cause is clearly evident. The nurse understands that the first line of drug choice is amoxicillin (Amoxil) given at 80 to 90 mg/kg per day.

Care may also include high doses of cefdinir (Omnicef) in combination with tympanocentesis (drainage of fluid from the middle ear by using a small-gauge needle to puncture the tympanic membrane) (Venes, 2009). The fluid is then cultured to determine the identity of any microbes that may be present. The use of complementary therapies is not recommended since there is insufficient evidence of its effectiveness. Finally, prevention through the reduction of risk factors is highly encouraged. To minimize the recurrence of otitis media, the nurse can teach parents to eliminate identified environmental allergens, feed infants in upright position, and encourage medical follow-up to check for complications such as chronic hearing loss.

clinical alert

Rupture of the tympanic membrane

The rupture of the tympanic membrane brings immediate relief of pain, a gradual decrease in temperature, and the presence of a purulent discharge in the external auditory canal. Rupture of the tympanic membrane may lead to scarring and hearing loss.

Lower Airway Disorders

BRONCHITIS

Bronchitis is a nonspecific bronchial condition in which there is inflammation of the bronchial tubes. Tracheobronchitis is the term used when the trachea is prominently involved. Bronchitis may be acute or chronic. Acute bronchitis is commonly preceded by a viral upper respiratory tract infection and may last for 1 to 3 weeks. The incidence of acute bronchitis is highest during the winter months. Children are usually affected in their first 4 years of life. Chronic bronchitis lasts for months or years and is more common among adults, particularly smokers.

Viruses are usually the causative organism. The tracheobronchial epithelium is invaded by the infectious agent, and this leads to activation of inflammatory cells

and release of cytokines, giving way to the occurrence of symptoms. If the tracheobronchial epithelium becomes significantly damaged or hypersensitized, then a protracted cough may last for 1 to 3 weeks.

Signs and Symptoms

Cough is the first prominent symptom for bronchitis, with rhinorrhea occurring 3 to 4 days later. The child also has a dry, hacking cough that is worse at night. In a few days, the cough becomes productive and purulent. This does not necessarily imply a bacterial infection but rather it indicates leukocyte migration.

Diagnosis

Based on the fact that a virus is usually the causative organism, bronchitis is diagnosed based on the child's symptoms. In children older than 6 years of age, *M. pneumoniae* can be a common cause and bronchitis can then be determined by the identification of this bacterium.

Nursing Care

Bronchitis requires symptomatic treatment, including antipyretics, analgesics, and humidity. Cough suppressants are administered with caution as they interfere with clearance of secretions. The condition is self limiting, and antibiotics, although frequently prescribed, do not hasten improvement in uncomplicated cases.

The nurse must remember that adequate oxygenation is a very important aspect of care in patients with bronchitis. To be able to provide oxygenation, the nurse must see to it that the airway is open and free of obstruction. The airway can be open by administering prescribed bronchodilators. The nurse can encourage the child to clear the airway from secretions by coughing. The nurse may also provide a cool-mist vaporizer by the bedside, especially at night, to help liquefy secretions, which can then be coughed out easily. The nurse understands that secretions must be disposed in sealed plastic bags. Parents should be told that the young child may swallow secretions instead of coughing them out, and may vomit these accumulated secretions during the night.

The nurse encourages the child to take in fluids such as clear liquids and fruit juices. The nurse recommends bed rest to the parents. Tell parents to avoid exposing the child to second-hand smoke and to provide a clean environment with adequate nutrition.

RESPIRATORY SYNCYTIAL VIRUS

Respiratory syncytial virus (RSV) is an acute viral infection involving the bronchioles and alveoli. The infection is common among children who are 2 years or younger. By the age of 2 years, nearly every child has been exposed to the virus (Polark, 2004). The ailment is seasonal, with peaks during winter and early spring. It spreads from hand to eye, nose, and mucous membranes.

RSV most often begins as an infection in the nasal epithelial cells. The RSV virus then replicates in the host cell. The peak period for RSV is December through March. The host cell is destroyed and virus particles are released to propagate the infection. The infection results in the destruction of the epithelial cells of the respiratory tract. Exposure to RSV triggers a humoral immune response.

Primary RSV infection results in only a weak antibody response with IgM, IgG, and IgA produced. This response is not enough to destroy the virus completely or to prevent upper respiratory tract replication of the virus. Consequently, an upper respiratory tract illness develops. High levels of neutralizing antibodies are required to prevent the progression of infection from the upper respiratory tract to lower respiratory tract (Polark, 2004).

Signs and Symptoms

As the virus replicates in the nasopharynx, symptoms such as mild cough, nasal congestion, clear rhinorrhea, and increase in the oral secretion (drooling) occur. Low-grade fever may also be present. The thick mucus, exudate, and mucosal edema obstruct the smaller airways (bronchioles). This obstruction leads to a reduction in expiration, air trapping, and hyperinflation of the alveoli. The obstruction interferes with the gas exchange, which may lead to hypoxemia (decreased oxygen) and hypercapnia (increased carbon dioxide in the blood), which in turn leads to respiratory acidosis. Often RSV is accompanied by otitis media and conjunctivitis. RSV can result in hospitalization with infected infants and children.

Diagnosis

Positive identification of RSV is accomplished by either of two methods: enzyme linked immunosorbent assay (ELISA) or rapid immunofluorescent antibody (IFA) from direct or aspiration of nasal secretions or nasopharyngeal washings. The nurse understands that chest x-ray films reveal hyperaeration, hyperinflation, atelectasis, areas of collapse, and flattened diaphragm indicating air trapping.

Arterial blood gases (ABG) reveal decreased pH and a PaCO_2 greater than 45 mm Hg, indicating respiratory compromise and potential failure. Complete blood count shows increased WBC, which is indicative of infectious processes.

Nursing Care

The monoclonal antibody palivizumab (Synagis) has been shown to be effective in reducing the complications of RSV. Palivizumab (Synagis) is given intramuscularly to high-risk infants. The clinical goal is to return the child to a normal respiratory status. Medical therapy is aimed at relief of respiratory distress, improvement in oxygenation, and alleviation of airway obstruction.

Nurses must keep in mind that RSV is treated symptomatically with maintenance of hydration, oxygenation, and keeping the mucous membranes clear of mucus. Children may be managed at home. The nurse can tell the parents that hospitalization is recommended for children who have some other underlying illness or are in a debilitated state. In the hospital, nursing care includes mist therapy combined with oxygen administered by hood or tent in concentrations sufficient to alleviate dyspnea and hypoxia. The nurse administers intravenous fluids until the child shows signs of improvements.

Strict isolation is required for patients infected with RSV virus because it is easily spread from hand to eyes or nose and other mucous membrane. The nurse emphasizes hand washing and that contact precautions such as the use of gown, gloves, and masks are required (Fig. 24-6). Parents need to know that the first 24 to 72 hours is the critical time and in most cases there is complete recovery.

Figure 24-6 When a child has respiratory syncytial virus, contact precautions, such as the use of a gown, gloves, and masks, are required.

An antiviral agent such as RSV-IGIV or RespiGam has been used as a prophylactic to prevent RSV in high-risk children. This antiviral agent may be administered via endotracheal tube, hood, or tent. When an antiviral agent is administered, the nurse understands that crystallization of the medication can occur in the nares, endotracheal tube, or eyes. The nurse also understands that an antiviral agent can be teratogenic (an environmental agent capable of producing a birth defect) to the fetus of a pregnant woman.

Nursing Insight— Preventing RSV

For preventive purposes, RSV immunoglobulin (RSV-IGIV), an intravenous preparation of immunoglobulin G that provides neutralizing antibodies against RSV, may be given as an intravenous infusion just before the start of the RSV season. It is a monthly injection given to infants at high risk of severe disease such as those born prematurely or those with chronic lung disease and those fitting the AAP criteria throughout the RSV season.

PNEUMONIA

Pneumonia is a lower respiratory tract infection of the pulmonary parenchyma. It is more common in infancy and early childhood. It may occur as a primary infection or secondary to another illness or infection. Pneumonias are classified as lobar, bronchopneumonia, and interstitial.

Lobar pneumonia involves lobes of the lungs. Bronchopneumonia begins with involvement of the terminal bronchioles that become clogged with mucopurulent exudate and forms consolidated patches in the lungs, while interstitial pneumonia is more or less confined to the alveolar walls.

Viral pneumonia, a more common form, involves RSV infection in infants and parainfluenza and adenoviruses in older children, whereas *Streptococcus pneumoniae* is the common pathogen causing bacterial pneumonia. The nurse must remember that a viral infection can have a secondary bacterial infection 6 to 8 days after initial onset due to viral insult of protective mechanisms.

Most often, pneumonia is a complication of a pre-existing infection or a condition produced when a patient's defense mechanisms has been weakened. Interference in normal clearing mechanisms from the nasopharynx, epiglottis, epithelial cells, and mucociliary flow by allergy, viral infections, or irritants may allow colonization and subsequent infection with the organisms causing pneumonia. This depresses the function of alveolar macrophages and neutrophils. Phagocytosis is impeded by respiratory secretions and alveolar exudates. In the tissues, the causative agent multiplies and spread through the lymphatics, bloodstream, and sinuses. The severity is related to the virulence of the invading microorganism.

Signs and Symptoms

The symptoms of pneumonia are variable depending on the site affected; however, the general symptoms are high fever, cough, rapid respirations, chest pain, retractions, and nasal flaring and body malaise. Rhonchi or fine crackles are heard on auscultation.

Diagnosis

Clinical features and chest x-ray exams aid in the diagnosis of pneumonia. It is not always possible to identify the causative agents based on x-ray exams alone. Clinical history, the child's age, and laboratory examinations help in identifying the causative agent. Radiographic examination shows diffuse or patchy infiltration with peribronchial distribution.

diagnostic tools Chest Radiograph

The nurse must recognize the importance of chest radiograph in the diagnosis of pneumonia. Opacities, seen as white areas on the x-ray plate represent consolidation and are typical in cases of pneumonias.

Nursing Care

Most cases of pneumonia can be treated at home with rest and fluids and symptomatic management with analgesics and antipyretics. Antibiotics are given for bacterial pneumonia and not for viral pneumonia. If antibiotics are given, the drugs may range from amoxicillin (Amoxil) to the third-generation cephalosporins, depending on the severity of the condition.

Oxygen administration via nasal canula with cool mist, chest physiotherapy, and postural drainage are initiated for patients requiring hospitalization (Fig. 24-7). Bronchodilators also might be used. Treatment of a child with pneumonia is supportive depending on the severity of the symptoms.

Labs: Sputum Culture and Sensitivity

To be able to establish the causative organism and the appropriate antibiotic that works best, culture and sensitivity test of the sputum are performed. Coughed out sputum is difficult to obtain from children, especially those who are very young. A specimen may be obtained via a direct throat swab immediately after coughing. In some cases, a sterile catheter may be inserted directly into the trachea through the endotracheal tube or during direct laryngoscopy. During sleep, children usually swallow their sputum; therefore, an early morning fasting specimen obtained via gastric aspiration may also be obtained. The gastric content can be collected before breakfast by inserting the naso-oral tube into the stomach.

The nurse must place the specimen in the appropriate container and properly label it with the patient's name, the nature of the specimen, date and time collected, and the examination desired. Ideally, the specimen must be sent immediately to the laboratory. If this is not feasible, the specimen is kept in a refrigerator until it is taken to the laboratory. Results of the test may be reported in 2 or more days.

Nursing care revolves around administration of oxygen and antibiotics. Fluids are given to prevent dehydration. The nurse can administer an antitussive medication at bedtime for cough. Nursing care measures such as changing the child's clothes and linen should take place frequently to prevent chills. The nurse must remember that positioning the child on the affected side naturally splints the chest and reduces pleural rubbing that causes discomfort. It is also helpful to elevate the child's head to expand the ribcage.

The nurse can assess the child's sputum for color, amount, and consistency. The sputum assessment must be adequately recorded in the child's record.

To detect any change in condition, the nurse assesses vital signs and breath sounds. The nurse must also assist the child and the parents in alleviating anxieties through continuous emotional support and reassurance. It is important for the nurse to inform the parents that complete recovery from pneumonia may occur in about 2 weeks. Even if the child is feeling better after treatment, gradual return to normal activities like school and play are encouraged. The nurse can reinforce to parents that adequate food, fluids, and rest are important during convalescence.

Figure 24-7 Oxygen administration via nasal canula.

SEVERE ACUTE RESPIRATORY DISTRESS SYNDROME

Acute respiratory distress syndrome (SARS) was first reported in Asia in 2003. The coronavirus SARS Co-V is its main causative agent.

Signs and Symptoms

Fever of greater than 100.4°F (38°C) is the most common symptom and the main criterion in the current WHO case definition for suspected or probable SARS. Fever is accompanied by other symptoms including chills, cough, rigor (stiffness of some body parts), headache, dizziness, malaise, and myalgia. Initial symptoms may resemble those of an atypical pneumonia. Often the symptoms increase in severity, which necessitates intubation and mechanical ventilation. The SARS coronavirus is spread by droplet shed from respiratory secretions of an infected person.

Diagnosis

The diagnosis of SARS continues to be based on clinical and epidemiological findings until standardized reagents for virus and antibody detection become available and methods have been adequately field tested. At present, there are no defined criteria for SARS CoV test results to confirm or reject the diagnosis of SARS (Kamps & Hoffman, 2003).

In patients reported with SARS, laboratory investigation shows the presence of lymphopenia, leukopenia, thrombocytopenia, elevated lactate dehydrogenase, aspartate aminotransferase, and creatinine kinase levels.

Nursing Care

The treatment for SARS is still developing because the condition is relatively new and research is still underway. SARS has been treated with antibiotics because the signs and symptoms are nonspecific and because confirmatory laboratory testing has not yet been established. Antibiotics are then necessary to cover respiratory pathogens for community-acquired or nosocomial pneumonia. Antiviral drugs and steroids together with noninvasive mechanical ventilation have also been used as treatment modalities.

Vigilant nursing care is vital in caring for children with SARS. Since the treatment for SARS is still being studied, it is important to prevent its transmission. Three important points are to be considered by the nurse to prevent SARS: case detection, patient isolation, and contact tracing. If a child with a suspected case of SARS is admitted in the

hospital, he or she must be isolated because SARS is transmitted through droplet infection. All health care providers, especially nurses caring for the child, should observe strict infection control measures, which include wearing masks, gloves, caps, and gown. Hand washing is essential before and after entering the child's room. Similarly, the nurse should instruct the child's visitors to observe proper infection control measures. If the admitted child is placed on assisted ventilation, the nurse must assist and monitor the child accordingly.

The nurse can be active in SARS case detection, and suspected cases must be reported immediately for proper management. Contact tracing can be achieved by identifying exactly who had close contact with the child. The most likely contacts are members of the same household, friends, and other relatives. People who had contact with the child must be monitored even at home during home health visits. The nurse encourages these people to seek medical consultation.

nursing diagnoses Lower Respiratory Disorders

- Risk for Ineffective Airway clearance related to excessive secretions in the airway, tracheobronchial inflammation, or obstruction
- Risk for Ineffective Breathing Pattern related to tracheobronchial inflammation or obstruction
- Risk for Impaired Gas Exchange related to ventilation perfusion imbalance
- Anxiety related to perceived threat of hospitalization, or to invasive procedures or changes in health status of the child
- Risk for Deficient Fluid Volume related to inadequate fluid intake or excessive losses through abdominal route
- Fatigue related to increased respiratory effort

Infectious Conditions

PERTUSSIS

Pertussis or whooping cough is a highly contagious bacterial infection of the respiratory tract that causes paroxysmal cough. A “whooping” sound is produced as the child tries to take a breath. The disease is still a major cause of morbidity and mortality in children younger than 2 years. Sixty million cases a year occur worldwide (Long, 2004). In the United States, 11,647 cases were reported between 1976 and 2003 (Bocka, 2005).

The causative organism is *Bordetella pertussis*, a gram-negative coccobacillus. The disease is spread via droplet infection and direct contact with discharges from respiratory mucous membranes of an infected child. Pertussis is highly contagious; approximately 80% to 90% of susceptible individuals exposed to the infection develop the disease.

In this condition, *Bordetella pertussis* attaches to and multiplies on the respiratory epithelium, starting in the nasopharynx and ending primarily in the bronchi and bronchioles (Bocka, 2005). A tracheal cytotoxin is produced that is responsible for the local epithelial damage that produces the respiratory symptom.

Signs and Symptoms

Pertussis lasts for 6 weeks and is divided into three stages: catarrhal, paroxysmal, and convalescent stages. Each of the stages lasts for 1 to 2 weeks. The incubation period ranges from 3 to 12 days.

where research and practice meet: Severe Acute Respiratory Distress Syndrome (SARS)

Two studies have reported SARS among children. In the first study, Hon et al. (2003) reported persistent fever, cough, progressive chest radiograph changes, and lymphopenia. In 10 teen-age patients, symptoms of malaise, chill, and rigor were similar to those of adults. Younger children presented chiefly with cough, runny nose, rigor, or myalgia.

Fever was the presenting symptom in the second study; with 19 out of the 21 patients having the symptom. Prodromal symptoms included malaise, loss of appetite, chills, dizziness, and rhinorrhea. During the respiratory phase of the illness, half of the children had cough, of which one third was productive (Chiu et al., 2003).

The catarrhal stage presents like the common upper respiratory infection with the presence of nasal congestion, rhinorrhea, sneezing, lacrimation, and conjunctival suffusion. This is the most communicable stage, but pertussis remains communicable up to 3 weeks after the onset of cough.

The paroxysmal stage presents with intense coughing lasting for several minutes. In older infants and toddlers, the characteristic “whoop” follows coughing as the child attempts to breathe. Infants younger than 6 months may not exhibit the “whoop.” Instead, they may have episodes of apnea. Apnea occurs because the airway is still partially closed. The child turns red while coughing and vomiting usual follows the coughing episodes.

The convalescent stage presents with chronic cough lasting for weeks. Older children and adolescents may not show signs of the three stages; instead, the symptoms are an uninterrupted cough, feelings of suffocation or strangulation, and headache.

The child with pertussis typically does not typically have a fever. The presence of conjunctival hemorrhage and facial petechiae is visible and is due to the forceful, intense coughing.

Diagnosis

It is not easy to diagnose pertussis because the initial symptoms are similar to those of other upper respiratory tract infections. The diagnosis of pertussis is based on a history of severe coughing with or without a whoop, redness of the face during coughing and incomplete or absent pertussis vaccination.

When blood testing is performed there is profound lymphocytosis, usually more than 70% of the total WBC count, which often increases to 20,000 to 40,000 or even 100,000 cells/mm². Chest radiography may show focal atelectasis and/or peribronchial cuffing.

The criterion standard for diagnosis of pertussis is isolation of *B. pertussis* in a culture from a swab taken from nasopharyngeal secretions. Polymerase chain reaction (PCR) testing to detect DNA is also commonly done. The Centers for Disease Control and Prevention (CDC) recommends both culture and PRC tests if a child has a cough lasting longer than 3 weeks. Many health care professionals now consider serological testing with ELISA to be the criterion testing standard (Bocka, 2005).

Nursing Care

The goals of therapy include limiting the number of paroxysms; observing the severity of cough; and maximizing nutrition, rest, and recovery (Guinto-Ocampo, Bennett, & Attia, 2008).

Antibiotic therapy is given to eradicate the infection, reduce morbidity, and prevent complications. Erythromycin (Erythrocin) is the drug of choice for pertussis. It is given at 40 mg/kg per day (not to exceed 2 g) qid for 14 days. Children allergic to erythromycin (Erythrocin) are given trimethoprim sulfamethoxazole (Bactrim).

The nurse can communicate to parents that the most important preventive measure is vaccination against the disease with DTaP. The vaccine is a combination of diphtheria and tetanus toxoids. The child must be immunized before the age 7. Children who are younger than 5 years of age must complete three doses of DTaP. The vaccine may not prevent the illness entirely, but it has been shown to lessen disease severity and duration.

Hospitalization is required for when the child younger than 1 year of age who has developed pneumonia, has apnea, cyanosis, or hypoxia, and with moderate to severe dehydration. While in the hospital, the nurse can implement droplet precaution. Droplet precaution is an isolation technique that decreases transmission of organisms when an infected child coughs, sneezes, or spits (Venes, 2009). Droplet precautions are recommended for 5 days after the commencement of therapy or 3 weeks after the onset of paroxysmal cough if no antimicrobial therapy has been given.

During hospitalization, the nurse must vigilantly monitor the child's vital signs and oxygen saturation. Nursing care also centers on the child's hydration and nutritional status. If the child is unable to drink, an intravenous infusion is given. The nurse should accurately record coughing, feeding, vomiting, and weight changes. The nurse also instructs the parents that no special diet is required for the child, as the child is fed according to what is tolerated. The same is true for the child's activities. For as long as the child can tolerate, he or she can participate in regular activities and play. The prognosis for recovery is good for children who are well managed. It is important for the nurse to emphasize the importance of follow-up check-ups.

Nursing Insight— Pertussis vaccination

In December 2005, the American Academy of Pediatrics approved recommendations from the Committee on Infectious Disease (COID) for universal vaccination of DTaP for adolescents at the 11 or 12 year visit to boost protection against pertussis.

TUBERCULOSIS

Tuberculosis (TB) is a chronic bacterial infection, usually of the lungs that is spread through the air. *Mycobacterium tuberculosis*, its most common causative agent, may also attack other organs and body parts. The CDC reported 14,093 cases of active TB in 2005 in the United States. In addition, an estimated 10 to 15 million people have latent TB. There was a declining rate of TB until the mid-1980s, when outbreaks drew new attention to TB. This outbreak was brought about by the increase in immunosuppressed individuals, particularly those with HIV and increased drug-resistant strains.

Tuberculosis remains a public health concern. The World Health Organization (WHO) estimates that approximately one third of the world's population is infected with *Mycobacterium tuberculosis*. The global burden of tuberculosis continues to grow due to factors like, HIV epidemics, population migration patterns, increasing poverty, social upheavals, crowded living conditions in developing countries and inner city populations in developed countries, inadequate health coverage, poor access to health services, and inefficient tuberculosis control programs (Munoz & Stark, 2004).

Aside from *Mycobacterium tuberculosis*, *Mycobacterium bovis* may also affect children as the microorganism may be present in unpasteurized milk or milk products. Latent tuberculosis infection (LTBI) occurs after the inhalation of infective droplet nuclei of *M. tuberculosis*. Conditions such as lowered body resistance, HIV infection, malnutrition, untreated upper respiratory tract infection (URTI), and other debilitating conditions increase the chance acquiring an active infection.

Transmission of tuberculosis is person-to-person through airborne droplet nuclei. It rarely occurs by direct contact with infected discharge or a contaminated fomite (any substance that adheres to and transmits infectious material) (Venes, 2009). Young children with tuberculosis rarely infect other children or adults because the tubercle bacilli are sparse in the endobronchial secretions of children and cough is often absent or lack the force necessary to suspend the infectious particles (Munoz & Stark, 2004).

When the organism enters the lungs, there is proliferation of epithelial cells that surrounds and encapsulates the multiplying bacilli as a way of warding it off. This process forms the typical tubercle. The extension of the primary lesion causes progressive tissue destruction as it spreads within the lungs. The tubercle bacilli are carried to most tissues of the body through the blood and lymphatic vessels. Multiplication of the bacilli is likely to occur in organs with conditions that favor their growth such as the brain, kidneys, and bones.

Signs and Symptoms

Many children with TB do not develop symptoms early in the infection. Low-grade fever, mild cough, and flu-like symptoms that resolve within a week may be observed. Anorexia and weight loss may follow as the disease progresses.

Diagnosis

The diagnosis of TB in children is challenging because children exhibit a variety of symptoms. Exact diagnosis of TB is based on the child's physical signs and symptoms, the history of exposure to TB, x-ray films that may show evidence of *M. tuberculosis* infection, and laboratory culture that may confirm the diagnosis. Early morning gastric contents from the stomach may be helpful in diagnosing TB. However, it takes about 4 weeks for the culture test to confirm the diagnosis because the bacillus grows slowly on a culture medium.

Ethnocultural Considerations—Bacille Calmette-Guérin vaccine

Bacille Calmette-Guérin (BCG) vaccine is a preparation of a dried, living but attenuated culture of *Mycobacterium bovis*. It is used worldwide in areas with a high incidence of tuberculosis (TB) to provide passive TB immunity to infants and to protect adults who have an unavoidable risk of TB infection. In many foreign countries where BCG vaccination is widely used, the TST skin test is not useful because patients vaccinated with BCG will have a positive skin test (Venes, 2009).

The BCG vaccine is not routinely given in the United States because researchers have shown that BCG vaccine has worked well in some situations but poorly in others. The best use of BCG vaccination appears to be the prevention of life-threatening forms of tuberculosis in infants and young children.

Nursing Care

The basic principles of management of tuberculosis are the same for children and adults. They consist of proper nutrition, anti-TB drugs, supportive care, and prevention of reinfection.

The American Academy of Pediatrics recommends a combination of isoniazid (INH), rifampicin, and pyrazin-

Labs: Tuberculin Skin Test

The tuberculin skin test (TST) is an exact indicator whether a child has been infected with the tubercle bacillus. The skin test consists of injecting a measured amount of the intermediate strength of 5 tuberculin units of tuberculin purified protein derivative (PPD) intradermally to form a small wheal in the forearm. In 48–72 hours, a positive reaction is marked by an area of red induration (an area of hardened tissue). Reactions greater than 10 mm in size are considered positive in non-immunocompromised patients (NIAID, 2006). The American Academy of Pediatrics recommends that administration and interpretation of skin test be performed and read by trained health care professionals (Fig. 24-8).

amide (PZA) given daily for the first 2 months followed by INH and rifampicin (Rifadin) given two to three times a week by direct observation of therapy for the next 4 months. Direct observation therapy (DOT) means that a health care worker or other responsible, mutually agreed-on individual is present when medications are administered to the child. DOT has been recommended for treatment for children and adolescents with TB in the United States because it decreases the rate of relapse, treatment failures, and drug resistance.

Children with TB are usually treated in out patient clinics. However, in case of serious infection and involvement of other organs, children may need hospitalization. Children started with drug therapy are not contagious and require only standard precautions. Children with no cough and negative sputum smears may be cared for without isolation. Children with contagious infections must be placed in isolation.

During the child's hospitalization, the nurse must work closely with the family and the child to ensure that optimal care is provided. The nurse can explain the nature of disease and how children are at high risk of getting the infection. The nurse must emphasize good hand washing to reduce the chance of transmission from one person to another person. Nurses can also teach children to cover their nose and mouth with tissue paper when sneezing

Figure 24-8 Nurse is performing a tuberculin skin test.

and coughing. Proper disposal of the tissue paper in waste baskets must also be emphasized.

During hospitalization, the nurse must assist the child in collecting different specimens for the diagnosis, which includes sputum for culture. Children are unable to cough properly, so sputum may be difficult to collect from the young child.

The family of the child can be informed about the benefits of DOT. Nurses can discuss with the family about the ways of giving the medicines (e.g., tablets may need to be crushed well to facilitate its oral intake). The availability of liquids preparation in syrup form may be explored. The nurse can tell the family that they need to follow precautionary measure to prevent from latent infection. The nurse should emphasize regular follow-up visits and regular intake of medications.

INFLUENZA

Influenza or flu is a common infection of the respiratory system caused by viruses. Infants and children are most vulnerable to the influenza virus. It is estimated that children are three times more likely to become ill with influenza than adults are. Each year, more than 36,000 persons, especially older individuals and those with chronic medical conditions, die from influenza in the United States (American Lung Association's Influenza Prevention, Program, 2008). The disease rapidly spreads worldwide in seasonal epidemics. Influenza is most common during the winter months.

Three types of virus cause influenza. Influenza types A and B are the major influenzal pathogens and cause epidemics. These viruses mutate and create different strains. Influenza type C causes mild symptoms and does not cause epidemics.

Influenza is spread through droplets when an infected person coughs, sneezes, or speaks. Indirectly, articles contaminated by nasopharyngeal secretions may spread the infection. Influenza causes a lytic (cellular destruction) infection of the respiratory epithelium with loss of ciliary function, decreased mucus production, and desquamation of the epithelial layer. These changes may permit secondary bacterial invasion directly from the epithelium or through the middle ear space. The rapid multiplication of the virus in the mucosa causes problems in the immune response mechanism (Torpy, 2005).

Signs and Symptoms

With the influenza virus there is the sudden onset of fever and chills accompanied by a flushed face, photophobia (intolerance to light), myalgia (pain in the muscles), hyperesthesia (sensitivity to sensory stimuli), and prostration (exhaustion). Complications include severe viral pneumonia, encephalitis, and secondary bacterial infections such as otitis media, sinusitis, or pneumonia. Flu symptoms in children are similar to that of adults except that children have higher degrees of fever of up to 105.1°F (40.6°C).

Diagnosis

The diagnosis of flu is based on the child's signs and symptoms and epidemiologic considerations. In the presence of a known epidemic, a child who has symptoms of fever, malaise, and respiratory illness may easily diagnosed. Laboratory tests may also isolate the virus from the nasopharynx if done early in the course of illness.

Nursing Care

In uncomplicated cases, influenza is treated symptomatically since symptoms usually recede in 48 to 72 hours. Adequate rest and fluid intake are important components of the regimen. For fever and pain, acetaminophen (Children's Tylenol) or ibuprofen (Children's Advil) is given. Antiviral drugs such as oseltamivir (Tamiflu), amantadine (Symmetrel), and rimantadine (Flumadine) are currently used to manage influenza. These medications are usually given in the first 48 hours to decrease the severity and duration of the illness. Antibiotics are given when there is evidence of a superimposed bacterial infection like prolonged fever and deterioration of the condition.

Influenza vaccines are now widely used for prevention. There are two routes for the vaccines: intramuscular and nasal spray. Vaccination is recommended annually to populations at risk since the flu virus is continuously changing. Katz and Hall (2005), in a cost-benefit analysis for the recommended universal influenza immunization in children age 6 to 23 months found that influenza vaccine is less costly than hospitalization for the child.

Since influenza is a self-limiting condition, nursing care is supportive. Depending on the severity of influenza, the child recovers within 1 to 2 weeks. The nurse must emphasize to the parents the importance of adequate rest and sleep. When the child has the flu, more fluids should be offered. An electrolyte solution is recommended. The nurse can reiterate the importance of having an annual vaccination.

“What to say” — Salicylates (aspirin)

The nurse can instruct the parents to avoid giving salicylates (aspirin) because of the possibility of Reye syndrome. Reye syndrome is an encephalitis-like illness following a viral infection. Reye syndrome is highly associated with the intake of salicylates (aspirin) during the course of the viral disease. The symptoms include nausea, vomiting, lethargy, and indifference; in severe cases, there may be irrational behavior, delirium, and rapid breathing. Warn parents to watch out for these symptoms, especially if aspirin has been given to the patient prior to consultation.

Pulmonary Noninfectious Irritation

FOREIGN BODY ASPIRATION

Anything that is caught in the respiratory tract and blocks the air passage is called foreign body (FB) aspiration. Young children are at greater risk of aspirating foreign bodies based on curiosity and the habit of putting things in the mouth. Foreign body aspiration may occur at any age but it is most common among toddlers. Almost 2.5 million children are affected each year in the United States, and FB aspiration leads to 300 deaths annually. The most frequently aspirated objects are organic food items such as peanuts, popcorn, hot dogs, or vegetable matter and fruit gel snacks. Nonfood objects include balloons, coins, pen tops, and pins (Qureshi & Mink, 2003).

 **medication:** Oseltamivir (Tamiflu)

Oseltamivir (o-sel-**tam**-i-vir)

Pregnancy Category: C

Indications: Uncomplicated acute illness due to influenza infection in adults and children >1 year who have had symptoms for < 2 days
Prevention of influenza in patients > 13 years

Actions: Inhibits the enzyme neuraminidase, which may alter virus particle aggregation and release.

Therapeutic Effects: Reduced duration of flu related symptoms

Pharmacokinetics:
ABSORPTION: Rapidly absorbed from the GI tract and converted by the liver to the active form, oseltamivir carboxylate, 75% reaches systemic circulation as the active drug.

Contraindications and Precautions:
CONTRAINDICATED IN: Hypersensitivity and children <1 year old

Adverse Reactions and Side Effects:
CNS: Insomnia, vertigo. Respiratory: bronchitis. GI: nausea, vomiting

Route and Dosage:
PO:
Children >88 lb (40 kg): 75 mg twice daily for 5 days
Children 50.6–88 lb (23–40 kg): 60 mg twice daily
Children 33–50.6 lb (15–23 kg): 45 mg twice daily
Children < 33 lb (15 kg) and >1 year: 30 mg twice daily

Nursing Implications:

- Monitor influenza symptoms. Additional supportive treatment may be indicated to treat symptoms. Treatment should be started as soon as possible from the first sign of flu symptoms. Administer with food or milk to minimize GI irritation.
- Drug should be used within 10 days of constitution.
- Caution patients/parents that Tamiflu should not be shared with anyone even if they have the same symptoms.
- Tamiflu is not a substitute for flu shots according to immunization guidelines.
- Advise patient to consult health care professional before taking any medications concurrently with Tamiflu.

Data from Deglin, J.H., & Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

In the child, the aspirated object may stay in the same place of obstruction or move with air. There is a possibility that if the child forcefully coughs the object may be spit out. During the presence of FB the bronchioles and bronchi may become larger during inspiration and smaller during expiration. Small objects may cause little damage and large objects may occlude the whole airway passage, causing more severe symptoms. A sharp object not only blocks the airway but also may lead to severe trauma and the child may have complications such as inflammation and abscess, atelectasis, and emphysema.

Signs and Symptoms

After aspiration, the child patient exhibits symptoms of choking, gagging, wheezing, or coughing. Dyspnea, cough, stridor, and hoarseness are present when the obstruction is in the laryngotracheal area. If the obstruction is in the larynx, the child may be unable to speak and breathe. If the object is in the bronchioles, the child may show difficulty in breathing and unequal breath sounds. The child's condition may worsen with the total obstruction and the

child may become cyanotic or unconscious. The nurse understands that any delay in removal of the foreign body may be fatal.

Diagnosis

The child's history and physical signs help in the diagnosis of foreign body aspiration. In children, a foreign body should be suspected in the presence of acute or chronic pulmonary lesions. The nurse can communicate to the family that an x-ray exam with fluoroscopic examination can be helpful in locating the site of the aspirated object. Definitive diagnosis of FB aspiration is through bronchoscopic examination.

The nurse who is knowledgeable in assessing respiratory emergencies can make a difference in saving the child's life. The CUPS (critical, unstable, potentially unstable and stable) assessment method may be a useful tool for the nurse as it includes actions that the nurse can take for each level of emergency.

 **assessment tools** Pediatric Respiratory Emergencies

Assessment	Critical	Unstable	Potentially Unstable	Stable
Airway	Completely or severely obstructed	Partially obstructed, excessive secretions or blood	Open with secretions	Open
Breathing rate	May be slow, absent, or very fast with periods of slowing	Increased	Occasionally increased	Normal
Breathing effort	Absent or greatly increased with periods of weakness	Increased	Normal	Normal
Breath sounds	Grunting, faint, or absent	Wheezing or stridor, decreased breath sounds	Normal or slight wheezing	Normal
Skin color	Pale, mottled, or blue	Pink or pale	Pink	Pink
Inspection	Normal, decreased, or absent chest movement	Normal or decreased chest movement	Runny nose, red eyes, fever	Runny nose
Actions	Immediately open airway, suction, give high concentration oxygen with assisted ventilation, and transport	Move at moderate pace; give high concentration oxygen; prepare for transport; reassess frequently	Move at moderate pace; help into position of comfort; give high concentration oxygen; prepare for transport	Begin focused history and physical exam

Data from Rahm, N.S., Hansen, J.D., & Sanddal, N.D. (1997). *Critical trauma care by the basic EMT*. Bozeman, MT: Critical Illness and Trauma Foundation, Inc.

Nursing Care

If a large object has been swallowed then it may be difficult for the child to remove the foreign body spontaneously by coughing. In this case, the child will need instrumental assistance to remove the obstruction. The nurse

understands that delays in the treatment may lead to swelling in the obstructed site and inflammation may set in, hampering the removal of the object. The foreign body may also adhere to the lumen of the air passage.

Medical management involves the removal of foreign bodies from the respiratory tract by direct laryngoscopy or bronchoscopy. The child is hospitalized during and after the procedure for observation of laryngeal edema and respiratory distress.

In the hospital, the nurse must closely monitor the child's vital signs and assess the level of consciousness. The nurse can explain any procedures to the parents to help allay anxieties. Initially, the child may be placed on NPO and the family should be encouraged to follow the medical regimen. The nurse can provide cool mist vaporizer and administer antibiotic therapy if deemed appropriate.

The nurse, especially in the community, plays very important roles in foreign body aspiration since the community nurse is the involved in health care in the home setting where the accident commonly occur. In the community setting, the nurse must be skillful in Heimlich maneuver and can provide health education to parents regarding the procedure. Parents can be taught about safety precautions to avoid foreign body aspiration. For instance, the nurse can communicate to the parents that toys should not have small detachable parts and food size should be appropriate for age.

Collaboration in Caring— The Heimlich maneuver

The Heimlich maneuver is a life saving way of removing the foreign body. In a choking child older than 1 year of age, abdominal thrusts are necessary. In a choking infant back blows and chest thrusts are performed. The community health nurse can encourage the parents to complete a cardiopulmonary resuscitation course (CPR) at the American Red Cross (ARC), the American Heart Association (AHA), or other community agencies that teach CPR.

Heimlich maneuver on a conscious child older than 1 year of age:

1. Give five blows to the child's back with heel of your hand with the child sitting, kneeling, or lying.
2. If the obstruction persists, go behind the child and pass your arms around the child's body; form a fist with one hand immediately below the child's sternum. Place the other hand over the fist and pull upwards into the abdomen. Repeat five times.

3. Check the child's mouth for any obvious obstruction that can be removed.

4. If necessary, repeat the sequence and ask for help to call 911 or rush to the nearest hospital

Heimlich maneuver on an infant:

1. Lay the infant on your arm or thigh with the infant's head down.
2. Give five blows to the infant's back using the heel of your hand.

3. If the airway obstruction continues, turn the infant over with head down and give five chest thrusts using two fingers at a distance of 1 fingerbreadth below the nipple level in midline.

4. Check the infant's mouth for any obvious obstructions that can be removed.
5. If necessary, repeat the sequence and ask for help to call 911 or rush to the nearest hospital (The AHA Subcommittee on Pediatric Resuscitation, 2006. <http://pediatrics.aappublications.org/cgi/content/full/117/5/e989>)

SMOKE INHALATION

Fires continue to be one of the most hazardous forms of manmade disasters and are responsible for approximately 5000 deaths per year in the United States. The majority of these deaths are due to smoke inhalation rather than to surface burns (Mandel & Hales, 2005). Smoke is a mixture of gases and aerosolized particulate matter generated by combustion. Incomplete combustion produces noxious substances that when inhaled are toxic to humans.

Smoke inhalation may cause three types of injury: heat, chemical, and systemic. Smoke tends to be dry but with high temperature. Heat produces immediate injury to the mucosa resulting in erythema, ulceration, and edema, thus compromising the upper airway. If significant edema ensues, symptoms related to obstruction such as dyspnea, stridor, and cyanosis occur. Chemical injury is related to the inhalation of substances generated during combustions. Irritant gasses such as carbon dioxide combine with water in the lungs to form corrosive acids; aldehyde cause denaturation of proteins, cellular damage, and edema of pulmonary tissues (Winklestein, 2005).

Systemic injury occurs from gases formed during combustion that are nontoxic to the airways but may cause

injury or death by interfering with oxygen utilization. Carbon monoxide and hydrogen cyanide are substances that can be formed when materials such as silk, nylon, polyurethane, and organic matters are burned. These substances are considered as asphyxiant and lead to neurological symptoms (Clardy & Manaker, 2006).

Signs and Symptoms

Symptoms from heat injury are proportionate to the damage to the upper airway. Burns in the face and neck may accentuate the symptoms. Edema of the upper airway usually manifest within 24 hours of injury. Dyspnea and stridor are the initial symptoms. Chemical injury may result in erythema, edema, and ulceration of the airways. Cough, bronchorrhea, dyspnea, and wheezing may not appear until 12 to 36 hours after the exposure. Moderate carbon monoxide (CO) poisoning presents with constitutional symptoms like headache, malaise, nausea, and dizziness, and alterations in mental status. Severe CO poisoning can produce seizures, syncope, cherry red mucus membranes, falsely high PO₂ readings or coma.

Diagnosis

Diagnosis of smoke inhalation is based on the signs and symptoms of the injury, especially in survivors of the fire. However, the nurse understands that diagnosis of CO poisoning requires careful neurological examination and should be based on compatible history and clinical findings.

Nursing Care

Treatment is aimed at managing upper airway obstruction and possible CO poisoning. Urgent attention to the adequacy of airway, breathing, and circulation is obligatory. The immediate administration of 100% oxygen via a high flow system is important to reverse tissue hypoxia. If the child is comatose, intubation is recommended to deliver the highest possible FIO₂ and to prevent CO₂ retention. After the initial stabilization, treatment of concomitant burns injury is initiated.

It is important for the nurse to remember that nursing care of children with smoke inhalation involves prioritizing life-sustaining systems of respiration and circulation. Nurses assist in emergency intubation and monitor the patients accordingly. Signs of carbon monoxide poisoning should be recorded and reported without delay.

Recovery for children with minor burns and smoke inhalation is good provided adequate nutrition is provided when the patient is medically cleared to have oral intake. The nurse should offer foods that are attractively served so that the child is encouraged to eat. Favorite toys may be placed at the bedside so that the child is not bored and will maintain normal development. For infants, a child life specialist can offer stimulation and calming music. Nurses can encourage parents to participate in the care of the child.

PASSIVE SMOKING

Passive smoking is defined as a nonsmoker's inhalation of the smoke coming from the smoker. The smoke inhaled by nonsmokers is called environmental tobacco smoke (ETS). The term was first used by the German physician Fritz Lickint in 1939. Since then, numerous studies were

conducted about the effects of cigarette smoking on non-smokers. There is conclusive evidence about the ill effects of smoking and ETS on health. The findings on passive smoking and disease have been the foundation of the drive for smoke-free environments and for educating parents concerning the effects of their smoking on their children's health (Samet & Sokrinder, 2006).

The nonsmoker breathes "sidestream smoke" from the burning tip of the cigarette and "mainstream smoke" that has been inhaled then exhaled by the smoker. ETS contains more than 4000 chemicals, some of which have irritant properties and some 60 known or suspected carcinogens. Inhalation of ETS may bring both short-term and long-term effects. The short-term effects are manifested as irritation to the upper airways, while the long-term effects are related to the consequences of inhaling the chemicals in ETS such as nicotine and carbon monoxide for prolonged periods of time.

Signs and Symptoms

Short-term effects are manifested in symptoms such as stuffy, runny nose, watery eyes, sneezing, coughing, and wheezing. Headache and nausea may also be felt. The long-term effects are the negative results of frequent and long-term exposure. Numerous studies found strong relationships between passive smoking and lung cancer, heart disease, miscarriage, birth defects, lung infection, ear infection, and worsening asthma and other allergic conditions.

Diagnosis

The diagnosis of conditions related to passive smoking is based on history and evidence of exposure to ETS. At present, 1.1 billion adults worldwide are smokers, implying that some ETS exposure is almost unavoidable for children and for the two thirds of adults who do not smoke (Samet & Sockrider, 2006). Measurements of several components of ETS have been made in homes, workplaces, and public places to characterize the contribution of smoking to indoor air pollution. Dangerous levels of ETS components usually come within those measures.

Nursing Care

Treatment for children is focused on the specific ailments that exposure to ETS has produced. One most important component to be addressed in passive smoking is its' control. Strategies to control ETS are currently being undertaken by both the government and private sectors through education, regulation, legislation, and litigation.

The nurse plays an active role through health education, especially to parents. The nurse, through health education, must emphasize the negative effects of smoking, both for the smokers and the recipients of environment tobacco smoke. To support "stop smoking campaigns" means the nurse must be a good role model and give up any personal smoking habits.

Nurses must also support the call of the World Health Organization (WHO) for the right of every child to grow up in an environment free of tobacco smoke. Efforts should be made by the nurses to persuade parents, especially pregnant women, to give up smoking. This is one way of advocating for the rights of children.

Respiratory Conditions Related to Allergens

ALLERGIC RHINITIS

Allergic rhinitis is an inflammation of the nasal membranes predominantly in the child's nose and eyes. Airborne particles of dust, dander, or plant pollens in children who are allergic to these substances cause allergic rhinitis. It appears alone or in combination with a cold.

Nursing Insight— How does inflammation of the nasal membranes occur?

Inflammation of the mucous membranes is characterized by a complex interaction of inflammatory mediators and is triggered by an immunoglobulin E (IgE)-mediated response to an extrinsic protein.

The mediators that are released immediately include histamine, tryptase, chymase, kinins, and heparin. The mast cells quickly synthesize other mediators including leukotrienes and prostaglandin D₂. These mediators then lead to the symptoms of rhinorrhea.

Next mucous glands are stimulated, leading to increase for secretions produced. Vasodilatation then leads to congestion and pressure. Sensory nerves are also stimulated, leading to sneezing and itching. This sequel happens in a matter of minutes and is called the early phase response.

In the next 4–8 hours there is a complex interplay of neutrophils, eosinophils, lymphocytes, and macrophages. This interplay brings about continued inflammation, termed as late phase response. The phase may persist for days and systemic effects range from fatigue to sleepiness to malaise to generalized weakness.

Signs and Symptoms

Symptoms associated with allergic rhinitis range include sneezing, itching (of nose, eyes, ears, palate), rhinorrhea, postnasal drip, congestion, headache, earache, tearing, red eyes, eye swelling, fatigue, drowsiness, and malaise. There is nasal itching and so to relieve the itching the child performs what is called allergic salute by rubbing the nose upwards.

Diagnosis

A thorough history and physical examination of the child confirm allergic rhinitis. A nasal smear is done to determine the number of eosinophils in the nasal secretions. A radioallergosorbent test (RAST) is done to determine specific IgE antibodies. Skin testing is often done to identify the specific allergen.

Nursing Care

Treatment for allergic rhinitis in the child involves pharmacological management. Pharmacological management includes short-acting antihistamines, longer acting histamines, nasal corticosteroid sprays, decongestants, and leukotriene inhibitors. There is evidence to prove that high-dose allergy shots are recommended if the allergen cannot be removed and if the child's symptoms are hard to control. This includes regular injections of the allergen

given in increasing doses, which in turn help the body to adjust to the allergen.

Nursing care for the child with allergic rhinitis falls under three broad categories:

- Identify triggers in the environment both outdoors and indoors that bring about allergic rhinitis. Pollen tends to be very high from late spring until summer, so reduce the child's outdoor exposure. Keep windows and doors shut during this season. Bathing after being outdoors helps to reduce the pollen present on hair and skin.
- Indoor measures include covering mattresses and pillows with dust covers. Bed linen should be washed more frequently every 2 weeks in hot water. Carpets and stuffed toys that harbor dust mites should be removed. If the allergen identified is a pet, it should be removed.
- Carry out prescribed drug therapies when necessary.
- Encourage parents about the benefits of allergy shots.

Across Care Settings: Education

Education about environmental control measures involves both the avoidance of known allergens (substances to which the patient has IgE-mediated sensitivity) and the avoidance of nonspecific irritants and triggers. In the clinic setting, the nurse can explore possible allergens of the child with the parents to obtain important information that might determine the cause of the allergic rhinitis. Parents must understand the possible complications that allergic rhinitis may cause. These complications range from otitis media, eustachian tube dysfunction, and acute sinusitis to chronic sinusitis.

ASTHMA

Asthma is a chronic disorder of the airway characterized by the triad symptoms of bronchial smooth muscle spasm, inflammation and edema of the bronchial mucosa, and production and retention of thick, tenacious, pulmonary secretions leading to airway obstruction. The term **status asthmaticus** is used to refer to persistent and intractable asthma in which the child does not respond to therapy and a medical emergency ensues.

Ethnocultural Considerations— Asthma

In the United States, the poor, especially of black or Hispanic background, experience disproportional high rates of both asthma prevalence and morbidity (Castro, Schechtman, Halstead, & Bloomberg, 2001; Mannino et al., 2002). There is great worldwide variability in prevalence, with industrialized areas having consistently high rates.

Genetic, environmental/extrinsic factors and intrinsic factors predispose the child to develop asthma. Although allergens play an important role in asthma, 20% to 40% of children with asthma have no evidence of allergic disease. Among the extrinsic factors are allergens such as dust; pollen; animal hairs; chemical sprays; perfumes; baby powder; molds; and foods such as nuts, chocolates, oranges, and chicken. Conditions such as changes in weather, pollution,

and smoke may also trigger an attack. Intrinsic factors include exercise, anxiety, strong emotions such as fear and laughter, and infections.

When any of the factors trigger an asthma attack, the response comes in 10 to 20 minutes. The allergen/antigen binds to the allergen-specific immunoglobulin E (IgE) surface, causing activation of resident airway mast cells and macrophages. Proinflammatory mediators, such as histamine and leukotrienes, are released. They provoke contraction of the airway's smooth muscles, increased mucus secretion, and vasodilatation. Consequently, microvascular leakage and exudation of plasma into the airway walls cause them to become thickened and edematous with subsequent lumen constriction (Kieckhefer & Ratcliffe, 2004).

Signs and Symptoms

Signs and symptoms in the child during the early phase are wheeze; paroxysmal, irritative, and nonproductive cough; prolonged expiratory phase; tachypnea; retractions; and nasal flaring. As the disease becomes chronic, cough persists especially at night. There may be enlarged AP diameter of the chest wall or barrel chest and elevated shoulders.

Diagnosis

The asthma diagnosis for the child is based on clinical symptoms, history, physical examination, and to a lesser extent, laboratory tests. The nurse can explain to the parents that radiographic examinations are done to rule out the presence of coexisting disease or infection and to evaluate the condition of the lungs. Generally, chronic cough in the absence of infection, wheezing, and prolonged expiratory phase is sufficient to establish a diagnosis (Winkelstein, 2005).

Nursing Care

Treatment consists of early relief of symptoms through drug therapy and prevention of further attacks through allergen control, environmental manipulation, and health education. The goal is to enable the child to have a regular life as possible by keeping the lung function functioning within normal limits. The nurse provides adequate health education about the use of a Peak Flow Meter to help the parents increase their capacity to care for the child (Procedure 24-1).

Drug therapy depends upon the level of severity of the disease. There are two approaches to this therapy; one is the quick-relief or rescue medications and the second is the long-term control medications.

The U.S. Department of Health and Human Services 2007, the National Asthma Education and Prevention Program, expert panel report 3: Guidelines for the diagnosis and management of asthma has provided a revised classification scheme for asthma severity (Table 24-2).

The guidelines recommend daily anti-inflammatory agents to control the levels of persistent asthma, with increasing doses of medication as necessary. The use of low-dose control medications such as inhaled steroids, cromolyn sodium (Intal), nedocromil (Tilade), or an anti-leukotriene agent such as montelukast sodium (Singulair) tablet usually taken at night that is recommended for children with mild persistent asthma (Fig. 24-9). Higher dose

of steroids with the addition of long-acting beta antagonists may be needed for moderate and severe persistent asthma. For quick relief of bronchospasm and for children with asthma, short-acting inhaled beta antagonists are recommended. For more detailed information of the guidelines visit <http://www.nhlbi.nih.gov/guidelines/asthma/index.htm>.

The Asthma Action Plan (<http://www.lungusa.org/atf/cf/%7B7A8D42C2-FCCA-4604-8ADE-7F5D5E762256%7D/AAP.PDF>) is an educational communication tool used between the health care provider and the patient, with their family and caregivers, to properly manage asthma and respond to asthma episodes. The Asthma Action Plan is completed by the child's primary care provider. It includes the symptoms and management for each color zone including peak flow measurements appropriate for each color zone. Nurses can provide adequate instructions on how to use, interpret, and complete the form.

A peak flow meter, which can be purchased over the counter, is an essential companion for the Asthma Action Plan for children older than 6 years old. The peak flow meter is portable handheld device that is used to measure the ability to push air out of the lungs. To determine the child's zone for children younger than 6 years old, the symptoms alone are used. The "personal best" peak flow is determined when the child is symptom free. A peak flow meter package usually contains a form where peak flow readings are recorded regularly. A personal best normal may be obtained from measuring the patient's own peak flow rate. Therefore, it is important for the patient, parents, and the doctor to discuss what is considered "normal."

Nursing care for children with asthma involves assisting with relief of symptoms and providing health education to patients and family. Asthma attacks are frightening and stressful both for the child and family; therefore, the nurse should have a calm approach in its initial management. Administering quick relief medications without delay is important. Essential nursing interventions include giving medications on time, liquefying secretions through

Figure 24-9 The respiratory therapist helps the child use a metered dose inhaler to control asthma.

Procedure 24-1 Using a Peak Flow Meter

The peak flow meter is a portable handheld device that is used to measure the child's ability to push air out of the lungs. The American Lung Association recommends the following steps in using the peak flow meter (<http://www.lungusa.org>).

Purpose

The purpose of a Peak Flow Meter is to keep track of the results and help the parents and child to learn about asthma. Keeping a daily record may also help determine if the child's asthma is getting worse.

Equipment

- Peak Flow Meter
- Peak Flow Record

Steps

1. Before each use, make sure the sliding marker or arrow on the Peak Flow Meter is at the bottom of the numbered scale (zero or the lowest number on the scale).
RATIONALE: Initial calibration ensures an accurate reading.
2. Instruct the child to stand up straight and to remove gum or any food from the mouth.
RATIONALE: Proper body alignment is essential for an accurate reading.
3. Instruct the child to take a deep breath and to put the mouthpiece of the Peak Flow Meter into the mouth. Close the lips tightly around the mouthpiece. Be sure to keep the tongue away from the mouthpiece.
RATIONALE: A tight seal is necessary for measuring an accurate reading.
4. Instruct the child to take in one breath and to then blow out as hard and as quickly as possible. Blow a "fast hard blast" rather than "slowly blowing" until all of the air is emptied from the lungs.
RATIONALE: A fast hard blast empties all the air from the lungs. This helps ensure an accurate measurement.
5. Teach the parents that the force of the air coming out of the lungs causes the marker to move along the numbered scale. Record the number where the marker landed on a *Peak Flow Record*.
RATIONALE: Teaching the parents about how to use and record the measurement of the Peak Flow Meter increases their capacity to care for the child.

6. Repeat the entire routine three times (if the routine is done correctly the numbers from all three tries are very close together).

RATIONALE: Repeating the entire routine three times helps ensure accurate data collection.

7. Record the highest reading. Do not calculate an average.

RATIONALE: The highest reading provides the most accurate data.

8. Measure the peak flow rate at the same time each day. A good time to measure the peak flow rate is between 7 and 9 A.M. and between 6 and 8 P.M. Note, It may be a good idea to measure the peak flow rate before or after using asthma medicine.

RATIONALE: A consistent time of day provides the best information about the child's ongoing lung function.

7. Keep a chart of the peak flow rates on a *Peak Flow Record*.

RATIONALE: Having written documentation records information about the lung function from day to day and may help with early identification of problems.

Clinical Alert A Peak Flow Meter package usually contains a *Peak Flow Record* where the peak flow readings are recorded regularly.

Teach Parents

Teach parents about the child's personal best. The "personal best" peak flow is determined when the child is symptom free. It is important for the child, parents, and the doctor to discuss what is considered "normal." Remind parents of the need to discuss the readings with the physician.

Documentation

10/12/10 0900 Peak flow meter used. Green zone, good

control; 80% of personal best, no symptoms noted.

Continues to take usual medication.

-I. Bustamante-Gavino, RN

adequate hydration and positioning the child properly (head of bed elevated 30 degrees) to provide comfort, and lung expansion. The side lying and semi-prone positions are also recommended. It is vital that the nurse reports and records the child's respiratory assessment as well as responses to medications so that appropriate management may be initiated immediately. The nurse can also ensure that respiratory treatments happen in timely manner and

that ordering a p.r.n. (as needed) treatment may be necessary.

The community nurse can offer health education to families that emphasizes adherence to the treatment regimen correctly, preventing infection, and avoiding asthma triggers. Nurses are in the best position to provide health education because they are in contact with the patients and the parents most of the time.

Table 24–2 Criteria for Classification of Asthma Severity in Children 0–4 Years of Age

Severity	Day Symptoms	Night Awakenings	SABA Use*	Limit to Activity
Intermittent	≤2 days/week	None	None	≤2 times/week
Mild Persistent	3–6 days/week	1–2 times/month	>2 days/week	Minor
Mod. Persistent	Daily	3–4 times/month	Daily	Some
Severe Persistent	Several times/day	>1 time/week	Several times/day	Extremely

*Short-acting beta 2 agonists (SABA) such as albuterol use does not include prevention of exercise-induced bronchospasm (EIB).
 Source: The U.S. Department of Health and Human Services (2007). National asthma education and prevention program. Expert panel report 3: Guidelines for the diagnosis and management of asthma.

Nursing Insight— Spacers

The nurse understands that for children less than 5 years of age, a spacer or a valved holding chamber (VHC) is recommended which is attached to the MDI. A spacer may deliver the medication to the child's lungs better than an inhaler alone and may be easier for the child to use than an MDI alone. In addition, for ease of delivery, child sized masks are available that fit the VHC. With this device there is more medication deposited in the lungs and less systemic side effects. After VHC use, the nurse can have the child follow with mouth washing and spitting to decrease swallowing medication and side effect including, in the case of inhaled corticosteroids (ICS), prevention of oral *candidiasis* (U.S. Department of Health and Human Services, 2007).

Across Care Settings: What to do in cases of an acute asthma attack

An asthma attack may occur anytime and anywhere. It may happen in the home, at a school, in a mall, or in a park. To guide parents, teachers, and people who work in places where children go, the nurse can provide the following tips:

Teachers and school administrators should be familiar with the health history of the child. It is important to coordinate care and share information with the school health nurse. The nurse should also know the school district's rules and regulations regarding carrying asthma medications to school, including where the medications are to be kept and how to use the medications. In coordination with the child's physician and parents the nurse can fill out an emergency asthma action plan, including the child's triggers. The nurse needs to post emergency phone numbers in case of an attack. In addition, the nurse must know the child's peak flow readings, the child's personal best, and when the child runs into trouble. The nurse can also educate the teachers and other personnel who come in contact with the child.

Parents: Be sure that you carry the child's quick relief medications. It is helpful if the school-age child carry it too, along with the instructions about how the medication is used.

Nurses can give information on environmental control and creating an allergen-free environment. In addition, through community health education, the nurse can emphasize that when child exhibiting difficulty breathing, wheezing, and coughing, it is important to be calm and reassure the child. It is important to find out if the child's medicine is available; if not, call 911.

Personnel in parks, mall, and play areas should be briefed about possible pediatric emergencies including management in an emergency situation.

summary points

- ◆ The differences between the adult and child respiratory system affect function and subsequent respiratory conditions.
- ◆ It is essential that the nurse have a good understanding of congenital respiratory conditions and structural anomalies in children along with an understanding of signs and symptoms and prescribed treatment.
- ◆ Nurses must provide adequate emotional support to parents whose children have life-threatening respiratory conditions.
- ◆ The diagnosis, signs and symptoms, and nursing care measures are important in caring for children with respiratory conditions.
- ◆ Nursing care for children with infectious respiratory conditions includes close monitoring and correct treatment to prevent spread of infection.
- ◆ Nursing care for noninfectious respiratory conditions is aimed at managing the upper airway to prevent obstruction and further damage.
- ◆ During health teachings, nurses should emphasize to parents an awareness of the ill effects of the different forms of air pollutants, including environmental tobacco.
- ◆ The goal for children with asthma is to enable the child to have as normal a life as possible by keeping the lung function functioning within normal limits.
- ◆ The nurse can educate the family about the child wearing a medical alert bracelet.

review questions

Multiple Choice

1. A 5-month-old infant is admitted to the hospital's pediatric unit with a history of Bronchopulmonary Dysplasia (BPD). What are the nurse's priority nursing actions? (*Select all that apply.*)
 - A. Administer Albuterol (Ventolin) nebulizer as ordered.

- B. Monitor the infant's oxygen saturation levels.
 C. Calculate the infant's intake and output.
 D. Administer antibiotic therapy as ordered.
2. The pediatric nurse is aware that the child with cystic fibrosis (CF) has discharge planning needs. Which of the following is important to include in the discharge-teaching plan?
 A. Communicating to the family about a well balanced, low-protein, high-calorie diet
 B. Communicating to the family about when to administer pancreatic enzymes
 C. Communicating to the family that vitamin supplements are not necessary
 D. Communicating to the family that cystic fibrosis (CF) a self limiting illness
3. A 2-year-old child is discharged from the out-patient surgical unit after having had a tonsillectomy. The pediatric nurse knows that the discharge teaching is effective after the parents verbalize which of the following statements as the most important aspect of the teaching?
 A. "I will administer cherry flavored acetaminophen (Children's Tylenol) for pain."
 B. "It's important to have my child to gargle to prevent an infection."
 C. "I will bring my child to the emergency room if I see excessive swallowing."
 D. "I will offer my child ice cream to help soothe the pain in the throat."
4. When caring for the pediatric patient, the nurse is aware that there are differences in the anatomy and physiology between the child's and the adult's airway that predispose the child to contracting a respiratory condition. (*Select all that apply.*)
 A. Infants are obligatory nose breathers until about 4 weeks of age so it is essential to maintain nasal patency.
 B. The trachea of the adult is shorter and narrower in diameter than the trachea of the child.
 C. The epiglottis of the child is more flaccid and does not close properly, which can lead to airway obstruction.
 D. The increased amount of soft tissue in the child's neck makes the child more susceptible to edema and infections.
5. Which assessment must the pediatric nurse include when evaluating the respiratory status of a child? (*Select all that apply.*)
 A. Skin turgor
 B. Oxygen saturation levels
 C. Skin color and moisture
 D. Respiratory rate and depth

True or False

6. The best time for the pediatric nurse to assess the child's respiratory status is when the child is awake and active.
7. Excessive drooling in the newborn with a history of polyhydramnios in the mother's obstetrical history may be indicative of a diaphragmatic hernia.
8. The pediatric nurse understands that two primary goals in caring for a child with cystic fibrosis are to control infection and improve aeration.

Fill-in-the-Blank

9. In the newborn diagnosed with a congenital diaphragmatic hernia (CDH), the nurse understands that there is an opening between the _____ and _____ cavities through which the abdominal organs can herniate into the thoracic cavity and present with symptoms of _____.

Matching

Match the appropriate signs and/or symptoms the nurse would observe in each of the following respiratory conditions. Write the letters on the blank provided before the item number.

- | | |
|---|---|
| _____ 10. Croup | a. Dry, hacking cough |
| _____ 11. Pharyngitis | b. Facial pain, headache, and fever |
| _____ 12. Sinusitis | c. Rigor, chills, and myalgia |
| _____ 13. Bronchitis | d. Hoarse, barky cough |
| _____ 14. Asthma | e. Pain on swallowing |
| _____ 15. Severe acute respiratory distress syndrome (SARS) | f. An irritating, nonproductive cough, nasal flaring, retractions |

CONCEPT MAP

Caring for the Child with a Gastrointestinal Condition

It's all right to have butterflies in your stomach. Just get them to fly in formation.

—Laura Moncur's Motivational Quotations: Dr. Rob Gilbert

LEARNING TARGETS *At the completion of this chapter, the student will be able to:*

- ◆ Identify the organs in the gastrointestinal system.
- ◆ Describe the functions (ingestion, digestion, absorption, metabolism, and elimination) of the gastrointestinal system.
- ◆ Describe the nursing diagnoses, goals, and priority interventions related to children with various gastrointestinal conditions.
- ◆ Plan nursing care for children with gastrointestinal tract conditions.
- ◆ Develop and implement specific teachings plan for parents whose children have various gastrointestinal conditions.
- ◆ Explore treatment and pharmacological options for various gastrointestinal tract conditions.

moving toward evidence-based practice Probiotic Use in Antibiotic-Associated Diarrhea Prevention

Johnston, B.C., Supina, A.L., & Vohra, S. (2006). Probiotics for pediatric antibiotic-associated diarrhea: A meta-analysis of randomized placebo-controlled trials. *CMAJ*, 175(4), 377–383.

The purpose of this study was to assess the efficacy of probiotics in the prevention of antibiotic-associated diarrhea in children. Adverse events associated with coadministration of probiotics and antibiotics were also explored. The incidence of antibiotic-associated diarrhea in children who received broad-spectrum antibiotics was reported as 11% to 62%. A systematic review of probiotic trials was completed. The analysis included six pediatric trials with a total of 707 patients. A significant reduction in the incidence of antibiotic-associated diarrhea in children was reported in all studies. Four of the six studies reported use of *Lactobacillus GG*, *L. sporogenes*, or *Saccharomyces boulardii* and showed evidence of preventive effects with no reported adverse

events. None of the studies provided a definition for adverse events although four reported minor events to include rash, gas, vomiting, increased phlegm, and chest pain. “The potential protective effects of probiotics to prevent diarrhea in children do not withstand intention-to-treat analysis” (p. 377). Further studies are needed.

1. Based on the findings from this study, are probiotics effective in the treatment and prevention of antibiotic associated diarrhea?
2. How is this information useful to clinical nursing practice?

Suggested Responses for Moving Toward Evidence-Based Practice on the Electronic Study Guide or DavisPlus.

Introduction

Children who experience a gastrointestinal (GI) tract condition can have an isolated condition or may encounter several disorders because the GI tract involves numer-

ous organs. In addition, any alteration in the GI tract can affect the child's overall growth and development. Normal growth and development relies on the healthy functioning of the GI tract. The function of the GI tract is to ingest and absorb nutrients and to eliminate waste prod-

ucts. An understanding of the basic anatomy and physiology of the GI tract and common disorders will help the nurse care for the child experiencing alterations in GI tract functioning.

A & P review The Gastrointestinal System

The GI system is responsible for ingestion, digestion, absorption, metabolism, and elimination of solid and liquid nutrients. Each organ in the system performs a specific function in this process. The system is divided into the upper and lower portions. The upper portion includes the mouth (teeth, gums), the esophagus, and the stomach. The lower portion consists of the small intestine, large intestine (colon), rectum, and anus. In addition, other organs are a significant part of the GI system: the liver, pancreas, and gallbladder.

The upper portion of the GI system is responsible for nutrient intake or ingestion: the mouth and esophagus. The tongue senses the taste and texture of food, which initiates salivation. Digestion begins in the mouth with the release of the enzymes amylase and ptyalin, which begin the breakdown of complex starches into disaccharides. The esophagus transports food to the stomach by the process of peristalsis. In the stomach food mixes with gastric fluids and is then propelled into the small intestine.

The lower portion of the GI system handles the remainder of the digestion, absorption, and metabolism processes with the assistance of the liver and pancreas. The small intestine does most of the work of absorption through a system of villi and folds, which increases the absorptive surface. The small intestines further convert disaccharides into monosaccharides. Hindrance of this process can lead to diarrhea. The small intestine is primarily responsible for absorption of carbohydrates, fats, proteins, minerals, and vitamins into the systemic circulation. The duodenum forms the first portion of the small intestines. Pancreatic and bile ducts empty in the upper portion of the duodenum. The duodenum is followed by the jejunum, where the majority of water, protein, carbohydrates, and vitamins are absorbed. Fat breakdown occurs mainly in the jejunum through the secretion of lipases by the pancreas. The lymphatic system then absorbs fats. Proteins are converted to amino acids by the pancreatic enzyme trypsin, which are absorbed via the capillary walls of the villi into the systemic circulation. The last and longest segment of the small intestines is the ileum, which absorbs bile salts, vitamins C and B₁₂, and chloride.

The large intestine takes care of elimination. The content of the intestines enters the cecum through the ileocecal valve, which is located in the right lower quadrant of the abdomen and forms the beginning of the large intestines. The appendix, which is described as a blind tube containing lymphoid tissue, is attached to the cecum. The ascending colon rises along the right anterior portion of the abdomen, followed by the transverse colon, which lies horizontally across the abdomen and then forms the descending colon along the left lateral abdomen. The sigmoid colon follows the descending colon into the pelvic cavity. The sigmoid colon then connects to the rectum,

where stool is stored until it is expelled through the anal canal and through the anus. Elimination culminates in the removal of solid waste products through defecation.

Accessory Structures

The liver is located below the right diaphragm and is the largest and heaviest organ in the body. The liver is a vascular organ composed of right and left hepatic lobes. The liver is responsible for metabolizing carbohydrates, fats, and proteins and also breaks down toxic substances such as drugs. In addition, the liver stores vitamins and iron and produces antibodies, bile, prothrombin, and fibrinogen for coagulation.

The gallbladder, which lies within the inferior surface of the liver, excretes and stores bile. The bile is then secreted into the duodenum through the cystic duct and common bile duct, where it assists in the digestion of fats.

The pancreas can be found between the spleen and stomach in the left upper quadrant of the abdominal cavity. The pancreas produces pancreatic enzymes, which are excreted into the duodenum by way of the pancreatic duct. The pancreatic enzymes assist in the metabolism of proteins, fats, and carbohydrates. Insulin and glucagon are also produced by the pancreas and secreted directly into the blood stream. ♦

Developmental Aspects of the Gastrointestinal System

The GI system plays an essential role in a child's growth and development. Because the GI system is complex, the nurse must understand the ways in which each developmental stage contributes to the promotion of the health of the child.

The infant has several physiological mechanisms in place to ensure the adequate intake of nutrients. The infant has a built-in safeguard to prevent choking while swallowing and sucking. The posterior portion of tongue is raised against the soft palate while the infant sucks that separates the mouth and throat. This allows the infant to suck and breathe at same time. The infant also has a longer posterior soft palate, which assists him or her in swallowing milk. In addition, the passage from mouth to pharynx is smaller, which helps to control the amount of liquid that is taken in. The nurse can teach the parents that the infant's stomach usually empties in 2.5 to 3 hours and this is the reason that the infant has frequent feedings. Digestion takes place in the intestines so it is important that the intestines function properly. In addition, the liver and pancreas do not mature until 6 months of age. The nurse can therefore tell the parents that infants younger than 6 months of age do not require solid foods. Pancreatic lipase is essential for fat and protein metabolism but is not adequately secreted until age 1 year, which limits the body's ability to absorb fats, such as those present in cow's milk and reinforces the need to carefully introduce foods into the infant diet, limiting foods to those that are specially prepared for infant digestion.

Nursing Insight— Infant stools

Infant stools are watery and frequently related to food passing quickly with not enough time to absorb water. Infants do not absorb water as rapidly as older children do. When defecating (evacuation of the bowels, feces), the infant may appear to be straining because of immature muscle coordination (Venes, 2009).

By 2 years, the child's salivary glands reach adult size (Murphy, 2004). The average toddler gains 5 to 6 lb. (2.3 to 2.7 kg) per year. The stomach capacity increases to about 500 mL and the liver matures to become more efficient in vitamin storage, glycogenesis (the formation of glycogen from glucose [Venes, 2009]), and amino acid changes (Murphy, 2004). The growth of the child's digestive system slows during the toddler years, which leads to a reduction in caloric needs from those of the infant period. The average toddler needs approximately 102 kcal/kg (46 kcal/lb) as opposed to 108 kcal/kg (50 kcal/lb) during infancy. Since the toddler characteristically has a decreased appetite and reduced metabolic rate, his or her appetite may be sporadic or appear finicky. Because of this sporadic behavior, the toddler may also go on food fads or "jags," preferring only one item and refusing others that he or she has preferred in the past.

By age 4 to 5, the GI system is mature enough for the child to eat a full range of food, with stools becoming more like those of adults (Murphy, 2004). The preschool-age child continues to have appetite fluctuations, with periods of overeating or refusal to eat. The preschool-age child gains about 4 to 5 lb (1.8 to 2.3 kg) per year.

By the time the child reaches the middle school age years, the GI tract has become relatively stable. The digestive system is adult size and functioning. Stools are usually passed once per day and are well formed.

Nursing Insight— Infant bowel sounds

In the newborn, bowel sounds are audible within the first few hours of life. A newborn with a scaphoid abdomen or signs of respiratory distress should be evaluated carefully for bowel sounds and/or decreased breath sounds in the chest, which may be evidence of congenital diaphragmatic hernia. A congenital diaphragmatic hernia is an opening between the chest and abdominal cavities through which abdominal organs may herniate into the chest cavity, compromising respiratory and cardiac structures.

clinical alert

Abdominal pain in children

In children, abdominal pain can be referred from an extra-abdominal source such as pneumonia, a urinary tract infection, or testicular torsion or can be associated with a systemic disease. Abdominal pain is a common complaint in ill children and can be found in conditions such as streptococcal pharyngitis, lower lobe pneumonia, sickle cell disease, cystic fibrosis, as well as in other conditions.

A child's abdominal pain experience is usually limited and the child may be unable to accurately describe or pinpoint the location or sensation.

Structural Gastrointestinal Disorders

INGUINAL HERNIA

Inguinal hernia is the most common type of hernia in children, accounting for 80% of all childhood hernias, or approximately 10 to 20 in 1000 live births (Mao, 2005). An inguinal hernia arises from the failure of the processus vaginalis to atrophy and close during the eighth month of gestation. This provides a canal that allows for abdominal fluid or structure (bowel, ovary, or Fallopian tube) to extend up to or through the inguinal ring into the scrotum or labia.

This type of hernia is five times more common in males with a 30% incidence among premature children (Mao, 2005). An inguinal hernia is defined as the protrusion of bowel through the inguinal canal and is usually evident by a protrusion in the inguinal area and a bulging of the scrotal sac (Mao, 2005). In females, the hernia may involve a protrusion through the round ligament into the labia. Inguinal hernias in the pediatric population are generally considered indirect, meaning that the hernia "passes through the internal abdominal ring, traverses the spermatic cord through the inguinal canal and emerges at the external inguinal ring".

Signs and Symptoms

Most inguinal hernias are painless and may be more apparent with coughing, crying, or straining and disappear during quiet periods.

Diagnosis

An inguinal hernia is identified by a painless swelling in the inguinal area that extends toward or into the scrotum. Most inguinal hernias are observed by 6 months of age with more than 50% diagnosed before 1 year of age.

Nursing Care

Elective surgical correction is the treatment of choice for the healthy child.

Nursing Insight— Incarcerated Hernia

An incarcerated hernia is a portion of the intestine that cannot be returned to the abdominal cavity. The condition causes obstruction or pain and if left untreated can lead to strangulation (Venes, 2009) and requires prompt referral and correction to prevent the bowel from becoming strangulated and necrotic.

The majority of inguinal hernias are managed on an outpatient basis. The initial nursing care of the child hospitalized for the hernia repair involves parental education and preoperative preparation of the child.

“What to say” — Inguinal hernia

If the child has an inguinal hernia, the nurse can tell the parents that the surgery will repair the defect caused by the hernia. Recovery for an inguinal hernia is usually rapid and the child will return home the same day as the surgery. After surgery, the nurse can inform the parents that the child's vital signs are monitored frequently and that the child's position will be changed often to avoid undue stress on the surgical area. Postoperative care includes keeping the wound clean and dry and managing the child's pain. For a child who is not toilet trained, changing diapers as soon as possible is important to prevent wound irritation and infection.

Discharge instructions include informing the parents on wound care and the importance of keeping the surgical site clean and dry. The nurse can also tell the parents that the child can resume normal activity within 4–6 weeks and that they may be given a prescription for stool softeners for the child to prevent straining during defecation (Venes, 2009).

UMBILICAL HERNIA

The nurse understands that umbilical hernia is the most common type of hernia in infants. An umbilical hernia is the protrusion of the intestine through the abdominal fascia, which is often identifiable during crying, defecation, or coughing (Fig. 25-1). An umbilical hernia occurs as a result of failure of the umbilical ring to close, which normally begins at the end of the first trimester. The incidence of umbilical hernias is estimated at one out of every six live births. Umbilical hernias are more common in premature and low-birth-weight infants and ten times more common in African American children. Umbilical hernias are also more common in children with Down's syndrome and in children with hypothyroidism.

Signs and Symptoms

The majority of umbilical hernias are asymptomatic. Umbilical hernias may also appear to be more prominent when the infant is crying.

Figure 25-1 An umbilical hernia is the protrusion of the intestine through the abdominal fascia.

Diagnosis

Umbilical hernias can be identified as a soft midline swelling in the umbilical area, which can be reduced with pressure.

Nursing Care

Most umbilical hernias resolve spontaneously by 3 to 5 years of age, though there is a decreased likelihood of spontaneous closure for hernias, larger than 1.5 cm in diameter or for those with a large, proboscis-like defect (elongated or extensible tubular process). Surgery is considered for persistent hernias beyond the age of 5, incarcerated hernias, and hernias that enlarge dramatically. Postoperative complications of umbilical hernia repair are rare.

The nurse should instruct the parents about umbilical hernia and prognosis for the spontaneous resolution of the umbilical hernia. The initial nursing care of the child hospitalized for the repair of an umbilical hernia involves parental education and preoperative preparation of the child. The majority of umbilical hernias are managed on an outpatient basis. Postoperative care includes keeping the wound clean and dry and managing the child's pain. A pressure dressing is generally maintained for 48 hours postoperatively. The child may resume a normal diet and activity postoperatively, although parents should be instructed to have the child avoid strenuous activities for 2 to 3 weeks after the surgery.

ANORECTAL MALFORMATIONS

Anorectal malformations range from simple, such as an imperforate anus to include other associated anomalies of not only the GI systems but also the GU system and pelvic organs. The incidence of anorectal malformation is approximately one in 4000 to 5000 births and is more common in males. As one of the most common groups of congenital defects, these abnormalities are caused by abnormal or arrested development. The location of the abnormality and actual organ systems involved is related to the week of gestation at which the development was disrupted (Potts, 2002). The etiology of anorectal malformations is unknown.

Signs and Symptoms

Anorectal abnormalities are generally apparent at birth. Rectal atresia (closure) and stenosis (constriction or narrowing of a passage) may initially present as a normal appearing anal opening but is later detected as an abnormal situation. Additional signs of rectal stenosis include vomiting, abdominal distention, and difficult stooling. Rectal atresia is defined as a complete obstruction that precludes the passage of stool. Immediate surgical intervention is mandatory for rectal atresia. On the other hand, rectal stenosis may present with a ribbon-like or narrow stool, which is not always readily apparent at birth. More extensive defects may present with evidence of a rectal connection to the vagina or urethra as the opening through which the stool passes.

Absence of a rectal opening is referred to as an imperforate anus. This defect can be manifested in several forms, which include a fistula or connection from the distal rectum to the perineum or GU system. Passage of meconium through the vagina, urethra, or an opening under the scrotum is early evidence of an imperforate anus though the presence of a fistula may not be evident at birth. In this condition, as peristalsis increases the meconium is forced through the abnormal passage.

Diagnosis

Diagnosis is made by physical examination and radiological imaging, which indicates the level of the defect and location of fistula formation (Potts, 2002). The visualization of gas in the bladder or urethra during imaging also indicates the presence of a fistula connection between the bowel and associated structure (Potts, 2002). Magnetic resonance imaging (MRI) of the lumbosacral spinal cord is required for all children presenting with an imperforate anus to rule out the presence of a tethered spinal cord, which is common in children with this malformation (Bishop, 2006). An ultrasound (outlines the shape of tissues and organs) of the abdomen and pelvis, an intravenous pyelogram (provides information about the structure and function of the kidney, ureter, and bladder), and voiding cystogram (radiography of the bladder) are performed to evaluate associated defects of the urinary tract.

Nursing Care

Management of anorectal malformations may require extensive treatment, depending on the extent of the defect and associated organ involvement, including GI, urinary, and reproductive systems. Repeated manual dilation can be used to treat anal stenosis. The creation of a new anal opening may be used to correct anatomically lower anorectal defects.

A two-stage repair is generally necessary for anatomically higher anorectal defects. The first stage of anorectal repair involves resection and the creation of a temporary colostomy. The second stage involves “the closure of the colostomy and a pull through procedure in which the blind pouch of the rectum is anastomosed to the anus” (Potts, 2002, p. 668).

Nursing care for anorectal malformation may involve the initial diagnosis of an anorectal defect by observation of the passage of meconium and assessment of the patency of the rectum through the insertion of a rectal thermometer (Potts, 2002). Overall nursing care depends on the type of defect and the extent of surgical correction. Care of the infant before surgery includes caregiver education and maintenance of intravenous fluids while the child is kept NPO.

In addition to basic needs of the child undergoing surgery of the GI tract, pain control and the importance of infection control must be stressed related to the location of the surgical incision and the potential for fecal or urinary contamination. For high anorectal malformations colostomy care is also required. With the presence of a colostomy the nurse should stress the importance of good skin care in the postoperative period. Nasogastric decompression is often required early in the postopera-

tive period. Oral feedings are generally initiated with the reestablishment of peristalsis and once stooling has begun.

Discharge instructions include colostomy care, wound care, prevention of infection, and the procedure for anal dilation if appropriate for the defect. The importance of adequate fluids is also stressed. The caregiver should be instructed on the potential need for dietary fiber and the possible use of stool softeners or bulking agents in the future. In addition, the caregiver should be advised of the potential for delayed toilet training.

Obstructive Gastrointestinal Disorders

HYPERTROPHIC PYLORIC STENOSIS

The etiology of hypertrophic pyloric stenosis is unknown. Suggested causal theories include a deficiency in inhibitory neuronal signals or molecular causes, such as a mechanism similar to that of Hirschsprung’s disease discussed later in this chapter (Bishop, 2006). Ganglionic cell immaturity has also been suggested as a causative factor.

Ethnocultural Considerations— Occurrence of hypertrophic pyloric stenosis

Hypertrophic pyloric stenosis occurs in approximately 6–8 of 1000 live births in the United States (Bishop, 2006). The incidence of pyloric stenosis is more common in the Caucasian population compared to 1.8 per 1000 live births in the Hispanic population and 0.7 in the African American population. Males, especially firstborns, are affected two to four times more often than females are and there may be a positive family history.

Signs and Symptoms

Hypertrophic pyloric stenosis typically occurs in a healthy male infant with a pattern of normal feedings and new onset of nonbilious vomiting. The vomiting usually begins with episodes of regurgitation and nonprojectile vomiting during the first few weeks of life (Parks & Yetman, 2004). Vomiting usually occurs immediately after a feeding and may become projectile in nature. The infant generally appears hungry immediately after vomiting and eagerly wants to feed again. Weight loss, dehydration, and constipation may also be seen. During palpation, in an infant between 3 and 12 weeks with projectile, nonbilious vomiting and an olive-shaped mass, pyloric stenosis may be suspected.

Visible reverse, or left to right, peristalsis may be observable in the left upper quadrant upon abdominal assessment and the stomach may become enlarged with retained food and secretions (Parks & Yetman, 2004). Jaundice and hiatal hernia are associated secondary features, which may occur in a small percentage of affected infants (Reichard & Lake, 2005).

clinical alert

Vomiting

Projectile vomiting is the classic and most common symptom of hypertrophic pyloric stenosis.

Diagnosis

Diagnosis of hypertrophic pyloric stenosis can be made by palpating the pyloric mass. The mass is olive-shaped, movable, firm, and best palpated from the left side and located above and to the right of the umbilicus in the mid-epigastrium (the superior central portion of the abdomen) beneath the liver edge (Bishop, 2006). An abdominal x-ray film may show an enlarged stomach with diminished or absent gas in the intestine (Bishop, 2006). Examination of the pylorus on ultrasound shows elongation and thickening of the pylorus, which may be confirmed by a barium upper GI series. Confirmation by an upper GI series demonstrates a “string sign,” which is caused by the barium passing through narrowed pylorus (Bishop, 2006).

diagnostic tools Ultrasound

A diagnosis is often made after the history and physical examination. The diagnosis can be established 60% to 80% of the time by an experienced examiner. If the diagnosis of hypertrophic pyloric stenosis is inconclusive an ultrasound can be used to demonstrate an elongated muscular surrounding a long pyloric canal. Ultrasound confirms the diagnosis of hypertrophic pyloric stenosis.

Nursing Care

Treatment for hypertrophic pyloric stenosis is surgery. The surgical procedure of choice is the Ramstedt pyloromyotomy (incision and suture of the pyloric sphincter) and is performed by laparoscopy (abdominal exploration) with an endoscope. The pyloric mass is split without cutting the mucosa and the incision is closed (Bishop, 2006). The operative mortality rate is very low, 0 to 0.5%. Endoscopic balloon dilation has also been successful in infants with persistent vomiting.

Initial care of the child with the diagnosis of pyloric stenosis should include a careful history and assessment of the child. The nurse needs to be alert to signs of dehydration, such as changes in skin turgor, appearance of the mucous membranes, depressed fontanel, presence or absence of tears, urine output, and changes in vital signs as well as weight loss and evidence of discomfort.

Before surgery, the child is given nothing by mouth (NPO) and a nasal gastric tube is inserted to provide gastric decompression (the removal of pressure). Surgery may be performed without delay in infants without dehydration and electrolyte imbalances. If dehydration is present, the dehydration imbalance is corrected with intravenous fluids and administration of appropriate electrolyte therapy.

Postoperative care includes maintaining fluid and electrolyte balance. The nurse should communicate to the family that it is common for the infant to experience some vomiting in the first 24 to 36 hours after surgery (Parks & Yetman, 2004). Fluid balance is maintained through administration of intravenous fluids and oral liquids as

tolerated. Small, frequent, clear liquid feedings, such as electrolyte solutions, are begun about 4 to 6 hours postoperatively. Formula or breast feedings may be resumed in 24 hours if clear liquids are tolerated. It is important for the nurse to continue to monitor for signs of dehydration and for the infant’s response to oral fluids. After surgery, the family members can be instructed on the importance of saving wet diapers that are weighed in order to measure output. Postoperative care also includes monitoring the surgical site for signs of infection, keeping the wound clean and dry, and providing pain relief.

Discharge instructions include care of the incision and observation for signs of infection. The nurse must instruct caregivers to observe the infant’s response to feedings, as some vomiting may still occur within the first 48 hours postoperatively. Vomiting beyond 48 hours must be reported to the child’s health care provider.

nursing diagnoses Hypertrophic Pyloric Stenosis

- Fluid Volume Deficit related to the effects of frequent vomiting
- Nutritional Imbalance: Less than Body Requirements related to vomiting and gradual reintroduction of feedings.
- Pain related to surgical trauma
- Risk for Infection related to surgical incision.
- Caregiver Knowledge deficit related to postoperative care of the infant

INTUSSUSCEPTION

Intussusception is a condition that occurs when a proximal section of the intestine and the mesentery (the peritoneal fold that encircles the small intestine and connects it to the posterior abdominal wall) “telescopes” into a distal section of the intestine (Mow, 2005; Venes, 2009). Most intussusception conditions occur between the ages of 5 and 9 months but children can be susceptible until early school age. The incidence of intussusception is 1 to 4 per 1000 live births and is four times more common in males (Mow, 2005). Suggested predisposing factors to the development of intussusception include the presence of polyps, Meckel’s diverticulum, Henoch–Schönlein purpura, constipation, lymphomas, lipomas, parasites, rotavirus, adenovirus, and the presence of foreign bodies. Intussusception may also occur as a complication of cystic fibrosis (Petersen-Smith, 2004).

Signs and Symptoms

The most characteristic symptom of intussusception is acute abdominal pain caused by the spasm of the telescoping bowel. This pain frequently mimics the pain experienced by “colicky” infants because it is acute, causing the infants to cry and pull their legs up toward the abdomen. The pain is relieved once the abdomen relaxes. The other classic symptom is the presence of currant jelly stools. Vomiting may or may not be present and it may or may not be projectile. Other symptoms of intussusception include fever, dehydration, abdominal distention, lethargy, and grunting due to pain.

Diagnosis

Diagnosis of intussusception is based on a history of the characteristic symptoms and the physical findings during examination. The presence of a “sausage-shaped” mass in

the upper right quadrant (Danca's sign) during palpation of the abdomen is indicative of intussusception (Petersen-Smith, 2004). Although the upper right quadrant is the most common site, the mass may be felt in other abdominal areas too. The abdomen is distended and tender on palpation and bowel sounds may be either increased or decreased.

assessment tools Classic Symptomatic Triad for Intussusception

The classic symptomatic triad for intussusception includes:

- "Paroxysmal, episodic abdominal pain with vomiting every 5–30 minutes.
- Screaming and drawing up legs with periods of calm, sleeping, or lethargy between episodes (Fig. 25-2).
- Stool, possible diarrheal in nature, with blood (current jelly)" (Petersen-Smith, 2004, p. 862).

diagnostic tools Intussusception

A flat-plate x-ray film in the child can appear normal early in the course of the disorder. However, an abdominal "ultrasound establishes the diagnosis in 90% of the cases" (Petersen-Smith, 2004, p. 862).

Nursing Care

A barium or air enema is used to both diagnose and treat intussusception. In radiological reduction, the barium (contrast media) or air allows visualization of the telescoped bowel. The pressure applied by the enema may cause the telescoped bowel to return to its normal position, thus relieving the obstruction. Reduction rates are reported as high as 65% to 90% through the instillation of barium or air. If radiological reduction is ineffective or if peritonitis, perforation, or shock is evident, prompt surgical correction is required (Petersen-Smith, 2004). The surgical procedure either repairs the bowel or removes any portion that has been permanently damaged.

When the child has been diagnosed with intussusception, the nurse can provide information about the condition and reassurance to the parents. If the treatment is managed through radiological reduction, the child should be observed for passage of stool and barium or contrast material as indicated.

Figure 25-2 Infant with paroxysmal, episodic abdominal pain displays screaming and drawing up the legs.

If the child is having surgery, preparation before surgery includes placing the child NPO, inserting a nasogastric tube, and initiating intravenous fluid therapy. The nurse is responsible for monitoring the infant for signs of perforation (a hole), peritonitis (inflammation of the abdominal cavity), or shock in addition to evidence of increased pain. The nurse also monitors and records the child's stools. The nurse understands that the spontaneous passing of a stool may indicate a resolution of the obstruction. Postoperative care and discharge instructions will be similar to that of the child surgery for pyloric stenosis.

clinical alert

Signs of perforation and peritonitis

The child with perforation has acute pain, beginning over the perforated area and spreading over the abdomen. The abdomen may become rigid and the child may experience nausea and vomiting, tachycardia, fevers, chills, sweats, confusion, and decreased urinary output (Venes, 2009).

The child with peritonitis has moderate or mild abdominal pain that worsens with movement. Fever, change in bowel habits, and malaise are also common. In addition, the child has nausea, loss of appetite, and fever or hypothermia. During the nursing assessment, the nurse notes that the abdomen is distended with decreased bowel sounds (Venes, 2009).

MALROTATION AND VOLVULUS

Abnormal rotation of the intestine around the superior mesenteric artery during fetal development may lead to malrotation of the intestine. Malrotation may present in utero or remain asymptomatic throughout life. Malrotation is the most serious type of intestinal obstruction because it may lead to intestinal necrosis, peritonitis, perforation, and death related to a complete twisting of the intestine around itself or volvulus. The incidence of malrotation is approximately one in 500 live births.

Signs and Symptoms

Symptoms of malrotation or volvulus may occur at any age but are most common in the first month of life. Fifty percent to 75% of children who become symptomatic do so in the first month of life, with approximately 90% becoming symptomatic within the first year.

A major symptom is intermittent bilious or green vomit. Additional symptoms include abdominal distention, recurrent abdominal pain, lower GI bleeding, a palpable epigastric mass, dehydration, lethargy, and shock.

clinical alert

Shock

Signs of shock include tachycardia; tachypnea; hypotension; and cool, clammy, or cyanotic skin (Venes, 2009).

The child's stools may be bloody, which suggests ischemia and possibly gangrene of the bowel. Without surgical correction, ischemia can lead to infarction of the bowel, which is demonstrated by painful abdominal

Nursing Care Plan A Child Who Has Undergone Abdominal Surgery

Nursing Diagnosis: Imbalanced Nutrition: Less than body requirements related to inability to ingest nutrients by mouth

Measurable Short-term Goal: The child will receive adequate fluid intake

Measurable Long-term Goal: The child will receive adequate nutrients to meet metabolic needs and for healing.

NOC Outcome:

Nutritional Status (1004) Extent to which nutrients are available to meet metabolic needs

NIC Interventions:

Nutrition Therapy (1120)
Diet Staging (1020)

Nursing Interventions:

1. Maintain NPO status as ordered by caregiver.

RATIONALE: To promote bowel rest and healing related to the surgical procedure.

2. Assist mother with pumping and storing breast milk if appropriate.

RATIONALE: Pumping helps to maintain milk production. Breast milk contains maternal antibodies, which may aid healing.

3. Maintain intravenous access and administer fluids and medications as prescribed. Monitor intake and output.

RATIONALE: To provide short-term fluid, electrolyte, and caloric support (specify actions of medications) and maintain fluid balance.

4. Auscultate for presence of bowel sounds each shift.

RATIONALE: Adequate bowel motility is required before the reintroduction of oral fluids and foods.

5. Collaborate with the care provider to introduce oral clear liquids and progress to small, frequent feedings as tolerated. (For infants, progress from glucose water or oral rehydration solution to half-strength formula, to full-strength formula.)

RATIONALE: To determine tolerance of oral fluids and foods by introducing in small amounts.

distension and shock. Older children show recurrent abdominal pain, intermittent vomiting, chronic diarrhea, and symptoms related to failure to thrive or malabsorption (inadequate absorption of nutrients from the intestinal tract) (Venes, 2009).

Thirty percent to 60% of children with malrotation have associated anomalies, such as diaphragmatic hernia, omphalocele, gastroschisis, intestinal atresia, imperforate anus, Meckel diverticulum, Hirschsprung disease, and congenital heart disease.

Diagnosis

Diagnosis is based on history, physical examination, and radiographic studies such as barium enema and upper GI series, which is the definitive procedure to diagnose the condition. “The abnormality has a characteristic ‘corkscrew’, ‘coiled’, or ‘bird’s beak appearance’”.

Nursing Care

Surgical treatment for malrotation and volvulus includes resection of nonviable intestinal segments with anastomosis (surgical connection). Short bowel syndrome is a potential postoperative complication because extensive portions of the bowel are either reconstructed or removed. For the asymptomatic child younger than 2 years of age, timely repair is indicated to prevent potential complications.

Preoperatively nursing care includes intravenous hydration to restore fluid and electrolyte balance, nasogastric suction, and administration of intravenous antibi-

otics. Postoperative care is comparable to that of an infant or child undergoing abdominal surgery.

Inflammatory Disorders

IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS) is a common cause of recurrent abdominal pain in children. IBS affects boys and girls equally, with diagnosis usually during school-age and adolescence. The cause of IBS is thought to involve a combination of factors, including motor, autonomic, and psychological functions. A diagnosis of IBS is generally made by ruling out organic causes for the symptoms, such as other inflammatory diseases, lactose intolerance, and parasitic infections.

Signs and Symptoms

IBS is a GI disorder that causes a variety of symptoms, including abdominal pain, flatus, bloating, constipation, or diarrhea or a combination of both constipation and diarrhea. IBS is sometimes referred to as “nervous stomach” or spastic colon. IBS is classified as a functional GI

disorder because the symptoms occur when the intestines or bowels function improperly. When the intestines are exposed to certain “triggers,” the bowels respond with muscle spasms instead of normal peristalsis. These muscle spasms result in one or more of the symptoms of IBS. Triggers that can cause the symptoms of IBS to “flare” include eating large amounts of food at one time; eating spicy, high-fat or gas-causing foods; or stress. Most children with IBS have various symptoms including variable stool patterns, alternating between constipation and diarrhea.

Children with IBS have pain beginning with a change in stool frequency or consistency (Bishop, 2006). IBS does not cause constant symptoms. Exacerbations can occur at any time and cause one or more symptoms. Perhaps the most common symptom seen in IBS is abdominal pain. There are a variety of reasons and causes for abdominal pain in children. Most children have abdominal pain at some point.

Diagnosis

Since there is no specific test or procedure to diagnose IBS, the diagnosis is based on clinical signs and symptoms. A diagnosis of IBS is made when other GI disorders are ruled out.

assessment tools Irritable Bowel Syndrome

Abdominal pain *and* any two of the following:

- Pain is relieved with bowel movement.
- Onset of pain coincides with a change in stool frequency.
- Onset of pain coincides with a change in stool consistency.
- The symptoms of IBS must be present for at least 3 months in the preceding 12 months.

Additional symptoms may appear if the classic symptoms are severe or the child has frequent exacerbations. Children with frequent bouts of IBS or those who suffer several symptoms simultaneously may experience headache, nausea, mucus in the stools, anorexia, and weight loss.

Nursing Care

Treatment for IBS is almost always purely dietary. Discovering what foods trigger symptoms is most important. Food diaries are very useful in helping determine what foods should be avoided. In addition, eating more fiber and less fatty foods seems to help prevent intestinal muscle spasms. Drinking plenty of liquids including water can promote regular stool elimination patterns. Healthy toilet training and toileting patterns can control some symptoms. Promoting a healthy routine for regular bowel elimination can decrease the symptoms as well as the stress related to worry about bowel movements at school or at other inconvenient times. Encouraging positive strategies for managing stress can prevent exacerbations. Children need a balance of school, physical activity, socialization, and other age-appropriate activities. Children need to be taught to share feelings, concerns, and other typical growth and development issues with a parent or other interested caring adult. Medications are rarely used in the treatment of IBS in children. If constipation becomes a chronic problem, stool softeners may be indicated for

short-term use. Antispasmodics such as hyoscyamine (Levsin), atropine (Atriofine-Care), scopolamine (Isopto), and phenobarbital (Donnatal), and propantheline bromide (Pro-Banthine) may be used in severe cases.

clinical alert

Irritable bowel syndrome

Symptoms of IBS accompanied by fever, severe abdominal pain, and/or vomiting blood require immediate attention. Surgical evaluation and/or intervention may be necessary.

Family support and education are the primary goals in nursing care. The nurse can assist the caregiver and child in developing strategies that will decrease symptoms. Nutritional strategies include eating more slowly, avoiding carbonated drinks, and including fiber in the diet. The child also needs support and assistance in developing strategies to reduce environmental stressors.

“What to say” — Irritable bowel syndrome

The nurse should communicate to the family and school that stress can trigger the symptoms of IBS in many children.

Often, family circumstances present stressful situations. Parents may need help in dealing with certain situations that are stressful to their child and exacerbate the symptoms of IBS. Family counseling may be an option. At home, parents and children can be taught to keep a food diary so they can determine the triggers that cause “flares” of IBS.

Teachers must also be aware of the condition and may need to be involved in helping the child reduce or cope with the stress related to school. The school counselor can be a good resource for the child.

INFLAMMATORY BOWEL DISEASE

Inflammatory bowel disease (IBD) is a general term often used to refer to two major forms of chronic intestinal inflammatory conditions, Crohn’s disease and ulcerative colitis, which have common epidemiology and clinical features. Both Crohn’s disease and ulcerative colitis are characterized by extraintestinal and systemic features, yet they are distinct disorders as described in the following sections.

Crohn’s Disease

Crohn’s disease is a chronic inflammatory disease characterized by periods of exacerbations and remissions. Crohn’s disease can affect any portion of the GI tract. The bowel may present with a combination of nonsequential areas of pathology and disease-free sections of bowel. Crohn’s disease rarely affects the oropharynx, esophagus, and stomach; the small bowel is affected 25% to 30% of the time; the colon and anus are affected 25% of the time; the ileocolonic region is affected up to 40% of the time; and diffuse disease occurs 5% of the time (Petersen-Smith, 2004). The

majority of Crohn's disease occurs in the terminal ileum, with resultant potential nutritional deficiencies.

The incidence of Crohn's disease in the Western population is 16 out of 100,000 and has increased during the past few decades. It is more common in Caucasians, and affects males and females equally. The age at onset is between 10 and 20 years, and the condition occurs throughout the lifespan with peaks in the second, fourth, and sixth decades of life. Although the cause of Crohn's disease is unknown, it is thought that the susceptibility to Crohn's is most likely inherited and "is most likely a genetically determined response that is immunologically mediated" (Petersen-Smith, 2004, p. 869). The incidence in siblings is as high as 35% (Petersen-Smith, 2004).

SIGNS AND SYMPTOMS. Children with Crohn's disease may have an acute or insidious onset. Common signs and symptoms include abdominal pain, diarrhea, anorexia, and weight loss. Clinical presentation of Crohn's disease varies extensively depending on the area of the intestine that is involved and the severity of the inflammation (Campbell & Balistreri, 2005). If the disease is limited to the colon, symptoms are similar to those of ulcerative colitis. Upper GI tract involvement is manifested by vomiting and epigastric pain. Small bowel involvement is manifest by cramp-like pain commonly located in the right lower quadrant and is associated with tenderness and a feeling of fullness.

Extraintestinal symptoms may include but are not limited to fever, growth delay, delayed sexual development, arthralgias (joint pain) or arthritis in the large joints, stomatitis (inflammation of the mouth lips, tongue, and mucous membranes), aphthous ulcers, uveitis (inflammation of the eye), conjunctivitis, renal stones, and erythema nodosum (a tender, red, nodular rash on the shins) (Petersen-Smith, 2004; Venes, 2009).

DIAGNOSIS. Diagnosis is based on client history, physical findings, and laboratory results. Laboratory findings may include leukocytosis, microcytic anemia, low serum iron and total iron-binding capacity, low serum albumin, thrombocytosis, and elevated sedimentation rates and C-reactive protein.

NURSING CARE. In children, the treatment for Crohn's is pharmacological, nutritional, and surgical. The goals of treatment include "controlling the disease, including remission and preventing relapses," while maintaining adequate nutrition (Potts, 2002, p. 678). Corticosteroids are effective for reduction of inflammation in moderate to severe disease and may be given orally, rectally, or intravenously for acute exacerbations. Metronidazole (Flagyl) and ciprofloxacin (Cipro) have demonstrated effectiveness in the treatment of perianal complications. Antibiotics such as ampicillin (Marcillin), gentamicin (Garamycin), clindamycin (Cleocin), and metronidazole (Flagyl) are effective during acute exacerbations (Petersen-Smith, 2004). Immunosuppressive medications are useful with corticosteroid-resistant disease (Potts, 2002).

Surgery for a child with Crohn's disease may be indicated if the child does not respond to medical treatment, or in the case of bowel strictures, obstruction, perforation

where research and practice meet: Crohn's Disease

Research exploring the use of an enteric-coated fish oil preparation in adult Crohn's disease patients found that those who received the fish-oil preparation were less likely to have relapses than patients who received placebos. Fish oil has been found to not only have anti-inflammatory actions but also to increase the absorption of nutrients resulting in improved nutrition.

Nursing care includes the administration of medication and nutritional management, emotional support, and community referral (Potts, 2002). The focus of care during periods of remission involves monitoring compliance. As symptoms resolve, the child may resist taking medications. The adolescent with Crohn's disease presents unique challenges in the treatment of his or her disease. Adolescents have a natural desire to be "normal" and to be like their peers. This may lead the adolescent to resist taking prescribed medications that cause obvious side effects, such as those experienced with prolonged use of steroids.

or intractable bleeding or diarrhea. Surgical correction involves removal or resection of the diseased segment with resection or anastomosis (connection). The nurse should communicate to the family that surgical repair does not cure Crohn's disease (Potts, 2002).

Across Care Settings: Promoting growth

The nurse understands that no special diet is indicated for children with Crohn's disease. Nutritional therapy may be helpful in correcting malnutrition and promoting growth. A well-balanced, high-protein diet is recommended for children whose symptoms do not prohibit oral intake. Fiber-containing foods, such as seeds, popcorn, and corn, may produce symptoms and obstructions in children with intestinal stricture though there is no evidence that avoiding specific foods influences severity of the disease in most children. A dietitian teaches the family how to provide for adequate nutrition to promote growth. High-calorie liquid supplements may be recommended as well as supplemental vitamins, especially the fat-soluble vitamins, and minerals.

Emotional support is another important nursing intervention for both the child and family in the management of this chronic condition. The nurse can communicate to

medication: Steroid Side Effects

CARDIOVASCULAR: Edema hypertension, congestive heart failure
CENTRAL NERVOUS SYSTEM: Vertigo, seizures, psychoses, headache
DERMATOLOGICAL: Acne, skin atrophy, impaired wound healing, petechiae, bruising
ENDOCRINE AND METABOLIC: Cushing's syndrome, growth suppression, glucose intolerance, and sodium and water retention
GASTROINTESTINAL: Peptic ulcer, nausea, vomiting
GENITOURINARY: Menstrual irregularities
NEUROMUSCULAR AND SKELETAL: Muscle weakness, osteoporosis, fractures
OCULAR: Cataracts, elevated intraocular pressure, glaucoma

Data from Deglin, J.H., & Vallerand, A.H. (2009). *Davis's drug guide for nurses* (11th ed.). Philadelphia: F.A. Davis.

the family that the child with Crohn's disease may experience depression, anxiety, and low self-esteem. Early detection of psychological problems requires referral, which often involves both the child and family (Potts, 2002).

nursing diagnoses The Child with Crohn's Disease

- Imbalanced Nutrition: Less than Body Requirements related to inability to ingest, and absorb food and nutrients
- Risk for Fluid Volume Deficit related to excessive losses through diarrhea
- Pain related to inflammation and irritation of the bowel
- Potential for Delayed Growth and Development related to effects of physical illness and inability to maintain nutritional needs
- Anxiety related to threat to self-concept from change in health status

Ulcerative Colitis

Ulcerative colitis is an acute or chronic inflammation of the colon, which is characterized by recurring bloody diarrhea (Petersen-Smith, 2004). Unlike Crohn's disease, ulcerative colitis involves a continuous segment of the colon. The pathology of ulcerative colitis is described as a superficial, acute inflammation of mucosa with microscopic crypt abscess (Petersen-Smith, 2004).

The cause of ulcerative colitis is unknown. The probability of a genetically determined and an altered immunologically mediated response to the intestinal mucosa is likely (Petersen-Smith, 2004). Infectious agents, autoimmune responses, and environmental factors play a role though no specific responsible agents have been identified (Bishop, 2006).

The incidence of ulcerative colitis is increasing, especially in industrialized countries, though is relatively uncommon in tropical and underdeveloped countries (Bishop, 2006). Ulcerative colitis is more common in the Jewish population. In addition, there is a higher risk in families who have a close relative with ulcerative colitis (Bishop, 2006). The overall incidence of ulcerative colitis is 0.05 of every 1000 persons. The peak onset occurs between ages 16 and 20, with approximately 20% of the cases occurring in children and adolescents younger than 20 years (Bishop, 2006).

SIGNS AND SYMPTOMS. Ulcerative colitis is characterized by abdominal pain, bloody diarrhea, urgency, and tenesmus (a painful spasmodic contraction of the anal sphincter leading to the sensation of constantly needing to empty the bowel). Children experience left lower quadrant pain with cramping, which increases before defecation and passing flatus (Petersen-Smith, 2004). Weight loss and delays in growth and sexual maturation may also occur. Other manifestations, though not present in all cases, may include arthritis/arthritis of the large joints, oral ulcers, primary sclerosing cholangitis (chronic liver inflammation leading to scarring of hepatic ducts), uveitis, and skin lesions such as those found in pyoderma gangrenosum (a rare, ulcerating skin disease) and erythema nodosum (a tender, red, nodular rash) (Bishop, 2006; Petersen-Smith, 2004).

DIAGNOSIS. Diagnosis of ulcerative colitis in a child is based on history and physical findings. Radiological and endoscopic examinations are used to evaluate the characteristics and location of the lesions.

Labs: Laboratory Findings for Ulcerative Colitis

Laboratory findings for ulcerative colitis may include elevated sedimentation rate, microcytic anemia, and elevated white blood cell count with left shift, antineutrophil cytoplasmic antibodies (ANA) present in 80% (Petersen-Smith, 2004).

NURSING CARE. Goals of the treatment of ulcerative colitis include disease control, inducing remission, preventing relapse, and achieving normal growth and life-style (Petersen-Smith, 2004). Pharmacological, nutritional, surgical, and psychosocial management may be included in the plan of care. Intravenous or oral steroids are used for moderate to severe ulcerative colitis, with dosages tapered when the child is in remission. Immunomodulatory agents (alternative medications such as vitamins, minerals, and natural foods), such as azathioprine (Imuran) or 6-mercaptopurine (Purinethol), are used to wean the patient off of steroids. Aminosalicylates (antibacterials effective against mycobacteria) are given orally or rectally. Iron supplementation is given to correct anemia and antispasmodics may be given before meals (Petersen-Smith, 2004).

The nurse can communicate to the family that nutritional recommendations include use of a diet high in protein and carbohydrates with normal fat and decreased roughage. Vitamin and iron supplements are recommended. Nutritional supplements may also be used.

Ulcerative colitis is curable surgically with a total mucosal proctocolectomy with the ileal pouch-anal anastomosis as the most common restorative surgery. Failed medical therapy and persistent hemorrhage are the most common indications for surgical correction.

As with Crohn's disease, nursing care includes medication and nutritional management, emotional support, and community referral (Potts, 2002). A referral should be made to an ophthalmologist to rule out ophthalmologic manifestations of the disease. Psychosocial therapy may be indicated, as depressive disorders are common (Petersen-Smith, 2004). Refer to care of the child with Crohn's disease for general nursing management.

Now Can You—Distinguish between Crohn's disease and ulcerative colitis?

1. Discuss the differences between Crohn's disease and ulcerative colitis.
2. Discuss nursing care for Crohn's disease and ulcerative colitis.

APPENDICITIS

Appendicitis is an inflammation of the appendix, which is a small sac-like structure at the end of the cecum. Appendicitis is considered the most common condition requiring abdominal surgery in childhood (Potts, 2002). In appendicitis the lumen of the appendix becomes obstructed with fecal matter, lymphoid tissue, tumor, parasite, foreign body, or inspissated (thickened) cystic fibrosis secretions, which cause the appendix to become distended and subject to ischemia and necrosis (Petersen-Smith, 2004).

The characteristic symptoms are caused by the inflammation around the infected appendix with approximately “a 36-hour period from the onset of pain to the rupture of the appendix, with 80% of children perforating within 48 hours” (Petersen-Smith, 2004, p. 856).

The incidence of appendicitis increases with age, with the average age of occurrence at 10 years. The incidence is slightly higher in boys than in girls and more common in Caucasians (Potts, 2002). The risk of perforation is twice as likely for children younger than 8 years of age. Perforation occurs in approximately one third of children before treatment is initiated (Petersen-Smith, 2004). Appendicitis occurs in approximately 7% to 9% of the population and accounts for 1% to 8% of children presenting to emergency departments with a complaint of abdominal pain (Fig. 25-3).

SIGNS AND SYMPTOMS. The most reliable diagnosis of appendicitis is gained through an evaluation of the sequencing of the symptoms (Petersen-Smith, 2004). One of the earliest symptoms is periumbilical pain (pain around the umbilicus). This pain often awakens the child peaking at 4-hour intervals. The periumbilical pain subsides and then is followed by the classic sign of right lower quadrant pain. In appendicitis, vomiting generally follows periumbilical pain, unlike the vomiting associated with gastroenteritis, which precedes the pain. Anorexia is common and stools may be described as low in volume and mucus-like.

clinical alert

Appendicitis

Children with suspected appendicitis who respond yes to being hungry most likely do not have appendicitis since in most cases the child does not feel like eating (Potts, 2002).

DIAGNOSIS. The child diagnosed with appendicitis experiences a progression of symptoms with no single test providing overall confirmation of the diagnosis. Laboratory findings may demonstrate an elevated white count. An elevated white count does not distinguish simple appendicitis from perforated appendicitis. Children with appendicitis may also have a normal white blood count. An abdominal radiograph may reveal fecal matter, or some other obstruction, although this rarely confirms the diagnosis. If there is uncertainty in young children, ultrasound and computed tomography (CT) scan may help differentiate abdominal pain from other causes though the usefulness is variable (Mow, 2005).

Nursing Insight— Appendicitis physical examination

Rebound tenderness	Presence of involuntary guarding, rebound tenderness with pain over McBurney’s point, which is located 1.5–2 inches in from the right anterior superior iliac crest on a line toward the umbilicus—best elicited on palpation.
--------------------	--

Figure 25-3 Appendicitis physical examination reveals rebound tenderness.

Heel-drop jarring test	Stands on toes for 15 seconds, then drops on heels—inability to stand straight or climb stairs; winces when getting off examination table.
Psoas sign	Abdominal pain with right hip flexion against resistance
Obturator sign	Pain on passive internal rotation of the flexed right thigh
Rovsing sign	Deep pressure in lower left quadrant elicits pain with a sudden release (Petersen-Smith, 2004).

NURSING CARE. Treatment for children who have appendicitis is surgical and an appendectomy is curative if performed before perforation. If perforation occurs, a course of postoperative antibiotics is needed (Bishop, 2006).

Ethnocultural Considerations— Empacho

Empacho is a Spanish word for indigestion, stomach pains, and cramps. A common belief in the Hispanic culture is that the symptoms are caused by a “ball of undigested food clinging to some part of the GI tract and are due to being forced to eat against one’s will or lying about the amount of food eaten” (Potts, 2002, p. 673). Treatment includes massaging and pinching the spine (Potts, 2002).

Nursing care of the child with appendicitis who has undergone an appendectomy includes monitoring intake and output, wound care, and pain control. The child will be NPO for 24 hours or until peristalsis returns. Most children are discharged to home in 2 to 3 days. If the procedure is performed by laparoscope (abdominal exploration with an endoscope) (Venes, 2009), the child may remain in the hospital overnight or be discharged the day of surgery. If perforation occurred, drains may protrude from the incision or the wound and remain open to pre-

vent infection and allow healing (Potts, 2002). In the case of a perforated appendix, intravenous antibiotics are given for 7 to 10 days. The child generally remains NPO with a nasogastric tube in place until bowel function returns.

OMPHALITIS

Omphalitis is an infection of the umbilical stump. This occurs once the umbilicus is colonized with streptococci, staphylococci, or gram-negative organisms, which may cause a local infection (Thilo & Rosenberg, 2007).

SIGNS AND SYMPTOMS. Omphalitis is manifested by redness and edema of the soft tissue around the umbilical stump.

DIAGNOSIS. Local and systemic cultures should be obtained to confirm diagnosis (Thilo & Rosenberg, 2007).

NURSING CARE. Prevention through good perinatal care and caregiver education is paramount to the occurrence of omphalitis. Intravenous broad-spectrum antibiotics, such as nafcillin (Unipen), vancomycin (Vancocin), or third-generation cephalosporins (Cefotaxime) are used to treat omphalitis (Thilo & Rosenberg, 2007).

Nursing care of omphalitis is aimed at prevention and education of the parent or caregiver. The potential for infection can be minimized by keeping the cord clean and dry. Several methods may be used to provide cord care, which include use of an antimicrobial such as bacitracin (Baciguent) or use of triple dye. Other experts suggest the use of alcohol, cleansing with soap and water, cleansing with sterile water or a neutral pH cleanser, povidone-iodine, or natural healing with no treatment. Before discharge, the parent or caregiver needs to be instructed on the recommended method of cord care and the importance of placing the diaper below the level of the cord to avoid irritation. Parents should also be instructed regarding the expected process for stump deterioration and symptoms of infection that should be reported to their health care provider. Cord separation generally takes place in 10 to 14 days.

MECKEL DIVERTICULUM

Meckel diverticulum arises from a remnant of the fetal development in the midgut, which normally is obliterated by the seventh to eighth week of gestation. Failure of this destructive process results in an omphalomesenteric problem (referring to the umbilicus and mesentery fistula or fibrous band [Venes, 2009]). The fibrous band, known as Meckel diverticulum, connects the small intestine to the umbilicus. A Meckel diverticulum averages 1 to 10 cm in length and is the most common congenital malformation of the GI tract, present in 1% to 4% of the population. Meckel diverticulum is twice as common in males, who are also more likely to experience complications than females.

SIGNS AND SYMPTOMS. Symptoms of Meckel diverticulum are recognized in childhood, with 65% in children younger than 5 years of age and the peak at 2 years of age. Meckel diverticulum is manifested by abdominal pain. Pain may be described as periumbilical or lower abdominal. The pain is similar to appendicitis or volvulus and may be vague and recurrent. A major manifestation in the
