Two older methods for estimating energy requirements have been published. Culley and Middleton developed a method for disabled children that takes level of motor function into account.[93] The energy consumption based on motor function status was 14.7 kcal/cm of height and 77 kcal/kg for children without motor dysfunction, 13.9 kcal/cm and 75 kcal/kg for ambulatory children with some motor dysfunction, and 11.1 kcal/cm and 64 kcal/kg for nonambulatory children with motor dysfunction. Krick and colleagues reported a factorial method approach in determining energy needs in children with CP.[46] This method accounts for energy intake based on estimated REE needs, muscle-tone alterations, normal growth needs, and catch-up growth or nutritional repletion in malnourished children. The formula is summarized as

SUMMARY

Monitoring nutrition and growth status in children and adults with CP and other severe types of developmental disabilities is an essential component of care. This chapter summarizes the previous work in the area and outlines clinical approaches to determining nutritional status and estimating energy needs. Although data are not available to provide precise definitions of the levels of severity of malnutrition and growth failure and their effect on long-term outcome, it is clear that many patients with moderate to severe CP or other disabilities have malnutrition and growth failure as the result of inadequate energy intake. Nutritional status assessment every three to six months will enable the clinical care team to identify malnutrition and growth failure and will provide an objective means of following the response to nutritional intervention.

Inborn Errors of Metabolism and the Liver

49

Charles P. Venditti, MD, PhD and Gerard T. Berry, MD

INTRODUCTION

The liver is a nutritional clearing house, metabolizing, partitioning, and distributing dietary nutrients and their metabolites both within the liver and among the different organs in the body. Inborn errors of metabolism involve small molecules, as well as large complex molecules and organelles.[1] It is not surprising that the liver with its varied array of anabolic and catabolic pathways features prominently in hereditary enzyme deficiencies, solute transport defects, and perturbations in organelle biogenesis.

Furthermore, the liver plays a central role in whole body metabolism. Hepatocytes, functionally heterogeneous in their spatial distribution along the tracts from the periportal to the centrilobular zones, are the prime movers in a complex process that involves (1) transport of water and solutes across membrane bilayers; (2) biosynthesis of small and complex molecules, the latter of which are largely destined for export; (3) interconversion of metabolites assimilated from ingested food such as amino acids; (4) catabolism of decaying macromolecules; (5) oxidation of fuels such as the free fatty acids, oleic, stearic, and palmitic acids, the most important energy source for hepatocytes; and (6) synthesis and export of glucose, as well as the hormonal regulation of its storage form, glycogen, the first line of defense in fasting adaptation.

The experiments of nature that result in the heritable defects in glycogenolysis, gluconeogenesis, mitochondrial fatty acid oxidation,

carnitine metabolism, ketogenesis, and glucose transport underscore the essential role of the liver in fasting adaptation. The endocrine system and especially circulating insulin govern the interorgan flux of metabolites that are converted to glucose in the liver or to the ketone bodies, acetoacetate and 3-hydroxybutyrate, that spare glucose. The liver is the site of ketogenesis but oxidation of ketone bodies only occurs in extrahepatic tissues as the hepatocytes are devoid of succinyl-CoA:3-oxyacid-CoA transferase activity (SCOT), the enzyme needed to utilize ketone bodies. Hepatic ketogenesis hinges on the carnitine-dependent translocation of long-chain fatty acids across the inner mitochondrial membrane. The temporal regulation of glycogen phosphorolysis, glucose-6-phosphate hydrolysis, gluconeogenic enzyme activities, carnitine palmitoyltransferase activity and, hence, fatty acid oxidation and ketogenesis depends on changing concentrations of hormones such as insulin and glucagon. Fasting produces a decrease in the ratio of insulin to glucagon, and the magnitude of this alteration depends on the duration of fasting. Inborn errors of hepatic glucose release and export, glycogenolysis, gluconeogenesis, and fatty acid oxidation/ketogenesis characteristically surface at different postprandial times following the last meal. Specifically, hypoglycemia may occur within just a few postprandial hours in a patient with glucose-6-phosphatase deficiency, whereas, of all the inborn errors, a defect in fatty acid oxidation requires the longest period of fasting to result in hypoglycemia.

INBORN ERRORS OF METABOLISM

Many inborn errors of metabolism affect the liver. In some of these biochemical genetic disorders, such as phenylketonuria (PKU), the enzyme function in the hepatocyte is defective but the complications related to accumulation of phenylalanine metabolites are extrahepatic. Other disease types globally affect the hepatocyte or damage one or more organelles. In addition to hepatocytes, the liver contains other cell populations, such as the Kupffer cells, which can also be affected; this may lead to alterations in hepatic function or size. Mechanisms of hepatic injury, including discrete involvement of organelles (as evidenced by biochemical or pathologic findings) are discussed for selected disorders of amino acid, ammonia, organic acid, carbohydrate, glycogen, fatty acid, complex lipid, cholesterol, bile salt, glycosaminoglycan, glycoprotein, and metal metabolism.

Timing of the Presentation of Inborn Errors of Metabolism

Inborn errors of metabolism, especially as envisioned by Garrod in 1909, are most commonly thought of as being the so-called small molecule diseases, in which the pathophysiology is usually a result of the excess of a potentially toxic intermediate. The absence of a necessary substrate more often concerns the symptoms in small molecular diseases. Nutritional treatment approaches typically focus on minimizing pathometabolite production, usually by dietary precursor restriction, while trying to balance demands for substrate utilization and interconversion with obligatory metabolism. Anaplerotic strategies, aimed at relieving product deficiency past the site of a block in a pathway, also have a place in the treatment of inborn errors of metabolism. Yet, the large molecule or complex macromolecule disorders, and, in particular, the storage diseases are now the subject of intense scrutiny as enzyme replacement therapy has transformed molecular history. This division is artificial in that all of the biochemical genetic diseases arise as a result of abnormalities in protein structure and function. In turn, these abnormalities are caused by alterations in nuclear or mitochondrial genes and their expression.

Most disorders of intermediary metabolism may not show signs in the fetus. The placenta and maternal circulation provide a constant supply of calories, which reduces the metabolic stress on the affected pathway of the fetus. Maternal hepatic function is also a means of elimination of many of the toxic metabolites that would otherwise cause symptoms. The free exchange of metabolites from the affected fetus to the maternal circulation has been demonstrated in a number of disorders. However, a metabolic toxicity syndrome featuring maternal liver disease can be seen when the fetus is affected with one of several disorders. The best-described syndrome is when the fetus is affected with long-chain hydroxylacyl-CoA dehydrogenase (LCHAD) deficiency.[2] Other inborn errors in which this can be seen include carnitine palmitoyl transferase type I (CPT I) deficiency[3] and short-chain acyl-CoA dehydrogenase (SCAD) deficiency.[4] A history of maternal illness during pregnancy should always be sought when evaluating patients for metabolic disease.

Prenatal effects can be seen in several different classes of inborn errors. Lesions of the electron transport chain can feature multiple antenatal effects such as intrauterine growth retardation.[5] Other disorders of energy metabolism—such as deficiencies of pyruvate carboxylase, pyruvate dehydrogenase, and fumarase can feature central nervous system

(CNS) dysgenesis.[6] Renal cystic changes are seen in multiple acyl-CoA dehydrogenase deficiency,[7] the neonatal variant of carnitine palmitoyl transferase II (CPT II) deficiency,[8] and in the congenital disorders of glycosylation (CDG).[9] Peroxisomal disorders may have a combination of dysmorphic features and hepatocellular involvement by birth.[10] A number of sterol synthetic defects—including Smith–Lemli–Opitz syndrome, lathosterolosis, desmosterolosis, and Conradi-Hunerman syndrome—can feature multiple malformations.[11] These patients can develop cholestatic liver disease and may secrete inadequate quantities of normal bile acids. More specifically, hepatobiliary malformations and developmental defects have been noted to also occur in the setting of hereditary metabolic disease such as ductal plate malformations, which is seen in phosphomannose isomerase deficiency[12]; a CDG; and biliary atresia, which has been documented in one set of siblings with Niemann-Pick type C disease[13] and one patient with deficiency of the mitochondrial trifunctional protein.[14]

A few storage disorders may appear with prenatal or peripartum pathology caused by the accumulation of normal cellular materials as the result of a block at one or more steps of their degradation. Examples in which the disease may be evident at birth include several lysosomal storage disorders, glycogen storage disease (GSD) type IV, CDG type I, and Niemann-Pick type C.[15] The recognition of accumulated material in the liver and in other tissues, or the secondary alteration of the somatic structure as a result of the perturbations in metabolism, may take months to occur. Early nutritional manipulations have not been studied in the settings described above.

Each inborn error of metabolism can arise as the result of more than one DNA mutation within the gene. Each mutation can have different effects on the phenotype because of varying levels of residual function of the affected protein. In the case of multimeric proteins, the net activity of the complex may be different based on the structure of the altered subunits. The residual activity, the net metabolic stress on the body (in the case of catabolic errors in intermediary metabolism), and the amount of substrate combine to determine the timing of the recognition of the altered phenotype. Epigenetic or non-genic factors also can influence the phenotype seen in recessive enzymopathies in a less predictable fashion, best evidenced in the intrafamilial variability seen in cystic fibrosis.

Categories of Inborn Errors of Metabolism Involving the Liver and Gastrointestinal Tract

Table 49-1 outlines many of the disorders that have a known disturbance in the structure or function of the liver and GI tract as a result of inborn errors of metabolism in the pediatric population. Selected examples of these disorders are discussed briefly in the subsection on mechanisms of pathogenesis and comments on the nutritional approaches to management are highlighted in the text and listed in Table 49-1.

A few examples of metabolic diseases in which the liver serves the primary role in maintaining normal extrahepatic concentrations of metabolites and in which the signs are exclusively extrahepatic should be mentioned. A prime example of the importance of hepatic metabolism as it relates to CNS effects is PKU due to defects in phenylalanine hydroxylase. The enzymatic blockage prevents the conversion of phenylalanine to tyrosine. Consequences of the increased phenylalanine and lowered tyrosine concentrations include alterations in the transport of neutral aromatic amino acids into the brain and the production of neurotransmitters. As a result, mental retardation and seizures can occur. By lowering the blood phenylalanine concentration, many of the effects on cognition can be prevented or reversed. Hepatic size, synthetic functions, and laboratory tests are normal. A low phenylalanine diet provides the mainstay of therapy for these patients.

Nonketotic hyperglycinemia (NKH) is due to defects in the glycine cleavage system. Although the system is found in the brain and kidney, the majority of the activity is expressed in the liver. Except in the atypical form, the failure of the cleavage system results in the accumulation of glycine in all tissues; however, the pathophysiology is due to elevated glycine levels in the CNS. Unlike PKU, in which no symptoms are seen in the early neonatal period, infants with NKH may present with intractable seizures within hours of birth. Glycine levels are massively elevated in the cerebrospinal fluid in the neonatal period, implying that intrauterine elevations are a feature of this disorder. The liver in these patients is unremarkable.

Another example of an inborn error of metabolism where the liver is responsible for whole body metabolism is hyperoxalosis type I, a disorder of glyoxyalate metabolism. It is caused by a deficiency of alanine-glyoxylate aminotransferase, which is due to either a mutant protein or a mistargeting event whereby the enzyme localizes to the mitochondria in lieu of the peroxisomes, where it normally participates in glyoxyalate metabolism. Patients with this disorder progressively deposit calcium oxalate crystals throughout the body because of increased production of oxalate by the liver. The liver is spared, but many other organs—including

the kidneys, heart, skin, retina, peripheral nerves, arteries and skeleton—are not. Nephrocalcinosis eventually leads to end-stage renal failure and ultimately death. Liver or combined liver–kidney transplantation is needed to treat this disorder, depending on the duration and magnitude of the blood oxalate elevation. A liver is transplanted to stop the production of oxalate and provide a reserve for the defective enzyme, and in patients with coexisting renal failure, kidney transplantation is also required to provide essential functions and ensure adequate oxalate clearance.

TABLE 49-1 Metabolic Disorders that Feature Liver Disease/Gastrointestinal Dysfunction

Class of Disorder	Enzyme Defect	Nutritional/Medical/S Treatment
Carbohydrate Metabolism		
Galactosemia	Galactose-1-phosphate uridyltransferase	Remove lactose from diet
Hereditary fructose intolerance	Fructose 1-phosphate aldolase	Remove sucrose, fructose sorbitol from diet
Fructose 1,6-bisphosphatase deficiency	Fructose 1,6-bisphosphatase	Avoidance of fasting; Rem sucrose, fructose and sor diet
Glycogen synthase defect (GSD0)	Glycogen synthase	Avoidance of fasting
Glycogen storage disease (GSD)	Glucose-6-phosphatase	Continuous calories, noct cornstarch feedingstype I Liver transplantation?
Glycogen storage disease (GSD type Ib)	Glucose-6-phosphate translocase (G6PT)	Continuous calories, noct cornstarch feedings Liver transplantation?
GSD, type III	Amylo-1, 6-glucosidase (debrancher enzyme)	High carbohydrate diet, fr feedings may be needed
GSD, type IV	Amylo 1,4 ->1,6 transglucosidase (brancher enzyme)	Pts may need liver transp
GSD, type VI	Liver phosphorylase	Therapy depends on sym
GSD-IXa		
GSD-IXb		
GSD-IXc (PHKG2)		
Phosphorylase kinase deficiency	Phosphorylase kinase	Therapy depends on sym
Fanconi Bickel Syndrome	GLUT2	Pts always have a renal F syndrome

Transaldolase deficiency[34]	Transaldolase	Cirrhosis in early infancy ; children with hypomorphic mutations
Glycerol-3-phosphate dehydrogenase I deficiency		Neutral lipid accumulation and transient hyperlipiden infancy
Citrullinemia type 2	Citrin (SLC25A13 gene)	Transient infantile cholest syndrome
Amino- and Organic Acid Disorders		
Tyrosinemia, type I	Fumarylacetoacetate hydrolase	NTBC, dietary tyrosine re Eventual need for liver transplantation
Maple syrup urine disease	Branch chain oxoacid dehydrogenase	Leucine restriction; isoleu valine supplementation us needed thiamine in respo Liver transplantation?
Propionic acidemia	Propionyl-coenzyme A carboxylase A, B	Branched chain amino ac restriction, carnitine supplementation Liver transplantation?
Methylmalonic Acidemia	L-Methylmalonyl coenzyme A mutase (*mut* class) MMAA (*cblA* class) MMAB (*cblB* class)	Branched chain amino ac restriction, carnitine supplementation hydroxylcobalamin IM (no patients respond) Liver transplantation?
Urea Cycle and Related Disorders		
Carbamyl phosphate synthase deficiency	Carbamyl phosphate synthetase	Stringent dietary protein r Sodium benzoate and/or phenylbutyrate L-citrulline Liver transplantation?
Ornithine transcarbamylase (OTC) deficiency	Ornithine transcarbamylase	Stringent dietary protein r Sodium benzoate and/or phenylbutyrate L-citrulline Liver transplantation?
Citrullinemia	Argininosuccinate synthase	Stringent dietary protein r Sodium benzoate and/or phenylbutyrate L-arginine Liver transplantation?
Argininosuccinic acidemia	Argininosuccinate lyase	Stringent dietary protein r Sodium benzoate and/or phenylbutyrate L-arginine Liver transplantation?

N-Acetyl glutamate synthase deficiency	N-acetyl glutamate synthetase	Stringent dietary protein r Sodium benzoate and/or phenylbutyrate L-citrulline N-carbamyl glutamate Liver transplantation?
Hyperornithinemia-hyperammonemia-homocitrullinuria (HHH) syndrome	ORNT1 mitochondrial ornithine transporter	Stringent dietary protein r Sodium benzoate and/or phenylbutyrate L-citrulline
Lysinuric protein intolerance	SLC7A7	Stringent dietary protein r L-citrulline, HSM
Fatty acid oxidation defects		
Carnitine palmitoyltransferase-I (CPT-I) deficiency	Carnitine palmitoyltransferase-I	Avoidance of fasting Carnitine may be useful Can be associated with m HELLP syndrome
Carnitine palmitoyltransferase-II (CPT-II) deficiency	Carnitine palmitoyltransferase-II	Avoidance of fasting Carnitine may be useful Can be associated with d kidneys and brain malforn
Primary carnitine deficiency	Na^+/carnitine cotransporter	Treatment with L-carnitine eliminate fasting hypoglyc liver disease, cardiomyop myopathy
Carnitine-acylcarnitine translocase deficiency	Carnitine-acylcarnitine translocase	Neonatal lethality in most
Very long chain acyl-CoA dehydrogenase (VLCAD) deficiency	Very long chain acyl-CoA dehydrogenase	Avoidance of fasting Carnitine may be useful Probably not a Mendelian
ACAD9 deficiency	Very long chain acyl-CoA dehydrogenase	RC complex I assembly fa
Long chain 3-hydroxyl acyl-CoA dehydrogenase (LCHAD) deficiency	Long chain 3-hydroxy acyl-CoA dehydrogenase	Avoidance of fasting Carnitine therapy may pro dysrythmias Can be associated with m HELLP syndrome
Medium chain acyl-CoA dehydrogenase deficiency	Medium chain acyl-CoA dehydrogenase	Avoidance of fasting Carnitine may be useful
Short chain acyl-CoA dehydrogenase (SCAD) deficiency	Short chain acyl-CoA dehydrogenase	Can be associated with m HELLP syndrome
HMG-CoA lyase deficiency	3-hydroxy-3-methylglutaryl-CoA lyase	Avoidance of fasting
Multiple Acyl-CoA dehydrogenase deficiency	ETFA, ETFB, ETFDH	Can be associated with c anomalies

		Riboflavin therapy is bene certain mutations
Mitochondrial energy production/Primary lactic acidosis syndromes		
LARS disease	Leucyl-tRNA synthetase deficiency	Translational defect
Electron transport chain (ETC) deficiencies	Complexes I, II, III, IV (Cytochrome c oxidase), V (ATPase) of the ETC	Clinically heterogeneous, prenatal manifestations
POLG1 MPV17 TWINKLE Deoxyguanosine kinase (DGOUK)	DNA Polymerase-gamma 1	Mitochondrial DNA deplet disorder Mitochondrial DNA deplet disorder Mitochondrial DNA deplet disorder Mitochondrial DNA deplet disorder
GRACILE syndrome	BCS1L gene defect	Neonatal lethality
Succinyl-CoA synthetase deficiency	SUCLA2 SUCLG1	Liver disease/mitoDNA de Liver disease/mitoDNA de
Thymidine phosphorylase deficiency		MNGIE/mitoDNA depletio Bone marrow transplanta
Pyruvate carboxylase deficiency	Pyruvate carboxylase	Features neurodegenerat
PEPCK deficiency	Phosphoenolpyruvate carboxykinase	Extremely rare, may be a with cirrhosis
Storage Disorders		
Gaucher, type I, II and type III	β-glucosidase	Can feature nonimmune h fetalis
Niemann Pick, type A	Acid sphingomyelinase	
Niemann Pick, type B		
Niemann Pick, type C (NPC type 1)	NPC1 gene	
Niemann Pick, type C (NPC type 2)	NPC2 gene, NPC2	Can feature nonimmune h fetalis
Sandhoff disease	HEXB gene	
Sialidosis, type II	Neuraminidase or alpha-N-acetyl neuroaminidase	Can feature nonimmune h fetalis
Galactosialidosis	Protective protein deficiency	Can feature nonimmune h fetalis
Sialic acid transport disorder (infantile free sialic acid storage disease)	SLC17A5	Can feature nonimmune h fetalis
I-cell disease	*N*-acetylglucosaminyl-1-	Can feature nonimmune h

	phosphotransferase	fetalis
GM1 gangliosidosis	β-galactosidase	Can feature nonimmune h fetalis
Multiple sulfatase deficiency	SUMF1 (sulfatase-modifying factor-1 gene)	
Wolman disease	Lysosomal acid lipase	Can feature nonimmune h fetalis
Farber Disease type I	Ceramidase	Can feature nonimmune h fetalis
Mucopolysaccharidosis, type VII	β-glucuronidase	Can feature nonimmune h fetalis
Congenital disorders of glycosylation		
Multiple enzymopathies; phosphomannomutase (type I) N-acetylglucosaminyl-transferase II (type II),	GDP-Man:GlcNAc2-PP-dolicholmannosyltransferase	Can feature hyperinsulinis protein-losing enteropathy nonimmune hydrops fetal Oral mannose for phosphomannomutase de
Phosphoglucomutase 1 deficiency		Hepatomegaly, hypoglyce uvula/cleft palate, Certain features respond galactose therapy
Sterol Synthesis Defects		
Smith-Lemli-Opitz syndrome	7-dehydrocholesterol reductase	Malformation syndrome
Lathosterolosis	3B-hydroxy steroid-delta-5 desaturase	Malformation syndrome
Desmosterolosis	24-dehydrocholesterol reductase	Malformation syndrome
Conradi-Hünermann syndrome	3B-hydroxysteroid-8,7-isomerase, others	Malformation syndrome
Mevalonic acidemia	Mevalonate kinase	Dysmorphic features, HSI
Peroxisomal Biosynthesis and Function		
Zellweger disease	Peroxisomal biogenesis defects	Dysmorphic features, malformations
Infantile Refsum disease	Peroxisomal biogenesis defects	Dysmorphic features
Bile salt metabolic defects	Delta(4)-3-oxosteroid 5β reductase, 3 β-hydroxy-Δ5 steroid dehydrogenase-isomerase, Oxysterol 7α-hydroxylase	Cholestatic liver disease treat first two with chenodeoxycholic acid +/– cholic acid
Metal Metabolism		
Neonatal iron storage disease/perinatal	Defect(s) uncertain	Prenatal and neonatal letl Liver transplantation?

hemochromatosis		
Juvenile hemochromatosis	hemojuvelin; hepcidin antimicrobial peptide	
Hemochromatosis, other	HFE 3 (transferrin receptor-2) HFE4 (ferroportin) Atransferrinemia Aceruloplasminemia	Autosomal dominant inhe Neurological syndrome
Wilson disease	ATP7B	Penicillamine
Indian childhood cirrhosis	Defect(s) uncertain	
Idiopathic copper toxicosis	Defect(s) uncertain	
Other disorders		
Glycine-*N*-methyltransferase	Glycine-*N*-methyltransferase	A cause of hypermethione
Progressive Familial Intrahepatic Cholestasis Syndromes (PFIC1-4), including Byler disease (PFIC1)	ATP8B1, ABCB11, ABCB4; Progressive PFIC3-beta-hydroxy-delta-5-C27-steroid oxidoreductase	PFIC1-3 may encode tran proteins
Vitamin Malabsorption Disorders and Chronic Diarrhea		
Congenital folate malabsorption	SLC	IM folinic acid
Imerslund-Grasbeck disease	CUBN (cubilin)	IM OH cobalamin
Intestinal biotin transporter defect	Unknown etiology	One patient reported to da
Chronic diarrhea	Congenital chloride diarrhea	High chloride diet, electro replacement
	Congenital secretory diarrhea due to defective sodium/hydrogen exchange	Electrolyte replacement, a balance
	glucose-galactose malabsorption	Remove glucose and gala from diet, provide fructose
	lactase deficiency	Avoid lactose
	sucrase-isomaltase deficiency	Avoid sucrose, symptoma with oral yeast and yeast-extracts
A/hypobetalipoproteinemia (A)	MTTP gene (recesive)	
Hypo A/hypobetalipoproteinemia	APOB gene (dominant)	

The last group of metabolic disorders includes those in which the signs and symptoms can be hepatic and extrahepatic. Included are a large

number of conditions, such as the urea cycle, fatty acid oxidation, and organic acid disorders, as well as others that affect storage and transport. Liver transplantation has been employed as a treatment modality in some of these diseases with variable success.[16]

Hepatic Injury

The metabolic processes within the hepatocyte, as in any cell, are closely regulated and interactive; they are responsive to external as well as internal stimuli. Central to the well-being of any cell are adequate stores of energy or the means to produce energy from readily available substrates as needed. With this energy, the cell maintains its homeostasis, grows, synthesizes material for export, exports, transports, and recycles unneeded or decaying materials. All of these processes are affected by one or more biochemical genetic disorders.

Compartmentalization of cellular functions is a necessary part of the synthetic and degradative pathways, as well as being essential for the production and maintenance of electrochemical gradients in energy production. Hepatic metabolism is quantitatively and even qualitatively different in the periportal inflow zone compared to the perivenous outflow area. Periportal cells are responsible for the majority of gluconeogenesis, glycogen synthesis by the indirect pathway, urea synthesis, and fatty acid oxidation. This regionalization may allow for discontinuous histopathologic findings during acute and less than massive metabolic insult. As the degree of hepatic injury becomes more severe, or as the duration of repeat injury increases and fibrosis occurs, the distinctions become less obvious.

Pathophysiology

For many of the biochemical genetic disorders, common histologic appearance and laboratory perturbations exist, precluding exact diagnosis without the use of extraordinary testing. The common pathways of hepatic pathophysiology include inflammation, necrosis, and cholestasis as the result of alterations in homeostasis; steatosis as the result of the accumulation of intermediates and the response to metabolic stress; and the accumulation of relatively nontoxic macromolecules, which usually alter cellular function on the basis of mass effects rather than chemical composition. It is also clear that the pathophysiology in some instances is different with many metabolic diseases if the patient is a newborn infant rather than a child or an adult. A factor that can confound diagnosis of a

metabolic disorder is the nonspecific malhandling of metabolites by a diseased liver, particularly methionine and tyrosine.

Cholestasis and Hepatobiliary Disease

Cholestasis can result from multiple groups of metabolic disorders. Defects in bile acid metabolism, absence of peroxisomes, and disorders of amino acid, lipid, carbohydrate, or complex molecule degradation, metal metabolism, and transport can lead to the recognition of cholestasis.

Cystic fibrosis, an extremely common autosomal recessive disease, is due to defects in the cystic fibrosis transmembrane conductance regulator (CFTR), whose gene is located on chromosome 7q31.2. Although respiratory disease, pancreatic exocrine insufficiency, and failure to thrive are easily recognized as components of the clinical spectrum, hepatobiliary disease may be seen in very early infancy with impaired intrahepatic and extrahepatic biliary drainage. CFTR is localized to the intrahepatic biliary epithelium and is a regulator of cholangiocellular bile production. Cholestasis is felt to be secondary to defective chloride transport across this epithelium. Focal biliary cirrhosis can occur early with later evidence of steatosis and fibrosis. In a minority of patients, prolonged neonatal jaundice with cirrhotic change is seen. In rare instances, liver transplantation may be required (see Chapter 55).

Other transport system defects can also cause a cholestatic change in the liver. Citrullinemia Type 2, a urea cycle disorder, can feature cholestasis as the neonatal hepatic presentation. A series of disorders—the progressive familial intrahepatic cholestasis syndromes—feature mutations in a variety of proteins likely involved in cannilicular transport. Four distinct genetic loci exist, and mutations have been demonstrated in patients from diverse backgrounds, including the Old Order Amish[17] and an Eskimo isolate from Greenland.[18] Three of the genes appear to encode transport-related proteins while the fourth encodes a steroid oxidoreductase.[19–21]

The genetic basis of other cholestatic syndromes, such as North American Indian childhood cirrhosis, appears to involve novel proteins and illustrate that the current understanding of the mechanisms of cholestasis are far from complete[22] (see Chapter 56).

Bile acid synthetic defects can present with cholestatic liver disease and progress to cirrhosis.[23] A number of these rare enzymopathies are known to exist and it is likely that others remain to be discovered. Cheondeoxycholic acid and cholic acid can be used to treat patients with

these disorders, in some instances, with great efficacy.

Hepatocellular Necrosis

Hepatocellular necrosis manifesting with jaundice, edema, ascites, hepatic synthetic failure, or hepatic encephalopathy is a major common pathology due to catabolic errors. The laboratory studies show variable degrees of elevation of serum transaminases, hypoglycemia, hyperammonemia, hypofibrinogenemia, and hypoprothrombinemia. The clinical picture is similar to that of sepsis, and the laboratory findings can be indistinguishable from those of a severe viral hepatitis (see Chapter 62).

Galactosemia is a typical example of a disorder in this group. Classic galactosemia is due to a severe deficiency of hepatic galactose-1-phosphate uridyl transferase (GALT) activity. As a result of significant impairment of the function of the enzyme, a syndrome of neonatal-onset toxicity occurs when the at-risk infant is exposed to significant amounts of dietary lactose or galactose. The toxic metabolites are galactose-1-phosphate (a substrate of the enzyme) and galactitol (the result of aldose reductase activity on the sugar). Because there is trapping of cellular phosphate as galactose-1-phosphate, hepatic intracellular ATP/ADP ratios may be altered. Interference with other enzymatic systems has been postulated. Both mechanisms can lead to severe acute hepatocellular damage, which is reversible if treated immediately. The acute manifestations of the disease in the extended neonatal period often are noted within a few days of the onset of milk feedings. Vomiting and diarrhea are common. Most patients present with jaundice caused by an unconjugated hyperbilirubinemia. Severe hemolysis occurs in some patients so that the clinical presentation resembles erythroblastosis fetalis. Ascites has been a prominent early finding. With the progression of hepatic disease, bile stasis, pseudoacinar formation, and portal fibrosis are seen. An end-stage cirrhotic liver can result whose histology is indistinguishable from that of other metabolic etiologies. Laboratory findings include derangements of hepatic function, albuminuria, hyperaminoaciduria, hyperchloremic metabolic acidosis, hypergalactosuria, and elevated blood galactose concentrations. There is increased production and elimination of galactitol and the presence of increased concentrations of tissue galactose-1-phosphate. In the untreated state, alterations in carbohydrate composition of glycoproteins, such as transferrin, can be seen paralleling the CDG.

The other affected organ systems in the neonate include the lens of the eye, the CNS, the immune system, and the renal tubules. Increased

synthesis of galactitol in the lens is associated with cataract formation. CNS findings in the infant include alterations in the level of consciousness and hypotonia. Cerebral edema and increased intracranial pressure can occur. A high frequency of *Escherichia coli* sepsis has been noted with fulminant courses. With prompt supportive therapy and the elimination of lactose and galactose from the diet, the acute toxicity syndrome resolves. Chronic, or long-term, effects of GALT deficiency occur in the CNS and ovary. Dietary therapy attempts to minimize offensive carbohydrates precursors from the diet but may never eliminate aberrant metabolites derived from endogenous production.

Hereditary fructose intolerance (HFI) usually presents with vomiting, diarrhea, and sometimes hypoglycemia. Symptoms are related to the ingestion of fructose or sucrose. The pathophysiology includes phosphate trapping, with resultant similar intrahepatic pathologic progression in the face of additional carbohydrate, and, as in galactosemia, there is renal tubular dysfunction. Beneficial effects from the withdrawal of the offending carbohydrates are seen in 2–3 days. Older patients characteristically avoid sucrose and have an unusual history of not having any dental caries. Two common mutations are known in the Caucasian population and molecular diagnosis is possible in some cases. Dietary therapy to eliminate fructose is completely effective at preventing the complications of this disorder.

Neonatal iron storage disease, or perinatal hemochromatosis, is a disorder resulting from severe prenatal hepatic disease. There is no single etiology for the disease; nor is there a clear genetic link to any single enzymatic defect, although a recessive pattern of inheritance seems likely. The liver shows diffuse fibrosis with hepatocellular nodular regeneration and ductal transformation. Siderosis in the apical cytoplasm of the tubular hepatocytes is typical. Some patients have had Down syndrome. A newer entity, GRACILE, reported in Finish infants, presents with growth retardation, lactic acidemia, anemia, and hemochromatosis.[24] The defect is in the BCS1L gene, involved in the assembly of complex III of the respiratory chain, and has been mapped to a locus on 2q33.37 and cloned. Other conditions may feature neonatal hemochromatosis, such as the tricho-hepato-enteric syndrome.[25] The neonatal onset cases, regardless of distinct etiology, all seem to be severe entities with a difficult clinical course. Although liver transplantation can be curative, some patients may benefit from antioxidant treatment without surgical intervention.

Juvenile hemochromatosis, another form of primary hemochromatosis, can be caused by mutations in hemojuvelin[26] or the gene encoding

hepcidin antimicrobial peptide.[27] This condition, like the more commonly seen adult variant caused by mutations in the HFE gene, can feature severe iron overload with hepatocytic iron deposition, liver fibrosis, hypogonadotrophic hypogonadism, and cardiac involvement. Two other genetic forms of primary hemochromatosis are also known. HFE3 is caused by mutations in the gene encoding transferrin receptor-2 and is intermediate in severity.[28] HFE4, the only documented autosomal dominant form of the disease, is caused by a mutant ferroportin gene.[29] Dietary restriction of iron is usually not effective in patients with hemochromatosis and many adults require prophylactic phlebotomy to reduce body iron stores.

Other inborn errors of metabolisms can feature hepatocytic iron deposition by unclear mechanisms. Atransferrinemia, caused by mutation in the structural gene for transferrin, produces a syndrome of microcytic anemia and iron overload and is treated by plasma infusions to provide functional transferrin. Aceruloplasminemia produces a syndrome of hepatic and CNS iron deposition. The basal ganglia seem to be most affected and the syndrome is dominated by neurological signs. Ceruloplasmin is low, as is serum iron, but excessive iron deposition is seen in the liver, brain, and pancreas (see Chapter 9).

Disorders of copper metabolism are another group of important metal metabolic diseases. The prototype is Wilson disease, an autosomal recessive disorder characterized by intracellular hepatic copper accumulation, cirrhosis, and, in a sizable number of patients, neurologic abnormalities. The primary defect resides in the ATP7B gene, which encodes a polypeptide that acts as a membrane copper-transport protein. The protein likely plays a role in intracellular copper delivery as well as release of copper into the bile. Like galactosemia and hereditary fructose intolerance, patients with Wilson disease can have a renal tubulopathy featuring aminaciduria and phosphaturia. Neurological and psychiatric presentations are well described. Chelation therapy can be used to enhance copper excretion. Some patients with hepatic failure will need liver transplantation. Another group of less well-characterized disorders of copper overload exist; these include Indian childhood cirrhosis and idiopathic copper toxicosis. The exact basis of these disorders is not known at present.

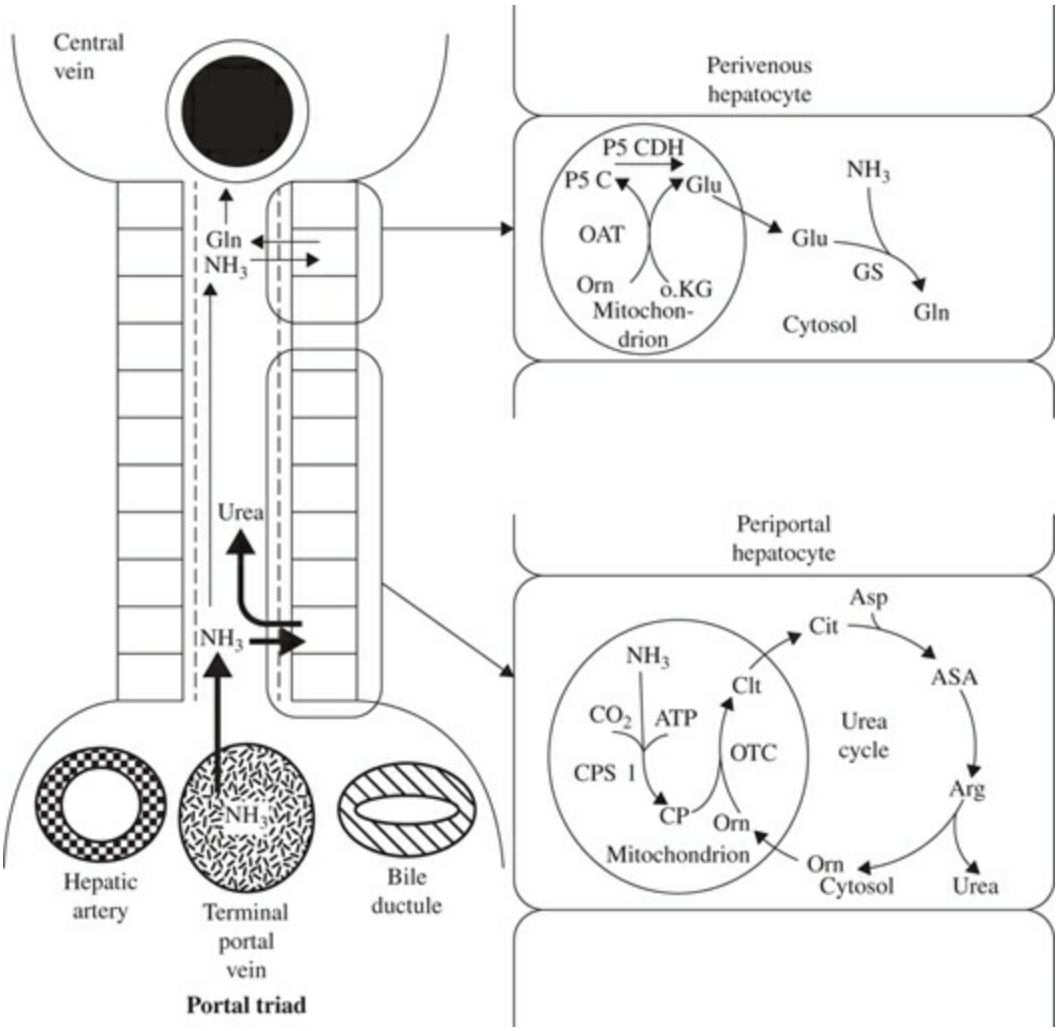

Figure 49-1 Depicted is the nonhomogeneous distribution of enzymes involved in ammonia metabolism in the hepatocytes of an acinar sinusoid as they are linearly distributed from the portal triad to the region of the central vein or terminal hepatic venule. The specific enzymatic reactions are shown for an individual periportal and perivenous hepatocyte. The glutamine synthetase (GS) and ornithine aminotransferase (OAT) enzyme activities are expressed exclusively in the one to three cell layers surrounding the central vein, that is, the region of zone 3 of the liver lobule, whereas the urea cycle enzymes are concentrated within the periportal hepatocytes. However, the urea cycle enzyme activities are higher in zone 1 immediately surrounding the portal triad than in the middle zone 2. The hepatocytes are shown as *squares*, the hepatic mitochondria as *shaded circles*, and the lining of the space of Disse as the *interrupted lines* on either side

of the linear array of hepatocytes. Arg, arginine; ASA, argininosuccinate; Asp, aspartate; ATP, adenosine triphosphate; Cit, citrulline; CP, carbamylphosphate; CPS-I, carbamylphosphate synthetase type 1; Gln, glutamine; Glu, glutamate; α-KG, α-ketoglutarate; NH_3, ammonia; CO_2, CO_2 or bicarbonate; Orn, ornithine; P5C, pyrroline 5-carboxylate; P5CDH, pyrroline-5-carboxylate dehydrogenase. B. The medications sodium phenylacetate and phenylbutyrate and sodium benzoate promote alternative waste nitrogen disposal by participating in these two mitochondrial reactions. (Adapted from Tuchman M, Lichenstein GR, Rajagopal BS, et al. Hepatic glutamine synthetase deficiency in fatal hyperammonemia after lung transplantation. *Ann Intern Med*. 1997;127:447.)

Urea cycle enzyme disorders may appear as early as 1–3 days of age. Figure 49-1 shows a functional overview of the urea cycle and highlights the compartmentalization of metabolism within the cellular zones of the liver. Infants show combinations of vomiting, lethargy, increased respiratory drive, and CNS dysfunction that may progress to seizure activity. Their glucose concentrations are normal, with normal or slightly alkalotic blood pHs. Markedly elevated plasma ammonium concentrations are a common feature. Blood urea nitrogen concentrations may be low. The common pathogenesis is an inability to detoxify ammonia, which is produced as the result of the catabolism of amino acids. Thus, either protein ingestion or catabolic stress can trigger hyperammonemia. The presentation of the individual disorders is nonspecific, and specialized laboratory testing such as quantitative plasma amino acid analysis and measurement of urinary orotic acid concentration is used to separate the diseases. The enzymes of ureagenesis are present in intestinal, renal, and hepatic compartments, but only in the liver are the full complement of activities of the urea cycle present to enable the conversion of NH_3 to urea. In the liver, only the proximal enzymes *N*-acetyl glutamate synthase, carbamoylphosphate synthetase, and ornithine transcarbamylase are localized within the mitochondrial matrix. In biopsied material examined by electron microscopy, pleomorphic mitochondria with swollen cristae and electron-dense matrices are seen. Other hepatocellular changes include alterations in the appearance of the endoplasmic reticulum. Chronic injury, as the result of either prolonged hyperammonemia or repeated episodes of metabolic crisis, may cause portal fibrosis. Synthetic function of the liver

is normal, although elevations in serum transaminases can occur. Such elevations may be present between episodes of hyperammonemia and despite the use of ammonia-trapping agents and enhancers of alternative nitrogen metabolic pathways. In the acute hyperammonemic crisis, detoxification by hemodialysis or hemofiltration may be essential.

In alpha-1 antitrypsin deficiency due to the PI ZZ phenotype, the protein has a lysine residue instead of a glutamic acid at position 342. The altered protein is not secreted, because the reactive loop center of one molecule is inserted into the beta-pleated sheet structure of a second molecule. This protein is retained within the endoplasmic reticulum, as is reflected by the accumulation of periodic acid–Schiff (PAS)–positive diastase-resistant material. In some susceptible individuals, the accumulation of the abnormal protein damages the endoplasmic reticulum or Golgi membranes, leading to hepatocellular damage and cirrhosis. Liver transplantation is required in some instances.

Tyrosinemia type I can present in early infancy with varying degrees of hepatomegaly and a mild elevation of serum transaminases. The biochemical lesion is a defect in fumarylacetoacetate hydrolase. Common features also include abnormalities of coagulation, with clotting factors often markedly reduced. Vitamin K does not correct the disorder. Renal dysfunction is usually evident. A porphyuric presentation with neuropathy due to increased succinylacetone can be seen in the acute setting. Specialized testing (i.e., quantitative analysis of plasma amino acids by anion exchange chromatography) usually reveals hypertyrosinemia, an increased urinary excretion of succinylacetone, and an elevated serum alpha-fetoprotein concentration. The hepatic disease is progressive and advances from microscopic cirrhosis, which can be seen in the first weeks of life, to macronodular cirrhosis with regenerating nodules. Hepatocellular carcinomas are frequent. In this disorder, biochemical abnormalities may be seen prenatally. The molecular mechanism of the hepatic and renal damage is not known, although the intracellular compartmentalization of toxic metabolites has been proposed to induce local damage. The inhibition of 4-hydroxyphenylpyruvate dioxygenase by fumarylacetoacetate is a major factor in the recognized biochemical abnormalities, and treatment with 2-(nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC) corrects these but does not always prevent the progression to hepatocellular carcinoma. Dietary therapy consists of limiting tyrosine intake in conjunction with NTBC administration. Serum alpha-fetoprotein, a marker of hepatocellular carcinoma, and routine liver imaging studies are longitudinally followed to help decide which patients

need to undergo liver transplantation.

The ACAD9 deficiency is a defect in very long chain fatty acid oxidation but secondarily results in a mitochondrial respiratory chain defect involving Complex I. Severe defects may be associated with hepatic failure (reference Vockley).

Steatosis

Steatosis can be associated at some point in the natural history of a number of the organic acidopathies that result from enzymatic defects in the metabolism of branched-chain amino acids or odd-chain fatty acids. Propionic acidemia and methylmalonic acidemia, due to defects in either subunit of the heterodimeric propionyl coenzyme A carboxylase or the activity of the enzyme methylmalonyl-CoA mutase, are the prototypes for these disorders. Figure 49-2 displays the location of the blocks in the pathway of propionyl-CoA metabolism. Affected infants present with severe metabolic acidosis, refusal to feed, vomiting, and alterations in CNS function. Hepatomegaly is found in a fraction of the patients. The livers at autopsy have shown fatty infiltration and necrosis, and the reticuloendothelial cells may have increased iron deposits. The exact mechanism of the fat deposition is unknown but may relate to an imbalance between the rate of fat synthesis and the rate of export of lipoproteins. Laboratory findings of a metabolic ketoacidosis with hyperammonemia and hyperglycinemia are characteristic during the initial presentation and subsequent metabolic crises.

Almost all the disorders of beta-oxidation of fatty acids from defects in carnitine palmitoyltransferase I, carnitine/acylcarnitine translocase, and carnitine palmitoyltransferase II through to the utilization of hydroxy-, medium-chain, or short-chain fatty acids have been associated with some degree of hepatic dysfunction and fat accumulation. An overview of these disorders is depicted in Figure 49-3. In the majority of cases when histology has been performed, the accumulation occurs as macrovesicular lipid storage. Hypothetical mechanisms of fat accumulation in these disorders include effects of a constant supply of fatty acids with a block in their utilization, increased availability of glycerol, and net intracellular accumulation. Dietary management of this group of disorders varies with the nature of the block but generally includes avoidance of fasting, restriction of dietary amino acid (for organic acidurias) and fat intake, and careful monitoring for nutritional status. Anaplerotic therapy remains investigational. The newly described glycerol-3-phosphate dehydrogenase 1 deficiency is associated with hepatic steatosis and transient

hyperlipidemia.[30]

Hepatic Pathology Resulting From Peroxisomal Disease

The absence of hepatocyte organelles and their functions can result in recognized hepatic disease in late fetal or early infant life. The best characterized group of these disorders includes those due to the peroxisomal diseases, which comprise a group of disorders with effects on multiple viscera, skeletal development, and the CNS. Zellweger disease, the paradigm for peroxisomal disorders, is caused by biosynthetic defects in the formation of the peroxisome. As a result, more than 50 enzymes involved in multiple pathways can be perturbed. The peroxisomes are responsible for the oxidation of amino acids, alcohols, dicarboxylic acids, pipecolic acid, and phytanic acid, as well as very long-chain fatty acids. They are also essential for the synthesis of bile acids, ether-phospholipids such as the plasmalogens, and cholesterol, and they are a major reservoir of the hydrogen peroxide–degrading enzyme, catalase. Zellweger disease was also called cerebrohepatorenal disease because of the organ systems involved in the neonate. The infants have distinct dysmorphic features, an enlarged fontanelle, profound hypotonia, hepatomegaly, and neurodegeneration. Neuronal migratory defects are often seen. The liver has micronodular cirrhosis and fibrosis on examination. The laboratory abnormalities are explained by the missing multiple enzyme functions. Diagnosis can be strongly suspected by the constellation of physical findings and is confirmed by the abnormalities in very long-chain fatty acid metabolism. The dysmorphia varies with the severity of the defect. For example, infantile Refsum disease, considered to be a milder phenotype of the peroxisomal biogenesis disorders, generally presents with failure to thrive and milder degrees of hepatocellular dysfunction in older infants or toddlers with dysmorphic facial features.

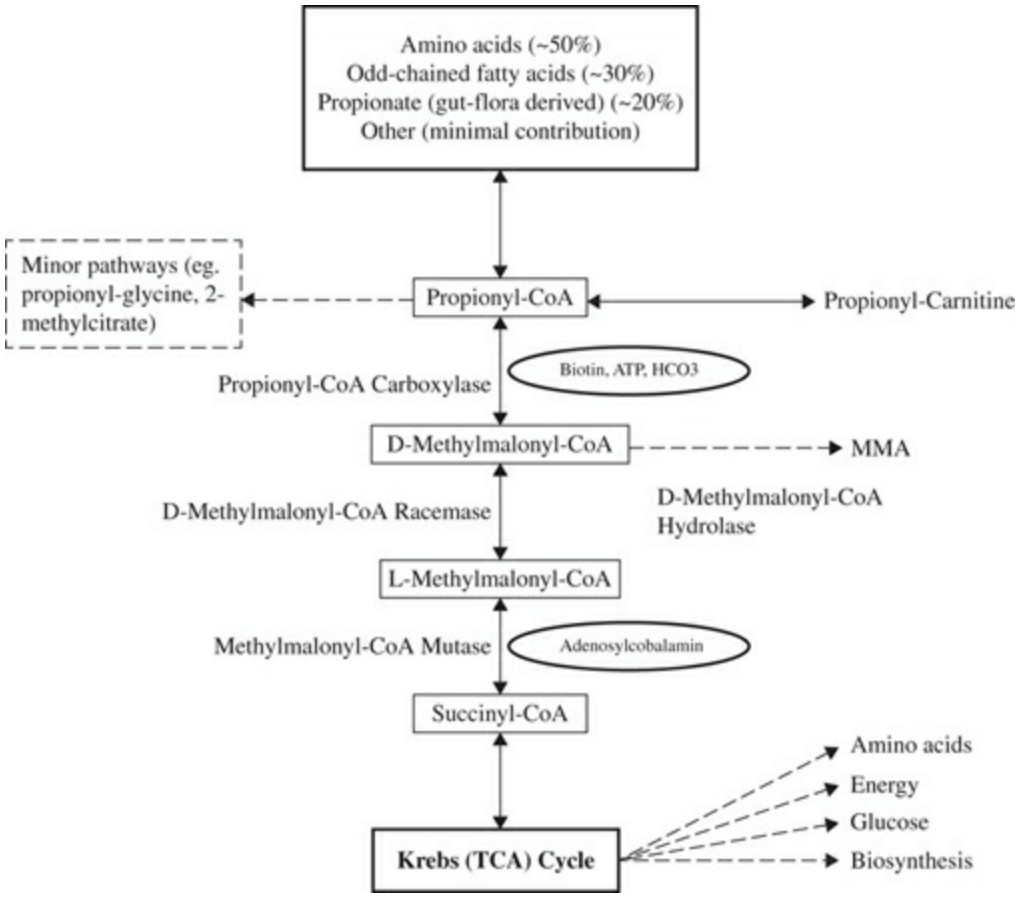

Figure 49-2 Major pathway of the conversion of propionyl-CoA, a major 3-carbon metabolite, into succinyl-CoA. The precursors are indicated with their approximated contribution to whole body propionate metabolism. The biotin-dependent enzyme, propionyl-CoA carboxylase converts propionyl-CoA into D-methylmalonyl-CoA that is then racemized into L-methylmalonyl-CoA and isomerized into succinyl-CoA, a Krebs cycle intermediate. The L-methylmalonyl-CoA mutase reaction requires adenosylcobalamin, an activated form of vitamin B_{12}. The formation of adenosylcobalamin requires intracellular metabolism of cobalamin. (Adapted from Chandler RJ, Venditti CP. Genetic and genomic systems to study methylmalonic academia. *Mol Genet Metab.* 2005;86(1–2):34–43.)

Hepatic Disease due to Glycosylation Defect

Disorders of glycosylation result from various defects in the formation or processing of the carbohydrate residues attached by N- or O-linkages of

peptides. These disorders can be considered “prelysosomal” storage disorders, as improperly glycosylated proteins initially accumulate in the endoplasmic reticulum. This may, in turn, lead to cellular dysfunction via the unfolded peptide response. The most common hepatic pathology is steatosis, but hydrops and severe hepatocellular dysfunction have been reported. Common clinical manifestations include failure to thrive, GI dysfunction or dysmotility, hypotonia, cognitive delays, and alterations in fat distribution. Mannose supplementation has been used as a treatment for mannose phosphate isomerase deficiency (CDG 1b). The newly described PGM1 enzyme deficiency is associated with fasting hypoglycemia, hepatic glycogenosis, abnormal circulating glycan-containing proteins and may respond to galactose therapy.[31]

Hepatic Disease due to Mitochondrial Dysfunction

Multiple reports have described infants with severe or fatal hepatic disease of early onset due to a mitochondrial depletion syndrome. In some cases, increased fat has been seen histologically; however, ultrastructural examination of other patients’ tissues has shown increased numbers of mitochondria with morphologic abnormalities, and even glycogen storage within the mitochondria. Focal biliary necrosis has been reported, but fibrosis is a later finding. Lactic acidosis, hypoglycemia, and synthetic defects have also been reported. In all cases, activities of the electron transport chain complexes with subunits encoded by mitochondrial DNA have been reduced. The amount of mitochondrial DNA has been reduced to less than 10% of normal. Mutations in the nuclear genes encoding deoxyguanosine kinase (DGOUK), thymidine phosphorylase (MNGIE), MPV17 (causing Navajo hepatoencephalopathy), polymerase–gamma (POLG), and succinyl-CoA synthase (SUCLG1) genes have been identified in some patients. The gastrointestinal phenotypes are variable and can feature hepatic failure, seen in patients with mutations in DGUOK, POLG, and MP17; hepatomegaly with encephalopathy, seen in the one patient with succinyl-CoA synthase deficiency and intestinal pseudo-obstruction, a prominent feature of thymidine phosphorylase (MNGIE) deficiency.

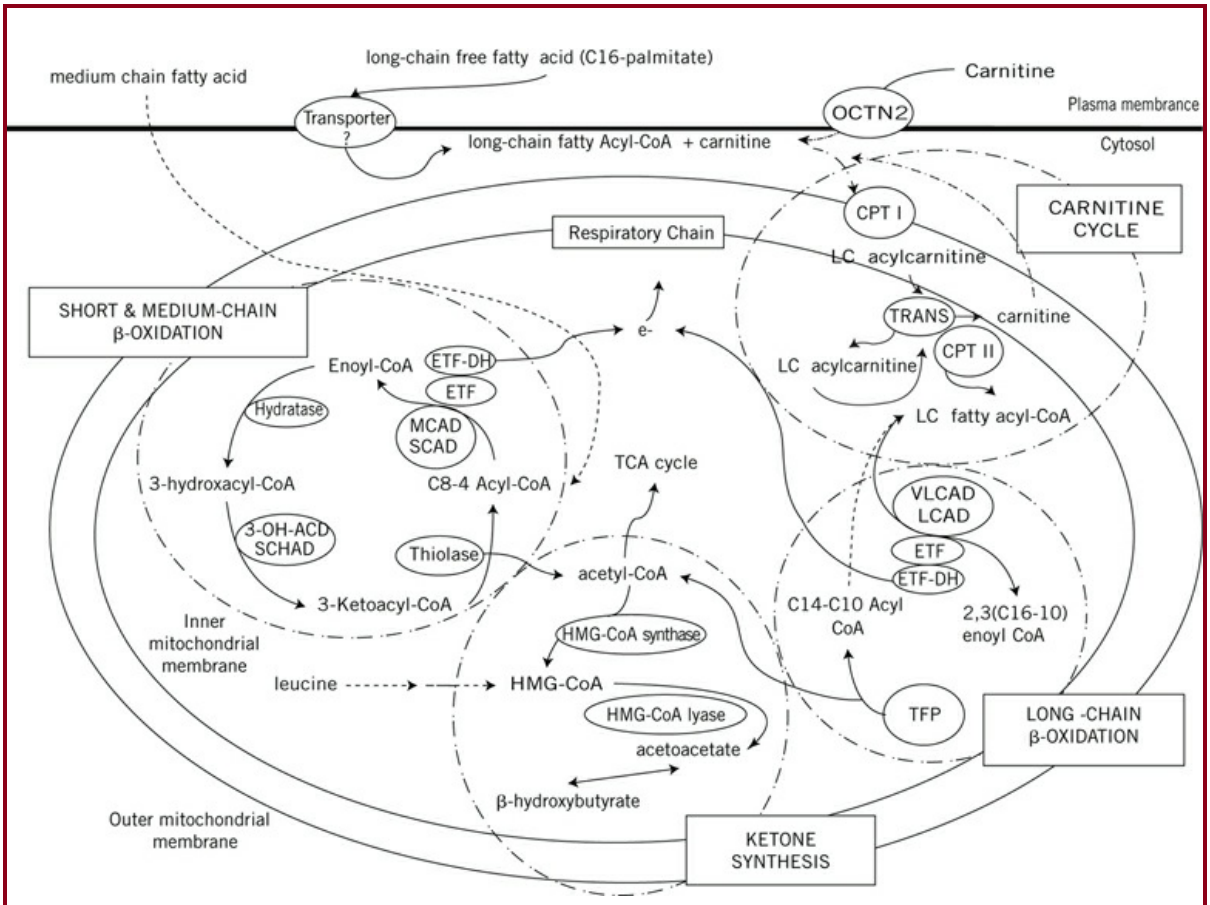

Figure 49-3 An overview of mitochondrial fatty acid oxidation. Carnitine enters the cell through the action of the organic cation/carnitine transporter (OCTN2). Palmitate, a typical 16-carbon long-chain fatty acid, is transported across the plasma membrane and can be activated to form a long-chain (LC) fatty acyl-CoA. It then enters into the carnitine cycle, where it is transesterified by carnitine palmitoyltransferase-I (CPT-I), translocated across the inner mitochondrial membrane by carnitine/acylcarnitine translocase (TRANS), and then reconverted into a long-chain fatty acyl CoA by carnitine palmitoyltransferase-II (CPT-II) to undergo β-oxidation. Very long chain acyl-CoA dehydrogenase (VLCAD/LCAD) leads to the production of (C16-10) 2,3 enoyl-CoA. Trifunctional protein (TFP) contains the activities of enoyl-CoA hydratase (hydratase), 3-OH-hydroxyacyl CoA dehydrogenase (3-OH-ACD), and β-ketothiolase (thiolase). Acetyl CoA, FADH, and NADH are produced. Medium- and short-chain fatty acids (C8-4) can enter the mitochondrial matrix independent of the carnitine cycle. Medium-chain acyl-CoA dehydrogenase (MCAD), short-chain

acyl-CoA dehydrogenase (SCAD), and short-chain hydroxy acyl-CoA dehydrogenase (SCHAD) are required. Acetyl-CoA can then enter the Krebs (TCA) cycle. Electrons are transported from FADH to the respiratory chain via the electron-transfer flavoprotein (ETF) and the electron-transfer flavoprotein dehydrogenase (ETF-DH). NADH enters the electron transport chain through complex I. Acetyl-CoA can be converted into hydroxymethylglutaryl-CoA (HMG-CoA) by β-hydroxy-β-methylglutaryl-CoA synthase (HMG-CoA synthase) and then the ketone body acetoacetate by the action of β-hydroxy-β-methylglutaryl-CoA lyase (HMG-CoA lyase). (Adapted from Venditti CP, Stanley CA. Disorders of mitochondrial fatty acid oxidation. In: Behrman RE, Kliegman RM, Jenson HB, eds. *Nelson Textbook of Pediatrics*, 17th edition. Philadelphia, PA: W.B. Saunders; 2003.)

Hepatic Disease due to Storage Disorders

Material either synthesized within the cell or accumulated through endocytic processes as part of the body's recycling of macromolecules is the sine qua non of the heterogeneous storage disorders. In the GSDs type I, III, or IV presenting in early infancy, there is accumulation of glycogen as well as fat. GSD type I should also be thought of as a steatosis disorder. In Niemann-Pick type A, sphingomyelin accumulates in hepatocytes, as well as in the reticuloendothelial elements, but in Niemann-Pick type C, the accumulated material includes both sphingomyelin and cholesterol. In the latter disorder, hepatocellular necrosis and a progression to fibrosis can also occur, blurring the distinctions made here about disorders primarily associated with hepatocytic dysfunction or storage with minimally altered hepatocytes. The accumulation and storage of glucocerebroside in Kupffer cells in Gaucher disease and of glycolipids and complex lipids in other disorders lead to liver enlargement but relatively little hepatocellular functional abnormality. In many cases, the histopathology and histochemical staining patterns can identify the disorder.

Hepatic Disease due to Porphyrias

The heme biosynthetic pathway begins in the mitochondria with a condensation reaction of glycine and succinyl-CoA and ends with the production of heme, which is then used for hemoglobin formation in the bone marrow and, of equal importance, for cytochrome formation. Defects

in any of the steps in this pathway represent a group of eight disorders that can feature cutaneous, psychiatric, neurologic, and hepatic symptoms. One disorder of this group, protoporphyria, can be associated with severe liver disease that can require liver transplantation.

Other Disorders With Primary Gastrointestinal Disturbances

Chronic diarrhea can be a manifestation of a number of inborn errors of metabolism, including lactase and sucrose–isomaltase deficiencies, glucose–galactose malabsorption, congenital chloride diarrhea, and congenital secretory diarrhea due to defective sodium/hydrogen exchange. Diarrhea, malabsorption, and protein-losing enteropathy can also be features of other disorders discussed in this chapter, such as cystic fibrosis, lysinergic protein intolerance, and phosphomannose isomerase deficiency. Selective vitamin malabsorption disorders, such as congenital folate malabsorption, the intestinal biotin transporter defect,[32] and Imerslund-Grasbeck disease[33] might also be included as metabolic disorders where the primary defect lies in the GI tract.

CONCLUSION

A wide variety of catabolic, anabolic, and transport defects affecting the GI tract can be recognized. The age of presentation ranges from mid-gestation to adulthood and encompasses a wide range of symptoms and signs, some of which are nonspecific. For some disorders, the pathophysiology has been delineated and molecular determinants characterized, but in the majority only the broader features are currently comprehended. The vast array of biochemical genetic diseases, these unfortunate experiments of nature, continues to provide great insight into the secrets of normal hepatic metabolism in man.

Inborn Errors of Fasting Adaptation—Glycogen Storage Disease

50

David A. Weinstein, MD, MMSc and Katalin M. Ross, RD, LDN

Glycogen storage disease (GSD) is caused by a defect in any of multiple enzymes involved in the synthesis or utilization of glycogen.[1,2] Glycogen is stored predominantly in the liver and muscles, and the symptoms of the disorder depend on the location of the defect. Hypoglycemia is the cardinal manifestation of the hepatic glycogenoses due to the inability to utilize glycogen as a source of glucose in a fasting state. Weakness, muscle cramps, and myopathy are the main features of the muscle forms of GSD. Since the disease processes are very different, this chapter is focused on the hepatic glycogenoses that are more dependent on nutritional therapies.

NORMAL PHYSIOLOGY OF GLUCOSE METABOLISM

Following consumption of a meal, carbohydrates absorbed into the blood stream provide fuel for the brain, muscle, red blood cells, and kidneys. The liver is freely permeable to glucose. After being taken up by the liver, glucose is phosphorylated by glucokinase to form glucose-6-phosphate (G6P). G6P is subsequently converted to glucose-1-phosphate, and

glycogen synthase creates chains of glucose molecules by catalyzing the formation of α-1,4-linkages. A branching enzyme forms α-1,6-linkages approximately every 10 glucose units along the chain. During periods of fasting, debranching enzyme hydrolyzes the α-1,6-linkages at branch points and leads to the formation of free glucose. In addition, a cascade of enzymatic reactions activates hepatic glycogen phosphorylase, the rate-limiting enzyme in glycogenolysis, which hydrolyzes the α-1,4-linkages from the outer branches of glycogen to form G6P. Glucose-6-phosphatase (G6Pase) catalyzes the terminal reaction of glycogenolysis and gluconeogenesis, the hydrolysis of G6P to glucose and inorganic phosphate in hepatocytes and renal epithelial cells, allowing glucose to be released into the systemic circulation.[3]

Glucose is stored predominantly in muscle, liver, and kidneys as glycogen for use during fasting. Although muscle stores at least twice as much glycogen as the liver, muscle lacks G6Pase. Thus, muscle is unable to release glucose for systemic use, and the muscle forms of GSD are not associated with hypoglycemia. There are five major types of hepatic GSD that affect glucose homeostasis. The location of each of the enzymatic defects is shown in Figure 50-1.

The clinical severity of the glycogen storage diseases varies widely depending on multiple factors including the degree of impairment of glycogenolysis, whether endogenous glucose can be produced by gluconeogenesis, and the availability of alternative fuels (lactate, ketones) during periods of hypoglycemia. Patients with severely limited endogenous glucose production (GSD I) present with seizures, failure to thrive, or developmental delay. In contrast, patients with normal gluconeogenesis and abundant alternative fuels have a milder phenotype (GSD 0 or GSD IX), and they can be asymptomatic until an illness impairs normal dietary carbohydrate intake.

HEPATIC GLYCOGEN SYNTHASE DEFICIENCY (GLYCOGEN STORAGE DISEASE TYPE 0)

Type 0 glycogen storage disease (GSD 0) is caused by a deficiency in hepatic glycogen synthase, which leads to a marked decrease in liver glycogen content.[4] GSD 0 is due to mutations in the GYS2 gene located on chromosome 12p12.2 and is inherited in an autosomal recessive manner. To date, approximately 20 mutations have been reported with no identified dominant mutation. Although no high-risk population has been identified,

a common mutation, R246X, has been found in people of Italian ancestry.[5]

Pathophysiology

After consumption of carbohydrate, the inability to store glucose as glycogen in the liver results in postprandial hyperglycemia. Glucose taken up by the liver gets shunted down the glycolytic pathway leading to postprandial hyperlactatemia. During fasting, fatty acid oxidation is robust leading to formation of high concentrations of ketones that can be used as an alternative fuel during period of hypoglycemia. Amino acids and lactate can also undergo gluconeogenesis, and these alternative fuels can serve as substrate for endogenous glucose production.

Presentation

The typical presentation of GSD 0 is recurrent ketotic hypoglycemia associated with intercurrent illness.[6] The physical examination is usually normal, and the liver is not enlarged unlike the other hepatic glycogenoses. During infancy, fasting ketotic hypoglycemia develops on cessation of night-time feeding. Weaning from overnight feeds proves to be difficult with hypoglycemia and symptoms of agitation and fussiness are often misconstrued as colic. Significant ketonemia develops with fasting and serves as an alternative energy source for the brain.[7] The protection from the prominent ketonemia may explain why developmental delay has only been described in 22% of children with GSD 0.[8] Other manifestations are often subtle including short stature, failure to thrive, hyperlipidemia, or elevation of hepatic transaminase concentrations.[5]

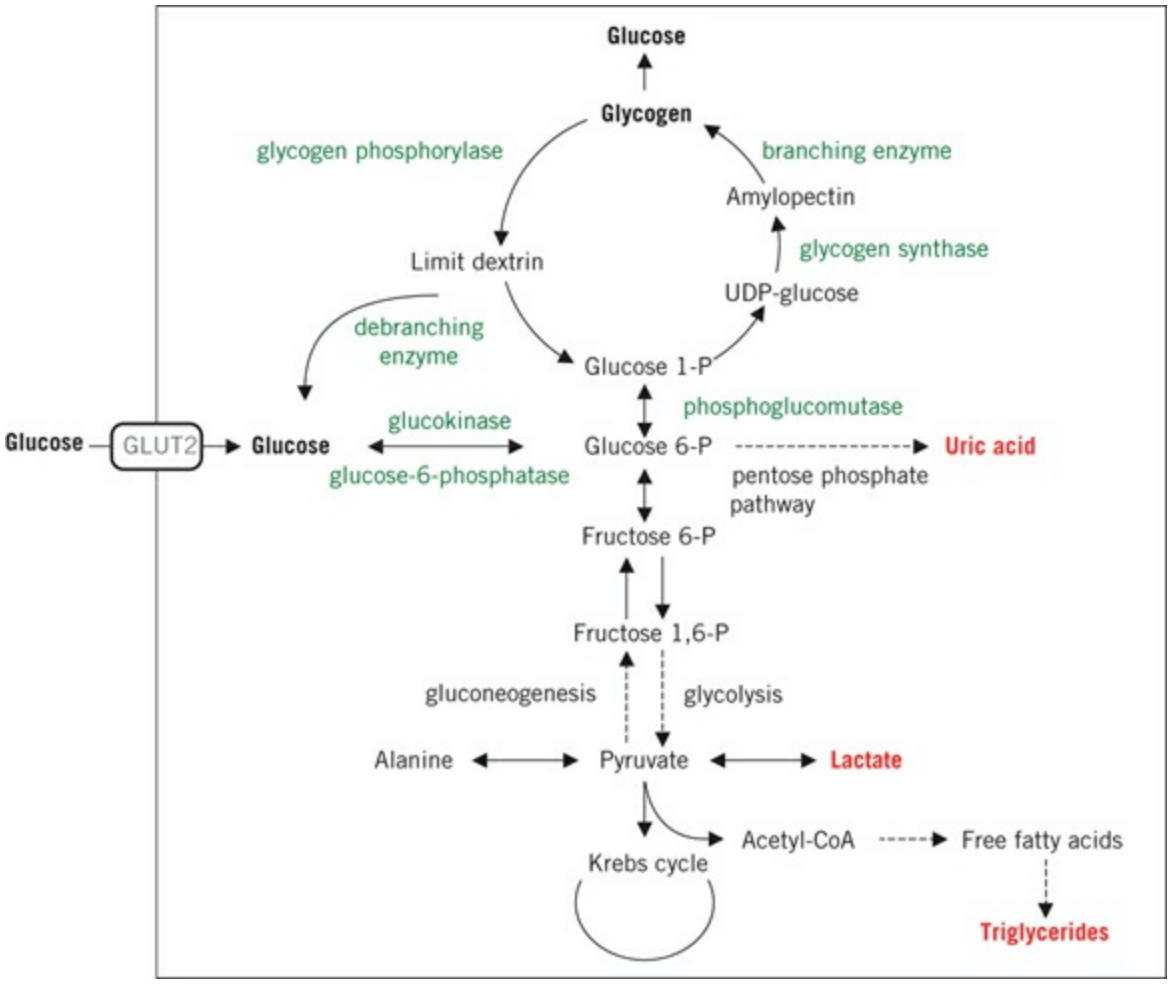

Figure 50-1 Schematic representation of the glycogen storage diseases.

Most children with GSD 0 are identified incidentally during a gastrointestinal illness or period of poor nutrition when hypoglycemia is discovered in a lethargic child. GSD 0 can also be misdiagnosed as diabetes because of postprandial hyperglycemia and fasting ketonuria; however, this presentation would lack symptoms of polyuria and polydipsia.[8]

Diagnosis

The diagnosis of GSD 0 is usually made when fasting ketotic hypoglycemia is found to alternate with postprandial hyperglycemia and hyperlactatemia.[8] Patients usually present after an overnight fast for baseline assessment, and a glucose or galactose tolerance test can be used to assess for the unique biochemical pattern. The gold standard for making

the diagnosis of GSD 0 is by mutation analysis using DNA extracted from blood.[4] Testing in commercial laboratories is now available. Although liver biopsies are no longer recommended to make the diagnosis, a few cases with no identifiable mutation in the GYS2 gene have been diagnosed by liver biopsy with demonstration of decreased hepatic glycogen content or abnormal enzyme activity.

Nutritional Management

The goal of treatment is to prevent hypoglycemia and minimize the associated lactic acidosis. Amino acids can serve as the precursors for gluconeogenesis, and thus a high protein diet is preferred (2–3 g/kg). Since hyperlactatemia and hyperlipidemia occur after ingestion of carbohydrates, a low carbohydrate diet is preferred, and low glycemic index, complex carbohydrates are preferred over simple sugars.

Infants with GSD 0 are usually asymptomatic due to frequent feeds. As children grow; however, it may be difficult to wean the infant from overnight frequent feeds without additional support. In children, uncooked cornstarch (UCS) with 1–1.5 g/kg administered at bedtime is used to prevent hypoglycemia in conjunction with a high protein, low carbohydrate diet as previously discussed. In addition to the bedtime cornstarch dose, some children require frequent snacks every 2–4 hours during the day to prevent hypoglycemia during the daytime.[5] Daytime cornstarch is occasionally used (0.5 g/kg) for children and adults who have higher energy needs secondary to an active lifestyle.

In addition to assessing the patient's intake to monitor compliance with the above guidelines, it is critical to ensure that patients receive adequate calories and that no vitamin or mineral deficiencies are present. Unlike other forms of GSD that have a more restricted diet, vitamin and mineral deficiencies are rare in GSD 0. Osteoporosis is common in GSD 0 due to abnormal bone mineralization in the setting of acidosis, and it is important to ensure that appropriate calcium and vitamin D intake is occurring.

Monitoring of blood glucose and blood ketone concentrations is recommended on a routine basis. Cornstarch therapy overnight is titrated to keep blood ketone concentrations under 0.5 mmol/L. During illness and periods of suboptimal food intake, blood ketone monitoring is the first clue that a child or adult with GSD 0 is becoming catabolic. Supplementation with glucose and extra cornstarch is recommended if ketones are increasing as high concentrations of ketones may lead to vomiting and worsening hypoglycemia.

Natural History and Prognosis

Although overnight hypoglycemia is common in infants and young children, fasting is usually better tolerated with age. Most children over 7 years of age tolerate a typical overnight fast without development of hypoglycemia, and fasting up to 18 hours has been reported in teenagers.[9] This improvement, however, is not universal, and some children continue to develop hypoglycemia with overnight fasts. Although severe hypoglycemia is unusual in older children and adults, ketosis remains common in untreated individuals, and most patients report feeling better with continued glucose supplementation overnight. In addition, fatigue with exertion is common in untreated individuals, and glucose supplementation improves stamina during sports and other active periods.

There is limited experience with adults confirmed to have GSD 0, but there is no reason to believe the prognosis is not excellent for these patients. Short stature and osteopenia are common in untreated children, but improve with prevention of hypoglycemia, lactic acidosis, and ketosis. The long-term complications commonly seen in the other forms of GSD, such as hepatic adenomas, cirrhosis, kidney dysfunction, and muscular abnormalities, have not been reported in teenagers and adults with GSD 0. There are no formal guidelines for screening in this condition.

GLUCOSE-6-PHOSPHATASE DEFICIENCY (TYPE I GSD; VON GIERKE DISEASE)

G6Pase converts G6P to glucose in the final step of both glycogenolysis and gluconeogenesis.[10] The enzyme is present in the liver, kidneys, and intestines, but it is not present in muscle. At the cellular level, G6Pase is a complex enzyme system located in the endoplasmic reticulum (ER) membrane and consists of a catalytic unit that faces into the ER lumen, a calcium-binding protein, and three transport proteins that facilitate transport of G6P (T1), phosphate (T2), and glucose (T3).[11] Abnormalities of any of these components can cause abnormal enzyme function and the clinical phenotype of GSD I. There are three major subtypes of GSD I. More than 85% of patients have mutations that impair the catalytic function of the enzyme (GSD type Ia). Defects in the T1 glucose-6-phosphate transporter account for most other cases (GSD type Ib). Abnormality of the phosphate transporter (GSD type Ic) is rare.

GLYCOGEN STORAGE DISEASE TYPE IA (VON GIERKE DISEASE)

GSD Ia is caused by mutations in the G6PC gene on chromosome 17q21, which encodes G6Pase.[12] The disease is inherited in an autosomal recessive manner, and the incidence is estimated to be 1 in 100,000 live births. GSD type Ia is particularly common in people of Ashkenazi Jewish heritage, and 1 in 68 individuals in this population have been reported to be carriers of the disease.[13] Although GSD type Ia occurs in all ethnic groups, common mutations have also been reported in people of Chinese, Japanese, and Mexican heritage.

Pathophysiology

The inability to convert G6P to glucose results in hypoglycemia whenever exogenous glucose administration is not occurring. Increased concentrations of G6P develop in hepatocytes and shunting into alternative pathways results in the following:

- Lactic acidosis (as a result of increased glycolysis)[14]
- Hyperuricemia (as a consequence of shunting into the pentose phosphate shunt leading to increased synthesis of uric acid; decreased renal excretion also occurs as lactate and uric acid share the same transporter in the kidney)
- Hypertriglyceridemia (as a result of increased synthesis of acetyl CoA)[15]

With prevention of hypoglycemia and glycogenolysis, all metabolic abnormalities abate.

Presentation

Most children do not present with symptoms until 3–6 months of age although hypoglycemia may occur soon after birth. During infancy, as the period between feeds increases or as an acute illness disrupts normal feeding, symptomatic hypoglycemia develops. The symptoms of agitation and fussiness associated with hypoglycemia may go unrecognized until the child presents with failure to thrive, tachypnea (from lactic acidosis), seizures, lethargy, and developmental delay. If hypoglycemia in infancy is missed, GSD I occasionally is diagnosed when hepatomegaly and a protuberant abdomen are discovered during a routine physical exam.

Diagnosis

The simplest and most rapid means of determining the defect in a child with hypoglycemia suspected to have GSD is to obtain serial blood measurements of glucose, lactate, and ketones during a fasting study. Hypoglycemia and lactic acidosis will manifest in a child with GSD type Ia after a brief fast of 3–4 hours. During the study, children should have secure intravenous access to allow for rapid correction as hypoglycemia can develop precipitously. Glucagon must be administered with extreme caution as it will not rescue the child from hypoglycemia, and it can exacerbate hyperlactatemia. Typically, glucose concentrations are monitored every 15–30 minutes after the initial two hours. After the plasma glucose has fallen below 50 mg/dL, a sample for blood glucose and lactate determination should be obtained. As many of the portable meters are inaccurate in the setting of lactic acidosis, close clinical observation is needed during the test. As soon as the test is completed, intravenous glucose is administered to bring down lactate concentrations and maintain euglycemia.

Mutation analysis on DNA extracted from leukocytes is the recommended test for confirming the diagnosis in a child suspected of having GSD Ia. A total of 88 different mutations have been reported. Since many of the genetic tests for GSD type Ia are designed to pick up only the common mutations, complete gene sequencing is recommended for anyone not in a high-risk population.[16] Mutation analysis allows for noninvasive diagnosis, and the technique can be utilized for preimplantation screening and prenatal diagnosis. Liver biopsy is no longer recommended for diagnosing a patient with suspected GSD I, and it should be reserved for those patients in whom GSD Ia is suspected but the mutation analysis is nondiagnostic.

Nutritional Management of the Infant with Type I

Treatment consists of providing a continuous dietary source of glucose to prevent blood glucose from falling below the threshold for glucose counter-regulation, approximately 70 mg/dL (4 mmol/L).[17] A continuous source of glucose can be provided by nocturnal intragastric infusion (via nasogastric tube or gastrostomy) or by using uncooked (raw) cornstarch. An estimate of the minimum amount of glucose required can be obtained by using the following formula to calculate the basal glucose production rate:

$$y = 0.0014x^3 - 0.214x^2 + 10.411x - 9.084,$$

where y = milligrams of glucose per minute and x = body weight in kilograms.[18]

To avoid excessive caloric intake, the optimum feeding schedule and amounts of cornstarch is determined by metabolic monitoring to ensure that the biochemical goals of therapy are achieved. Cornstarch doses should be weighed on a gram scale to avoid over treatment that commonly occurs when doses are estimated.

Since nonglucose sugars cannot be converted back to glucose, patients with GSD, type I must restrict intake of fructose, sucrose, and galactose. Mothers of infants with type I GSD are often encouraged not to breast-feed as the main source of carbohydrate in breast milk is lactose. The formulas most commonly used to treat GSD type I are outlined in Table 50-1.

TABLE 50-1 Commonly Used Formulas in GSD Type I

Formula	Carbohydrate Source	Grams Carbohydrate per 100 mL	Calories/Ounce	General Commen
Enfamil Prosobee Lipil Mead Johnson	Corn syrup solids	7.2	20	Most commonly used formu
Nutramigen Lipil Mead Johnson	Corn syrup solids and modified cornstarch	7	20	Used with protein allergies an malabsorpti issues
Pregestimil Mead Johnson	Corn syrup solids, dextrose, modified cornstarch	6.9	20	High conter of MCTs as fat (55% of calories)
Neocate Nutricia	Corn syrup solids	7.9	20	Commonly used with food allergi
Elecare Abbott	Corn syrup solids	7.2	20	Commonly used with food allergi malabsorpti
Tolerex Novartis	Maltodextrin, modified corn	23	30	Commonly used in sick

	starch			day manageme
Vivonex RTF Novartis	Maltodextrin, modified corn starch	17.5	30	Can also be used in sick day manageme
Osmolite Abbott	Maltodextrin	14.4	32	Isotonic Kosher
Enfagrow Soy Mead Johnson	Corn syrup	7.9	20	Iron-fortified formula for toddlers

MCT = medium-chain triglyceride.

Source: Information obtained from "Pediatric Nutrition Reference Guide" by Texas Children's Hospital, 9th edition, 2010.

The formula chosen must not contain the nonutilizable sugars. Prosobee is the most commonly used formula as it is a nonspecialized, standard infant formula that is easy to obtain and less expensive than the other specialized formulas. The specialized formulas may be indicated, however, if there is a medical necessity, such as malabsorption or intolerance. Tolerex is commonly used for sick day management as a smaller volume is required to meet the carbohydrate needs of the child. It is commonly well tolerated in infants even though it is an adult formula, but it should not be used as the primary source of nutrition due to the relatively low concentration of protein.

Hypoglycemia is prevented in the infant with GSD I through frequent formula feeds provided every 1.5–3 hours. As a result of the need to frequently eat, feeding aversions commonly develop. When solids are introduced, complex carbohydrates such as pastas, legumes, vegetables, and oatmeal are encouraged. UCS is typically not tolerated in infants younger than 6 months due to lack of pancreatic and intestinal amylase that is required to digest cornstarch. The ability to digest UCS therapy, however, differs for each infant, and many infants cannot absorb cornstarch adequately until around 12 months of age, and many children with GSD Ib will not tolerate cornstarch well until 2 years of age.[17] Pancreatic enzyme replacement therapy has been attempted in some infants who develop severe diarrhea with cornstarch, but this intervention is not recommended. Variable response to this intervention has occurred, and some patients have worsened due to possible overdigestion of cornstarch. Use of exogenous enzymes may also delay endogenous enzyme production.

Although it is commonly theorized that UCS therapy can lead to obesity in GSD I patients, it must be noted that this is a misconception. In comparing an infant receiving overnight cornstarch supplementation with overnight continuous formula feeds, the infant receiving the cornstarch actually receives fewer calories and a more optimal feeding schedule is promoted. For example, a typical 12-month-old patient with GSD I requires approximately 4 g/h of glucose. To meet the glucose needs, 60 mL/h of Prosobee is required providing ~480 kcal over the 12-hour period. In contrast, when treated with 15 g cornstarch in 2 ounces Prosobee every four hours, only 284 cal are administered during the same 12-hour period. Not only is there the 41% reduction in calories, but the cornstarch therapy is associated with lower insulin concentrations and more stability in the morning.

In addition to saving calories, cornstarch therapy is associated with fewer neurologic complications when compared with continuous feeds. If a continuous feed is interrupted due to a mechanical problem or leakage of formula, severe hypoglycemia rapidly develops due to the high insulin state. In contrast, the low insulin state associated with cornstarch administration minimizes plasma glucose fluctuations and, blood lactate concentrations increase sufficiently to provide the brain with an alternative fuel. This decreases the risk of hypoglycemia-induced seizures.

Nutritional Management of Children and Adolescents With Type I

Children and adolescents with GSD type I are usually treated with UCS therapy given in boluses around the clock. If regular UCS is used, feeds should be administered every 4–5 hours around the clock. With aging, many children and adults clinically are stable with feeds administered every six hours, but it comes at the expense of elevated triglycerides and lactate concentrations. Spacing to six hours even at night should not occur unless all markers of metabolic control are optimal.[19]

When dosing cornstarch, it is critical to note that glucose requirements do not continue to rise with aging and weight.[18] Basal glucose needs are primarily dependent on brain glucose utilization, and glucose requirements stabilize after 7 years of age. Although additional support is needed during puberty, older children and adults usually have similar glucose requirements (10–12.5 g/h). Weight-based dosing will lead to overtreatment.

Recently, an extended release cornstarch preparation (Glycosade) was

introduced. The new therapy typically extends the duration of fasting by 2–3 hours overnight, but some adults can maintain optimal metabolic control for up to 10 hours.[20] The extended release cornstarch is only recommended for night use at this time as it may be too slow to adequately meet the metabolic needs during the day. Standard dosing is 120 g of Glycosade at bedtime for a prepubertal child, 135–150 g for a pubertal adolescent, and 135 g for an adult. Initiation of the therapy should be performed with very close monitoring as the response can be variable, and most children have initiation of the therapy in the hospital. Although the therapy has been used in Europe since 2009, long-term studies on Glycosade are lacking, and close follow-up is strongly recommended for anyone on the therapy.

Dietary fat should be restricted to about 20% of the total energy intake and cholesterol is restricted to <300 mg/d. Carbohydrates, mostly in the form of starches, typically provide about 60%–65% of the daily calories, of which cornstarch accounts for 30%–45%. Dietary galactose and fructose continue to be restricted along with restriction of sucrose.

Due to dependence on starch and the restrictions on fruit and dairy products, patients often have dietary intakes that are deficient in vitamins and essential minerals. Calcium and vitamin D supplementation are extremely important in combination with a daily multivitamin supplementation. Adult multivitamins can be used in children as long as the patient is monitored to avoid vitamin A toxicity. It is also important for iron concentrations to be monitored as iron absorption is typically abnormal in GSD I due to effects of cornstarch and abnormal hepcidin regulation.

Natural History and Prognosis

Prior to the 1970s, many children with GSD I died in infancy or early childhood. Recurrent severe hypoglycemia can cause brain damage, but the prognosis has improved dramatically with early diagnosis and long-term maintenance of optimal metabolic control.[19] Although most people with GSD Ia do well into adulthood, both acute and long-term complications remain common (Figure 50-2).

Hyperlactatemia is the most common acute complication of GSD Ia. Lactate is generated as a consequence of counter-regulation associated with hypoglycemia or secretion of stress hormones (cortisol, epinephrine, glucagon, growth hormone). Lactate can also result from increased counter-regulation when glucocorticoids, stimulants, or sympathomimetics are utilized. Elevated lactate concentrations are an under-recognized cause

of gastroesophageal reflux in young children. During illness, lactic acidosis alters gastric motility and causes vomiting. Lactate elevation acutely also presents as tachypnea, and it frequently is misdiagnosed as bronchiolitis in many infants and young children. Anesthesia and the stress of surgery cause increased secretion of counter-regulatory hormones, and severe lactic acidosis can develop despite maintenance of normal blood glucose concentrations.

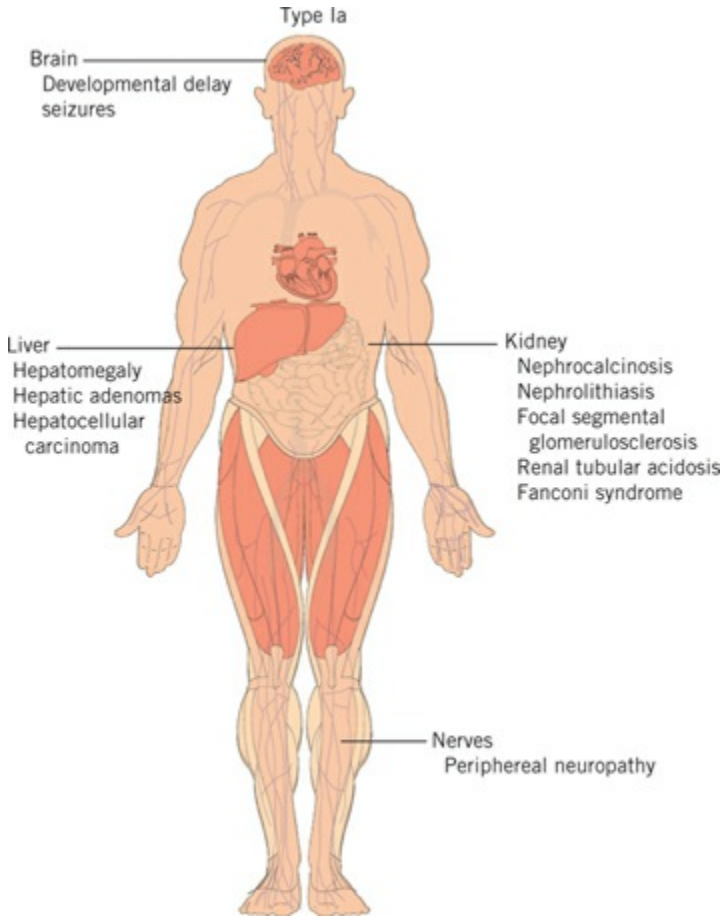

Figure 50-2 Complications associated with GSD type Ia.

There is increasing evidence that optimal metabolic control can prevent most long-term complications.[21] A strong link between suboptimal control (triglycerides over 500 mg/dL or lactates over 3 mmol/L) and complications including hepatic adenomas, renal disease, and osteoporosis has been demonstrated. Hepatic adenomas previously were detected in approximately 70% of patients by the end of puberty, but the prevalence of adenoma formation has been falling with improved metabolic control.[21,22]

The mean age at diagnosis is approximately 15 years, but adenomas occasionally develop during childhood.[23] There is no gender predisposition, and no difference has been found in the rate of adenoma formation in patients treated with cornstarch compared with those treated with continuous overnight intragastric drip feeding. Most adenomas remain stable over time, but they may be associated with hemorrhage or degenerate into hepatocellular carcinoma.[24] High alkaline phosphatase concentrations and elevation in the erythrocyte sedimentation rate (ESR) may be seen in patients with adenomas. Ultrasonography is the preferred screening method. When malignant transformation is a concern, magnetic resonance imaging using ferumoxide contrast provides greater definition and may be the best at differentiating benign adenomas from hepatocellular carcinoma.[25] Imaging is recommended at least annually after 5 years of age, and every six months if adenomas appear to be enlarging. Both α-fetoprotein and carcinoembryonic antigen have proven unreliable markers for determining malignant transformation.[24] As there are no good markers for determining development of hepatocellular carcinoma, resection of any lesion over 5 cm that is growing is recommended.

Treated children usually show no significant impairment of renal function except glomerular hyperfiltration. Some patients have a distal renal tubular acidification defect associated with hypercalciuria.[26] Urinary citrate excretion normally increases with age, whereas in GSD Ia, there is an inverse relationship between age and citrate excretion.[27] The combination of low citrate excretion and hypercalciuria appears to be important in the pathogenesis of nephrocalcinosis and nephrolithiasis. Citrate supplementation may prevent or ameliorate nephrocalcinosis and the development of urinary calculi. Increased albuminuria may be observed in adolescents. More severe renal injury with proteinuria, hypertension, and decreased creatinine clearance due to focal segmental glomerulosclerosis and interstitial fibrosis, which ultimately progresses to renal failure, may be seen in young adults.[28] Patients with persistently elevated concentrations of blood lactate, lipids, and uric acid appear to be at increased risk of nephropathy.[29] Normalization of metabolic parameters decreases proteinuria, and optimal therapy from an early age may delay or prevent renal disease.[19,29]

Anemia is common in patients with GSD Ia and is associated with suboptimal metabolic control.[30] Whereas anemia is usually mild, an unusual, unremitting iron resistant anemia occurs in a subset of patients.[31]

The anemia can be profound with hemoglobin concentrations as low as 4 g/dL and is characterized by microcytosis (mean corpuscular volume 50–70 fL), widening of the red cell distribution width (RDW), and iron studies consistent with iron deficiency. Neither erythropoietin nor treatment with oral and intravenous iron significantly improves the anemia. This form of iron resistant anemia has been associated with large hepatic adenomas (>7 cm in diameter) which inappropriately express hepcidin, a peptide that inhibits intestinal absorption of iron and macrophage recycling of iron. Resection of the hepatic adenomas has been associated with rapid correction of the anemia.[31]

With patients surviving into adulthood, osteoporosis is likely to be a common cause of morbidity.[32] Osteoporosis develops without abnormalities in calcium, phosphate, parathyroid hormone, or vitamin D metabolism.[33] Poor metabolic control has been associated with decreased bone mineral content. The etiology is likely multifactorial, including systemic acidosis, elevated cortisol concentrations, delayed pubertal development, inadequate dietary calcium, and lack of physical activity.[34]

Obesity is another common complication of GSD due to the need for constant carbohydrate intake. The caloric intake of patients should be monitored closely by a registered dietician. Patients benefit from carbohydrate counting as overconsumption of carbohydrate is common. Other complications, seen rarely in type Ia GSD, include pancreatitis, polycystic ovaries, and a bleeding diathesis.[35] Pancreatitis is related to hyperlipidemia, and treatment with Gemfibrozil or Niacin is recommended when hypertriglyceridemia persists despite attempts to improve metabolic control. Pancreatitis has been associated with use of growth hormone and glucocorticoids due to stimulation of glycogenolysis and worsening hypertriglyceridemia. Polycystic ovaries are common in poorly controlled GSD, but it does not appear to be inherent to the disease.[36] Fertility appears to be unaffected and more than 100 children have been born to mothers with GSD Ia. Platelet dysfunction associated with hyperlipidemia and acidosis is also a consequence of poorly controlled GSD. Bleeding is usually not a problem in patients in good metabolic control.

GLYCOGEN STORAGE DISEASE TYPE 1B

Type Ib GSD is caused by defects in the G6P transporter T1 that is responsible for transport of G6P into the lumen of the ER. The transporter is encoded by G6PT1 gene on chromosome 11q23 and is inherited in an

autosomal recessive manner.[37] The incidence is estimated to be 1 in 1,000,000 live births although the incidence of GSD Ib appears higher in Italy.

Pathophysiology

The inability of G6P to interact with the G6Pase enzyme prevents endogenous glucose production. Similar to GSD Ia, hepatomegaly and hypoglycemia develop shortly after birth. In contrast, however, patients with GSD Ib also manifest neutropenia and inflammatory bowel disease (IBD).[38] Immune dysfunction develops as a consequence of both disturbed myeloid maturation and functional defects of circulating neutrophils and monocytes. IBD is also attributed to neutropenia and impaired neutrophil function but persists despite granulocyte colony stimulating factor (G-CSF) therapy.[39]

Presentation

Symptomatic hypoglycemia may occur soon after birth, but most children present around 3–6 months of age. Neutropenia is occasionally the first abnormality noted during an evaluation for a serious bacterial infection usually from *Staphylococcus aureus*, *Streptococcus pneumoniae*, and *Escherichia coli*. IBD typically develops in the second decade, but it can present within the first few years of life.

Diagnosis

Full gene sequencing is commercially available. To date, approximately 70 mutations in the G6PT gene have been described.[40] Diagnosis by liver biopsy is not recommended; if performed, differentiation between the types requires an analysis of G6Pase activity in intact and fully disrupted microsomes as enzyme activity normalizes in type Ib when freezing disrupts the integrity of the ER. Typically, the diagnosis is made clinically when a patient with biochemical features of GSD I develops neutropenia and/or IBD.

Nutritional Management

The nutritional management of GSD Ib is the same as GSD Ia. Although GSD Ib is easier to manage metabolically, restriction of nonutilizable sugars is also critical in this condition.

Natural History and Prognosis

Long-term complications appear to be less frequent than in GSD Ia (Figure 50-3). IBD is the major cause of morbidity, and a Crohn's-like IBD almost universally develops by the end of puberty.[41] Periodic screening of inflammatory markers is recommended, and serologic studies may be of benefit if there is laboratory evidence of systemic inflammation.[42] A colonoscopy often is performed when IBD is suspected based on clinical features and laboratory studies, but a normal study does not rule out the condition. The IBD in GSD Ib frequently is isolated to the small intestine; consequently, a capsule endoscopy may reveal disease in patients in whom a colonoscopy reveals no evidence of bowel inflammation. Although the IBD responds to therapy with G-CSF, this comorbidity continues to occur even when neutropenia is treated.[43] Salicylate therapy (i.e., Pentasa) is the first line treatment of GSD enterocolitis. Entocort helps when terminal ileum disease is present, and Humira has been rarely needed when severe disease is present.[44] Patients with GSD Ib may benefit from probiotic therapy, but formal studies of this intervention are still lacking. Probiotics appear to prevent overgrowth of pathologic bacterial species, and treatment may decrease the frequency of IBD exacerbations and *Clostridium difficile* infections.

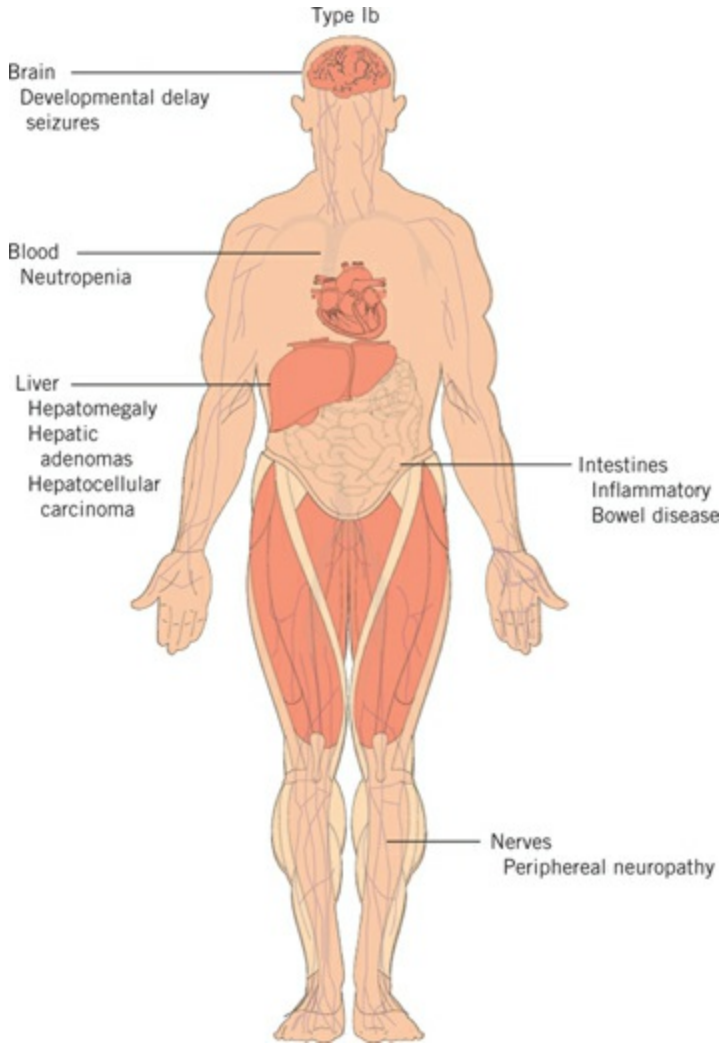

Figure 50-3 Complications associated with GSD type Ib.

Neutropenia occurs almost universally in GSD Ib, but the onset of this complication is variable. Low neutrophils are documented before the age of one year in two-thirds of patients, but neutropenia is first noted between the ages of six and nine years in 18% of patients.[38] Most patients had intermittent neutropenia without any clear cyclical course. Children with GSD Ib are prone to oral complications, including recurrent mucosal ulceration, gingivitis, and rapidly progressive periodontal disease. Therapy with recombinant human G-CSF improves infection-related morbidity by increasing numbers of circulating neutrophils and improving in vitro neutrophil function.[39] There is increasing evidence that overtreatment with G-CSF can be significant cause of morbidity, and recommended dosing in GSD Ib is lower than in other conditions. The recommended starting dose is 2.5 mcg/kg/d, and the lowest dose should be used that prevents serious

infections. Most children respond well to doses of 1–2 mcg/kg/d. Higher doses of G-CSF have been associated with hypersplenism, splenic ruptures, and esophageal varicies. Of concern is recent development of leukemia in several patients. Vitamin E supplementation has recently been reported to improve immune function, but studies on this intervention are limited.[45]

DEBRANCHING ENZYME DEFICIENCY (TYPE III GSD; CORI DISEASE; FORBES DISEASE)

Type III GSD is caused by a deficiency of the glycogen debranching enzyme. The incidence of GSD III is estimated to be 1 in 100,000 live births. Populations with a high incidence of GSD III include people from the Faroe Islands, people from the Indian subcontinent, and Jews of North African descent.[46,47] GSD III is inherited in an autosomal recessive manner with the gene for the debranching enzyme located on chromosome 1p21.[48] There are four distinct isoforms with differentially expressed clinical phenotypes associated with specific mutations.[49] Type IIIa affects both liver and muscle and accounts for 80%–85% of patients with GSD III in the United States; type IIIb affects only the liver and accounts for approximately 15% of patients.[2]

Pathophysiology

Release of glucose from glycogen requires sequential action of both glycogen phosphorylase and glycogen debranching enzyme. After glycogen phosphorylase has acted on the outer branches of glycogen leaving four glucose residues, the debranching enzyme utilizes two distinct catalytic activities to remove them. The first is a transferase activity that transfers three of the four glucosyl residues distal to the glycogen branch point to the outer end of an adjacent chain. Secondly, the amylo-1,6-glucosidase activity of the same enzyme also hydrolyses the branch point glucose residue. Without the function of the debranching enzyme, the breakdown of glycogen is interrupted with an abnormal form (limit dextrin) left to accumulate in affected tissues.[3]

Presentation

Type III GSD exhibits wide clinical and genetic variability. In infancy and early childhood, fasting hypoglycemia and hepatomegaly may be indistinguishable from GSD I; however, unlike GSD I, blood levels of

lactate and uric acid are normal. Biochemical abnormalities include elevated aspartate transaminase (AST), alanine transaminase (ALT), creatine kinase concentrations, and hyperlipidemia.[50] Serum transaminase concentrations are typically considerably more elevated than in GSD I, and often the AST and ALT concentrations are over 1000 U/L at presentation. Creatine kinase concentrations may be normal at presentation, and normal concentrations do not exclude muscle involvement.

Diagnosis

Mutation analysis from full gene sequencing is commercially available for the diagnosis of both type IIIa and IIIb GSD. Measurements of enzyme activity from biopsy of liver and muscle as well as demonstration of abnormal glycogen (limit dextrin) were the standard in diagnosis prior to mutation analysis. Skin fibroblast or lymphocyte enzyme activity can be used to screen for GSD III, but these studies may not be definitive and cannot be used for subtyping. A fasting study demonstrates ketotic hypoglycemia without the hyperlactatemia characteristic of GSD I. Glucagon fails to elicit a glycemia response after a fast, but does elicit a glycemic response when given two hours after a carbohydrate-rich meal.

Nutritional Management

In this type of GSD, gluconeogenesis can occur and protein can therefore be utilized as a substrate for endogenous glucose production. In infancy, hypoglycemia can be problematic, and patients are treated with a high protein diet (3 g/kg) along with intermittent cornstarch therapy. Without cornstarch, hypoglycemia and ketosis invariably occur, but treatment with 1–1.75 g/kg at four- to six-hour intervals during both day and night maintains normoglycemia, increases growth velocity, and decreases serum transaminase concentrations.[51] As patients get older, hypoglycemia is less common, and the minimum amount of cornstarch is used to maintain normoglycemia. Continuous nocturnal feeding of a nutrient mixture consisting of glucose or glucose oligosaccharides, and protein or amino acids, combined with intermittent high protein feedings during the day may be especially beneficial for patients who have significant growth retardation and myopathy.[52] In GSD III, galactose and fructose can be converted into glucose, and strict restriction of these sugars is not necessary. Overstorage of carbohydrates can be problematic, and concentrated sweets should be avoided to avoid excessive glycogen storage.

Natural History and Prognosis

Patients with type III GSD typically do well throughout childhood and as young adults, but complications can occur as patients get older (Figure 50-4). Hepatic adenomas can develop in adults with GSD III, but the frequency is much less than in the GSD I population. Cases of hepatocellular carcinoma have been reported.[22] Hepatic fibrosis is common in children with both GSD IIIa and IIIb, and cirrhosis and portal hypertension can develop.

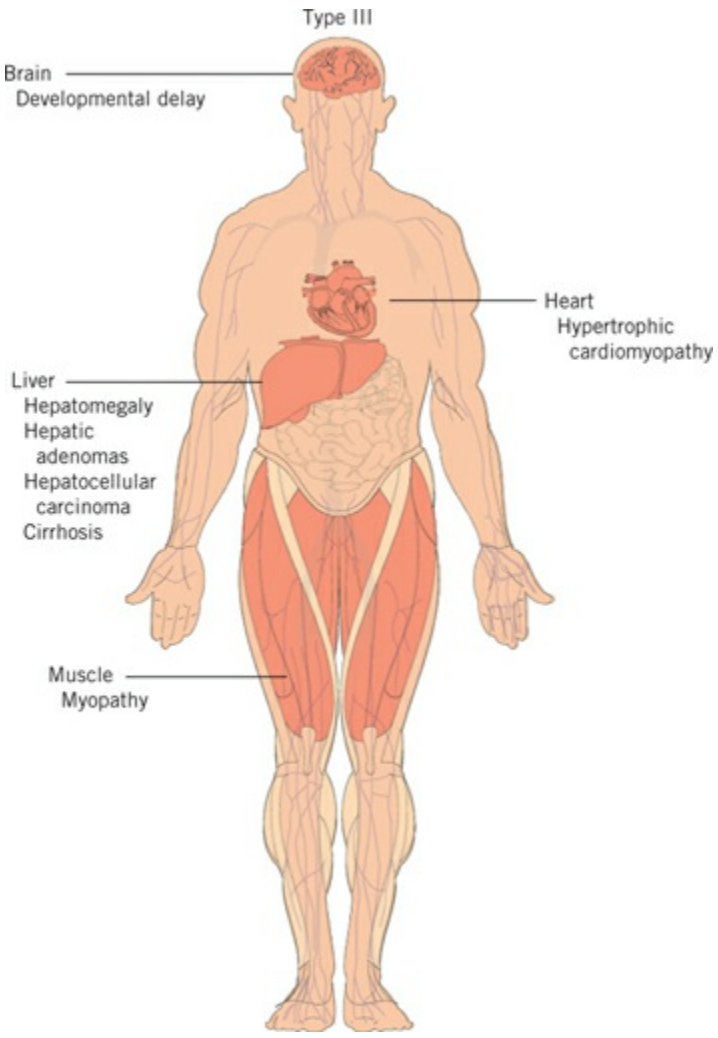

Figure 50-4 Complications associated with GSD type III.

With GSD IIIa, complications related to the muscle disease become increasingly common with aging. In the third to fourth decades of life, myopathy becomes prominent with slowly progressive muscle weakness.[53] Exercise is restricted because it causes elevations in serum creatine kinase

and aldolase concentrations. Unlike in McArdle's disease (GSD V), treatment with carbohydrate prior to exercise does not prevent muscle damage or symptomatology.[54]

Cardiac complications may also develop in patients with GSD IIIa. Usually by the time a child has finished puberty, concentric left ventricular hypertrophy is detectable by echocardiography. Ventricular function is usually normal, but severe cardiac dysfunction and arrhythmias can occur.[55] Rare cases of severe cardiomyopathy in infants and children have been reported, so annual echocardiograms are recommended for all children with GSD IIIa. The hypertrophic cardiomyopathy in GSD III appears largely due to overtreatment with carbohydrate. Restriction of carbohydrate intake and a high protein diet has successfully resulted in decreased ventricular hypertrophy and improved function.[56,57]

Liver transplantation in GSD III is not recommended. Normalization of glucose concentrations does not prevent cardiac or muscular disease, and transplantation may hasten the development of complications.[58] Several of the immunomodulators, including cyclosporine, may exacerbate the myopathy leading to earlier clinical deterioration. Since liver pathology is not the major source of morbidity in GSD type IIIa, liver transplantation should only be performed when there is high risk for hepatocellular carcinoma or evidence of substantial cirrhosis or liver dysfunction.

GLYCOGEN PHOSPHORYLASE DEFICIENCY (TYPE VI GSD; HERS DISEASE) AND GLYCOGEN PHOSPHORYLASE KINASE DEFICIENCY (TYPE IX GSD)

Both types VI and IX GSD result from impaired glycogenolysis. Type VI GSD is due to hepatic phosphorylase deficiency, whereas type IX GSD results from abnormal phosphorylase kinase (PHK) activity, the enzyme that activates hepatic phosphorylase. Phenotypically, these diseases are similar, and they are therefore discussed as one entity in this section. Their estimated prevalence is approximately 1 in 100,000, but this is almost certainly an underestimation. Together, they account for approximately 25%–30% of all cases of GSD.[59] Type IX GSD is more common in people of Scandinavian heritage, and 1 in 1000 people of Mennonite heritage have type VI GSD.[60]

The hepatic glycogen phosphorylase gene (PYGL) is located on

chromosome 14q21-22 and is inherited in an autosomal recessive manner.[2] PHK is present in liver and muscle, and it is a complex enzyme consisting of four subunits: α, β, δ, and γ. The α-subunit is encoded by the PHKA2 gene located on Xp22.2-p22.1 and is inherited as an X-linked disease. The β-subunit is encoded by PHKB2 gene on chromosome 16q12-q13, and mutations are inherited as an autosomal recessive variant of GSD IX. The γ-subunit, encoded by the PHKG2 gene on chromosome 16p11-p12, contains the catalytic site of the PHK enzyme and is inherited autosomal recessively.[2]

Pathophysiology

Glycogen phosphorylase is the rate-limiting step in glycogenolysis stimulating the hydrolysis of the outer branches of glycogen. Glycogen PHK deficiency results in failure to activate glycogen phosphorylase. Fortunately, these disorders are typically mild and can be confused with "ketotic hypoglycemia." Mild hyperlipidemia and elevation in liver enzyme concentration are common in untreated children, whereas lactic acid and uric acid concentrations are typically normal.

Presentation

Fasting ketotic hypoglycemia is the cardinal manifestation although typically milder than GSD I and III. Children are usually discovered when hepatomegaly is detected on a routine physical examination or when hypoglycemia occurs as a consequence of prolonged fasting during an intercurrent illness.[61]

Diagnosis

It is possible to diagnose glycogen PHK deficiency by assaying the activity of the enzyme in leukocytes and erythrocytes. The blood assay, however, lacks sensitivity as there are liver, muscle, heart, and brain isoforms of this enzyme. Mutation analysis is now the preferred method for diagnosing these conditions. Sequencing of the PHKA2 gene (GSD IX alpha) is usually performed first in males; GSD VI is more common in females suspected of having one of these conditions. Mutations in the PHKB or PHKG2 genes are less common causes of GSD IX.[62]

Nutritional Management

The goal of treatment is to prevent hypoglycemia, normalize plasma ketone concentrations, and minimize systemic acidosis. Frequent small

meals are supplemented with UCS (1.5–2 g/kg given one to two times per day). Occasionally, children with GSD IX may have severe hypoglycemia and a phenotype similar to that of GSD I. Even when more prolonged fasting can be tolerated without development of hypoglycemia, most children and adults report improved energy and well-being with bedtime cornstarch administration because ketosis is prevented.[63] A high protein (2–3 g/kg/d) and a complex carbohydrate diet is recommended. Restriction of simple sugar intake results in decreased hepatomegaly.

Natural History and Prognosis

The prognosis of patients with GSD VI and IX is excellent. Treatment, however, improves growth and stamina in patients with these milder forms of GSD. Although most patients do very well, a more severe variant associated with significant hepatic transaminase elevation, hepatic fibrosis, and cirrhosis has been described in patients with mutations in PHKA2 or PHKG2.[64] There is evidence that aggressive treatment may delay or prevent onset of these complications.[65] Muscle symptoms occur occasionally, and these disorders are rarely associated with a proximal renal tubular acidosis and neurologic abnormalities.[66] A severe cardiac-specific PHK variant that can lead to cardiac failure has been reported.[67] Hyperlipidemia is common in untreated children and adults, and untreated adults may be at higher risk for cardiovascular disease.

Acute and Chronic Kidney Disease

51

Nutrition in Renal Disease

Nancy M. Rodig, MD

The following chapter will outline principles for the nutritional management of children with both acute and chronic disturbances of renal function. A significant decline in glomerular filtration rate will impair nitrogenous waste excretion; alter regulation of water, electrolyte, and acid–base homeostasis; and challenge the provision of optimal nutrition. This chapter will begin with a discussion of the nutritional management of acute kidney injury, which may be associated with a rapid decline in glomerular filtration rate and urine flow. Given the extreme physiologic abnormalities that may accompany severe acute kidney injury, the nutritional care of the critically ill child will be emphasized. The discussion will then turn to the care of children with chronic kidney disease, who are at increased risk for chronic malnutrition and growth impairment. Noting the shared issues faced by children with chronic kidney disease and those on maintenance dialysis, the nutritional management of these children will be discussed together. The nutritional care of children who have received renal transplantations will then be reviewed. As the range of clinical manifestations of both acute and chronic renal failure is broad, the need for individualized nutritional management is emphasized throughout.

ESTIMATION OF GLOMERULAR FILTRATION

RATE

Glomerular filtration rate (GFR) is equal to the sum of the filtration rates of all functioning nephrons and reflects functioning renal mass. Estimation of GFR allows clinicians to determine the severity and course of both acute and chronic disturbances of renal function and permits anticipation of necessary changes in therapy, including adjustments of nutritional support. The "gold standard" to measure GFR had been measurement of inulin clearance; however, this study is cumbersome and rarely employed in routine clinical practice. Alternatively, creatinine clearance based on a timed urine collection is readily available, though the collection is inconvenient, prone to error, and impractical in children who are not toilet trained. Estimation of GFR based on equations using serum creatinine and other variables such as age, height, and gender is convenient and easy to perform at the bedside. The Schwartz formula[1–3] (Table 51-1) and the Modification of Diet in Renal Disease (MDRD) formula[4] have gained widespread clinical use in North America for children and adults, respectively. Given the tubular secretion of creatinine and changes in methods used to measure creatinine, the Schwartz formula tends to overestimate GFR, and this overestimation increases with decreasing renal function.[5,6] More recently, data generated from the Chronic Kidney Disease in Children (CKiD) study have permitted the development of an updated and more accurate Schwartz formula, estimating GFR (creatinine clearance) from serum creatinine, the child's height, and a fixed proportionality constant[7]:

GFR (mL/min/1.73 m^2) = height (cm) × 0.413/serum creatinine (mg/dL)

This formula was developed from a study of children with mild to moderate CKD and is most useful in a GFR range of 15–75 mL/min/1.73 m^2. The updated Schwartz formula is less accurate in children with more normal renal funciton[8] and has not been validated in children with acute kidney injury. If an exact measurement of GFR is necessary, this can be determined by plasma disappearance of iohexol, a safe, nonionic, low-osmolar contrast agent. This study should be performed if renal function is believed to be stable, as the expense and effort would be not well spent if renal function is dynamic.

ACUTE KIDNEY INJURY

Acute kidney injury (AKI) is defined by a rapid and usually reversible

deterioration in GFR. Depending on the severity of the insult, AKI may be accompanied by impairment of acid–base homeostasis and loss of water and electrolyte regulation. In mild cases, nonoliguric AKI may be asymptomatic and only be detected when serum laboratory studies are performed. When severe, oliguric AKI may result in significant derangements of electrolyte and volume balance and necessitate the initiation of renal replacement therapy. Given the lack of a standardized definition of AKI, studies to identify preventive and therapeutic measures have been confounded. To address this classification, definitions have been proposed for adults, including the RIFLE[9] and AKIN criteria.[10] The RIFLE criteria consists of three levels of kidney dysfunction (Risk, Injury and Failure), and a pediatric modification of the RIFLE criteria (pRIFLE) has been validated and should facilitate the evaluation and treatment of children with AKI.[11]

The etiology of AKI has changed with advancement of medical and surgical practice, and this trend is most apparent in tertiary care centers. In referral centers, AKI due to primary renal disease is now less frequent than failure, secondary to ischemia, drug toxicity, or sepsis in children.[12] Underlying comorbidities or chronic conditions in critically ill children who develop AKI have been reported in as many two-thirds of these patients.[13,14] As in adults, the reported mortality for children with AKI is high, reaching 30%–40% and is greatest for those who require dialysis.[15–18] Preexisting or hospital acquired malnutrition has been identified as a contributing factor to the poor outcome of severe AKI,[19] and providing adequate nutrition should be viewed as a crucial element in the therapeutic effort.

TABLE 51-1 Estimation of GFR by the Schwartz Formula

$C_{cr} = k \times L/S_{cr}$

C_{cr} = creatinine clearance in mL/min/1.73 m^2

k = proportionality constant values:

Low birth infants during first year of life = 0.33
Full-term infants during first year of life = 0.45
Children and adolescent girls = 0.55
Adolescent boys = 0.7

L = length (cm)

S_{cr} = serum creatinine (mg/dL)

Nutritional support obligates the administration of volume, either in the form enteral feeds, intravenous nutrition, or a combination of these. If AKI is accompanied by anuria or oligoanuria (urine flow < 0.5–1 mL/kg/h), nutrition will be limited or volume status will be worsened unless renal replacement therapy is initiated. The modality of renal replacement therapy is determined based on the clinical status of the patient and the expertise of the center. Options for renal replacement therapy include peritoneal dialysis and hemodialysis, and hemodialysis may be performed on an intermittent or continuous basis. For hemodynamically stable patients with AKI, intermittent hemodialysis is typically performed daily for 2–4 hours per session depending on the size of the patient. During the several hour treatment, ultrafiltration of the daily fluid requirement in additional to any other desired fluid removal is attempted as hemodynamically tolerated. If the patient is hemodynamically unstable, continuous renal replacement therapy (CRRT) allows for gradual ultrafiltration of fluid and is the modality of choice in such patients.[20] Two commonly used modalities of CRRT are continuous venovenous hemodiafiltration (CVVHD) and continuous venovenous hemofiltration (CVVH). CVVHD provides clearance by primarily diffusive mechanisms with some convective clearance, whereas continuous CVVH uses solely convective clearance.

AKI: Energy Requirements

Though an essential component of care, the nutritional management of children with AKI has been insufficiently studied. The need to provide adequate nutrition is of particular importance in critically ill children who have sustained AKI, as the high prevalence of malnutrition in this group is associated with excessive morbidity and mortality.[21,22] Timely initiation of appropriate nutrition is essential to optimize tissue healing and organ recovery, though the lack of sufficient data to propose evidence-based recommendations is notable and underscores the need for study. Careful assessment of energy requirements in children with AKI is essential, though challenging. Inadequate caloric provision will result in poor protein retention, and excessive nutrition increases the risk for metabolic derangement and fluid excess.

Total energy requirements include resting energy expenditure, energy needed for physical activity, and diet-induced thermogenesis. In patients with uncomplicated AKI, energy expenditure has been shown to be comparable to healthy subjects as measured by indirect calorimetry.[23] AKI associated with sepsis or multiorgan dysfunction results in increased energy expenditure, and the increase in expenditure is believed to be proportionate to the underlying process leading to the critical illness.[24] Predicting energy needs based on the severity of illness is often inaccurate.[25] When the resting energy expenditure of 33 critically ill children was measured by indirect calorimetry, 55% of subjects were hypometabolic and 17% were hypermetabolic.[26] One study of critically ill adult patients compared the energy expenditure of patients who required dialysis for severe AKI to those who had normal or only moderately impaired renal function. These patients demonstrated increased energy expenditure, though there was significant individual variation. The measured energy expenditure was greater for those who required only supportive measures than for those who required dialysis with average hypermetabolism measured at 42% and 28%, respectively. It was proposed that AKI reduced energy demand secondary to diminished renal metabolic activity.[27] When based on predictive equations, studies of critically ill children with AKI demonstrate a high prevalence of insufficient energy provision.[28] The use of indirect calorimetry allows nutrition to be tailored to the needs of the individual patient and is the preferred method when feasible, though lack of expertise and resource constraints may be limiting. When assessment by indirect calorimetry is not possible, energy expenditure can be predicted according to the Schofield prediction equation[29] and the American Society for Parenteral and Enteral Nutrition guidelines for critically ill children.[30] Given the dynamic nature of illness and the complexities of predicting metabolic state, the use of standard equations is prone to inaccuracies.

The general recommendation for adult patients with AKI is that energy intake be tailored to the individual patient, and an early study based on indirect calorimetry suggested that AKI and sepsis increased energy needs up to 30%.[23,31–34] Pediatric patients with AKI who are relatively well and nonoliguric are unlikely to have significantly increased energy requirements. In contrast, critically ill children will have expenditures concordant with the severity of their illness. However, given the potential risks for both under and overfeeding,[26] targeted indirect calorimetry should be considered for children at high risk for metabolic alterations,

such as those with prolonged ICU stay, unexpected fluctuations of weight, or evidence of persistent inflammatory state. The reader is referred to Chapter 62 for further guidance regarding energy requirements for the critically ill child.

Hyperglycemia is not uncommon in critically ill patients with AKI. The potential for altered carbohydrate metabolism must be considered given that standard nutrition provides the majority of calories from dextrose, and patients on dialysis are delivered additional dextrose from dialysate. Hyperglycemia is a consequence of both accelerated hepatic gluconeogenesis and insulin resistance. Increased hepatic gluconeogenesis results from conversion of amino acids released during protein catabolism.[35] The kidney plays a direct role in glucose homeostasis, which is regulated by insulin.[36] During AKI, insulin resistance may be more likely given the loss of the kidney as a major target organ for insulin action. The consequences of insulin resistance and hyperglycemia have been shown to be significant. Both were associated with increased mortality in critically ill adults with AKI.[37] Critically ill infants and children who demonstrated sustained hyperglycemia suffered a threefold increase in mortality over those with well-controlled glycemia.[38] Hyperglycemia has also been correlated with prolonged ventilator dependency and increased length of hospital stay.[39] Given the association of hyperglycemia with increased complications and worse prognosis,[40] efforts to maintain normoglycemia should be made, though there is insufficient data to recommend strict glycemic control in children. Furthermore, the risks of attempting strict glycemic control, such as hypoglycemia, must be acknowledged.

AKI: Protein Requirements

AKI is a state of increased catabolism, which parallels the severity of the underlying illness. During metabolic stress, the catabolism of skeletal muscle allows for the generation of glucose, which is the preferred substrate for the brain, red blood cells, and renal medulla. This stress response is an effective short-term adaptation, though a prolonged response is maladaptive and can result in reduction of lean body mass. Studies evaluating critically ill adults with AKI have reported high protein catabolic rates.[41] Virtually all nitrogen arising from amino acids liberated during protein degradation is converted to urea, and the extent of protein catabolism may be assessed by calculating urea nitrogen appearance (UNA). In dialysis patients, UNA equals the sum of the urea in the dialysis

ultrafiltrate, urine, and the change in the body nitrogen pool. The UNA of critically ill children with AKI maintained on CRRT was evaluated in an early study and measured to be >180 mg/kg/day.[42] This compares to a mean UNA of 103 mg/kg/day among children on maintenance (chronic) peritoneal dialysis who are at baseline health.[43] Increased protein catabolic rate was confirmed in a subsequent report of critically ill pediatric patients on CVVH and CVVHD with mean UNA of 291 and 245 mg/kg/day, respectively. Nitrogen balance, defined as the difference between nitrogen intake and UNA, was often negative in these patients despite the provision of 1.5 g/kg/day of protein.[24]

If the care of a patient with AKI requires dialysis, the modality of dialysis must be considered when determining protein requirements. Hemodialysis leads to nitrogen loss, as amino acids and small peptides are filtered across the dialysis membrane.[44,45] During continuous dialysis, there will be continuous nitrogen loss. One study of pediatric patients on CRRT measured amino acid clearance to be 12% and 11% of daily protein intake on CVVH and CVVHD, respectively.[24] A subsequent study measured amino acid clearance while on CVVHD to be 20% of protein intake.[46] Peritoneal dialysis also results in significant protein losses through the dialysis effluent, and the degree of protein loss varies inversely with the body surface area of the child. Peritoneal protein loss was highest in infants (277 ± 22 mg/kg/day) and lowest in children who were above 50 kg (91 ± 15 mg/kg/day).[47]

Adult studies suggest protein intake for patients supported on dialysis should be between 1.8 and 2.5 g/kg/day with the lower range appropriate for those on intermittent dialysis and the higher range needed to achieve positive nitrogen balance for those on CRRT.[48,49] Data supporting recommendations for protein intake in pediatric patients with AKI are lacking. A child with uncomplicated AKI should be provided protein in the amount recommended for age with adjustment to provide ongoing needs. While protein intake is increased, electrolytes, acid–base balance, and uremia should be assessed daily. Nutritional guidelines for critically ill children estimate protein requirements to be 2–3 g/kg/day for 0–2 years, 1.5–2 g/kg/day for 2–13 years, and 1.5 g/kg/day for 13–18 years.[30] Should the child require renal replacement therapy, particularly continuous modalities of hemodialysis, amino acid clearance up to 20% of protein intake should be accounted for. Adjustment of protein intake is recommended with a broad goal of maintaining blood urea nitrogen (BUN) >40 mg/dL and <80 mg/dL.

AKI: Micronutrient Requirements

Trace element requirements in AKI are not clearly defined. Most recommendations are extrapolated from data studying patients with chronic kidney disease. In addition, many of the findings regarding trace element metabolism in AKI may represent the effect of the acute phase response and not necessarily reflect specific effects induced by AKI. As trace elements have small molecular weights and critical illness results in altered protein binding, hemodialysis will alter homeostasis. In vitro data have demonstrated clearance of trace elements during CVVH, including selenium, chromium, copper, and zinc.[50] The ultrafiltration rate or rate of convective fluid removal, was a significant factor affecting clearance. However, other studies evaluating micronutrient losses in patients on CRRT have demonstrated varying results.[51,52] Variations likely stem from differences in patient population, CRRT method, and assays employed. One study confirmed clearance of selenium.[53] As selenium is cofactor for the antioxidant glutathione peroxidase enzymes, impaired defense against antioxidant stress is of concern. Further studies are needed to determine trace element requirements in renal failure.

Recommendations for vitamin supplementation during AKI are provided by the ASPEN guidelines.[54] Additional water-soluble vitamins should be administered if the patient is on hemodialysis to replace expected losses. Supplementation with folate, vitamin B_{12}, pyridoxine, thiamine, and riboflavin is recommended. Vitamin C is metabolized to oxalate, which can accumulate in patients with AKI and result in renal tubule toxicity. Oxalate accumulation has not been adequately studied in AKI and until further pediatric data are available, supplementation of vitamin C should not exceed the recommended daily intake. Fat-soluble vitamins may accumulate in CKD, as they are not removed with dialysis. Little data regarding fat-soluble vitamins in AKI are available, though deficiencies, with the exception of vitamin K, have been reported.[55] ASPEN guidelines recommend supplementation of fat-soluble vitamins if the duration of AKI is limited (i.e., <2 weeks).

AKI: Electrolyte Homeostasis

The kidneys are responsible for the normal homeostasis of many electrolytes, and AKI predisposes the patient to electrolyte and acid–base disorders. Full discussion of electrolyte physiology in the setting of altered renal function is beyond the scope of this chapter, though a limited discussion is provided to serve as a basis for nutritional planning.

Given the potential for life threatening arrhythmias, hyperkalemia is a dreaded consequence of AKI. Potassium is the most abundant intracellular cation, with less than 2% of total body potassium present in the extracellular fluid. As potassium is primarily renally excreted, decreased GFR and renal tubular damage may result in significant hyperkalemia. In addition to decreased excretion, hyperkalemia may result from transcellular shift induced by acidosis and increased extracellular load secondary to enhanced cell turnover, hemolysis, or transfusion of red blood cell products. Therefore, potassium should be withheld during evolving AKI until acceptable potassium homeostasis is assured. If dialysis is initiated, potassium clearance should be anticipated if the dialysate contains no or little potassium. While on CRRT, potassium will be cleared continuously. If clinically appropriate, potassium salts may be added to the dialysate (typically up to 3 mEq/L) to mitigate the tendency for hypokalemia.

Similar to hyperkalemia, hyperphosphatemia is a common complication of oliguric and anuric renal failure. Phosphorus is the major intracellular anion with less than 1% present in the extracellular space. Serum phosphorus occurs in two forms, organic and inorganic. The inorganic fraction is the principal circulating form and routinely assayed for clinical use. When GFR is within the normal range and renal tubular function is intact, approximately 90% of serum inorganic phosphorus is filtered, and ~80%–90% of filtered phosphorus is reabsorbed. In AKI, hyperphosphatemia may cause hypocalcemia as a result of calcium–phosphate precipitation, which typically begins when the calcium × phosphorus product is greater than 70. Treatment for hyperphosphatemia includes restricting or eliminating all sources of phosphorus and administrating oral phosphate binders with enteral feeds. Calcium carbonate and calcium acetate are commonly used phosphorus binders in this setting and will provide supplemental calcium, which may be beneficial if hypocalcemia has developed. If the patient is hypercalcemic, noncalcium containing binders such as sevelamer carbonate should be considered.

AKI: Routes of Nutrition

After estimating the nutritional needs of a child with AKI, the next challenge is to determine the appropriate route of nutrition. If the child's gastrointestinal tract is functioning, enteral nutrition is the preferred method of support for the critically ill patient. Proposed benefits of enteral nutrition include intestinal trophism, reducing bacterial translocation, and

cost effectiveness.[56,57] Early initiation of enteral nutrition has shown benefits in both adults[58] and children[59] with respect to decreased incidence of septic complications and improved prognosis.[60] A specific benefit of enteral feeds in the setting of oliguric AKI is the potential for providing concentrated nutrition and thereby limiting fluid intake.

Though enteral feeds are preferred, they may not be tolerated in critically ill patients. The underlying illness and need for vasoactive medications may compromise gastrointestinal perfusion. An additional concern in the setting of AKI is the detrimental effect of uremia on gastrointestinal motility. Nasogastric feeds were well tolerated when applied carefully to a population of adult patients with AKI without significant increase in major gastrointestinal complications.[61] To decrease the risk of aspiration and improve tolerance of feeds when gastric emptying is delayed, transpyloric feeds should be considered. When critically ill children with and without AKI were studied, continuous transpyloric feeds were associated with increased gastrointestinal complications, including abdominal distension and excessive gastric residue. However, transpyloric feeds were overall effective and well tolerated.[62,63] Presently there is insufficient evidence to support gastric versus postpyloric feedings, though post-pyloric feeds should be considered in patients at significant risk for aspiration and for those who fail gastric feedings.[30]

If enteral feeds are initiated, both standard formulas and formulas appropriate for decreased renal function are available. Similac PM60/40 is an infant formula with lower mineral content suitable for infants with acute reduction of renal function, though more commonly utilized in chronic kidney disease. Suplena and Nepro are specifically designed for patients with chronic kidney disease who are predialysis and dialysis dependent, respectively. A selection of formulas are highlighted in Table 51-2. to permit comparison of caloric and mineral content; full nutritional content is available in Appendix III. Feeds should be initiated with hypo- or normocaloric formula at low rates of 0.5–1 mL/kg/h with gradual increase to normal caloric delivery for age over 36–48 hours as tolerated. Gastric residuals and abdominal exams should be monitored closely with advancement.[63] If the patient is volume restricted, the rate should be increased to the target volume and then gradually fortified using modular components to meet nutritional needs. To optimize digestibility, similar proportions of fat, protein, and carbohydrate should be used. In patients on CRRT, amino acid and small peptide losses may challenge the ability to

supply adequate protein enterally. If indicated, administration of 10% amino acids may be considered to achieve desired goals.[61]

In critically ill patients with AKI, enteral feeds often cannot meet nutritional needs. Parenteral nutrition (PN) combined with enteral support or total PN may be necessary. A balanced PN regimen usually provides 10%–20% of total calories by amino acids, 50%–60% of calories by dextrose, and 20%–30% by lipid emulsion. Modification of PN should be performed based on amino acid losses and dextrose absorption from dialysis therapies, especially in CRRT. Electrolyte composition should be guided by regular assessment of serial laboratory studies.

CHRONIC KIDNEY DISEASE

Chronic kidney disease (CKD) is defined as kidney damage based on persistent structural or functional abnormalities, which may be associated with reduced or normal GFR. In children, CKD arises more commonly from congenital than acquired renal disease. When reviewing registry data of children with CKD, the most common primary diseases were obstructive uropathy (21.1%), renal aplasia, hypoplasia, and dysplasia (17.5%), and reflux nephropathy (8.4%). Focal segmental glomerulosclerosis, an acquired glomerulopathy, accounted for 8.7% of cases.[64] When kidney damage is significant, there is progressive loss of functioning nephron mass leading to end-stage renal disease (ESRD). In 2002, the Kidney Disease Outcomes Quality Initiative (K/DOQI) of the National Kidney Foundation (NKF) proposed definition criteria and a classification scheme defining the stages of CKD (Table 51-3).[65] Given the importance of early detection and intervention, guidelines to facilitate the detection of kidney disease in children and adults have been proposed.[65,66] When compared to adult onset CKD, persistent kidney disease during childhood poses unique challenges, including abnormal growth. Despite advances in medical management, growth in children with CKD remains suboptimal.

TABLE 51-2 Standard and Renal Specific Formulas and Supplements

		Protein	Na	K	Ca	P
Product (manufacturer)	**kcal/mL**	**g/1000 mL**	**mEq/1000 mL**		**mg/1000 mL**

Recent data regarding growth outcomes of children with CKD is provided by the National Institute of Health sponsored CKiD study, a prospective study of North American children with mild to moderate CKD.[67] The median height standard deviation score (SDS) was −0.57, and 13% of the children had severe short stature as defined by a height SDS ≤ −1.88. Only ~25% of children with severe short stature were receiving recombinant human growth hormone (rhGH), a therapy proven safe and efficacious in children with growth failure associated CKD (CKiD paper). Lower levels of renal function and severe metabolic acidosis (CO_2 < 18 mEq/L) were associated with deficits of both height and weight. Of note, when compared to height growth, the weight of these children was relatively preserved, particularly in children with glomerular cause of kidney disease. The combined prevalence of overweight or obese children with CKD was comparable to the general population of children and adolescents in the United States when defined by age-based body mass index. Longitudinal studies of growth in the CKiD cohort are ongoing.

The youngest children with CKD comprise the most vulnerable population at risk for severe growth deficiency.[68] In the healthy state, one-third of total postnatal stature is achieved in the first two years of life. It is during this critical time that a significant loss of height potential can occur. The European Study Group for nutritional treatment of chronic renal failure in childhood identified infants with early onset chronic renal failure had lost approximately one standard deviation of height during fetal life and another standard deviation was lost by the third postnatal month.[69] This finding was consistent with reported average birth length of −0.74 SDS in 12 infants with chronic renal failure[70] and more recently corroborated in a report of the International Pediatric Peritoneal Dialysis Network.[71] In this study of over 150 children, the mean birth length was

−0.47 SDS, supporting a link between intrauterine growth and kidney disease.

An essential component of the care of children with CKD is the provision of adequate nutrition and regular evaluation of nutritional status. In 2008, the Kidney Disease Outcome Quality Initiative (KDOQI) Pediatric Clinical Practice Guideline for Nutrition in Chronic Renal Failure was revised and expanded.[72] While recognizing the lack of available data pertaining to nutrition in children with CKD, the recommendations were based on available evidence and expert opinion. The guideline provides recommendations for the evaluation of growth, nutritional status, and nutritional requirements for children with CKD stages 2–5 and includes recommendations for children on dialysis (CKD stage 5D). Though historically a focus has been directed at the recognition and treatment under nutrition, there is more recent evidence that obesity is an emerging problem in children with kidney disease.[67,73]

TABLE 51-3 Stages of Chronic Kidney Disease

CKD stage	GFR (mL/min/1.73 m^2)	Description: kidney damage with
1	>90	Normal or increased GFR
2	60–89	Mild decrease in GFR
3	30–59	Moderate decrease in GFR
4	15–29	Severe decrease in GFR
5	<15	Kidney failure
5D	<15	Kidney failure treated with dialysis

If available, the support of a renal dietician is indispensable in optimizing the dietary management of children with CKD. The modification of food and fluid intake proves to be challenging for most. Every child with CKD and their careprovider should receive nutritional counseling based on individual needs. In addition to addressing the specifics of the renal disease process, education level and social influences of the family must be considered. The dietary care plan requires appropriate modification based on the changes in the child's age, nutritional status, renal function, treatment modality, and medication regimen. Depending on the disease time course, a renal dietician may support an individual through the various stages of renal insufficiency,

maintenance dialysis, and renal transplantation. Families often need continual guidance and support to establish and consistently enforce prescribed dietary guidelines. Nutritional specialists can ease the burden of restrictions and increase the likelihood of success by providing practical suggestions for modifying or replacing favorite foods or fluids.

Though inadequate nutrition will negatively impact growth in children with CKD, the variable response to nutritional support highlights the complexity of growth impairment in this population. Alterations in the growth hormone (GH)/insulin-like growth factor-1 (IGF-1) axis independently affect growth in the uremic milieu. Although serum GH and IGF-1 levels are usually normal or high in growth-retarded children with CKD, uremic serum has high IGF-1 binding capacity that results in low IGF-1 bioactivity.[74] In conjunction with optimal medical and nutritional management, recombinant human growth hormone (rhGH) therapy significantly improves linear growth.[75–77] Recommendations for evaluation and treatment of growth failure in children with CKD have been published and include recommendations for rhGH therapy,[78] though recent data suggest that only ~25% of children with CKD and severe short stature (height SDS ≤ –1.88) are prescribed this therapy.[67,79] Secondary hyperparathyroidism and chronic metabolic acidosis are additional factors that impair growth. To optimize the utilization of nutrition for growth and response to rhGH, appropriate correction of secondary hyperparathyroidism and metabolic acidosis is critical.

CKD: Assessment of Growth and Nutritional Status

The importance of nutritional status has been emphasized in numerous clinical practice guidelines regarding the care of patients with CKD.[80,81] Nutritional status is a complex concept, and no single measurement is comprehensive. Therefore a multistaged evaluation of body composition is necessary. Measurements of nutritional parameters are complicated in CKD given the potential for fluid overload and potential abnormalities in the distribution of fat and lean tissue. Children with CKD prior to and after renal transplantation have been found to have discordant body composition with relatively high fat mass and low lean mass.[82] In addition, assessment methods recommended for children with CKD were developed in healthy children, and the validity may be limited in CKD. A comprehensive review has been published summarizing the methods recommended for nutritional assessment of children with CKD and details the advantages and disadvantages of these methods.[83]

The most recently published KDOQI Clinical Practice Guideline for Nutrition in CKD recommends a three-day dietary intake and a variety of anthropometric measurements. The measures and suggested frequency are summarized in Table 51-4. Of note, body mass index (BMI) varies with age and pubertal status. Children with CKD are shorter and sexually immature,[79] and it is thus recommended that BMI might best be expressed relative to height–age in children in this population, as this measure more effectively compares children with CKD to children of the same height and stage of sexual development.[84] There are limitations using BMI-height-age as an assessment of growth, such as when short stature is disproportionate to the degree of delay in sexual maturation. For adolescents on dialysis, a monthly assessment of normalized protein catabolic rate (nPCR) to provide an objective measure of protein intake is recommended. Adolescents with nPCR <1 g/kg/day were at significantly increased risk for weight loss, though there was no association between nPCR and weight in younger children.[85] Reflecting growth challenges faced by infants, the frequency of nutritional and anthropometric assessment is increased in younger children. These guidelines outline the minimum frequency of assessment, and more frequent assessment may be appropriate and should be tailored to the individual patient. In particular, infants and children with comorbid conditions, worsening growth, or acute medical issues may warrant more frequent monitoring.

TABLE 51-4 Nutritional and Growth Assessment

	Minimal Interval of Measurement (months)									
	Age < 1 year			Age 1–3 years			Age > 3 years			
Measurement	CKD stage			CKD stage			CKD stage			
	2–3	4–5	5D	2–3	4–5	5D	2	3	4–5	5D
Dietary intake	0.5–3	0.5–3	0.5–2	1–3	1–3	1–3	6–12	6	3–4	3–4
Height or length-for-age % or SDS	0.5–1.5	0.5–1.5	0.5–1	1–3	1–2	1	3–6	3–6	1–3	1–3

CKD: Supplemental Feedings

Though the etiology of growth failure in CKD is multifactorial, inadequate nutrition will adversely affect growth outcome.[86,87] In addition to impacting somatic growth, malnutrition is associated with increased morbidity and mortality in children with CKD.[88,89] Several studies have demonstrated altered spontaneous nutritional intake in children with CKD and generally lower intake of total energy than that in healthy children.[90,91] Protein intake has been variable, with some studies demonstrating lower[91] and other studies reporting higher spontaneous intake of protein than recommended.[92,93]

The etiology of decreased spontaneous energy intake in children with CKD is multifactorial. Vomiting and gastroesophageal (GE) reflux are common in infants with CKD. GE reflux was identified in nearly 75% of 22 infants studied by 24-hour esophageal pH monitoring,[94] and a variety of forgut motor disorders have been identified, including delayed gastric motility and emptying.[95] In the CKD population, diminished appetite has been associated with higher serum concentrations of inflammatory markers, including tumor necrosis factor-α, interleukin-6, C-reactive protein, and leptin.[96–98] Among children with CKD, systemic inflammation and disturbances in appetite-regulating hormones, such as ghrelin, have been identified and places these children at risk for cachexia, a state of muscle wasting with or without the underutilization of fat.[99] Furthermore, poor appetite may be a consequence of multiple medications prescribed as part of a complex CKD regimen and a preference for water in children with polyuria and increased obligatory water needs.

As nutritional intake may be suboptimal in children with CKD, the use of supplemental enteral feedings is commonly implemented. Given that growth velocity is maximal during infancy and predominantly dependent on nutrition, most studies have focused on the younger child. Nasogastric and gastric feeds were initiated in 35 children up to age 5 years with estimated GFR <26 mL/min/1.73 m^2. The aim of supplemental feedings

was to provide at least 100% of estimated average requirement for energy and 100% of the reference nutrient intake for protein for height–age. The benefit was most apparent in children 0–2 years of age (n = 26) with improved mean weight SDS from −3.1 at the initiation of feeds to −1.4 at 2 years. Improvement in height SDS was also significant with mean height SDS −2.9 at initiation and −2.1 at 2 years.[100] A subsequent report from the same center studied growth outcomes of 81 children who presented with CKD (estimated GFR <20 mL/min/1.73 m^2) in the first six months of life. Supplemental enteral feeds were commenced in 81% of patients when growth became subnormal. The mean height SDS was within the normal range at 1 year of age and continued to improve thereafter.[101]

Though supplemental feeds were associated with improved growth in some studies,[102–105] others have not demonstrated the same benefit. Several studies have shown stabilization of linear growth without significant catch-up growth.[106,107] Abitbol et al. studied 12 infants with congenital renal insufficiency who were provided controlled feeding regimens starting at 3 months of age. Six of these infants received supplemental nasogastric or gastric tube feedings. The average energy intake was 95% of recommended daily allowance (RDA) with average protein intake of 141% RDA. The study revealed that the major height deficit was incurred during the first six months of life, as the length SDS fell from −0.7 at birth to approximately −1.9 at 6 months. There was no catch-up growth noted as indicated by the length SDS of −2.0 at 24 months.[70] A multicenter experience comes from the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) survey, which reviewed the impact of supplemental feedings on growth and mortality in children <6 years of age at dialysis initiation. Questionnaires were completed on 137 patients, 70% of whom received supplemental feedings and outcome was compared to those who did not receive supplements. When compared to children between the ages of 2 and 5 years, significantly more children less than 2 years of age were provided supplemental feedings (~80% vs. 41%). Despite supplemental feedings, there was no difference in height and weight, and height and weight SDS did not improve over time with supplementation. In addition, mortality was unaffected.[108]

Another report from the International Pediatric Peritoneal Dialysis Network analyzed growth outcomes of 153 children in 18 countries initiating chronic peritoneal dialysis at <24 months of age.[71] During periods without enteral feedings BMI SDS uniformly decreased, whereas

nasogastric (NG) and gastrostomy feedings reversed this loss. Gastrostomy feeds were associated with superior growth outcome when compared to NG feeds. The proposed explanation for this difference was increased vomiting with NG feeds due to stenting of the gastroesophageal junction. Enteral feedings are an accepted standard of practice in the care of children with CKD who do not meet the RDA for energy and protein and are recommended in the KDOQI pediatric nutritional guidelines.[72] Studies thus far identify younger children as the group most likely to require this support, and the choice of nasogastric versus gastric feedings depends on the needs and comorbidities of the individual patient. Ideally, placement of a gastrostomy tube should occur prior to initiation of peritoneal dialysis (PD), and placement of percutaneous gastrostomy tube while on PD should be avoided given the risks for infection and PD failure. To encourage daytime oral intake and provide oral stimulation, continuous overnight feeds are generally preferred. Infants and toddlers who have been supported with tube feedings may experience oral aversion and feeding dysfunction and would benefit from the counseling of a multidisciplinary feeding team.[109,110]

CKD: Energy Requirements

Energy requirements for children with CKD should be considered to be the same as estimated for healthy children, as there is a lack of evidence to suggest needs are increased. When adjusted for lean body mass, the resting energy expenditure measured by indirect calorimetry of 25 children and adolescents on chronic hemodialysis was the same as for healthy controls.[111] Therefore, the energy intake should be 100% of the estimated energy requirements for chronologic age and adjusted for physical activity level and body size. As calculated energy requirements are estimates, all prescriptions should be individualized, and further adjustments should be made in response to weight loss or weight gain. Adequate energy intake is not only critical to allow optimal growth but prevents the utilization of protein stores as an energy source. Energy-malnourished children may require additional calories to restore normal growth and allow “catch up” growth if possible. With respect to macronutrient distribution, the recommended ranges for distribution of calories from protein, fat, and carbohydrate should not be different from that of the general pediatric population.[72] Given the increased cardiovascular risk of children with CKD,[112] preference for unsaturated fat and limiting saturated or trans fats should be counseled.

To increase energy intake and improve compliance, dietary modifications for children are typically less restrictive than those prescribed to adults. Dietary guidelines for adults often recommend specific amounts of a restricted nutrient, such as a “2 g sodium diet.” In pediatrics, restrictions are imposed only when clinically indicated and usually take the form of a diet low in a particular nutrient such as sodium, potassium, and phosphorus with education on which foods are high or low in that nutrient. Minimizing the number of dietary restrictions as allowable by metabolic balance will increase the likelihood of achieving energy goals. Individuals with poor appetites may respond to small, frequent meals and snacks. Energy can be added to foods by adding heart healthy oils or margarines, creams, syrups, or carbohydrate modules. For children who are underweight, low calorie or calorie free drinks should be restricted. If the child does not meet energy requirements, supplemental nutrition with energy-dense diet or commercial nutritional supplements should be provided. Oral supplementation is preferred, though enteral feedings may be required. Nonrenal pediatric feedings designed for children older than one year (Kindercal, Pediasure, Nutren Junior) have standard calcium, phosphorus, and potassium content, which may result in electrolyte disturbance depending on the volume required and the degree of renal insufficiency. Nutritionally complete renal formulas designed to be energy dense, high or low in protein, and low in electrolytes including phosphorus may be given to children older than one year. Suplena (Ross Products) is designed for CKD prior to dialysis dependence and Nepro (Abbott) is intended for patients on maintenance dialysis (Table 51-2). Serum magnesium should be monitored if used in younger children, as the magnesium content is higher in adult renal products than in infant or pediatric formulas.

Children with CKD may require volume restriction if urine output is limited. Volume restriction is most problematic if the intake of solid nutrition is limited due to age or oral aversion, which is of particular concern in infants and young children. If fluid restriction is indicated, fortification of feeds to increase caloric density will be necessary. Caloric density may be increased gradually by 2–4 kcal/ounce increments up to 50–60 kcal/ounce if needed, and the tempo of fortification will depend on individual tolerance. Both breast milk and commercial formulas may be fortified. It is not advisable to increase the energy density of formula by concentration alone due to the increased sodium, potassium, phosphorus, and overall renal solute load. Carbohydrate, protein, and fat modular products can be added to achieve the desired caloric density. Readily

available oils such as corn, canola, and safflower may be used for fat supplementation. The benefit of fat modular products is the process of emulsification, which prevents the fat from separating out of the formula during continuous feeds. When making a formula with increased energy density, an attempt should be made to preserve the proportionate distribution of energy from carbohydrate, protein, and fat as in the base formula.

Patients on maintenance dialysis may have specific nutritional issues related to renal replacement therapy. For children treated with peritoneal dialysis, early satiety or anorexia may result secondary to pressure exerted by the indwelling dialysate volume.[113,114] Intraperitoneal dialysate glucose absorption should also be considered when calculating total energy intake. Approximately 7–10 kcal/kg/day are absorbed by children on CAPD.[115] For patients on maintenance hemodialysis who are malnourished (BMI-for-height-age < 5%) and unable to meet nutritional goals via oral or enteral feedings, a trial of intradialytic parenteral nutrition (IDPN) has been suggested by some.[116] IDPN appears to be less effective therapy for psychosocial causes of malnutrition[117] and is not recommended in adult patients.[31] IDPN is infused continuously during the hemodialysis session through the venous limb of the circuit to prevent immediate clearance of trace elements and amino acids. Potential adverse outcomes include hyperglycemia, postinfusion hypoglycemia, and hyperlipidemia. IDPN should be utilized as a supplement to oral and enteral nutrition and not utilized as the sole or primary source of nutrition.

CKD: Protein Requirements

Care of CKD emphasizes supportive measures to retard disease progression. There has been concern that higher protein intake would induce intraglomerular hypertension and hyperfiltration injury, thereby hastening the progression of kidney disease. Given that a low protein diet was able to slow the deterioration of renal function in rodent studies,[118,119] prospective clinical studies prescribing low-protein diets were conducted in both adults[120–123] and children.[124] The results of prospective clinical studies in adults were contradictory. Overall the progression rate was not significantly influenced by protein restriction over a period of 2–3 years, though a low protein diet postponed the development of uremic symptoms and the start of dialysis for adult patients with advanced renal failure. In the pediatric study of nearly 200 children with CKD stages 3–4, a diet targeting 100% RDA for protein (0.8–1.1 g/kg/day based on ideal body

weight) was compared to a more liberal protein intake (mean 181% RDA). The diet with lower protein intake (achieving 120% of the RDA) did not affect the rate of decline in creatinine clearance or adversely affect growth.[124] Though these outcomes were not different, the increased phosphorus load of a higher protein diet must be considered, as studies have linked hyperphosphatemia and arteriopathy.[125,126] The association of high phosphorus load and cardiovascular risks provide the rationale for avoiding excessive protein intake in the CKD population.[127] Furthermore, avoiding excessive protein intake will limit accumulation of nitrogenous waste products.

Current recommendations for protein intake are based on the stage of CKD. For children with CKD stage 3, dietary protein intake should be 100%–140% of the daily recommended intake (DRI) for ideal body weight. For children with CKD stage 4–5, the recommended amount is 100%–120% of the DRI, as lower intake did not significantly delay dialysis initiation in the above cited pediatric trial. A diet targeting 100% of the DRI may be difficult for families to achieve and should be reconsidered if this restriction negatively impacts the child's total nutritional intake. For obese children, additional body protein is required for structural support of excess weight; estimation of protein requirements for obese children can be based on "adjusted" weight (i.e., adjusted weight = ideal weight for height + 25% × [actual weight – ideal weight]).[128] Ensuring adequate caloric needs overall is essential to reduce the inefficient use of dietary protein as a calorie source, resulting in increased urea generation. Even if protein intake exceeds recommended levels, protein malnutrition may occur if overall energy intake is low.

Of note, children on maintenance dialysis (CKD stage 5D) will incur dialytic nitrogen loss, and it is recommended to maintain dietary protein intake at 100% of the DRI for ideal body weight with an additional amount provided to account for protein and amino acid losses on dialysis (Table 51-5). Transperitoneal protein losses demonstrate significant variability and inverse correlation with body surface area. Infants were shown to have nearly twofold greater peritoneal protein losses per meter square body surface area than older children weighing more than 50 kg. Daily protein losses average 0.28 g/kg in the first year of life and decrease to < 0.1 g/kg in adolescents.[47] In addition, transperitoneal protein losses were twice as great in patients requiring maintenance PD due to steroid-resistant nephrotic syndrome when compared to children without nephrotic syndrome.[129] Additional dietary protein ranging from 0.15 to 0.35

mg/kg/day, dependent on patient age, should be provided to children on PD to account for losses. Amino acid and protein losses during HD vary according to the membrane characteristics of the dialysis filter and are inadequately studied in children. Based on adult data, it is recommended that additional 0.1 g/kg/day of dietary protein be provided to children on hemodialysis to compensate for losses. Given the significant variability in losses, regular assessment of growth, serum albumin, and urea levels is essential to determine if adjustment in protein intake is necessary. Regular assessment of predialysis urea levels may allow assessment of protein intake, though other clinical factors which affect blood urea nitrogen (BUN) must be considered. A predialysis BUN greater than 70–80 mmol/L may indicate excessive protein intake. However inadequate dialysis, recirculation of blood, and increased catabolism will also increase the predialysis BUN. Alternatively, persistently low predialysis BUN of <20 mmol/L may indicate inadequate protein intake.

TABLE 51-5 Recommended Daily Dietary Protein Intake in Children with CKD Stage 5D

Age	DRI (g/kg/d)	Children on HD (g/kg/d)	Children on PD (g/dk/d)
0–6 months	1.5	1.6	1.8
7–12 months	1.2	1.3	1.5
1–3 years	1.05	1.15	1.3
4–13 years	0.95	1.05	1.1
14–18 years	0.85	0.95	1.0

Source: Adapted from Group KW. KDOQI Clinical Practice Guideline for Nutrition in Children with CKD: 2008 update. Executive summary.[72]

CKD: Vitamin and micronutrient requirement

The specific vitamin requirements of children with CKD are poorly defined, underscoring the need for further study. The K/DOQI Pediatric Nutrition Guidelines recommends dietary of at least 100% of the DRI for thiamin (B_1), riboflavin (B_2), niacin (B_3), pantothenic acid (B_5), pyridoxin (B_6), biotin (B_8), cobalamin (B_{12}), ascorbic acid (C), retinol (A), α-tocopherol (E), vitamin K, folic acid, copper, and zinc for children with CKD stages 2–5D.[72] When dietary intake is considerably less than recommended, vitamin supplementation should be considered. Children on dialysis have additional risk for vitamin deficiency due to losses of water-

soluble vitamins from dialysis clearance. A study of children on peritoneal dialysis revealed the dietary intake of vitamins was lower than the DRI, and supplementation resulted in intakes that exceeded recommended amounts.[130–132] Children with a robust appetite for a variety of nutritious foods and children who receive a significant amount of nutrition from adult renal formulas will generally meet the DRI. If supplements are indicated, infants and small children can be given liquid or chewable multivitamin preparations at appropriate dosing, and adequate folic acid provision should be confirmed. Older children and adults can be provided B complex vitamins which generally contain 0.8–1 mg folic acid, such as Nephrocaps (Flemming & Company) and Nephrovite (R & D Laboratories, Inc.). Excessive amounts of vitamin A and vitamin C should be avoided. Excessive vitamin A can lead to hypercalcemia,[133] anemia, and hyperlipidemia. Vitamin C is metabolized to oxalate, which is renally excreted. Excessive vitamin C may result in elevated oxalate levels and complications of retention.[134]

In children with CKD, bone mineral metabolism and vitamin D homeostasis becomes disrupted. The most active form of vitamin D is 1,25-dihydroxycholecalciferol ($1,25[OH]_2D_3$), and the enzymatic step of 1α- hydroxylation occurs in the kidney. Impaired production of $1,25[OH]_2D_3$ in the context of CKD is multifactorial, including phosphate retention, loss of the renal enzyme, and inhibition of 1α- hydroxylation by fibroblast growth factor 23 (FGF-23).[135] With progression of renal disease, secondary hyperparathyroidism and defective bone mineralization may ensue due to inadequate $1,25(OH)_2D_3$ levels. Secondary hyperparathyroidism can begin as early as CKD stage 2. An early study of renal osteodystrophy in 29 children with moderate to severe CKD found that parathyroid hormone (PTH) levels were elevated in all children with GFR < 45 mL/min/1.73 m^2. “Early” renal osteodystrophy characterized by elevated PTH but normal serum chemistries was detected in one quarter of the patients.[136]

Deficiency of 25-hydroxyvitamin D has been well described in children with CKD and is associated with more advanced renal disease, dark complexions, and lower sunlight exposure in winter months.[137,138] The Kidney Disease: Improving Global Outcomes (KDIGO) and KDOQI guidelines recommend assessment of 25-cholecalciferol ($25[OH]D_3$) in CKD stages 2–5D be measured at least yearly and subsequent testing based on results and need for supplementation.[139] Supplementation with

vitamin D_2 (ergocalciferol) or vitamin D_3 (cholecalciferol) is suggested if the level is <30 ng/mL. Correction of vitamin D deficiency improved secondary hyperparathyroidism in children with CKD.[140] Guidelines for supplementation with ergocalciferol based on serum 25-cholecalciferol levels in children with CKD stages 2–4 have been provided by KDOQI (Table 51-6).[72,141] Given the potential effect of ergocalciferol therapy on calcium and phosphorus homeostasis, serum levels of calcium and phosphorus should be monitored at least monthly after initiation of therapy. Should hypercalcemia develop during supplementation, discontinuation of ergocalciferol should be considered. If hyperphosphatemia develops, interventions include restriction of dietary phosphate, initiation of a phosphate binder, and discontinuation of ergocalciferol supplementation. If indicated based on serum levels of PTH and vitamin D metabolites, supplementation with activated vitamin D should be provided. Calcitriol is commonly prescribed and dose adjusted to target-specific PTH levels based on renal function. The initiation and adjustment of calcitriol is typically the responsibility of a pediatric nephrologist. Due to potent effect on intestinal calcium absorption, calcitriol treatment can induce hypercalcemia and preclude its use at therapeutic doses. Newer vitamin D analogues have been developed which minimize intestinal calcium and phosphorus absorption while suppressing PTH levels as effectively as calcitriol.[142,143] Currently available active vitamin D sterols with less hypercalcemic effect include paracalcitol, alfacalcidiol, and doxercalciferol, though only paracalcitol has been studied in children.[144,145]

TABLE 51-6 Recommended Supplementation for Vitamin D Deficiency/Insufficiency in Children with CKD

Definition	Serum 25-hydroxyvitamin D (ng/mL)	Ergocalciferol (vitamin D_2) dose	Duration of therapy
Severe vitamin D deficiency	<5	8,000 IU daily (or 50,000 IU per week) × 4 weeks, then 4,000 IU daily (or 50,000 IU twice per month) × 2 months	3 months
Mild vitamin D deficiency	5-15	4,000 IU daily (or 50,000 IU every other week) × 12 weeks	3 months
Vitamin D insufficiency	16-30	2,000 IU daily (or 50,000 IU every 4 weeks) × 12 weeks	3 months

Executive summary. *Am J Kidney Dis*. 2009;53:S11–S104 and National Kidney Foundation. K/DOQI clinical practice guidelines for bone metabolism and disease in children with chronic kidney disease. *Am J Kidney Dis*. 2005;46:S1–S122.

Children with CKD are at risk for anemia secondary to erythropoietin deficiency and iron deficiency. The introduction of recombinant erythropoietin (rHuEPO) therapy in 1988 provided a highly effective treatment for correcting anemia associated with CKD.[146] Iron deficiency is the most common factor that limits the response to rHuEPO, and children on rHuEPO usually require large amounts of supplemental iron. For children on maintenance hemodialysis, it is strongly recommended that iron be given intravenously. For children who are pre-dialysis or on maintenance peritoneal dialysis, iron may be provided either orally or intravenously. Dosing of iron supplementation is guided by serum ferritin and transferrin saturation.[147]

Hyperhomocysteinemia is associated with folate deficiency and has been identified as an independent risk factor for cardiovascular disease in adults with chronic renal disease.[148,149] Hyperhomocysteinemia has also been found in children with chronic kidney disease, though a clear relation to vascular disease remains to be seen.[150] When children with and without CKD where studied, plasma homocysteine levels where found to increase with deterioration of renal function. Hyperhomocysteinemia was found in 5.2% of controls, 35.7% of non-dialyzed CKD, and 86.6% of children with ESRD on dialysis. Folate levels were also lower in patients than controls.[151] When children on peritoneal dialysis and hemodialysis were provided folic acid supplementation of 2.5 mg daily, plasma homocysteine concentrations were significantly reduced.[152] Currently there is no standard for monitoring homocysteine levels in children with CKD. Guidelines recommend that dietary intake for folic acid should achieve 100% the DRI. If dietary intake of folic acid is inadequate, supplementation should be considered.

CKD: Electrolyte Disturbances

Electrolyte disturbances commonly seen in children with CKD include hyperphosphatemia, hypocalcemia, and hyperkalemia. Though serum levels of sodium are typically within normal range, the inability to maintain sodium homeostasis will have significant clinical effect. Kidney disease associated with sodium retention may result in hypertension and edema. Alternatively, sodium losses from urine wasting in polyuric kidney

disease or losses from dialysis effluent may require sodium supplementation to ensure normal serum concentration and adequate growth. Dietary restrictions of electrolytes may pose significant challenges to the child and caregivers and contribute to inadequate energy intake overall. Restrictions should be applied only when indicated.

Hyperphosphatemia in CKD can lead to significant morbidity due to metastatic calcification, secondary hyperparathyroidism, and renal osteodystrophy.[153] More commonly seen when GFR falls <50 mL/min/1.73 m^2, hyperphosphatemia contributes to secondary hyperparathyroidism by lowering the serum ionized calcium, inhibiting the production of $1,25(OH)_2D_3$ and directly stimulating PTH secretion. Therefore, normal levels of serum phosphorus should be maintained to prevent renal osteodystrophy and poor growth. Guidelines recommend dietary phosphorus intake be restricted to 100% of the DRI for age when the serum PTH is above the target range for the stage of CKD and the serum phosphorus is within the normal range for age. Phosphorus intake should be restricted to 80% of the DRI if both the serum PTH and phosphorus levels are elevated.[72] Once a restriction of dietary phosphorus has been initiated, it is suggested that serum phosphorus concentrations be monitored at least every 3 months in children with CKD stages 3–4. For children with severe CKD or dialysis dependence (stages 5 and 5D), serum phosphorus concentrations should be followed at least monthly. In children who require phosphorus restriction, intake of milk, milk products, eggs, nuts, dried beans, peanut butter, whole grains, chocolate, and other high-phosphorus containing foods should be limited. Restriction of dietary phosphorus can challenge efforts to achieve adequate protein intake, as protein and phosphorus are often found in the same foods. Animal proteins have relatively favorable phosphorus to protein ratios when compared to the ratios in eggs, dairy products, legumes, and lentils.

In addition to limiting dietary phosphorus, intestinal absorption of phosphorus can be decreased with the use of phosphate binders. Options for phosphate binders include both calcium-based (calcium acetate, calcium carbonate) and noncalcium, nonmetal-containing binders (i.e., sevelamer carbonate, lanthanum carbonate).[154] Aluminum-containing binders are available, but long-term use has resulted in retention and toxicity.[155–157] First-line therapy for hyperphosphatemia in children is often a calcium-based binder given the wide availability of chewable and liquid preparations. However, children who receive calcium-based binders may experience hypercalcemia with associated risks of joint, vessel and

soft tissue metastatic calcification.[126] Sevelamer hydrochloride and carbonate have been shown to be effective and safe when studied in pediatric populations and reduce the likelihood of hypercalcemia,[158,159] though the hydrochloride salt has been associated with metabolic acidosis.[160] Lanthanum carbonate has not been studied in children. Calcium carbonate is readily available in a liquid form and sevelamer carbonate is available in packets, both suitable for younger children.

In formula-fed infants with CKD, one approach is to attempt feeds with standard formulas and use phosphate binders when indicated. Should hyperphosphatemia develop and persist despite prescription of phosphate binders, a low-phosphorus formula such as Similac PM 60/40 (Abbott Nutrition) may be provided. The nutrient content of Similac Advance (Abbott Nutrition), a standard infant formula, and Similac PM 60/40 is outlined in Table 51-2 for comparison. The calcium content of Similac PM 60/40 is lower than that of standard infant formulas. Therefore, ensuring adequate calcium intake and monitoring serum calcium, phosphorus, and parathyroid hormone is critical to guide therapy and promote normal bone mineralization. When indicated, calcium supplementation should be provided. In children with CKD stages 2–5D, it is suggested that the total calcium intake range 100%–200% of the DRI for age.[72] The calcium content of phosphate binders should be included in the daily calcium intake.

As with the development of hyperphosphatemia, progressive decline in kidney function predisposes to hyperkalemia. However, hyperkalemia does not typically occur in early stages of CKD due to adaptive mechanisms of individual nephrons as GFR declines. When hyperkalemia develops and persists, high-potassium containing foods should be limited. Unfortunately many high-potassium foods are favored by children and include potato products, tomato products, bananas, oranges, and chocolate. If necessary, potassium exchange resins, such as sodium polystyrene sulphonate, can be prescribed. Formula-fed infants who have significant CKD may require scheduled doses of sodium polystyrene daily, though this may result in increased spitting, aversion, sorbitol-induced diarrhea, and enteral tube obstruction. Methods to lower the potassium content of formula by pretreatment of the formula with sodium polystyrene sulphonate have been published.[161] One study demonstrated a ~60% reduction of potassium content, though the sodium content of the formula was disproportionately increased (~230%). The disproportionate effect was due, in part, to exchange for calcium and magnesium.[162] Increased

sodium content was seen in a subsequent report of formula pretreatment with sodium polystyrene sulfonate.[163] Should similar methods be employed, the potential complications of increased sodium intake and electrolyte abnormalities should be considered.

Sodium balance is directly linked to volume status. Kidney disease characterized by oliguria or anuria typically requires sodium and fluid restrictions to avoid clinical signs of volume excess, such as hypertension and edema. Children at risk for sodium retention are directed to limit dietary intake, including salty snacks, processed luncheon meats, canned soups, and packaged entrees. Food from fast-food restaurants should also be limited. Prior to the initiation of maintenance dialysis, diuretics may be used to improve sodium balance. After the initiation of maintenance dialysis, children continue to limit sodium intake, especially if hypertension is present. Infants on peritoneal dialysis may require sodium supplementation due to sodium losses incurred from ultrafiltrate, which is isotonic, coupled with the relatively low sodium concentration found in formula. To avoid hyponatremia and ensure adequate extracellular volume, sodium supplements may be needed (i.e., 2–5 mEq/kg/day) with close monitoring of electrolytes, volume balance, and growth.[164]

In addition to ensuring sufficient energy and protein intake, the effect of providing supplemental sodium and water to young children with polyuric, salt-wasting forms of chronic renal failure was studied. It was proposed that these children experience growth delay due to chronic intravascular depletion and negative sodium balance, and the provision of low caloric-density, high-volume, and sodium supplemented feeds would promote normal growth. The treatment group consisted of 24 children diagnosed with polyuric renal insufficiency (< 65 mL/min/1.73 m^2) in the first year of life and were compared to a historical population control and a literature control. The nutritional therapy prescribed consisted of an enteral formula diluted with water to a caloric density of 0.3–0.5 kcal/mL and supplemented with 2–4 mEq of sodium per 100 mL of formula. The average energy intake for the entire treatment group was 104 kcal/kg/day (102% RDA), and the average protein intake was 2.45 g/kg/day (153% RDA). None of the children received growth hormone. The patients provided this specified nutritional regimen maintained their height SDS at 1 and 2 years, with a net gain of height SDS of 0.15 during the two years. The change in SDS for height by regressional analysis was significantly greater in the treatment group than in the control groups.[165]

NUTRITIONAL MANAGEMENT AFTER RENAL TRANPLANATION

Renal transplantation is recognized as the preferred treatment for children with ESRD, conferring a survival benefit when compared to the survival of children maintained on chronic dialysis.[166] Furthermore, restoration of normal renal function can greatly improve a child's quality of life. If the kidney transplant functions well, normalization of fluid and dietary intake is permitted, though a no added salt diet is advised if the child is hypertensive. Children often have improvement in appetite after transplantation, though immunosuppressive drugs and other required medications may cause nausea, vomiting, constipation, diarrhea, and/or anorexia. These symptoms are typically treated symptomatically. Recent data demonstrate 5-year renal allograft survival of 84% and 78% for living and deceased donor source, respectively.[167] However, renal allograft function declines over time due to many factors including acute rejection episodes, chronic rejection, and nephrotoxic exposures. If a child has decreased allograft function, nutritional therapy should be based on guidelines for nutritional care of CKD as discussed above. The following section will discuss growth and metabolic disorders after renal transplantation.

Growth After Kidney Transplantation

The mean height of children at the time of kidney transplantation is approximately −1.8 SDS.[167] Though growth typically improves after transplantation, many children demonstrate abnormal growth overall.[168–170] The benefits of improved growth after transplantation are not equally realized in all children. Children less than 6 years of age demonstrate improved linear growth with an increase in height SDS of 0.68 two years after transplantation. Compared to younger children, older children have relatively stable height SDS. Though "catch up" growth has generally been restricted to younger patients, children who reach ESRD early in childhood incur the greatest height deficits overall.[167] Final adult height is positively associated with shorter duration of dialysis and height at the time of transplantation[171,172] and negatively associated with reduced renal funtion.[168] Given the known deleterious effects of steroids, including that of poorer linear growth, research efforts have focused on steroid sparing regimens utilizing early dose reduction, withdrawal, or avoidance of steroids.[173,174] Growth has improved with steroid minimization, though

the benefits have been primarily realized in young or prepubertal children.[171,175] If growth is poor, initiation of growth hormone should be considered.[147,176] Analysis of the NAPRTCS database comparing growth and allograft function in transplant recipients would suggest that this therapy is effective and safe[177] and is recommended by experts in the field.[178] The risks of growth hormone therapy in patient with recurrent rejection episodes should be considered.

Though linear growth may be suboptimal, registry data demonstrate a rapid increase in weight in children of all ages during the first six months after transplantation, with an average increase in weight of 0.81 SDS in the first year following transplantation.[167] This effect is compounded by an increase in the prevalence of pretransplant obesity.[179] Furthermore, studies have demonstrated worse 1-year allograft function in children who were obese at the time of transplanation[180,181] and worse graft outcome in those with rapid weight gain after transplantation.[182] Obesity is an independent risk factor for the development of systolic hypertension in children following renal transplantation.[183] Discordant body composition characterized by relatively low lean mass, high fat mass, and increased central adiposity after renal transplantation in children has been described.[82] Given the association of truncal obesity with increased cardiovascular morbidity in adults, this may suggest additional lifetime risks in these pediatric patients. These concerning trends underscore the need for dietary assessment and nutritional counseling after transplantation.

Posttransplant Dyslipidemia

Hyperlipidemia is a common and significant disorder after renal transplantation and occurs in up to 70% of adult recipients.[184,185] A known cause of cardiovascular disease, hyperlipidemia leads to increased morbidity and mortality in adult transplant recipients, a population which is already burdened with numerous cardiovascular risks.[186] Children also have a high incidence of lipid abnormalities after renal transplantation, reported in 15%–50% of those studied.[187,188] More recently steroid avoidance protocols have reported lower prevalence of elevated cholesterol compared to steroid-based regimens,[171] though another study found steroid minimization to be associated with lower HDL cholesterol[189] and underscores the need for further study. Though well documented in adults, the cardiovascular effects of hyperlipidemia in children are not

currently known.[190,191] In addition to dyslipidemia, children face numerous cardiovascular risks after transplantation, including diabetes, hypertension, and elevated BMI.[187] Furthermore, there are growing concerns that hyperlipidemia may promote allograft injury with increased risk of chronic transplant nephropathy and graft failure.[192,193]

Known risk factors for hyperlipidemia in adult renal transplant recipients include renal dysfunction, hypoalbuminemia, pretransplant hyperlipidemia, family history of hyperlipidemia, obesity, and specific diseases resulting in ESRD.[194] When risk factors for hypercholesterolemia or hypertriglyceridemia were studied in pediatric recipients, pretransplant hyperlipidemia, increased years since transplantation and reduced GFR correlated.[187] Immunosuppressive medications have also been associated with dyslipidemias, particularly steroids,[184,189,195] calcineurin inhibitors,[196,197] and sirolimus.[198,199] When comparing calcineurin inhibitors, the incidence of hyperlipidemia appears to be higher with cyclosporine than tacrolimus.[185,200,201] A longitudinal study of pediatric renal transplant recipients demonstrated that the prevalence of hyperlipidemia declined from 1 to 10 years posttransplant, and this was thought to be due to the reduction of immunosuppressive therapy. Elevated total cholesterol and total triglycerides declined from 70% to 35% and 46% to 15%, respectively.[202] Although diet may contribute to dyslipidemia, a study comparing healthy children to pediatric kidney transplant recipients did not find this assoication.[203] Both groups had similar intake of saturated fats, polyunsaturated fats, and cholesterol, though the serum levels of total cholesterol and triglycerides were higher in kidney transplant recipients. Of note, both groups took in low amounts of polyunsaturated fats and excessive amounts of saturated fats. Given additional risks for dyslipidemia burdening the transplant population, the need for counseling healthy diet and lifestyle is emphasized.

Posttransplant Diabetes Mellitus

Hyperglycemia and posttransplant diabetes mellitus (PTDM) are well known complications of solid organ transplantation. The reported incidence of PTDM in pediatric renal transplant recipients ranges from 1% to 7%, and risk factors include corticosteroid and calcineurin inhibitors. When compared to cyclosporine, tacrolimus-based regimens may present greater risk.[204–206] Corticosteroids alter carbohydrate metabolism by impairing peripheral utilization of glucose, elevating plasma glucagon concentration, and increasing gluconeogenesis.[207] Cyclosporine and

tacrolimus have been shown to inhibit insulin secretion from beta-cells.[208,209] Additional reported risk factors for PTDM include family history of type 2 DM, hyperglycemia in the two weeks after transplantation, African-American race, older age at transplantation (>13 years), and BMI ≥ 30 kg/m^2.[205,210,211] Increased weight and BMI were not identified as a risk factor.

In 2001, NAPRTCS published a report of 36 children who developed PTDM after renal transplantation.[210] The majority of patients (63.6%) presented within the first six months of transplantation, and the diagnosis was most frequently made by the detection of hyperglycemia on routine laboratory follow-up (64%). Three patients (9%) presented with diabetic ketoacidosis. The development of PTDM was a transient disorder in the majority, as less than one-third of patients remained on insulin therapy at follow-up. Another analysis of 16 children who developed PTDM noted that for patients who presented early after transplantation (mean 0.3 years), the disorder was more likely to be transient. Those who presented later (mean 2.7 years) were more likely to have persistent PTDM.[205]

Nutritional Management After Renal Transplantation

Guidelines for the nutritional management of pediatric renal transplant recipients underscore the nutritional challenges faced by these patients, including the side effects of medications and the potential for abnormal renal function. For children with reduced renal allograft function, dietary management with respect to protein, and phosphorus intake is similar as for children with CKD prior to transplantation. It is recommended that energy intake be 100% of the estimated energy requirements for chronological age with adjustment as needed to achieve desired growth outcomes. As many children are required to take in high quantities of fluids to ensure adequate intravascular volume and renal perfusion, this creates the potential for the intake of excessive calories. With the exception of underweight children, the majority of the fluid taken by children after transplant should be composed of water, fat-free or low-fat milk, and sugar-free drinks. The caloric source should be balanced among carbohydrate, protein, and unsaturated fats as recommended by the acceptable macronutrient distribution ranges. For those children who demonstrate glucose intolerance, hyperglycemia, or PTDM after transplantation, avoidance of simple sugars should be counseled. Derangements of glycemic control are typically associated with corticosteroid and calcineurin inhibitor therapy and during the first 3–6

months after transplantation when immunosuppressant dosing is highest. As the prevalence of posttransplant hypertension is high, restriction of dietary sodium should be recommended for those with hypertension or prehypertension. Given the risk factors for metabolic bone disease after transplantation, including corticosteroid therapy, preexisting metabolic bone disease, and residual hyperparathyroidism, calcium and vitamin D intakes of at least 100% of the DRI are recommended.

Pediatric renal transplant recipients are at increased risk for hyperlipidemia, and this risk will be lifelong given the current therapeutic options of dialysis and transplantation for treatment of ESRD. It is standard practice to monitor serum lipids after renal transplantation. Should hyperlipidemia develop, dietary modifications to reduce the intake of saturated fats should be employed. Healthy food preparation and heart-friendly fats such as canola oil, olive oil, and margarines should be emphasized. Delucci et al. offered the Step II American Heart Association diet (no more than 30% of total calories from fat, no more that 7% of calories from saturated fatty acids) to pediatric renal transplant patients with hyperlipidemia. Of 22 eligible patients, only 12 children were willing to participate. After 12 weeks of the diet, total cholesterol and LDL cholesterol declined modestly by 11% and 14%, respectively.[212] When the practical benefit of lifestyle change is limited, pharmacologic treatment should be considered. Lipid-lowering agents such as HMGCoA-reductase inhibitors have been used in pediatric renal transplant recipients with success.[213–216] However, these studies were small and larger controlled studies are needed to more clearly define efficacy and risk.

SUMMARY

Acute and chronic disturbances of kidney function in children require well-developed nutritional plans. Providing appropriate nutrition should be viewed as a critical element in the care of these children, as inadequate nutrition will negatively impact outcome, growth, and development. Alterations in renal function and clinical status during the disease course require repeated evaluations and adjustments of the nutritional care plan. If available, the assessment and counseling provided by a renal dietician is an indispensable resource for the child, caregivers, and clinicians.

Inflammatory Bowel Disease

52

Francesca Penagini, MD
Rob Heuschkel, MBBS, MRCPCH

INTRODUCTION

From the earliest clinical descriptions of children with Crohn's disease (CD) it was clear that significant undernutrition is a major feature of the disease. Furthermore growth retardation, which may have a nutritional component, is a common clinical manifestation. While on occasion undernutrition and short stature may be a feature of chronic ulcerative colitis (UC) in children, these manifestations are less prominent in this disease.

Early reports of nutritional therapy in children with inflammatory bowel disease were thus aimed at the restoration of normal nutrition. More recently a body of evidence has shown that in children with CD, nutritional therapy has a specific anti-inflammatory action in addition to its ability to restore their nutritional status to normal. Unfortunately there is no such firm evidence in children with UC, yet here also the provision of adequate nutrition still remains important.

The value of nutritional therapy in CD chiefly centers on the use of exclusive enteral nutrition (EEN) in the treatment of active disease. Enteral nutrition may be defined as the provision of a liquid formula diet by mouth or by tube into the gastrointestinal tract.[1] Bottle feeding of normal infants is excluded from this definition. Although it is now clear that oral feeding may be highly effective, research began with liquid formulae administered by intragastric tubes. The technique of tube feeding goes back at least as far as 1872, with a report by Clouston in the *Lancet* on "Forcible Feeding,"[2] whereas the work of Elsie Widowson (1947) drew attention to the adverse effect of malnutrition on human disease in general.[3] The advent of effective parenteral nutrition then made clinicians aware how

dramatic the benefits of nutritional rehabilitation from malnutrition could be. The development of a range of complete formula diets of varying compositions, designed for a range of situations, has now made enteral nutrition a highly desirable and practical alternative to parenteral nutrition.

It was Giorgini et al. in 1973 who first suggested that treatment of malnutrition could lead to resolution of inflammation in a child with CD.[4] They described resolution of terminal ileal inflammation on barium follow-through after a period of elemental diet. In adults with CD, Logan et al. produced evidence that protein and lymphocyte loss from the gut decreased during feeding with an elemental diet.[5] Then in Quebec, Morin et al. described four children with Crohn's whose growth failure responded to an elemental diet and this was confirmed in larger studies.[6,7] In France, an elemental diet was given to children with CD by continuous nasogastric infusion. This was called constant rate enteral nutrition (CREN) but was a cumbersome technique not popular with the children. They used a complex regimen using oligopeptides, whereas others reported the use of a high osmolality amino acid–based elemental formula. At St. Bartholomew's Hospital in London, a semi-elemental diet using extensively hydrolyzed milk protein given intragastrically was shown in a small study to be as effective as conventional steroids in the induction of a clinical remission.[8] Most importantly though this study showed there was no short-term growth while on steroid therapy, whereas enteral nutrition lead to short-term growth acceleration. In subsequent follow-up studies it was shown that this could on occasion be sustained for some time if the child remained in remission even when back on a normal diet after the period of nutritional therapy.[9] Central to this approach to therapy was the concept of a period of six to eight weeks of enteral nutrition followed by a graded return to a normal diet.

ROLE OF DIET IN ETIOLOGY OF IBD

The etiology of IBD remains one of the greatest challenges in gastroenterology today. The presence of unexplained gut inflammation has inevitably led researchers to try and identify factors in our diet that may trigger, or even cause, IBD. Although it appears highly likely that there are several environmental factors involved in the etiopathogenesis of IBD,[10,11] the evidence that some of these may be dietary remains tempting. Although many studies claim that the intake of certain food components is associated with IBD, the specific effect of each component remains

questionable due to methodological limitations and numerous confounding variables. A recent meta-analysis confirmed that a high dietary intake of fat, polyunsaturated fatty acids (PUFAs), omega-6 fatty acids, and meat increased the risk of developing both CD and UC. The risk of developing CD appears reduced with high intake of fruit and dietary fiber, whereas a high vegetable intake decreased the risk of developing UC.[12] Whether nutrition has a direct effect on disease pathogenesis, or whether these effects are indirect via modulation of the intestinal microbiota, or both remains debated.[13]

It was initially suggested that the adoption of an urban lifestyle may lead to an increase in the incidence of IBD, as increases occurring much more rapidly than could be explained by genetic factors alone.[14,15]

Even though positive associations between high *protein* intake and IBD risk have been repeatedly reported in epidemiological studies, neither consistent data nor biologically plausible mechanisms are available. A possible exception is the consumption of animal protein, which might contribute to the etiology of IBD through its byproducts, which can be metabolized by the microbiota to substances that negatively affect colonic health. A recent prospective study conducted by Jantchou et al. demonstrated that a high protein intake, specifically animal protein, was associated with risk of IBD.[16]

With regards to *carbohydrates*, studies report conflicting outcomes.[12] Sugar was the first food component to be implicated in the development of CD in 1976,[17] yet its contribution to the pathophysiology of CD remains to be proven. A case control study conducted by Russel et al. demonstrated that patients with a recent diagnosis of CD were shown to consume greater quantities of sucrose than control groups,[18] although this was not confirmed in patients with UC.[19]

Recently, a large prospective cohort study (EPIC) found no association between UC and intake of sugar at baseline.[20] It has been hypothesized that excessive intake of highly fermentable but poorly absorbed short-chain carbohydrates and polyols may lead to bacterial overgrowth and next to increased intestinal permeability, which may confer risk of CD in genetically susceptible subjects.[21]

The positive effect attributed to dietary *fiber* has clear underlying mechanisms. Fermentable fiber can be metabolized by the microbiota to short-chain fatty acids; acetate, butyrate, and propionate. Butyrate has potentially important functions in the intestine as a source of energy for enterocytes and as anti-inflammatory mediator. Despite these potential

beneficial effects, which have been demonstrated in vitro, the results of retrospective studies on the relation between consumption of fiber and risk of IBD have been conflicting. High-fiber diet has been found to attenuate experimental colitis in animal models[22] and showed benefit in active IBD.[23] However, a large prospective cohort study (EPIC) found no protective effect against UC of a high intake of dietary fibers.[20]

The composition of the gut *microbiota* is thought to be a critical environmental factor in IBD, and recent evidence suggests a connection between diet and the intestinal bacteria.[13,24] Although it makes biological sense that different dietary regimens may affect IBD risk through affecting the composition of the gut microbiome, data are limited because this endpoint has not usually been included in human studies to date. In animal models, manipulation of both the type and level of both fat and carbohydrates have led to dramatic effects on the gut microbiota.[25] In humans, Werner[26] showed that depletion of luminal iron alters the gut microbiota and prevents some CD-like symptoms.

Patients with a recent diagnosis of CD have been shown to consume greater quantities of sucrose than control groups,[18] although this was not confirmed in patients with UC.[19] Whether or not a diet low in fiber leads to an increased risk of CD remains disputed.[27] Many of these studies have had methodological problems and as a result make it difficult to confirm that dietary differences antedated the development of disease. Reif et al.[28] however, again showed that a high level of sucrose intake (>92 g/day) occurred before symptom onset in patients with both UC and CD (OR 5.3 and 2.8, respectively), in contrast fructose and fiber consumption were both negatively associated with a risk for IBD. This carefully controlled study also reported an increase in fat consumption prior to a diagnosis of IBD. Omega-6 fatty acids such as linoleic acid can be metabolized to arachidonic acid (AA), which serves as a precursor for a family of proinflammatory signaling molecules, the so-called eicosanoids. In contrast, omega-3 fatty acids, particularly eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) antagonize the formation of eicosanoid mediators from AA, suppressing inflammatory cytokines. Metabolites of AA are not only elevated in the mucosa of patients with UC,[29] but a prospective cohort study recently suggested that individuals with the highest relative concentrations of AA in adipose tissue, reflecting dietary intake, have a significantly increased risk of developing UC.[30] These studies concluded that up to 30% of adults with UC had a linoleic acid intake above the lowest quartile, with obvious implications for intervention

and potential symptom reduction.[29,30] These findings were mirrored by Geerling et al. who reported an increased risk of developing UC in those with a high consumption of monounsaturated and polyunsaturated (mainly n-6 PUFA) fats as well as vitamin B6.[31]

However overall, these findings suggest no more than that a low residue, highly refined diet is associated with the development of IBD, whereas a high fiber diet, rich in fruit and vegetables, and low in linoleic acid may be more protective. Large, prospective epidemiological studies will be necessary to adequately control for the many confounding variables that could affect this type of data.

Conflicting evidence is also available on the role of butyrate in the pathogenesis of UC. Data suggest that butyrate levels decrease in the distal colon,[32] with the ability of colonic mucosa to utilize butyrate being reduced even in macroscopically "normal" mucosa of patients with quiescent UC.[33] However, the response of distal UC and so-called diversion colitis to butyrate enemas has not been striking.[34,35] Dietary sulfates have been implicated in reducing the ability of colonocytes to utilize butyrate by their conversion to toxic sulfides like H_2S,[36] although luminal levels of sulfides do not appear to be significantly higher in patients with UC than in normal controls.[37] However, along with a putative role of oxidant injury in the pathogenesis of UC, all these mechanisms appear more likely to be involved as mediators of the injury in UC, rather than primary etiological factors.

It is also of note that researchers have been accumulating evidence over a number of years implicating the food borne pathogen *Mycobacterium avium* subsp. *paratuberculosis* in the pathogenesis of CD. Although detailed discussion of this is beyond the scope of this chapter, the presence of this organism in the food chain and its persistence in milk despite pasteurization, along with the characteristic Th1 immune response it evokes continues to hold interest.[38] However, well-controlled clinical trials have failed to show any benefit of antituberculous therapy.[39] Larger, population-based cohort studies are still needed to better define the importance of this and other specific dietary risk factors.

NUTRITIONAL COMPLICATIONS OF IBD

The chronic and relapsing nature of intestinal inflammation inevitably impacts on a patient's nutritional status. However, their nutritional state is not only determined by the dietary intake, but also by the patient's age,

type of disease, disease distribution as well as their disease activity. These factors all contribute to the wide range of nutritional complications seen; from almost none in a child with mild distal UC, to the most severe nutritional consequences of chronically active disease in a child with pan-enteric CD. Nutritional complications are rarer in children with UC, although a severe pancolitis may present with acute weight loss and significant iron-deficiency anemia.

Undernutrition in IBD may present in its different forms, most commonly as altered body composition, micronutrient deficiencies, and poor bone health; protein-energy malnutrition is exceedingly rare. Additionally, in pediatric IBD patients, growth failure and pubertal delay are associated with poor nutritional status. There are several factors that perturb the nutritional status in IBD patients. In particular, suboptimal intake, as a result of anorexia and food aversions, in combination with increased energy and nutrient losses, as a result of malabsorption and gut losses, can disturb the nutrient equilibrium and increase risk of undernutrition.[40] Moreover increased nutrient utilization and altered metabolism, as a result of activation of the immune system, tissue repair, and drug–nutrient interactions, may increase nutritional requirements well above those established for the general population (Figure 52-1).[41]

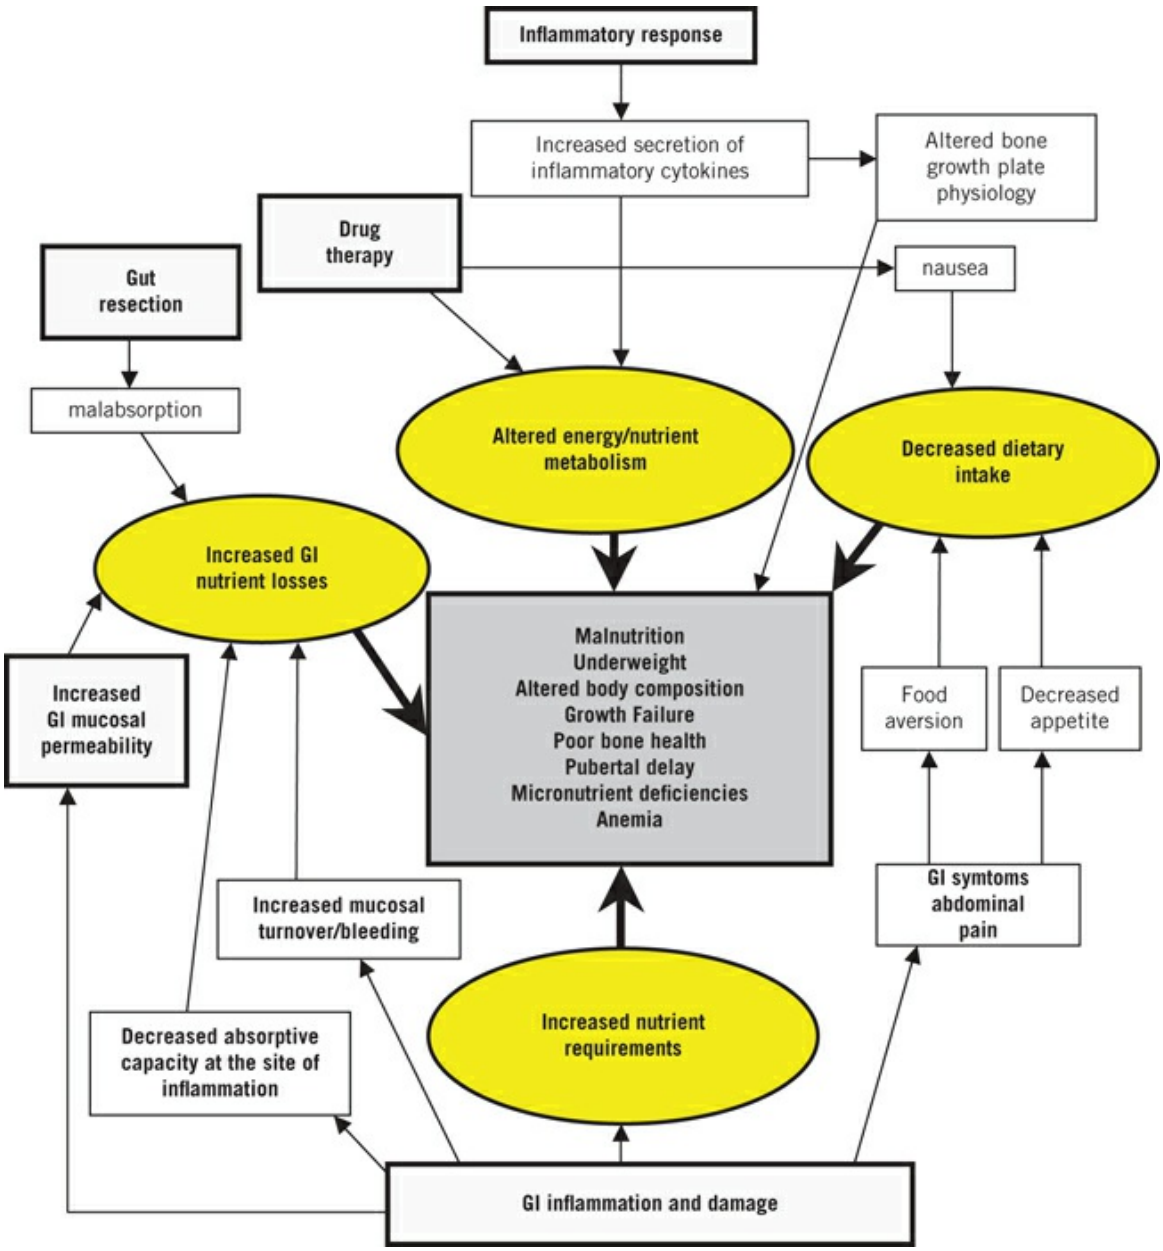

Figure 52-1 Mechanisms, inter-dependencies and key factors leading to nutritional compromise in patients with active Crohn's disease.

Caloric Deficiency and Growth Failure

The mechanisms surrounding the anorexia and undernutrition seen in IBD are complex and still poorly understood. As well as food avoidance as a result of abdominal pain or diarrhea, the reduction in caloric intake is due to the consequences of the systemic inflammatory response.[42,43]

Protein-energy malnutrition may occur as a result of unchecked disease

activity, with the associated anorexia being largely mediated by the proinflammatory cytokines IL-1 and TNF.[44] Activity of these cytokines leads to lean tissue loss,[45] reduced voluntary motor activity,[46] and protein synthesis, with a concomitant increase in protein catabolism.[47]

This state of increased need may not be met during active inflammation, and thus leads to chronic undernutrition. Winter et al. elegantly demonstrated the recovery of impaired pancreatic and gastric secretory activity with increasing body mass index (BMI) in severely malnourished (BMI ~14) adults with CD.[48] Many patients with IBD present features of protein energy undernutrition at the time of diagnosis, and this status fluctuates during the disease course. A history of weight loss is a common presenting feature of the newly diagnosed patients and accompanies almost every relapse, this was seen in approximately 60% of newly diagnosed CD children compared to 35% in UC patients.[49]

Protein intakes up to 1.5 g/kg body weight may be required per day to achieve adequate nutrition, with excessive supplementation perhaps even being counterproductive during the acute inflammatory state.[50] Increased protein oxidation and worsening of the nitrogen balance may result if overfeeding occurs during inflammation.[51] Children with IBD have abnormal anthropometry, whereas particularly those with CD present with low BMI, are underweight and thin compared to the national reference range or their healthy peer.[52]

Calorie intake in children with CD cannot be accurately determined by using estimates of average requirements (EARs), as four in five children will consume about 120% of EAR (range 100%–149%) while taking EEN as primary therapy at diagnosis.[53] Only the initial BMI was a predictor of subsequent weight gain on EEN, with a median of 11% being achieved over an eight-week course of treatment. Other authors have reported the intake in active disease to be 43%–82% of recommended values, yet with adequate calorie supplementation, improvements in linear growth can be achieved.[51,53–56] However, simple nutritional restitution may be insufficient to achieve adequate growth, suggesting that other factors are also important in mediating growth retardation.[57] An elegant study by Azcue et al.[58] demonstrated an inappropriately maintained resting energy expenditure (REE) in children with moderately active CD when compared to children with anorexia nervosa and similar degrees of malnutrition. This relative increase in energy expenditure, together with the voluntary reduction in intake further compromises nutritional status and hence optimal growth. Careful animal experiments, which did not look at body

composition, suggest that it is the reduced caloric intake that is largely responsible for the weight loss seen in active colitis. However, in this animal study, while able to restore calorie intake and body weight to normal, nutritional supplementation was unable to restore linear growth. At least in this animal model, 30%–40% of growth impairment is likely to be a direct result of the inflammatory process.[59]

Particularly in children with CD, active disease can have a profound and lasting effect on long-term growth,[60] and this is covered in greater detail later in the chapter. Although it is well documented that up to 90% of children with CD may present with impaired height velocity,[61] Hildebrand et al. also reported a subnormal growth velocity (<–2 SDS) in 24% of prepubertal children with UC, compared to 40% in those with CD.[62,60]

Body Composition

There are several reasons why body composition in IBD patients may differ from that of healthy individuals. The secretion of proinflammatory cytokines may alter energy metabolism, protein turnover, and energy substrate utilization, whereas the use of corticosteroids may increase body fat and have catabolic effects on lean mass (LM). There are few studies that have assessed body composition in children with IBD. LM has been consistently reported as being significantly lower in inflammatory bowel disease (IBD) patients compared to healthy control groups.[63] In a cross-sectional study,[64] it was found that children with longstanding CD had a 6% deficit in LM compared to healthy children after accounting for stature, age, pubertal stage, and race; however, fat mass (FM) was normal, suggesting nutritional cachexia. Thayu et al.[63] in a well-designed study of newly diagnosed children with CD, also reported gender associated differences in body composition. FM and LM relative to height (adjusted for age, race, and pubertal stage) were lower in female than in male patients. Compared to a cohort of healthy controls, body composition in girls was more consistent with wasting (low LM and FM), whereas in boys there was mostly preservation of FM and deficit in LM consistent with cachexia.

Osteoporosis

Owing to the fact that this complication is largely a problem of adult life, it is easy to forget that the accumulation of peak bone mass (PBM) occurs during adolescence and early adult life. The implications of a substantial

interruption in this process are only now becoming clearer as better long-term bone density data are becoming available. When disease activity is high, nutrient requirements increase as a result of malabsorption, enteric losses, and the metabolic cost of inflammation. Together these complications of inflammatory bowel disease also affect bone health by impairing normal bone mineral accrual, leading to reduced PBM, and in some cases, increased fracture risk due to early onset osteoporosis.

Much attention has focused on trying to tease out the relative importance of the factors that lead to reduction in bone mineral density (BMD) in patients with IBD. Inflammation with increased production of cytokines, growth failure, delayed puberty, malabsorption, decreased physical activity, and the use of glucocorticoids have been recognized as risk factors for suboptimal bone health in pediatric patients with CD or UC.[65] As the most important determinants of PBM appear to be age and genetic potential, these confound almost all studies in IBD trying to identify possible predictors such as nutritional status, disease duration, activity and distribution, and steroid therapy. Despite these shortcomings, poor bone health and reduced BMD has been commonly reported in adults with CD and is increasingly reported in children and young adult populations, both at diagnosis and over subsequent years. In a population-based study conducted by Schmidt et al.[66] 144 children and adolescents affected by IBD underwent a dual-energy X-ray absorptiometry of the whole body and spine. The entire IBD group showed significantly lower BMD Z-scores of the lumbar spine (L2–L4) in comparison to healthy controls. Low BMD with a Z-score ≤ –2 SD was present in 26.7% of the patients with CD and in 24.1% of the UC patients.[67] Despite this interpretation of BMD in the pediatric IBD population remains a problem given the significant pubertal and bone age delay, bone health remaining more complex than bone density alone. Bone mineral accrual during growth is highly related to muscle development, particularly during adolescence.[68,69]

In adults, it appears that up to 40% with established IBD have osteopenia (T ≤ –1.0; –1 to –2.5 SD from the mean), whereas around 10% have osteoporosis (T ≤ –2.5; >2.5 SD from the mean) when compared to age and sex matched controls.[70] The relative importance of disease activity, nutritional status, and cumulative steroid consumption remains debated. A large adult study did identify chronic steroid exposure as the only significant risk factor for the staggering 40% increased risk in osteoporotic fractures in adults with CD.[71,72] Furthermore, it appears that

BMD is no different to healthy age-matched adult controls within the first six months following symptom onset.[73]

However, up to 30% of children is still likely to have a significantly reduced BMD,[74,75] with children with CD tending to be more affected. Overall therefore, both unchecked inflammation and chronic steroid exposure lead to loss of bone mass.[76]

The impact of nutritional status is unclear, as the correlation with BMD may well be confounded by disease activity. Ahmed SF et al. suggest that the growth failure seen in children with CD leads to a reduction in the size/length of their bones, thereby leading to falsely low values of BMD. If adjustments for bone size are made, bone mass in children with active CD appears to be better than previously reported. If bone area is not considered, up to 65% of children with CD would be labeled with moderate to severe osteopenia, while this falls to 22% if appropriate corrections are made.[77] Although aggressive nutritional restitution is likely to minimize the chance of nutritionally dependent bone loss, whether or not supplementation with vitamin D and/or calcium provides added benefits remains to be determined by placebo-controlled studies. Identification of children at greatest risk is important, as urinary calcium excretion, plasma 25-OH vitamin D levels, and a baseline bone density scan allow monitoring and subsequent supplementation of documented deficiencies. There is great potential for bone remodeling if children are in good clinical remission. Following presentation with osteoporotic vertebral fractures and in a good nutritional state, a 16-year-old with CD displayed a dramatic recovery of vertebral height within three years of largely steroid–free therapy that controlled his disease activity.[78] Vitamin D deficiency is more common in adults and children with IBD, especially CD, than healthy controls.[79] Many factors are likely to contribute to this, including malabsorption secondary to mucosal disease or surgical resection, and reduced sunlight exposure, physical activity, and dietary intake.[80]

The fact that the consequences of osteoporosis occur so long after the diagnosis of IBD in childhood makes it imperative for pediatricians to be aware of the BMD data now accumulating on adults with IBD. Several larger series are now reporting the clear association with life-time steroid dose and the increased risk of osteoporotic fractures.[71] An ideal combination may be enteral nutrition and azathioprine/6-MP in the treatment of children with more severe CD. It is now clear that treatment regimens minimizing steroid therapy, and relying on nutritional therapy or other steroid-sparing agents, do not lead to the reduction in BMD seen in

patients receiving corticosteroids. Although the mechanism is still unclear, Infliximab has now been shown increase markers of bone formation.[81,82] Patients with a lifetime steroid exposure of 12.9 g have a significantly lower BMD than normal controls, whereas those with <2 g lifetime exposure are comparable to age-matched healthy controls.[83] However, it is also clear that osteopenia does occur in steroid-naïve patients.[84] Walther et al. demonstrated a similar proportion of osteoporosis in steroid-naive and steroid-treated patients.[85]

Besides corticosteroid therapy, which is known to influence bone integrity by inhibiting osteoblast proliferation and stimulating osteoclasts, the underlying systemic inflammation associated with CD has an independent detrimental influence on the bone health of children with CD. Inflammatory mediators such as TNF, IL-1β, and IL-6 may have a critical influence on mineral density and result in decreased bone formation, increased bone reabsorption, or both.[86]

Furthermore, unchecked inflammatory activity may lead to calcium and vitamin D malabsorption, which in turn increases parathyroid hormone secretion and further bone reabsorption.[87] Patients with small-bowel disease and/or resections are therefore also at risk of long-term osteoporosis.

Micronutrient Deficiencies

Identifying and treating macro- and micronutrient deficiencies are problematic for two main reasons. There is the initial difficulty of finding an accurate and reliable measure for each specific nutrient deficiency, followed by the inherent variability of a disease characterized by a remitting/relapsing course. There is also the impact of medical therapies and surgical interventions on nutrient status, for example, sulphasalazine inhibiting folate absorption and corticosteroids limiting calcium absorption. Clinically relevant micronutrient deficiencies in patients with IBD are unusual, and most are likely to occur when receiving long-term total parenteral nutrition (TPN).[88] Nonetheless, significant subclinical deficiencies in vitamins (B1, B6, C) and certain trace elements (magnesium, copper, and zinc) have been reported.[89]

Vitamin B12 deficiency occurs most often in patients with active terminal ileal CD, or following a resection of this part of the intestine. In addition to the usual consequences of these deficiencies, low serum B12 and folate levels may result in an elevation of homocysteine and hence contribute to a hypercoagulable state,[90] with folate supplementation

leading to a reduction in homocysteine levels.[91] Patients with IBD are also at risk of developing fat-soluble vitamin deficiency. A significant deficiency of both vitamins A and E has been documented in 16% of children with IBD, with moderate-to-severe disease activity leading to a deficiency in over 40% of children.[92] Whether or not this was a consequence of a poor dietary intake or disease activity was not made clear. The range of vitamin deficiencies in patients with long-standing IBD is wide. Two comprehensive studies documented deficiencies in biotin, folate, β-carotene, thiamine, and vitamins A, E, and C in 40%–90% of adults, despite inactive disease and adequate dietary intakes.[93,94]

Iron deficiency anemia is difficult to diagnose in children with CD. Both the anemia of chronic disease and the variability in serum ferritin as part of the acute phase response make clear guidelines impossible. Low values of serum ferritin (<15 μg/dL) certainly confirm iron deficiency, but this may also be present at much higher values. Combining the more stable serum transferrin receptor (sTfR) with serum ferritin has been of benefit in adults,[95] whereas a small pediatric study suggested basic red cell ferritin was a more reliable measure in the presence of inflammation.[96] Variable absorption and the common gastrointestinal adverse effects of oral iron also make the response to treatment difficult to interpret.[97] This, together with the potential exacerbation of colitis by the oxidative stress of oral iron supplementation, has led to successful trials of parenteral iron and erythropoietin use.[98,99]

Trace elements are reduced in up to 50% of patients with active IBD,[94] with zinc deficiency being the most common.[93] The latter has been implicated in the maintenance of intestinal barrier function by regulating tight-junction permeability, with supplementation leading to a reduction in gut permeability in both animal models of colitis and adults with active CD.[100] Authors have shown significantly reduced fractional zinc absorption in adolescents with stable CD compared to normal controls. This appears to be due to unusually high fecal zinc losses.[101]

Many micronutrients are also antioxidants (vitamins A, E, C and selenium), and thus, adequate supplementation may help counteract some of the oxidative stress that contributes to ongoing gut inflammation. Both serum selenium and erythrocyte glutathione peroxidase activity have been inversely correlated to plasma TNF-α levels in patients with active CD.[102]

Other Nutritional Consequences of IBD

Patients with long-standing IBD may of course also suffer the nutritional

consequences of their therapies. Sulphasalazine is most notable for its impact on folate metabolism by competitively inhibiting dihydropteroate reductase, but folate rarely requires supplementation. Patients with severe ileitis or a significant ileal resection may develop steatorrhoea, which in turn binds available free calcium, thus preventing calcium from binding to oxalate. High concentrations of luminal oxalates may lead to hyperoxaluria and renal calculi. A significant decrease in essential fatty acids has been correlated with a BMI < 50th centile and active CD,[103] irrespective of dietary intake.

INDICATIONS FOR NUTRITIONAL TREATMENT

The indications for nutritional intervention differ among the different types of IBD (Table 52-1). However, adequate nutritional support is an essential part of the long-term management of any chronic inflammatory disorder. In most cases, this involves the provision of nutritional supplements to complement an otherwise inadequate intake and may involve anything from overnight nasogastric feeds to long-term support on home parenteral nutrition. For UC, no exclusively nutritional therapy has been shown to be therapeutically effective. In contrast, over many years patients with active CD have responded well to EEN. There have only been anecdotal reports of patients with indeterminate colitis responding to EEN, although the responders are likely to be those with a more Crohn's-like phenotype.

TABLE 52-1 Indications for Enteral Nutrition in Crohn's Disease

- Exclusive enteral nutrition for active disease
- Perioperative parenteral nutrition and bowel rest
- Supplemental enteral nutrition for maintenance of disease remission
- Nutritional support to maintain adequate weight gain
- Dietary supplementation of vitamins/minerals

Ulcerative Colitis

There have been no studies showing that any form of nutritional intervention, used as sole therapy, can induce a remission in patients with active UC. Two randomized, prospective studies[104,105] clearly showed there was no role for exclusive total parenteral nutrition and bowel rest in

the management of acute UC. Although there were some nutritional advantages in the group on TPN, these were outweighed by the complications reported at the time.

Although often not as severe as in patients with CD, malnutrition does occur in children with UC.[106] However, although exclusively nutritional therapies are of no benefit in treating acute UC, nutritional support plays a vital role in minimizing further morbidity. Up to 10% of children with UC present with weight/height Z-scores ≤ –2,[107] and inevitably nutrition is compromised in acute disease, both by a reduced oral intake and by increased losses of both protein and blood from the gut mucosa.[108] Although the concept of continuing enteral feeds during an episode of acute colitis may raise concerns in some, the evidence clearly suggests that equal nutritional improvement occurs with TPN and total enteral nutrition (TEN) in active colitis.[109] Not only does the latter lead to fewer complications, it is less costly, more physiological, and much simpler to provide. However, there continue to be absolute contraindications to enteral nutrition (Table 52-2).

Although dietary supplementation plays a role in acute UC, there is no evidence that specific dietary exclusions are of benefit in the long-term. Well-balanced, healthy diets that include normal amounts of dietary fiber are to be encouraged. Short-term studies suggest improved gastrointestinal symptoms on isphaghula husk.[110] Initial data that suggested diets low in fiber were linked to an increased risk of colon cancer have now been refuted in large epidemiological surveys in women.[111] A study conducted by Sanchez-Fidalgo et al. demonstrated that dietary enrichment with extra virgin olive oil reduces the damage in acute colitis in murine models, by alleviating oxidative events and returning proinflammatory protein expression to basal levels. Extra virgin olive oil has demonstrated immunomodulatory and anti-inflammatory properties and in addition to its high monounsaturated fatty acid content evidences have accumulated on the favorable properties of minor, although highly bioactive, components present in the unsaponificable fraction (UF). Extra virgin olive oil UF diet might provide a basis for developing a new strategy in dietary supplementation for the prevention of UC.[112]

TABLE 52-2 Contraindications to Enteral Feeding

- Massive Hemorrhage
- Intestinal Obstruction
- Bowel perforation

- Toxic dilatation

Crohn's Disease

In children with CD, there are several reasons for nutritional intervention (Table 52-1).

Exclusive Enteral Nutrition

EEN is indicated as a first-line therapy in any child with acute CD, provided there are no absolute contraindications to enteral nutrition per se. The issue of whether or not enteral nutrition is as effective as steroid therapy at inducing a remission has been hotly debated for some time. However, what is clear from the pediatric literature over the last 20 years is that an exclusively nutritional therapy can be highly effective at inducing a remission from active disease.[113–115] The best results appear to be in those children with newly diagnosed disease,[116] although the pediatric evidence does remain limited in terms of the number of children reported. Studies have shown that EEN induces remission in up to 85% of children with newly diagnosed CD.[117,118] Large adult studies,[119,120] as well as some of the smaller pediatric studies,[115] suggest disease distribution does not affect the efficacy of the treatment. Colonic disease as well as terminal ileal disease appear to respond, with a similar reduction in inflammatory markers, disease activity, and improved mucosal histology.[114] More recent retrospective data however suggest that clinical remission with isolated colonic disease may only be about 50%, compared to about 75%–80% in the presence of any macroscopic ileal involvement.[121] Although there is only anecdotal evidence on the response of oral and perianal CD to EEN,[122] the authors have made use of EEN as an adjunct in treating severe perianal CD.

Adverse effects to using EEN in CD are very rare. However, we reported a case of refeeding syndrome in a child following her presentation with severe Crohn's colitis. A rapid loss of weight over the preceding four weeks, followed by treatment with exclusive polymeric nutrition, led to a dramatic fall in serum phosphate and signs of hypervolemia in the first few days of treatment.[123] It is important to remain aware of this complication when refeeding previously malnourished children with CD, as adequate supplementation in the first few days can prevent serious complications.

Perioperative Nutritional Support

Preoperative undernutrition has long been known to adversely affect surgical outcome. Although surgical outcome is related to the nutritional state of the patient[124] short-term preoperative use of TPN is insufficient to dramatically improve the nutritional status. Even 7–10 days of preoperative parenteral nutrition in malnourished "cancer" patients achieved only a 10% reduction in postoperative complications.[125] Parenteral nutrition may replace acute nutritional deficits in the immediate perioperative period and may also reduce length of small-bowel resection in adults with CD.[126,127] Uncontrolled studies in adults with IBD also suggest there is a reduction in postoperative complications following preoperative parenteral nutrition,[128] yet it appears most effective in patients with severe malnutrition and highly active disease.[129]

Improvements in the medical management of children with IBD are likely to continue reducing the need for surgery, yet recent studies still suggest that almost 60% of adults with CD will require an operation.[130] Older pediatric data showed that up to 80% of children with CD were needing surgery in the 15 years following diagnosis.[131] Emergency surgery may be unavoidable in a small number of children who present with fulminant colitis, however the majority will require surgery for treatment-resistant disease.

Although a child with acute, severe UC will require close monitoring of fluid and electrolytes in the perioperative period, they are less likely to have had a long period of active disease leading to chronic malnutrition.

Despite persistently active, treatment-resistant disease, surgery can often be planned some weeks in advance. In these circumstances, optimizing nutrition over a period of 4–6 weeks is likely to result in a much better postoperative course. Provided inflammatory activity and symptoms allow, several weeks of EEN in children with severe CD can lead to nutritional restitution prior to surgery. In isolated cases, the use of TPN for a several weeks may also be justified in preparation if enteral access is impossible. However, clinicians can be forced to compromise in the face of severe treatment-resistant disease, where disease activity does not allow time for any improvement in nutritional state and surgery should then not be delayed.

Postoperative support for all children, irrespective of the type of abdominal/perianal surgery should involve institution of enteral feeds as soon as possible. Adult evidence demonstrates no increase in complications when patients are fed enterally within 48 hours of colectomy.[132] Very early use of enteral supplements reduces early

postoperative complications even in undernourished adults, and leads to a better weight gain, as well as an improvement in physical and mental quality of life.[114] Routine use of postoperative TPN in well-nourished patients should be discouraged as it increases complication rates.[133] However, provision for TPN should still be made if enteral feeding is likely to be delayed for more than 1–3 days in any undernourished child who is likely to suffer a long convalescence without achieving full enteral feeds.

NUTRITIONAL TREATMENT OF ACTIVE CROHN'S DISEASE

In severe malnutrition, there is clear evidence of a secondary immune dysregulation.[134] Both T cell numbers and secretory IgA levels are consistently reduced, and there are also defects in bacterial phagocytosis, lysozyme, and interferon production. Although today's children with CD are not often severely malnourished, they are certainly well below their expected centile for weight.[135] It is therefore quite clear that this degree of malnutrition does little to attenuate tissue-damaging immune responses.

Parenteral Nutrition

The advent of parenteral nutrition in the early 1970s proved useful in managing intractable cases of CD[136] and its use became more widespread as an alternative primary therapy for severe disease.[137] As would later be clearly demonstrated for enteral nutrition,[60] it was parenteral nutrition that was first shown to reverse growth failure in children and adolescents with active CD.[55,138] However, as awareness of the septic and thrombotic complications associated with an indwelling line increased, the use of parenteral nutrition in CD declined. Although it still appears to be as effective as elemental nutrition in the short-term treatment of acute disease,[139] its complications, practical difficulties, and expense, limit its use. Furthermore, total parenteral nutrition induces mucosal atrophy and increases bacterial translocation,[140] something that is entirely preventable by luminal nutrition.

The combination of intravenous nutritional support and complete bowel rest has not been shown to be more effective in treating active disease than either EEN or TPN with oral feeding.[141] In a controlled study, 58%–71% of all groups achieved a clinical remission, indicating that

bowel rest per se has no added effect on the disease, but that improved nutrition in any form has clinical benefit. However, there have also been a number of case series suggesting that exclusive parenteral nutrition may be of significant benefit in severe Crohn's colitis,[126] with at least one study documenting endoscopic healing of mucosal ulcers on exclusive parenteral nutrition.[142] Despite this, the preference for nutritional support in most cases remains an enteral feed.

There has been limited success (35%) in achieving fistula closure on exclusive TPN,[143] with any improvement not being sustained once back on a normal diet. In view of other therapies, such as Octreotide and anti-TNFα antibody, TPN now has only a very limited role in the management of these fistulae.

Children only rarely have bowel resections large enough to require long-term home parenteral nutrition support. However, if in adults less than 100 cm of jejunum or less than 50 cm of small bowel with an intact colon remains, long-term parenteral nutrition is often necessary.[144] Yet over 70% of these patients will be on a full oral diet within 12 months of starting home parenteral nutrition.[145]

Enteral Nutrition

Elemental Diet

An elemental feed is a chemically defined diet whose protein source is amino acids or short-chain peptides, with short-chain carbohydrates and added fat, minerals, and vitamins. The National Aeronautics and Space Administration (NASA) had initially designed elemental diets for astronauts.[146] This was with the intention of providing a nutritionally complete diet of which as much as possible would be absorbed. However, although absorption was limited mainly to the upper small bowel, the diet did not prevent the production of stool as had been hoped.

Nutrition was initially used in inflammatory bowel disease as an adjunct in malnourished patients with growth failure. Elemental diets were developed and first used as sole therapy for IBD in adults in the 1970s.[147] It was then shown that nutrition had a beneficial effect on disease by reducing the increased gut permeability characteristic of CD.[5] Logan et al. studied seven adults with extensive jejuno–ileal CD. They showed a reduction in both gut protein and gut lymphocyte loss during a period of elemental feeding. This was the first report that an elemental diet could directly improve gut function, probably by reducing bowel inflammation.

In 1973, Giorgini et al.[4] reported the first successful use of enteral

nutrition in treating a child with acute CD. It was then shown that enteral nutrition was effective in treating a series of children with CD. Successful use in combination with drug therapy led on to a further study by the same group, which first showed exclusive CREN to be as effective as steroid therapy at inducing a remission.[148] While both these studies had few patients, they gave the first insights into the possible benefits of nutritional therapy as treatment for childhood CD. In addition to achieving disease remission, nutritional therapy was also found to have beneficial effects on inflammatory masses and fistulae.[6,148] Simultaneously, both Morin et al. and O'Morain et al.,[149] documented that an elemental diet improved linear growth in several children with active CD.

A variety of devices, formulas and regimens were then used to feed patients intragastrically. Continuous feeding[7,150] and then overnight feeds predominated[8] for the induction of remission. Supplementation of an elemental diet with glutamine, a gut-specific metabolic fuel, did not further improve efficacy, although the small numbers in this study make conclusions difficult.[151]

Semi-elemental Diet

Once elemental diets had achieved their first successes, short-chain peptide containing diets were suggested as a better nitrogen source than amino acids.[152] Silk et al. refuted previous evidence that free amino acids were better absorbed than di- and tripeptides. By using an intestinal perfusion technique in adults, he was able to demonstrate better absorption of amino acids from both casein and lactalbumin hydrolysates, than from an equimolar feed of free amino acids. Not only was there a more uniform absorption of amino acids, but the hydrolysates had a beneficial effect on jejunal absorption of water and electrolytes. There followed the first small randomized study of 7–8 children in each group, in which overnight nasogastric feeding of a semi-elemental diet was compared to prednisolone treatment in children with predominant small-bowel CD.[8] A 4–5-chain amino acid–based diet was as effective as steroids at achieving a remission in active CD. It again confirmed the North American finding that there was a clear acceleration in growth in the group not taking steroids.

Polymeric Diet

It therefore appeared that steroids may have a similar efficacy to semi-elemental feeds in the induction of remission. Several adult studies reported the efficacy of whole protein diet compared to both that of

elemental diets and to steroids. Raouf et al.[153] and others all found polymeric diets to be as effective as an elemental diet at inducing remission.

Polymeric diets were also shown to be as effective as conventional steroid treatment. Gonzalez-Huix et al.[109] confirmed this in adults, and Ruuska et al.[115] and Beattie et al.[154] in children. Ruuska et al. in a well-planned but small study (n = 19), showed a polymeric diet to be as effective as steroids in inducing a remission in children with acute CD. More recently Borrelli et al. demonstrated that a course of polymeric formula is equally effective to corticosteroids in inducing remission in children with active CD.[155] In this prospective 10-week open label trial, 37 children with active CD were randomized to receive oral polymeric formula alone or oral corticosteroids. At week 10, the proportion of patients achieving clinical remission was comparable between the two groups (polymeric formula: 15/19 [79%; 95% confidence interval (CI), 56%–92%]; corticosteroid group: 12/18 [67%; 95% CI, 44%–84%]; P = 0.4; not significant). However, the proportion of children showing mucosal healing was significantly higher in the polymeric (14/19; 74%; 95% CI, 51%–89%) than the corticosteroid group (6/18 [33%; 95% CI, 16%–57%]; $P < 0.05$). A further great advantage in using a polymeric diet then became clear. Although almost all children previously required feeding by intragastric tube, whole protein formulas such as AL110 (Nestlé-Clintec), used by Beattie et al.[113] and Nutrison Standard (Nutricia), used by Ruuska et al.[115] were palatable enough for daily oral consumption. Children rarely required a nasogastric tube to complete their entire nutritional needs. This provided a considerable improvement in the quality of life for children on several weeks of nutritional therapy.

The most recent and most definitive cohort study to date, by Fell et al.,[114] shows that a whole casein, polymeric diet (Modulen IBD, Nestlé Clinical Nutrition), rich in transforming growth factor β, is well tolerated and achieves a clinical and histological remission. Twenty-nine consecutive patients were treated with the exclusive enteral diet for an eight-week period. Although over half had mild disease, 12 had moderate-to-severe disease with a pediatric CD activity index (PCDAI) >30.[156] A nasogastric tube was only required in one patient for the first two weeks of treatment. Only 2 of 29 patients failed to show any clinical response, one with severe colonic disease, the other with an inflammatory mass requiring surgery. Twenty-three of 29 patients achieved a complete remission on PCDAI scoring. The PCDAI fell dramatically within two weeks of starting

the diet, but continued to fall until eight weeks of treatment. There was significant macroscopic and histological improvement after treatment, with mucosal healing occurring in the terminal ileum and colon of eight and two patients, respectively. Serum TNFα and mucosal mRNA for IL-1β and IL-8 were significantly reduced in both the terminal ileum and the colon after treatment. IFN-γ was significantly reduced and TGFβ was elevated in the terminal ileum alone. There is no direct evidence that the TGFβ in the enteral formula is responsible for the upregulation of mucosal TGFβ. Nonetheless, this study strengthens the findings by Breese at al.,[157] that polymeric enteral nutrition alone can achieve an improvement in histology and a complete normalization of some of the mucosal messenger RNA of proinflammatory cytokines involved in tissue damage.

Bannerjee et al. documented the most rapid reduction in proinflammatory cytokines to date, in children receiving EEN for active CD.[158] Within three days of starting an exclusive polymeric diet, there was a significant reduction in IL-6 and ESR. This, together with improvements in CRP, insulin-like growth factor-1 (IGF-1), and PCDAI by day seven, predated any measures of nutritional restituation (mid-upper arm circumference/triceps skinfold thickness). Further evidence showed that nutritional therapy in this situation is providing more than an optimal calorie intake.

The lipid composition of some polymeric diets has been held responsible for some of the variability in their efficacy.[159] High long chain triglycerides (LCT) concentrations have been associated with a poorer response in treating active CD, with suggestions that the high linoleic acid concentration may be responsible,[160] although high concentrations of medium chain triglycerides (MCT) in the feed does not affect its short-term efficacy.[161] However, the only two randomized studies have been unable to show a difference in efficacy between formulae containing either low or high amounts of long-chain triglyceride.[162] Only one randomized study appeared to show a significant difference in remission rates depending on the fatty acid composition of the polymeric feeds. Gassull et al. report a significantly better clinical remission rate in adults after four weeks of an exclusive enteral feed rich in n-6 fatty acids, compared to one high in monounsaturated fats (52% vs. 20%, respectively).[109] Why this conflicts with previous evidence remains unclear although the high percentage of synthetic oleate (79% of total fat) in this study may mask beneficial effects previously seen with formulas containing different fatty acid profiles.

There is limited evidence of milk intolerance in adults with active CD. True lactase deficiency is an unusual cause of symptoms in adults with active CD,[163] however, up to 46% complained of gastrointestinal symptoms related to milk intake. In contrast, exclusive enteral feeding with lactose-free, whole casein diets has not been associated with intolerance in children with active disease.

Although elemental or semi-elemental formula was initially used in EEN, available data does not show any significant difference in outcome based on the type of formula used.[164] A meta-analysis of 10 trials (334 adult patients) did not reveal any difference in efficacy between elemental and nonelemental formulations (odds ratio 1.10; 95% CI 0.69%–1.75%).[165] Polymeric formulas are generally less expensive and have better taste characteristics, permitting oral administration in many children. Moreover, the use of polymeric formula may be associated with better weight gain than an elemental diet.[164]

Steroids versus Enteral Nutrition

Contrary to these striking pediatric findings, large adult trials[166,119,167] as well as meta-analyses of the adult data, have found steroids to be more effective than enteral nutrition at inducing remission in active CD.[168] In the most recent Cochrane review comparing efficacy of induction between corticosteroids and EEN, meta-analyses of six trials (192 patients received EEN and 160 patients received steroids) favored corticosteroid therapy over enteral nutrition (95% confidence interval [CI] 0.21%–0.53%). The studies analyzed contained both adult and pediatric patients; however, many pediatric trials were excluded from this analysis owing to methodological weakness.[165] The meta-analysis by Griffiths et al., while including both children and adults, excluded most of the smaller pediatric studies. This large review (n = 413) reported that steroids were significantly more effective at achieving a remission than enteral diets (odds ratio 0.35; 95% CI 0.32%–0.58%). Like other analyses, this study also relies on clinical disease activity indices to document clinical remission rates, but these tend to favor steroid therapy by their reliance on a patient's general feeling of well-being. As a result, conclusions from these studies are frequently and inappropriately applied to children, despite there being clear differences between adult and pediatric patients. Most children have had much shorter disease duration and tend to be much more compliant with therapy. Furthermore, no comment is made on the differing adverse effects and abilities of the two treatments to heal gut mucosa, with

steroids having been well-documented to have limited effects on gut inflammation.[169] As yet no analysis has detected a significant difference in efficacy between elemental or polymeric diets.[170]

Despite the several small pediatric studies that suggest a useful role for enteral nutrition in active CD, the view has thus prevailed that enteral nutrition is less effective than steroid therapy. A meta-analysis of pediatric data was performed to maximize the available pediatric data.[171] Despite limited numbers of truly randomized children, sensitivity analyses allowed the authors to arrive at valid and important conclusions. The summary data clearly showed enteral nutrition to be as effective as steroids in the treatment of children with active CD. Additionally, a meta-analysis of pooled data from four randomized controlled trials in 144 children found no significant difference in remission rates at 8–10 weeks between EEN and corticosteroids (relative risk 0.97, 95% CI 0.7%–1.4%, random effects model).[172] Furthermore, to overturn this finding and demonstrate that steroids were significantly more effective than enteral nutrition would be close to impossible given the outcomes of the pediatric studies reported to date. All these studies principally address efficacy as their primary outcome measure, largely ignoring the very different side-effect profiles of each therapy. Corticosteroids have many significant adverse effects, whereas oral enteral nutrition has almost none. Prospective observational studies have also highlighted that even in the pediatric age group about 30% of children with CD, treated with corticosteroids within 30 days of diagnosis, are corticosteroid dependent at one year.[173]

Enteral Nutrition and Crohn's Colitis

There remains the further question of whether enteral nutrition is less effective at treating Crohn's colitis than Crohn's ileitis. Early use of enteral feed was limited to children with predominantly small-bowel disease,[174] with a suggestion that colonic disease was unresponsive to nutritional management.[175] More recent evidence from Thomas et al.,[176] Ruuska et al.,[115] and Fell et al.[114] however, supports the value of nutritional therapy in large-bowel and small-bowel disease. More recently Buchanan et al. retrospectively analyzed the remission rates of 114 children with CD treated with an eight week course of EEN and studied factors affecting treatment outcome, including disease phenotype. The analysis did not show any significant difference between the remission rates achieved by individuals with isolated small-bowel disease compared to those with isolated colonic disease [10⁄13 (77%) cf. 15⁄19 (79%)

respectively, $P = 0.88$], suggesting again that disease phenotype does not influence clinical remission.[177]

The improvement in colonic mucosal cytokine profiles after enteral nutrition,[114] provides hard evidence that there is an effect on colonic disease. Larger studies in adults also confirm that disease location does not appear to influence the response to treatment.[119,167,168] However, a more recent retrospective analysis of 60 children treated with EEN, suggested disease distribution may be relevant in the response to nutritional therapy. Children with any macroscopic ileal inflammation were significantly more likely to achieve a clinical remission than those children with colonic involvement alone (75% vs. 50%).[121,82] Despite this, many individuals with Crohn's colitis continue to respond extremely well, still making EEN the first choice for any child with CD, irrespective of their disease distribution.

Food Reintroduction

There has long been uncertainty as to the best way of reintroducing adults and children onto their "normal" diet after a period of EEN. The evidence for any of these different practices is very limited, with most approaches having been selected by experienced clinicians on the basis of theories prevalent at the time.

The best-described reintroduction program is based on the stepwise introduction foods, starting with the least allergenic.[178] One new food is introduced every 48 hours and if not tolerated, reintroduced at the end of the program. This systematic, but quite laborious program not only allows individual foods to be identified if causing immediate symptoms, but also gives the patients several more weeks on reasonable quantities of enteral nutrition while their normal diet is reestablished. The most frequently implicated foods causing discomfort in adults are cereals, dairy products, and yeast, although in children only a minority requires exclusion of specific items from their diet. In a two-year follow-up study of about 100 adults, the relapse rate was only just significantly lower in the group excluding dietary products that caused symptoms compared to those maintaining a normal diet.[179] There is thus insufficient evidence to routinely suggest exclusion of specific food items in children with CD.

Other units use less evidence based, but more practical reintroduction programs which range from the immediate introduction of a full diet, to a graded introduction over three weeks with the "ad libitum" diet increasing by 25% each week, along with the simultaneous reduction in enteral

nutrition.

ENTERAL NUTRITION AS MAINTENANCE THERAPY IN CROHN'S DISEASE

There has been much interest in whether dietary modification may prolong a remission in CD.

Numerous reports have considered and evaluated the role of partial enteral nutrition in the maintenance of remission and prevention of relapse. In addition to prolonging remission, such an approach may delay the requirement for further therapy (e.g., corticosteroids), while optimizing growth and nutrition. Partial enteral nutrition has been provided in various forms: overnight nasogastric (tube) (NG) feeds in conjunction with normal daytime eating, short course of NG feeds every few months, or as oral supplements in addition to oral eating throughout the day.

Initial studies suggested intermittent use of EEN for one month in every four could not only reduce steroid requirement and reduce disease activity, but also increase long-term growth rate in children with CD.[180] Although this intermittent use of EEN may have had a role in managing patients with otherwise intractable disease and a previous good response to enteral nutrition, repeated and prolonged use of exclusive enteral diets in most adolescents is difficult and mostly unnecessary. Given the availability of other, currently more effective maintenance agents, compliance with supplements of enteral nutrition is likely to be much greater if these can be shown to be effective.

Low-residue diets are not indicated in the maintenance of remission in CD. Unless required as a dietary modification in the presence of fibrosing/stricturing disease, they have not been shown to prevent disease relapse.[181]

A retrospective study in which a normal "ad libitum" diet of children with CD was supplemented with an additional 30% of the recommended daily calorie intake as polymeric feed, led to the halving of relapse rates within the first 12 months.[182] Small controlled studies also suggest an advantage to simple long-term calorie supplementation per se,[183] although larger, more definitive studies are still awaited. However, it is highly likely that a long-term nutritional supplement, in combination with a well-tolerated immunosuppressant, will provide the optimal maintenance therapy for most children with moderate-to-severe CD.

Several studies from Japan have also evaluated the role(s) of partial

enteral nutrition in adult populations. One study included 51 patients with CD in remission, who were randomized to receive half of their energy as elemental formula with normal diet (26 patients) or to have an unrestricted normal diet (with no additional supplements) (25 patients) for up to 24 months. Remission had previously been induced by EEN, parenteral nutrition, surgical resection, or corticosteroids. During the period of observation, the relapse rate of the treatment group was almost half of the free-diet group (34.6% vs. 64.0%; multivariate hazard ratio 0.40, 95% CI 0.16%–0.98%).[184]

Attempts at supplementing diets with specific anti-inflammatory agents continue, with fish oils receiving particular attention. Their effects on reducing mucosal eicosanoids (particularly leukotriene B4 and thromboxane A2)[178] have been widely reported. The n-3 fatty acids present in fish oils may also inhibit interleukin 1β and tumor necrosis factor production.[185] In addition, they also decrease platelet responsiveness,[186] and thus may act to reduce the multifocal gastrointestinal infarctions that have been reported as early pathogenic steps of CD.[187] Several large placebo-controlled, randomized studies have been performed on adults with both CD and UC,[188] but unfortunately much of the data remain conflicting. Although different methodology makes generalizations difficult, several important issues are raised. Although low-dose regimens cause no appreciable adverse effects,[189] compliance with high-dose fish oils in adults is poor, making long-term maintenance therapy in children even less attractive. Belluzzi et al.[188] found that supplementation with 2.7 g of n-3 fatty acids reduced the relapse rate in adults with CD, although another large study failed to confirm any benefit over placebo in using either >5 g/day of n-3 fatty acids, or maintaining a diet low in carbohydrate (84 g/day).[190] However, despite no clear-cut clinical benefits, significant changes are reported on a mucosal level. Colonic inflammatory cell infiltrates are reduced and the synthesis of LTB4 and TXA2 downregulated after supplementation with n-3 fatty acids.[190] It may therefore be that further refining of the composition, formulation, and dose is required before fish oil supplements become an accepted part of maintenance therapy. A small prospective study in children with CD (n = 38) suggests that adjunctive therapy with enteric coated omega-3 fatty acids and mesalazine (50 mg/kg/day) reduces relapse rates at 12 months compared to mesalazine alone.[191]

Other, more specific dietary interventions have been reported to prolong remission in CD. Although none of these have been assessed in

larger, placebo-controlled studies, they offer interesting clues to the role dietary modification may play in maintaining disease remission. A small study randomizing patients to a diet low in microparticles,[192] suggested significant benefits in disease activity and remission rates after four months when compared to 10 patients on a normal diet. Diets low in refined sugars have been not been found to prevent relapse rates in adults with CD.[193] Similarly, the presence of yeast in the diet of patients with CD may potentiate disease relapse, but larger studies are necessary before firm conclusions may be drawn.[194]

As the importance of gut microflora in the etiology of IBD has is increasingly recognized, so the prospect of modulating it by means of "functional foods" has gained much support. Although discussion is beyond the scope of this chapter, the mechanisms of action and potential implications of this exciting new field are great for patients with chronic intestinal disease driven by enteric flora. It is quite clear that over the next few years we are likely to see larger, placebo-controlled trials of both pro- and prebiotics. Prebiotics are the complex sugars such as fructo-oligosaccharides and inulin, which pass into the colon undigested where they may be selectively fermented by certain probiotic species.[195] Attempts to maintain remission in both UC and pouchitis with combined probiotic combinations has proved quite successful,[196] whereas *Lactobacillus GG* alone may have a role in improving gut barrier function and clinical status in children with CD.[197]

If long-term nutritional support is required, most children will tolerate a more palatable polymeric formula by mouth. However, some children will require supplementation by tube. Although short-term support can be given via a nasogastric tube, longer-term needs should be met via a more permanent device. Where nutritional support is needed for several months, placement of a percutaneous endoscopic gastrostomy (PEG) is ideal. Despite initial reservations about possible complications from fistulous tracts formation, PEG placement has now been documented to be uncomplicated in selected adults and children with IBD.[198] In patients receiving corticosteroids, adhesion of the gastric to the abdominal wall may be delayed, and thus early "pulling" of the PEG could lead to tract disruption.

THE ROLE OF ENTERAL NUTRITION ON GROWTH AND DEVELOPMENT

Epidemiology of Growth Failure

After the onset of symptoms, but before a diagnosis of CD is made, up to 46% of children will have a reduced height velocity, with only 12% having a normal height velocity up to the time of diagnosis.[61] In contrast only 3%–10% of children with UC may present with reduced height velocities at diagnosis.[62] Although much of this data are now over 10 years old, and an accurate diagnosis may now be made more quickly, it is clear that untreated CD has profound implications on a child's growth potential. Motil et al. reported in a cross-sectional study of their pediatric IBD patients that 23% had a Z-score < –1.64, with 50% of these having a bone age delayed by >1 year over their chronological age.[199] Physicians caring for children with IBD, particularly CD, therefore, have the unique opportunity to try and modify the impact that both disease and therapy has on the growth rate of their patients. Sawzcenko et al. recently reported that children with the IL6-174 promoter polymorphism are more growth retarded at diagnosis than those without.[200] Although levels of CRP were highest in children with this polymorphism, they appeared to be at no increased risk of developing CD than the other polymorphisms compared to 351 healthy controls. The authors speculate that IL-6 mediates growth failure in these children, and that genotyping at an early stage would allow the use of specific growth sparing/focused biological therapies.

A delay in presentation is associated with a significantly greater degree of growth impairment at diagnosis.[107] The length of this delay appears to correlate with a lower height Z-score at diagnosis, and hence with a lower final adult height.[201] A delay in diagnosing the more subtle presenting symptoms of jejunal CD may at least in part explain the more significant reduction in adult height seen in this particular group of children. Despite management within tertiary centers, 49%–65% of children with CD have a reduced height velocity in early puberty, with growth velocity remaining less than 4 cm/year during the first 1–2 years of therapy.[62,202] Hildebrand et al. report a mean Z-score for height of –0.6, two years after diagnosis in 46 consecutive children with CD.[62] Griffiths et al. reported that of 67 consecutively diagnosed children with CD followed to maturity, about two-third maintained or increased their Z-scores for height.[203]

The outcome of many of these studies reflects management where the mainstay of therapy was often corticosteroids, and so does not include the more recent move to the earlier use of steroid-sparing agents. However, although the most recent follow-up data show that the majority of children diagnosed with CD are closer to their expected adult height, almost 20%

will be at least 8 cm below the height expected by mid-parental centile.[201] Earlier diagnosis and identification of those children at risk of growth failure remain a significant problem for clinicians wanting to optimize growth outcomes.

Etiology of Growth Failure

The growth failure seen in children with IBD is multifactorial, with inflammation, undernutrition, and steroid therapy being its principal determinants.

Initial evidence suggested that chronic undernutrition was the main factor in the growth failure seen in children with IBD,[55] with studies confirming that simple nutritional restitution improved the linear growth of children with CD.[54,56] Children with active CD have a relative insufficiency of dietary intake when compared with children of the same age,[204] although they may compensate with an increased intake between disease relapses.[202] However, simply increasing the calorie intake, as seen in patients on steroids, does not confer the same benefit on growth as a lower calorie intake received on EEN.[176] The presence of low levels of IGF-1 in children with active CD strengthens this association, as the relationship between IGF-1 and malnutrition is now clear.[205] Both IGF-1 and its carrier protein IGF-binding protein-3, are increased significantly by treatment with EEN.[204,206] Further evidence that inflammation, and not only nutritional factors, plays a role in determining growth can be seen in studies of children undergoing surgery for active IBD. Although postoperative catch-up growth is not documented by all authors, several authors show a clear growth spurt occurring after the removal of an inflamed segment of bowel.[207] Although this is most striking in prepubertal children, the benefit is still substantial if surgery is carried out before the final stages of puberty.[135] This response may of course in part be the result of improved postoperative nutrition. However, Varille et al. neatly documented that even children undergoing localized resections for stricturing disease had a significant reduction in REE and increase in nitrogen utilization four weeks after surgery, despite maintaining preoperative nutritional and steroid regimens.[208]

There now seems little doubt that ongoing inflammatory activity plays a key role in the inhibition of growth.[209] Studies conducted in animal models and in humans show that proinflammatory cytokines have an effect on the hypothalamic–pituitary growth axis, influencing the growth hormone (GH)/insulin–like growth factor synthesis. In a colitis-induced rat

model, Ballinger et al.[210] showed that, despite nutritional supplementation to restore energy intake and to increase weight gain, inflammation contributed to 30%–40% of growth retardation. In rats with colitis, a negative correlation between plasma GH and IGF-1 levels was found, suggesting inflammation-induced hepatocyte resistance to GH stimulation. De Benedetti et al.[211] had previously suggested a direct effect of the proinflammatory cytokine interleukin (IL)-6 on the hypothalamic–pituitary growth axis.

Reported abnormalities of the somatotrophic axis in children with CD are variable. Some studies have reported low levels of IGF-1 but normal levels of stimulated or physiological GH secretion.[212,204] Farthing et al.[213] reported low-GH levels following insulin tolerance test in two out of five growth-retarded children with CD. None of the children was on corticosteroids and the GH insufficiency was attributed to the disease itself.[214] The link between systemic GH levels either from stimulation tests or physiological sampling, and serum IGF-1 levels and linear growth in IBD is still unclear although one group of investigators have reported an association between systemic IGF-1 level and height velocity in children with IBD.[204] The finding of relatively low serum IGF-1 levels with relatively normal GH levels in affected children and their association with short stature in affected cases points to the possibility of a state of GH resistance.

Downregulation of proinflammatory cytokines by enteral nutrition may partly improve growth by reducing IL-6, a potent inhibitor of IGF-1.[215] There is a dramatic reduction in CRP, with concomitant increase in IGF-1 and IGFBP-3, within 14 days of commencing EEN.[113,114] This clearly indicates that enteral nutrition also has a more rapid, direct anti-inflammatory action in addition to its longer-term nutritional benefits. As has been confirmed in children with rheumatoid arthritis,[160] systemic inflammation, as well as malnutrition, reduces IGF-1. Direct inhibitory effects of proinflammatory cytokines such as TNFα on developing growth plates[216] and a downregulation of IGF-1 by IL-6 are both likely to contribute to growth retardation.[211] The additional suppression of appetite by TNFα,[217] the failure to downregulate the REE during malnutrition in CD,[58] and the exacerbation of bowel symptoms by food intake, all add to the final reduction in height velocity.

Enteric losses during active disease can also contribute to the decline in nutritional state. Children with small-bowel CD have varying degrees of malabsorption, with some of the hypoalbuminemia occurring as a result of

enteric losses.[218] The most important determinant of hypoalbuminemia is the systemic inflammatory response. Although protein loss through an inflamed mucosa does occur, it is usually modest, nonspecific, and occurs in association with loss of globulins. The hypoalbuminemia seen in CD is more frequently associated with the hypergammaglobulinemia occurring as a result of the acute phase protein synthesis. The latter is principally mediated by IL-6.[219] Furthermore, a sustained protein intake of less than 0.4 g/kg/day[220] is necessary to achieve any reduction in serum albumin.

Bile acid malabsorption may not only occur in children with active terminal ileitis, as systemic effects of ileal inflammation but also lead to malabsorption in the proximal small bowel.[221] As a result fat malabsorption may occur in some children with CD. In addition, low concentrations of vitamins A, E, and zinc have been shown to correlate more with disease activity than nutritional state,[92,222] suggesting depletion occurs during the acute inflammation rather than as a result of chronic malabsorption.

On-going growth failure in the first years after diagnosis may be due to several factors. Growth velocity can be delayed well beyond nutritional restitution and normalization of inflammatory indices. This, together with the frequent use of high-dose steroids to achieve the initial remission, up to 85% of children in some studies,[223,203] may arrest normal growth for many months after diagnosis. However, the most recent data suggest that it is neither the disease distribution nor pubertal stage at diagnosis that determine final adult height,[224] but rather the use of corticosteroids during puberty. Children who were diagnosed with CD during puberty and were treated with corticosteroids were significantly shorter as adults when compared who did not receive corticosteroids. In this study, this was the only independent predictor of final adult height.

Glucocorticoids may impair growth through a variety of mechanisms including a local effect at the level of the growth plate by reducing cell number, cell proliferation, and proteoglycan content, and through a reduction of GH secretion and its action.[225] They can alter GH receptor expression and alter IGF-1 expression and sensitivity.[226,227] Clinical studies of the role of glucocorticoids in IBD and growth retardation report conflicting data. Although some studies have found that glucocorticoids use has no effect on growth retardation except when used in very high doses.[203,202] Markowitz et al.[57] and Burnham JM et al.[64] have reported a clear association of height with duration of glucocorticoid exposure and cumulative dose.

Nutritional Treatment of Growth Failure

Over 20 years ago, several small studies confirmed the central role of nutrition in the long-term management of growth failure in children with IBD. Motil et al.[199,228] concluded that neither low-grade chronic inflammation nor low-dose corticosteroid use reduced whole body protein synthesis, and that it was adequate dietary supplementation that led to a significant increase in growth velocity of children with growth failure. This was confirmed by others as nutritional therapies became more practical for the treatment of acute CD.[6,54] Sanderson et al. was the first to establish the benefit of enteral nutrition over steroid therapy on short-term growth in children with newly diagnosed CD.[8]

MECHANISM OF ENTERAL NUTRITION

Despite the wealth of information that exists about the benefits of enteral nutrition, the mechanisms of action remain largely unclear (Table 52-3).

The most frequently advanced theory is that the bacterial flora within the gut lumen is modified by enteral nutrition. The clinical evidence of any difference in flora between patients with CD and normal controls remains slim. It was shown in the late 1970s that there are higher bacterial counts within the terminal ileum of patients with active disease.[229] Studies at that time also suggested a reduction in fecal flora after enteral nutrition.[230] It is now clear that increasing severity of systemic disease is associated with an increase in the adherence of fecal bacteria to the enterocytes,[231] and this does not appear to be related to the degree of local mucosal inflammation. The response of acute CD to antibiotic therapy further implicates the bacterial flora in the disease pathogenesis,[232] although antibiotics such as the quinolones and metronidazole have other immunomodulatory effects in addition to their antimicrobial actions.[233] The organisms that appear increased in the lumen of patients with CD include Bacteroides, Eubacteria, and Peptostreptococcus.[234] Elegant work on mice that develop spontaneous colitis (TCRα-/-) has confirmed that feeding with an elemental diet prevents bowel inflammation.[235] Unlike the mice fed with the elemental diet, the mice fed with regular chow and that develop colitis are colonized by *Bacteroides vulgatus* in >80% of cases. Furthermore, instilling this strain into the rectum of the elementally fed mice, led to development of a typical Th-2 type, T cell–induced colitis. Further animal work has shown that elemental diet may reduce progression of granulomatous enteritis by modulating the activation of T cells, the

production of NO, and the generation of oxygen-free radicals.[235–237]

TABLE 52-3 Mechanisms of Enteral Nutrition

- Alteration in bacterial flora
- Reduction in antigenic load
- Whole body nutritional restitution
- Provision of enterocyte nutrition
- Direct immunoregulatory effect
- Increased concentrations of TGFβ
- Low lipid and fiber content

The reduction in antigenic load that accompanies EEN may also contribute, at least in part, to bowel rest. However, a whole protein diet, and even an ad libitum diet together with some parenteral nutrition, appear as effective as an exclusive elemental diet at inducing a remission.[114,115,141] The efficacy of polymeric diets and recent evidence that dietary supplementation with enteral nutrition may prolong a remission,[182] both suggest that reducing luminal antigens may only play a modest role in the efficacy of this therapy.

Whether enteral nutrition per se has either a direct and/or indirect immunoregulatory effect remains speculative. Degrees of moderate protein malnutrition have been associated with poor immune function. In rodents, protein deprivation leads to impairment of the mucosal immune response, as well as depleting a population of T cells that control oral tolerance.[238,239] This would suggest that poor nutrition inhibit T cells that downregulate the gut's response to foreign antigens. Enteral feeding may therefore have an indirect effect on the immune response by restoring an adequate nutritional status.

More recently, the direct influence of luminal content on immune function has been studied. Sanderson et al. provided evidence that luminal content can influence epithelial cell gene expression within the gut.[240] Short-chain fatty acids, such as butyrate, are bacterial metabolites from unabsorbed carbohydrates. Butyrate induces secretion of insulin growth factor–binding proteins (IGFBPs) by a complex process involving histone deacetylation.[241] Butyrate has also been shown to potentiate the secretion of IL-8 by intestinal epithelial cells (Caco-2) if these are stimulated with either lipopolysaccharide (LPS) or IL-1β. LPS was only able to induce IL-8 secretion if these cells were preincubated with butyrate, implying direct effects of the latter on gene regulation.[242] Epithelial cell gene regulation

by luminal products thus appears to be able to influence intestinal inflammation through release of inflammatory cytokines. Upregulation of the chemokine macrophage-inflammatory-protein-2 (MIP-2) increases local neutrophil recruitment.[243]

It has also been suggested that the presence or absence, of individual components of enteral feeds is important in immune regulation. The putative advantage of high TGF-β levels in both AL110 and CT3211 (~24 ppm) is based on the large body of experimental evidence that this cytokine has the ability to downregulate other proinflammatory cytokines.[244] Fell et al.[114] demonstrated mucosal upregulation of TGF-β within the terminal ileum after an eight-week course of TGF-β-rich CT3211. It is still unclear whether this is related to the increased luminal presence of TGF-β or is simply an epiphenomenon of tissue repair (Table 52-4).

It may also be that enteral nutrition plays a direct role in promoting the mechanisms involved in epithelial healing. There are numerous peptides involved in the restoration of a disrupted epithelial barrier. The ulcer-associated cell lineage (UACL)[245] secretes cytoprotective peptides that promote epithelial healing. Among them are epidermal growth factor (EGF), TGF-α, human spasmolytic peptide (hSP), and the family of trefoil peptides. The trefoil peptides in particular have been shown to be vital in protecting against mucosal damage.[246] Enteral nutrition may contribute toward the maintenance of mucosal integrity by boosting the proliferation of the UACL.[247]

Although the theory of "bowel rest" has its supporters, others continue to feel it is adequate nutrition alone that could induce remission and growth in these patients.[248] Kirschner et al.[54] demonstrated improved growth in children simply fed an extra 1000 kcal/day. The same group later confirmed that improved nutrition not only increased linear growth, but also returned previously low levels of IGF-1 to normal in children with active CD.[249] Thomas et al.[204] confirmed this finding with an elemental feed, which was as effective at increasing IGF-1 as prednisolone, yet better promoted linear growth.

TABLE 52-4 Data Showing mRNA Transcripts (103)/μg Total RNA from Biopsies Taken Before and After Treatment with CT3211 and Normal Controls

	Terminal Ileum			Colon		
	Control	Pretreatment	Posttreatment	Control	Pretreatment	Posttreatment
IL-1β	15**	350	16*	0.54**	130	18*
IFNγ	1**	8.6	1.1*	1.1*	3.5	1.2
IL-8	50	660	150	4.8*	1500	130*
IL-10	1.5	1.7	1.3	3.7**	1.9	1.2
TGF-β	16	4.2	3.4*	11	15	15

*Significant change ($p < 0.05$) with treatment assessed by *t*-test.

**Significant difference between pretreatment (diseased) and control values assessed by Mann–Whitney U-test.

There are likely to be many mechanisms responsible for the clinical efficacy of enteral nutrition. It is clear however, that the luminal environment is crucial to the expression of mucosal disease. Our ability to regulate specific aspects of this environment by nutritional or other means remains a great challenge. The multitude of variables that may be important in achieving a disease remission makes identification of single factors extremely difficult. Current attention is focused on modifying enteral formulas in line with the recent evidence on dietary fats, while continuing to ensure their clinical efficacy and tolerability.

Mucosal Healing

Attention has focused on the ability of treatments to achieve mucosal healing.[250] Breese et al.[157] gave an initial indication that enteral nutrition was able to downregulate intestinal mucosal inflammation. Enteral nutrition was as effective as cyclosporin and steroids in reducing the percentage of IL-2–secreting cells in the terminal ileum after treatment, while it appeared more effective than steroids at reducing the percentage of IFN-γ–secreting cells. Furthermore, it was only the enterally fed group that showed significant histological improvement.

Despite being only a small study, Breese et al. raised two important issues. First, that enteral nutrition may be able to heal mucosa, second, that mucosal cytokine analysis following treatment did not necessarily correlate with either clinical or histological indices of remission.

The mucosal cytokine responses of a much larger cohort of children were reported by Fell et al.[114] Although clear clinical and histological remission was achieved in over 70% of children, cytokine profiles also dramatically improved with a polymeric diet alone. The dramatic downregulation of the potent proinflammatory cytokines IL-1β, IFN-γ, and IL-8 is the most concrete evidence to date that enteral nutrition acts at the

mucosal level (Table 52-4).

The issue of whether clinical, endoscopic, histological, or immunological remission should be the gold standard remains a matter of personal practice. If we are to believe that the presence of chronic inflammation predisposes to long-term complications and malignancy,[251] it may be a state of immunological remission at the mucosal level, that should be achieved in children with a lifetime of CD ahead of them.

BODY COMPOSITION, ENERGY EXPENDITURE, AND PROTEIN METABOLISM

It has become clear that both in adults and in children, active gut inflammation is associated with alterations in body composition. Although substrate metabolism during active CD resembles that during starvation, these are more a consequence of malnutrition and may be easily reversed by treatment with EEN.[58,236] BMI, lean body mass (LBM), and fat mass are all decreased in children with IBD, and this may be related to poor calorie intake.[199] A higher BMI and LBM were both positively correlated with increased BMD, factors that again stress the importance of adequate nutrition in maximizing long-term BMD.

Enteral nutrition provides a simple but effective treatment for children with CD. Not only does it appear to influence disease activity directly, it also appears to have clear benefits on growth and nutrition. Gerasimidis et al. demonstrated that a 6–8-week course of EEN with a polymeric feed in children with active CD has a positive effect on body composition by improving LM but not fat mass.[252] In this study 17 children (male/female: 8/9; median age: 12.7 years) with active CD were treated exclusively for 6–8 weeks on a polymeric feed (Modulen IBD). Body impedance was measured at baseline, during EEN, and posttreatment on normal diet and converted to Z-scores of fat and LM. Lean but not fat mass improved at the end of EEN (initiation vs. end of EEN; fat mass [Z-score]: –0.5 vs. –0.3; $P = 0.141$; LM [Z-score]: –2.1 vs. –0.8; $P < 0.0001$). At baseline several children presented with suboptimal concentrations of carotenoids, trace elements, vitamin C, B6, and folate in plasma but not in erythrocytes. EEN improved concentrations for several nutrients, but more than 90% of patients had depleted concentrations of all carotenoids.

Early evidence suggested that REE was increased in patients with inactive CD.[253] It now appears however, that if the REE is calculated per unit of LBM, it is the same in active CD as it is in normal controls.[58] The

REE/LBM was found to be significantly lower in children with anorexia nervosa than in normal controls. When comparing these malnourished noninflammatory disease controls with children with active CD, the authors showed that the appropriate physiological response to starvation is lost during active inflammation. Thus this inappropriately elevated REE further contributes to weight loss. On treatment with elemental feed, their absolute REE did increase to above normal levels, but per unit of LBM only remained within the normal range. This study also showed that an elemental diet was significantly better than steroids at accruing lean body tissue and was again better at achieving linear growth.

Despite the documented increase in energy intake by children on steroids compared to those on an elemental diet,[176] the latter group has a significantly greater rise in their median height velocity standard deviation score (SDS) after four weeks on an elemental diet. Adequate calorie intake alone in the presence of steroid therapy (124% of RDA) is thus unable to achieve optimal growth. The short-term growth suppressant effects of prednisolone[254] probably override any advantage conferred by the improved calorie intake. IGF-1 levels appeared greater after steroid treatment than after enteral nutrition, yet a significant increase in IGF-1 was only associated with greater height velocity after an elemental diet.[204]

The rate of protein turnover in seven children with chronically active CD receiving steroids was considered to be similar to that of normal adolescent controls,[255] although their nitrogen balance was found to increase fourfold during nutritional supplementation. Another small study compared the effect of steroids (n= 6) and elemental feed (n = 6) after the first seven days of treatment in acute CD.[256] Labeled L-leucine studies showed an equal increase in protein turnover after seven days of treatment, whereas in the steroid treated group this was at the expense of total body protein stores. Clinical improvement was similar in each group. In a more recent study by Thomas et al.,[257] rates of protein turnover were also elevated in active CD. Labeled L-leucine studies and mass spectrometry analysis showed an equal reduction in protein turnover to normal levels, both by steroids (n = 4) and by elemental feed (n = 6). This study only assessed protein turnover after several weeks of treatment, and only after effective recovery and nutritional restitution were almost complete. Royall et al.[258] published evidence in 30 adults with active CD that proportionate increases in body fat, protein, and water occurred after 21 days of elemental nutrition. In this study, a sustained remission was only achieved in patients who showed a gain in total body nitrogen. Hannon et al.

demonstrated that in clinically stable adolescents with CD, enteral nutrition promotes anabolism by suppressing proteolysis and increasing protein synthesis.[259] In this study, leucine (Leu) and phenylalanine (Phe) kinetics were measured using stable isotopes under fasted and fed conditions during a single study visit in six adolescents with CD. In response to enteral nutrition, the endogenous rates of appearance of Leu and Phe (reflecting proteolysis) decreased significantly by 40%.

Further evidence that optimizing nutrition may contribute to a clinical remission arises from the study by Slonim et al.[260] The combination of a protein-rich diet (>2 g/day), together with subcutaneous GH led to a significant reduction in CDAI within four months, in a small group of adults with moderate-to-severe CD. Increased uptake of amino acids,[261] and improved intestinal and muscle protein synthesis are mechanism that are likely to be important in mediating this effect.[262] Direct effects of GH on IGF-1 are not felt to be as significant, as no correlation was found between IGF-1 levels and clinical response.

FUTURE DIRECTIONS

From the above discussion, it is abundantly clear that nutrition still has a major role to play in the management of children with IBD, and in particular those with CD. Although EEN is clearly effective in many children with active CD, it remains difficult for some children and their families to complete prolonged courses. Work is continuing to assess whether long-term supplementation of a normal diet prolongs remission.

Palatable whole protein formulae are being modified to include higher percentages of n-3 fatty acids, whereas the addition of pro- and prebiotics to feeds is also already underway.

Work also continues on isolating the specific factors within formulae that may directly act on mucosal inflammation. Upregulation of mucosal TGFβ may be a direct result of higher levels of TGFβ within a formula (Modulen IBD, Nestle), whereas further characterization of the gut microflora in children with IBD may allow specific supplementation with specific prebiotics, substrates that selectively stimulate the growth of certain favorable probiotic species.

CONCLUSIONS

Despite the ever-increasing choice of therapies available to children with inflammatory bowel disease, the role of nutrition remains central to their

optimal management. The impact of bowel inflammation on growth and development cannot be underestimated. As final adult height is determined during the pubertal growth spurt, it is crucial to minimize the impact that both the disease and its therapies may have on a child's growth potential. Advances in identifying children at particular risk of growth failure may, in the future, allow specific interventions to maximize growth.

We still strongly suggest that EEN remains the best primary therapy for the treatment of all children presenting with a new diagnosis of CD, apart from those with severe perianal disease. Thereafter, the challenge is to maintain a lasting remission, particularly during puberty. This is likely to be best achieved with early use of immunosuppressants such as Azathioprine/6-Mercaptopurine, hoping to minimize steroid use. Continued vigilance of undernutrition and appropriate use of dietary supplementation remains essential to an optimal outcome.

The consequences of developing a chronic inflammatory disease during childhood will be felt long after a child is handed over to our adult physician colleagues. Increased risks of osteoporotic fractures, high rates of surgery, and a reduced final height are only some of the areas where nutritional therapy is vitally important. The ability of therapies to achieve healing of the gut mucosa is of utmost importance in children who have a lifetime ahead of them. Although dietary therapies do not yet play a significant therapeutic role in maintenance therapy for IBD, it is likely that evidence about potential disease-modifying dietary supplements will continue to appear. It is important that as more potent immunological agents become available to treat these diseases, we do not forget the therapeutic role of nutrition in CD; its absence of adverse effects and its proven impact on growth and gut mucosa.

Although newer therapies may require less commitment from families and medical teams, their unknown long-term safety profile still makes enteral nutrition an excellent choice for children with CD for many years to come.

Celiac Disease

53

Dascha C. Weir, MD and Ciarán P. Kelly, MD

Celiac disease (CD) is an immune-mediated enteropathy secondary to permanent sensitivity to wheat gluten and related proteins in rye and barley. It results in characteristic histologic changes consisting of inflammation, crypt hyperplasia and villous atrophy of the small intestine in genetically susceptible individuals. Significant variability in the clinical presentation of CD in the pediatric population complicates recognition of the disease in many patients. Treatment for CD consists of a lifelong strict gluten-free diet (GFD). Adherence to this diet is associated with resolution of most related signs and symptoms and a decreased risk of related complications. With an explosion of new knowledge over the span of two decades, our understanding of CD has changed dramatically. CD has gone from a rare condition causing gastrointestinal symptoms in children of European origin to a common disorder causing symptoms that affect multiple organ systems in all ages virtually worldwide.[1]

The overall prevalence of CD is similar in Europe and North America affecting up to 1% of the population.[2,3] A large multicenter study in the United States, using serologic screening with biopsy confirmation to identify cases of CD, showed a prevalence of CD of 1:133 in individuals with no evident risk factors. Prevalence of CD in symptomatic patients was 1:56. The prevalence of diagnosed CD is much lower, especially in the United States. This reflects under-recognition and under-diagnosis related to the wide clinical spectrum of disease and the presence of silent disease.[4] In the United States, the prevalence of CD in people of non-European decent is not known. Studies suggest that, in the United States, Hispanic and African American populations have a lower prevalence of CD than non-Hispanic Caucasians.[5] For example, a study in Colorado showed that the incidence of positive serology in Hispanic children was three times lower than in non-Hispanic whites.[6] African Americans also represent a small number of patients currently diagnosed with CD. A large

center in New York City reported African Americans comprised 1.3% of their patients with biopsy-proven CD.[7] This is likely partially because of genetic differences in these populations. However, given the increasing recognition of CD in non-Caucasian populations internationally, serious consideration should be given to the possibility of under-diagnosis in minority populations in the United States.

CD is increasingly being diagnosed in other parts of the world, involving populations that were not traditionally thought to be effected by the disease. Reports from Mexico, South America, North India, the Middle East, Turkey and North Africa, have changed previous assumptions that CD is a European affliction.[8–17] CD is rare in people of Japanese, Chinese, and purely African-Caribbean decent.[18]

CD is associated with several autoimmune conditions and genetic disorders and often presents atypically or silently in these populations. In children, it is associated with autoimmune thyroid disease and with type I diabetes mellitus with a 7.8% and 4.5% prevalence of CD in affected children.[19,20] Up to 7% of patients with a selective IgA deficiency also have CD.[21] Patients with trisomy 21, Turner's syndrome and Williams syndrome have also been found to be at higher risk of CD than the general population.[21–24]

PATHOGENESIS

Environmental, immunologic, and genetic factors are all important contributors to the pathogenesis of CD. Clearly, enteric exposure to specific proteins in wheat, rye, and barley are essential to disease activation in a genetically susceptible person. Wheat, rye, and barley have common ancestry and are all derived from the Triticaeae tribe of the grass family. Broadly termed "gluten," the specific proline and glutamine-rich proteins that activate disease are gliadins in wheat, secalins in rye and hordeins in barley. Gluteins, the second major protein fraction of wheat gluten, is likely involved to a lesser degree. Multiple toxic antigenic epitopes have been described (Figure 53-1).

These peptides activate immune cells causing a chain of events that result in tissue damage. The mechanisms for this activation are incompletely understood but involve both adaptive and innate immunity. Partially because of their high proline content, these large cereal peptides are resistant to digestion by intestinal proteases and pass through the epithelium and into the lamina propria in an intact state. The mechanisms

of this passage through the intestinal barrier are not well understood. Tissue transglutaminase deamidates these peptides in the lamina propria, causing them to become negatively charged as the glutamine residues are converted to glutaminc acid. Deamidated peptides bind with far greater affinity to specific positively- charged residues on the peptide-binding groove of HLA-DQ2 or HLA-DQ8 major histocompatibility complex Class II molecules. These peptides are then presented by HLA-DQ2 or HLA-DQ8 to activate gliadin-specific CD4+ T cells thereby activating an intestinal inflammatory response leading to the characteristic histopathological changes of CD. Intraepithelial lymphocytes, T cells that are markedly increased in the intestinal biopsies of patients with active CD, are also involved. It is now evident that gluten can stimulate interleukin-15 production, leading to the transformation of some T cells into natural killer cells and ultimately to enterocyte destruction (Figure 53-2).[1,26,27] Recent studies suggest that both pathogenic and commensal microbiota may also play a role in the development of CD.[28–32]

Genetics are clearly a factor in the development of CD. Among monozygous twins, there is a 70%–75% CD concordance rate and first-degree relatives have a 10% risk of disease.[34,35] CD is strongly associated with HLA class II genes that map to the DQ locus. The HLA-DQ2 heterodimer is expressed in up to 95% of celiac patients with most of the remaining 5% expressing HLA-DQ8 heterodimer. These HLA types are present in 30%–40% of the general population. Only about 4% of people with these HLA types develop CD.[36–38] Additionally, CD is concordant in only 30%–40% of HLA matched siblings. Clearly, these HLA types are necessary but not sufficient for CD to develop and other genes are involved. Candidate susceptibility genes include myosin IXB (MY09B) and regions of chromosome 5, 6, 11 and 19.[1,39] In fact, up to 40 CD risk loci (including HLA) have been identified through genotyping.[28,40]

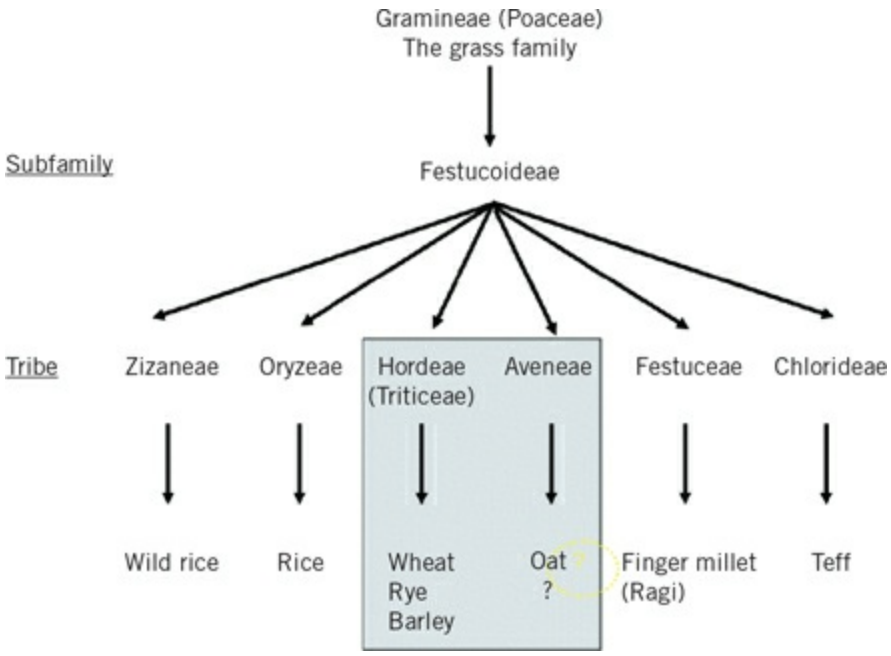

Figure 53-1 The grass family: grains in the tribe Triticeae mediate CD. Species of interest in the Festucoideae subfamily of the grass family are depicted. It seems likely that, for most patients with CD, only grains in the tribe Triticeae mediate CD.[25]

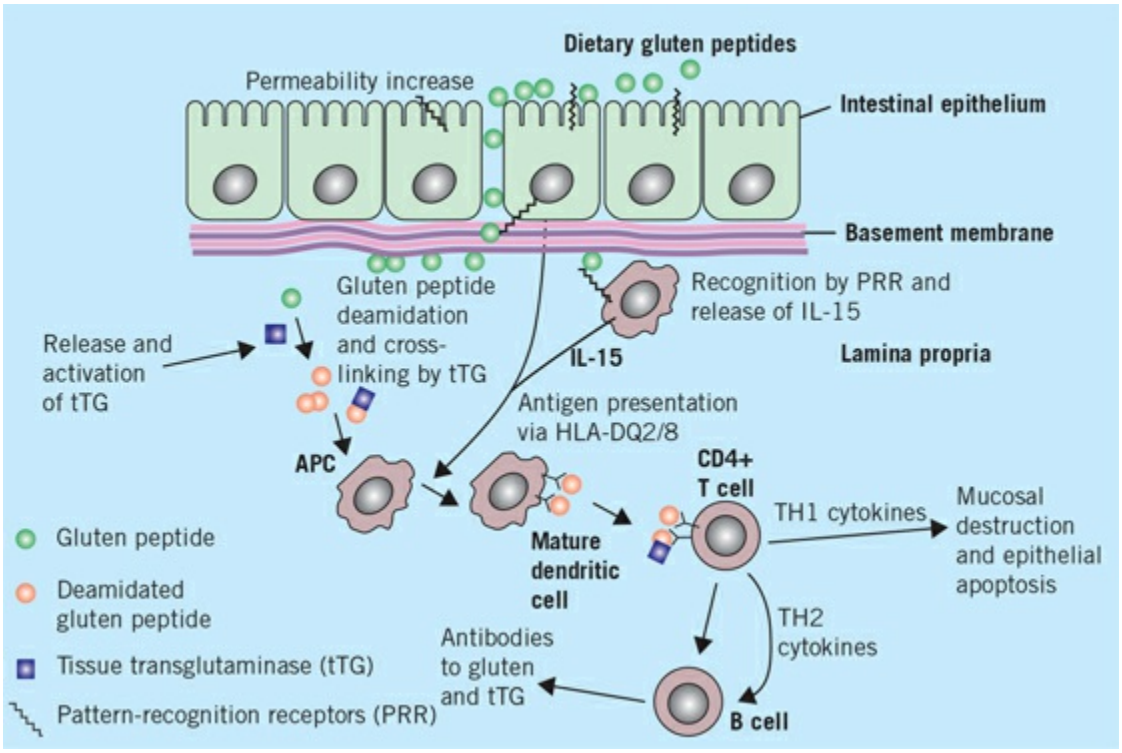

Figure 53-2 Adaptive and innate immune system responses in CD. Crosslinking of gluten by tTG potentiates presentation of peptides by antigen-presenting cells (APC); deamidation of gluten improves binding to HLA-DQ2 or HLA-DQ8, triggering adaptive T-cell responses (inflammation and tissue remodeling [Th1] or antibody production [Th2]). Cells of the innate system recognize gluten peptides directly via pattern recognition receptors, and release cytokines (IL-15) that drive adaptive responses. Dendritic and T cells circulate to mesenteric lymph nodes (where they encounter T cells) and back to lamina propria.[33]

Environmental factors, beyond exposure to gluten, also seem to play an important role in determining which genetically susceptible individuals develop CD. Epidemiologic studies suggest infant feeding practices can impact risk. Both the timing of gluten introduction and the amount of gluten exposure appear to affect risk of developing CD. Specifically, there is evidence that early exposure to gluten before 3 months of age or later initial exposure after 7 months of age increase risk of CD autoimmunity in high risk children. Larger amounts of gluten, introduced in early life, also seem to increase risk. Breastfeeding, particularly at the time of gluten introduction, appears to significantly reduce risk. It is not clear if this protective effect is permanent or if breastfeeding only slows the onset of disease.[38,41–47] Nonetheless, current recommendations suggest introduction of small amounts of gluten between 4–6 months of age ideally while the child is still breastfeeding.[48,49]

Exposure to multiple infections early in life, season of birth, birth by cesarean section, and alterations in the composition of intestinal microbiota have also been identified as possible risk factors in the development of CD.29–32,44,50–56

CLINICAL PRESENTATION

Traditionally, CD was thought to present primarily with gastrointestinal symptoms in the young. This “classical” presentation consists of poor growth, chronic diarrhea, abdominal distention, muscle wasting, poor appetite, and irritability typically seen in patients of 6–24 months of age. Edema, pallor and emesis are also seen. Rarely, children can present in celiac crisis with copious watery diarrhea, marked abdominal distension, dehydration, electrolyte imbalances, hypotension, and lethargy.[57] As serologic testing and our understanding of CD have improved,

"nonclassical" or "atypical" presentations of CD are increasingly being recognized. In pediatric patients, this form of presentation is characterized by delayed onset with gastrointestinal complaints such as nausea, bloating, recurrent abdominal pain, or constipation.[21] Many patients have no gastrointestinal complaints but have extraintestinal manifestations such as short stature, osteopenia, joint pains, pubertal delay, iron deficiency anemia, dental enamel defects, neurologic disorders, or elevated transaminases. Some patients, with classic histologic changes on intestinal biopsy, are entirely asymptomatic and are described as having "silent" CD.[18,57] A comprehensive study based in the United States reported that gastrointestinal symptoms were prominent in pediatric patients diagnosed before 3 years of age. However, in children diagnosed over the age of 3 years, the majority presented with nongastrointestinal manifestations. This study reported the average age of diagnosis in children to be approximately 9 years of age.[58] Other North American and European studies have shown similar trends.[59–64]

CD is increasingly being diagnosed in adults. In fact, the mean age of diagnosis is now in midadult life (circa 45 years of age).[1] Many of these patients have likely had CD since childhood. Adults can present with gastrointestinal symptoms such as diarrhea, flatulence, abdominal bloating, and discomfort but often present with extraintestinal manifestations such as iron deficiency anemia, macrocytic anemia, osteopenia, malaise, infertility, obstetrical complications, and neurologic conditions. Dermatitis herpetiformis, a pruritic blistering skin disorder, is also seen with CD but rarely occurs in pediatric patients (Table 53-1 and Figure 53-3).[18,57]

DIAGNOSIS

While the pathogenesis of CD and the genetic factors involved are still being elucidated, the resulting inflammation and tissue damage causes characteristic and well-recognized histopathologic changes. Small intestinal biopsy histology remains the gold standard in the diagnosis of CD. The spectrum of histopathologic changes in CD have been classified by Marsh with additional more recent modifications.[65] Marsh I lesions, an early but often nonspecific finding, are characterized by increased intraepithelial lymphocytes (>30 IEL per 100 enterocytes) and normal villous architecture. Marsh II lesions consist of crypt hyperplasia in the setting of increased numbers of intraepithelial lymphocytes (>30 per 100 epithelial cells). Marsh III lesions, type a–c, are characterized by partial to

total villous atrophy in addition to crypt hyperplasia and increased numbers of intraepithelial lymphocytes. Because of patchy distribution of these histopathologic changes, multiple biopsies taken from the duodenal mucosa are indicated.[63,66–68] Additionally, CD can involve the duodenal bulb only. It is therefore important that duodenal bulb biopsies are also obtained.[63,69] To avoid misinterpretation, biopsies (especially of the duodenal bulb) are best reviewed by an experienced gastrointestinal pathologist (Figure 53-4).

The development of accurate serologic markers has markedly improved our ability to identify patients with untreated CD and to monitor them after diagnosis. Serologic testing, coupled with clinical assessment and histopathologic confirmation, has become a cornerstone of diagnosis. IgA endomysial antibodies (EMA IgA) can be detected by indirect immunofluorescence using human umbilical cord or monkey esophagus. In pediatric patients, the sensitivity ranges from 89%–94% and the specificity ranges from 99%–100%.[70,71] However, this test is expensive and heavily operator dependent. IgA tissue transglutaminase (TTG IgA) is a less expensive, less operator-dependent assay. Its sensitivity ranges from 84.6%–100% and specificity ranges from 76%–97.4% in the pediatric population.[70,72,73] These tests perform less well in pediatric patient compared to adults, especially in patients under the age of 2 years. False negatives can also occur in the setting of mild enteropathy and in patients with IgA deficiency. TTG IgA and EMA IgA have largely replaced the older IgA and IgG antigliadin antibody tests. Antigliadin antibodies have poor test performance, with low specificity. Newer serologic markers, IgA and IgG deamidated gliadin peptide (DGP) antibodies perform better than the standard antigliadin antibody tests. DGP sensitivity ranges from 85.6–89.9 % and its specificity ranges from 92.5–95.5%.[74] However, DGP IgA and IgG do not perform better in pediatric patients compared to the TTG IgA and EMA IgA, even in patients under 2 years of age.[75,76] There is also a role for DGP IgG in patients with IgA deficiency, though in pediatric patients TTG IgG may also be used.[77,78]

TABLE 53-1 Clinical Manifestation of Celiac Disease in Children

Manifestations secondary to untreated CD	Associated diseases (or diseases secondary to untreated CD)
CD with classic symptoms	***Autoimmune diseases***

– Abdominal distension
– Anorexia
– Chronic or recurrent diarrhea
– Failure to thrive /weight loss
– Irritability
– Muscle wasting
– Celiac crisis (rare)

CD with nonclassic symptoms

– Arthritis
– Aphthous stomatitis
– Constipation
– Dental enamel defects
– Dermatitis herpetiformis
– Hepatitis
– Iron-deficient anemia
– Pubertal delay
– Recurrent abdominal pain
– Short stature
– Vomiting
– Type 1 diabetes
– Thyroiditis
– Sjogren's syndrome

Neurologic and psychologic disturbances

– Ataxia
– Depression
– Epilepsy with intracranial calcifications

Other disorders

– IgA nephropathy
– Osteopenia/osteoporosis

Genetic disorders

– Down syndrome
– Turner syndrome
– Williams syndrome
– IgA deficiency

Adapted with permission from Fasano, A.[57]

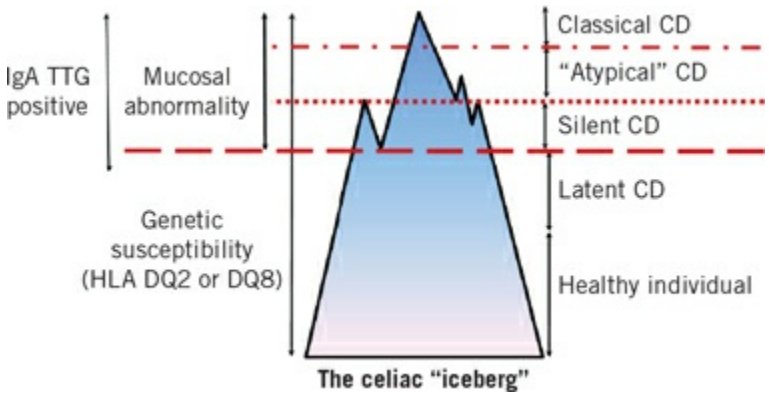

Figure 53-3 Clinical manifestations of CD—the celiac iceberg. CD presents with a wide range of symptoms. Classical CD with prominent diarrhea and malabsorption is now less common than atypical CD

presenting with iron deficiency anemia or other disease manifestations with mild or absent gastrointestinal symptoms. Many individuals have silent CD with no symptoms or disease manifestations despite positive tTG serology and abnormal small bowel histology. Only a subset of individuals with CD has been diagnosed. This subgroup is often referred to as the “tip of the celiac iceberg.” Most individuals with genetic susceptibility (HLA DQ2 or DQ8 positive) do not develop CD.

HLA typing has a limited role in the evaluation of pediatric CD, but may be useful in situations where diagnosis is difficult.[76] Because almost all celiac patients have either HLA DQ2 or DQ8, the absence of these markers effectually excludes the diagnosis.[79–82] Conversely, the presence of celiac HLA types has a low positive predictive value, as their presence is widespread in the non-celiac general population as discussed above.

New guidelines for the diagnosis of CD in children were developed and published by the European Society for Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) in 2012. For the asymptomatic child in a high celiac risk group, either by family history or associated condition, HLA typing is proposed as the first step of evaluation to guide who needs further serologic screening. Additionally, these recommendations suggest that a subset of children do not need biopsy confirmation of CD if they have: (a) symptoms compatible with CD, (b) a highly elevated TTG IgA (greater than 10X the upper limit of normal), (c) a positive EMA IgA on a second blood sample, and (d) HLA susceptibility for CD.[77] These recommendations have not yet been widely adopted in the United States, but will likely impact clinical practice into the future.

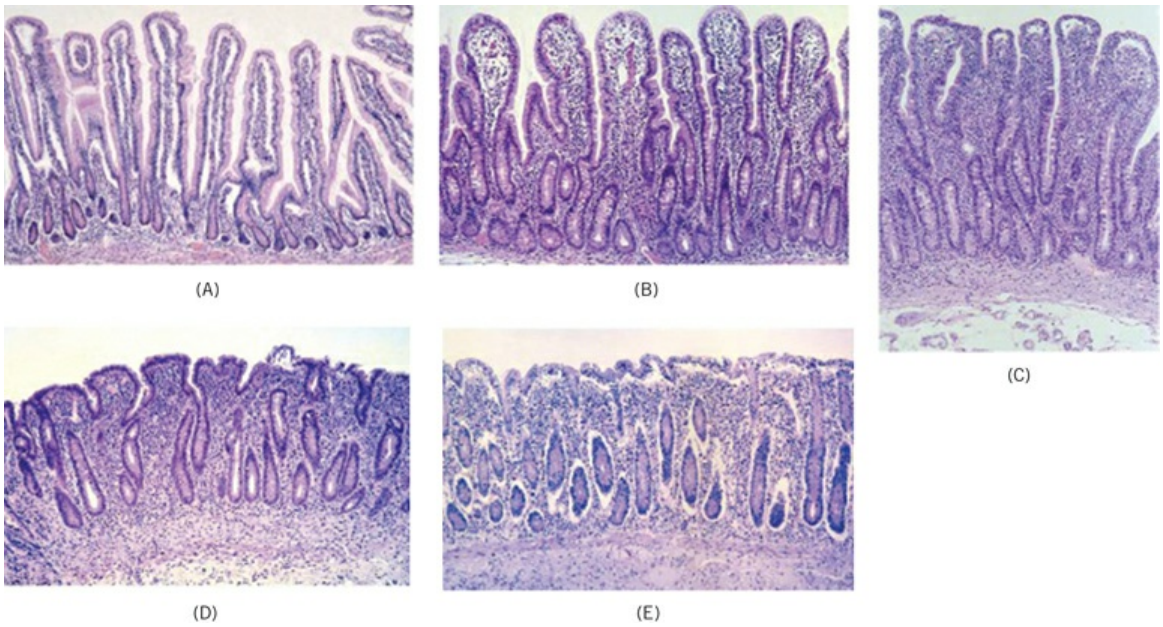

Figure 53-4 The spectrum of intestinal damage in CD, Marsh classification. A, Marsh I: increased intraepithelial lymphocytes; B, Marsh II: increased intraepithelial lymphocytes and crypt hyperplasia; C, Marsh IIIA: partial villious atrophy; D, Marsh IIIB: subtotal villious atrophy; E, Marsh III C: total villous atrophy. (Reproduced with permission from Green PH, Rostami K, Marsh MN.[201])

Serologic markers also have a role in monitoring disease control once a GFD has been initiated. TTG IgA gradually normalizes within 3–12 months on a GFD depending upon the initial antibody concentration. TTG IgA has greater sensitivity than EMA IgA in monitoring for continued gluten intake, but may not be sensitive enough to detect occasional or minor dietary errors.[70,83]

Positive TTG or EMA serology and/or resolution of symptoms on a GFD are not sufficient to make a definitive diagnosis of CD and, in most cases, do not replace the need for duodenal biopsies to make the initial diagnosis. However, repeat biopsies are no longer routinely recommended. Historically, repeat intestinal biopsies were used to confirm diagnosis and to monitor disease control. However, the availability of more accurate serologic markers has greatly reduced the use of repeat biopsies in patients with CD. A second biopsy is now typically limited to patients with poor clinical response to a strict GFD. Gluten rechallenge, once a mainstay of diagnosis, has also largely fallen by the wayside, especially in the pediatric

population. Rechallenge is now indicated only in patients on a GFD in whom the diagnosis remains in doubt (Figure 53-5).[18]

First-degree relatives of people with CD have a 10% risk of disease. In family members, symptoms may be subtle or differ significantly from those in the effected child. A careful review of symptoms or signs of possible CD in first-degree relatives should be sought routinely when a child or adolescent is diagnosed with CD. Serologic screening of all first-degree family members of a patient diagnosed with CD is recommended by some celiac specialists, but the cost to benefit ratio of this intervention is unclear.[84–86]

EFFECT OF CD ON GROWTH AND BODY COMPOSITION

Short stature is a common presenting sign of CD, especially in the pediatric population. It may be the only manifestation.[87–91] The pathophysiology of CD growth retardation is not fully defined, but is traditionally thought to be secondary to associated malnutrition. With the initiation of a GFD and nutritional rehabilitation, children with CD undergo significant growth acceleration. This catch-up growth appears to be most evident within the first year on a gluten- free diet.[92,93] There is some evidence that, even when diagnosed early, monitored closely and kept on a strict GFD, many children do not catch up completely and remain slightly below average height for age and skeletal age into adolescence.[94,95] New evidence suggests overlap of CD with growth hormone deficiency.[96–98] When catch-up growth on a GFD is not observed, further evaluation and possible growth hormone replacement is warranted.[99]

In addition to linear growth, body composition is also significantly affected by CD. Longitudinal study of children and adolescents with newly diagnosed CD has shown significant decreased weight, fat mass, and muscle mass compared to controls.[100] Decreased fat mass has also been described in children presenting with asymptomatic disease.[101] Similar findings have also been described in the adult population.[102] After one year on a GFD, affected children have been found to have complete restoration of body composition with no significant differences in weight, fat mass, or lean mass of the limbs compared to healthy controls. This restoration appears to occur faster and more completely when the GFD is initiated in childhood or adolescence compared to adulthood. It also

appears to be a lasting effect, as body composition in young adults who had initiated a GFD in childhood or adolescence has been shown to be normal.[100] Even without strict adherence, long-term maintenance of the diet through adolescence was associated with improvements in body composition.[103] As nonclassical forms of CD are increasingly being recognized, these characteristic changes in body composition may not be found consistently. Up to 39% of adults with CD are overweight or obese (specifically defined as a body mass index (BMI) > 25) at the time of diagnosis.[104–106] Overweight and obese status in children has also been noted in up to 19% of children at the time of diagnosis.[58,107,108]

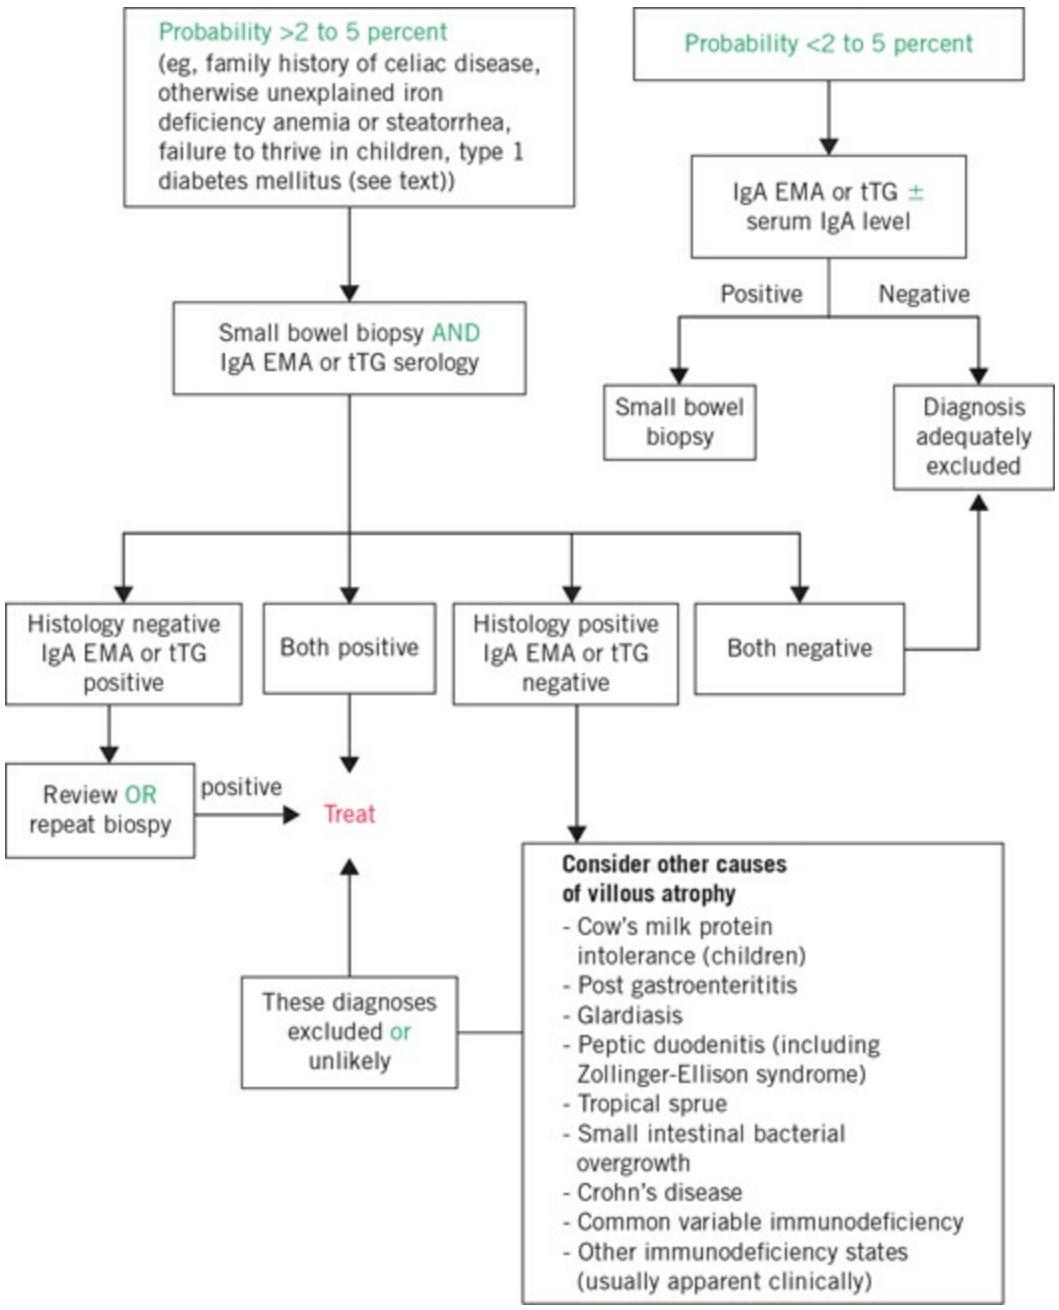

Figure 53-5 Making the diagnosis of CD.

Some patients with CD gain excessive weight on a gluten-free diet. A large study of adults in the United States, showed that up to 16% of patients who were underweight or normal weight at the time of celiac diagnosis transitioned to an overweight BMI class on a gluten-free diet. 22% of patients who were overweight at diagnosis gained additional weight on the diet.[106] However, other adults' studies have shown 18%–

54% of overweight celiac patients lost weight on the gluten-free diet.[109,110] Similar patterns have been noted in children with CD. Excessive weight gain has been shown to occur in children with CD on the gluten-free diet.[107] However, there is also data that shows overweight and obese children diagnosed with CD significantly lower or even normalize their BMI on the gluten-free diet.[108] Ongoing involvement of a dietician specialized in the gluten-free diet is essential (Figure 53-6 and 53-7).

Figure 53-6 A toddler with "classic" presentation of CD. A, At the time of the diagnosis; B, at the time of diagnosis (2); and C, after 1 year on a GFD.

Osteoporosis, rickets, and osteomalacia are all seen with CD. The specific mechanism of bone disease associated with CD is unclear, but is likely related to malabsorption of calcium and vitamin D and a possible effect of increased interleukins and other inflammatory mediators. Decreased bone mineral density is frequently seen in patients with CD, even in patients with clinically silent CD.[111] In untreated adult celiac patients, the reported prevalence of decreased bone mineral content is 22%–80%. In children and adolescents with CD, bone mineral density is often decreased at the time of diagnosis (3–39% prevalence).[112] However, after one year on a strict GFD, the bone mineral density of children and

adolescents with CD appears to normalize and reach the level of healthy controls. After 4 years of a GFD, these patients continue to have normal values.[111,113] Again, this restoration appears to be most consistent in the setting of early recognition and treatment.[114] Interestingly, patients who are poorly compliant did not appear to achieve peak bone mineralization.[113] Assessment of bone mineral density in children with CD is recommended at one year after diagnosis. Assessment of bone mineral density is also recommended in patients with poor adherence to the gluten-free diet.[115] The effect of the GFD on bone mineral density in adult studies has shown conflicting results. Some studies report improvement of bone mineral density on the diet and others show no such effect.[102,116–118] The age at diagnosis and initiation of the GFD seems to be a determining factor in bone restoration perhaps because of the increased activity of bone metabolism in childhood and adolescence.[119] There are conflicting data, however, on whether fracture risk is increased in adult patients with CD, so the clinical significance of this osteoporosis is not clear.[120,121]

Another characteristic change associated with CD involves dentition. Dental enamel defects of both deciduous and permanent teeth involving symmetric and chronologic distribution are well recognized in CD affecting up to 96% of children with CD and 83% of adults.[122,123]

NUTRITIONAL DEFICIENCIES

Nutritional deficiencies associated with CD are well recognized and should be an important consideration at the time of diagnosis and in continued management. Abnormal folate, iron and vitamin B12 levels are found in children, adolescents and adults with newly diagnosed or untreated CD. This appears to be true in patients with clinically silent disease as well as those with more “classic” manifestations. A study of screening-detected adolescent cases of CD in Finland (30% asymptomatic) found that 1/3 had abnormal folate or iron status.[124] European studies in adults have shown decreased levels of vitamin B12 in 11%–41% of patients with CD.[125,126] Additionally, there is some evidence that untreated adult patients with CD have reduced endogenous pools of zinc.[127] Children with active gastrointestinal CD have also been shown to have lower serum zinc levels than healthy controls and children with celiac on the GFD.[128] Fat soluble vitamins such as vitamin E, vitamin D and vitamin K levels may also be low.[129,130]

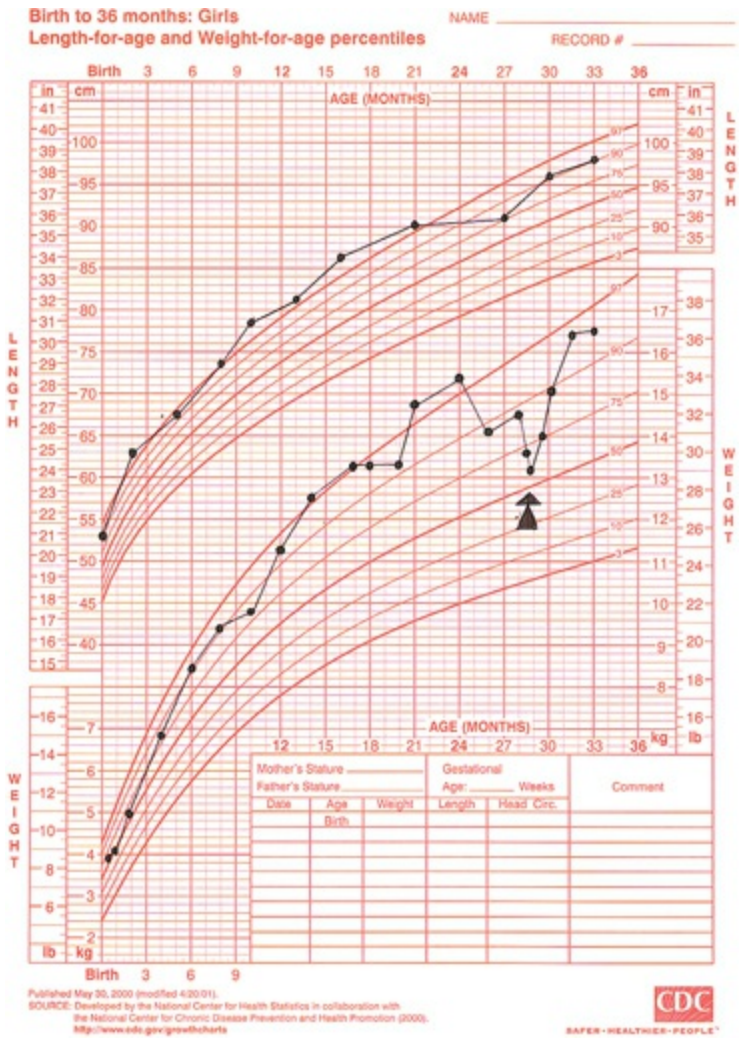

Figure 53-7 Growth chart of a classically presenting toddler with CD. The arrow indicates time of diagnosis and initiation of a GFD.

Iron deficiency anemia is the most common clinical presentation of CD in adults, but is also seen in children.[131,132] This is likely secondary to decreased absorption of iron in the proximal small bowel but may also be related to inadequate dietary intake as a result of CD associated anorexia or chronic inflammation. Megoblastic anemia due to folate or vitamin B12 deficiency is also seen. Thrombocytopenia, leukopenia and prolonged coagulation have also been reported in the pediatric population.[133] Notably, these abnormalities appear to resolve with treatment. For example, up to 95% of patients have correction of their anemia after 1 year on the GFD.[134]

OTHER EXTRAINTESTINAL MANIFESTATIONS

Hepatic involvement is seen in adult and pediatric patients with CD. In a European study of 114 consecutive pediatric patients with CD, mild hypertransaminasemia was observed in 32% of patients at the time of diagnosis. In 5 patients (4.3%), it was the only manifestation of CD. In these children, aminotransferases normalized within one year of initiating a GFD either before or at the same time as serologic marker normalization. Hypertransaminasemia does not seem to be related to malnutrition in these patients and the mechanism of hepatic injury is not clear.[135] Similar findings have been reported in the adult celiac population.[136] Severe liver disease that resolved with a GFD has also been reported in adults with CD.[137]

Pubertal delay can occur in both boys and girls with CD. Hypogonadism, infertility, and sexual dysfunction have all been described in the literature. Boys have been found to have an abnormal pattern of androgen resistance. Girls with untreated CD have been shown to have delayed menarche compared to their mothers and to girls with CD who are on a GFD.[138,139] Increased risk for recurrent miscarriage, premature delivery, intrauterine growth retardation, and lower birth weight babies have each been reported in women with untreated CD.[140–145]

Neurologic complications are a rare but recognized manifestation of CD. In fact, there are a growing number of reports linking neurologic symptoms with CD, sometimes as the presenting manifestation. Cerebellar ataxia, peripheral neuropathy and epilepsy have been described primarily in the adult celiac population. Depression and anxiety have also been described to affect up to a third of patients with CD.[146–148]

There are limited studies on other neurologic manifestations of CD in children where the risk of neurologic complications appears lower than in adults.[149] Headache is the most common neurologic complaint in children affecting almost a third of patients. Neurologic disorders such as hypotonia, developmental delay, learning disabilities, headache, and ataxia have been described in up to 52% of patients with CD diagnosed in childhood which was significantly higher than a healthy control group. There is conflicting data about the association of CD and attention deficit hyperactivity disorder (ADHD).[150,151] Focal white matter lesions in the brain have been reported in up to 20% of pediatric patients with CD.[152] The syndrome of bilateral occipital cerebral calcifications and seizures, also known as CD, epilepsy and cerebral calcifications syndrome (CEC syndrome), has also been well described and presents primarily in

childhood.[153] Epilepsy unrelated to CEC syndrome has been reported with CD in children.[154] There is no increase the incidence of tics in patients with CD.[155] Despite previous reports to the contrary, an association between CD and autism has not been confirmed.[57,148,156,157]

The spectrum of neurologic complications responds variably to a GFD. Up to half of children experiencing headaches improved on the diet. High rates of response in transient infantile hypotonia associated with classical early onset CD have also been reported, perhaps because of resolution of nutritional deficiencies.[155] In cases of epilepsy, improved seizure control has been reported but not seizure resolution. Depressive symptoms and anxiety may improve with a GFD in some patients but depression remains common in the treated celiac population. A few reports describe improvement of neuropathy and ataxia on a GFD, but for most patients these neurologic problems persist or progress despite gluten avoidance.[148]

NATURAL HISTORY

Overall mortality in patients with CD has been described as two times that of the general population. The risk of increased mortality appears higher in patients with malabsorptive symptoms with no increased risk in patients with minor or no symptoms. Increased mortality has also been observed in association with delayed diagnosis and with poor adherence to the GFD.[158–160]

Specifically, an increased risk of malignancy has been associated with CD since the 1960s. Patients with CD appear to be at increased risk for non-Hodgkin lymphoma, especially small-intestinal T cell lymphoma, small intestinal adenocarcinoma, squamous cell carcinomas of the esophagus, mouth and pharynx, and other gastrointestinal tract tumors. However, the absolute risk for malignancy remains small and recent data suggest that the risk while present is less than previously estimated and is low in patients with clinically silent CD.[159,161–165] The mechanism for this increased risk of cancer is not well understood but is perhaps related to chronic inflammation, increased exposure to environmental carcinogens secondary to intestinal permeability, immune surveillance abnormalities, or nutritional deficits.

Increased mortality and malignancy appear to be issues that primarily affect adult patients with CD. Few cases of cancer in children and adolescents with CD have been reported and increased risk of malignancy in this population has not been shown clearly.[162,164,166,167] Nonetheless,

prompt identification of CD and appropriate treatment likely has long-term effects into adulthood. Adult patients with CD who were diagnosed in childhood appear to have a normal mortality rate presumably a benefit of long-term adherence to a GFD.[159] Additionally, patients who adhere to a GFD appear to have decreased malignancy risk that approaches that of the general population.[164,165,168]

The prevalence of autoimmune disorders is higher in adolescents and adults with CD and in their relatives as compared to the general population.[169–171] This association is likely related to the common genetic background including HLA type.[172] It has been suggested that the risk of autoimmunity is related to the duration of gluten exposure and the age of diagnosis.[169] However, other studies have disputed this theory.[173,174] Specifically, the risk of thyroid autoimmune disorders is increased in patients with CD even when treated with the GFD.[175–177]

TREATMENT

Gluten and related proteins in rye and barley are clearly implicated in the pathogenesis of CD and eliminating these proteins from the diet is currently the mainstay of treatment. Adherence to a strict GFD leads to histopathologic remission, serologic normalization, resolution of most of the related symptoms, and likely prevention of long-term complications.

However, the GFD is often challenging and sometimes overwhelming to people with CD. Wheat-based foods are a major staple of the American diet and finding palatable gluten-free alternatives can be difficult and expensive. Additionally, gluten is a hidden ingredient in many foods and medications and labeling can be confusing. The initiation of a strict GFD can have significant implications on quality of life. In fact, both adults and children with CD report negative feelings towards the diet and report difficulties with adherence especially related to eating out of the home, traveling, and social events.[178,179] Thus it is not surprising that adherence to the GFD is a major issue in CD management. This is true across all ages especially in adolescents and young adults. Strict adherence with a GFD in this age group has been reported to be between 45% and 65%.[180,181] A very young age of diagnosis is associated with higher rates of adherence.[182] Screening detected disease, with either atypical or silent features, is associated with poorer compliance.[183] Patient and family education and support help the transition to a GFD and increase adherence. Intensive support is best given via a team approach with involvement of

both a physician and a dietitian experienced in CD. Involvement in support groups is also helpful.[178,179]

The role of oats in the GFD has been subject to change. Several studies now show that the inclusion of pure oats is safe for the majority of children and adults with CD. Rarely, in a small number of individuals, the avenin proteins in oats can trigger a response similar to gluten.[184–188] However, high levels of cross-contamination with wheat in the North American oats supply has been problematic and, in the past, led to recommendations for patients with CD to avoid all oats. As uncontaminated sources of oats have now become more readily available, the introduction of oats with clinical follow up may be attempted in patients with well-treated CD.[189]

Lactose intolerance is common in both children and adults with untreated CD. In fact, up to half of newly diagnosed patients are affected. Lactose intolerance in the setting of active CD is likely secondary to low lactase enzyme activity in the damaged small intestinal mucosa. Lactose containing foods may need to be avoided initially in newly diagnosed patients with significant symptoms. Fortunately, most patients can tolerate dairy intake within 3–6 months after initiation of a GFD.[190,191] However, primary lactose intolerance can coexist with CD.[192]

While general nutritional status improves with treatment, a lifelong GFD may not be nutritionally well balanced. Few gluten-free products in the United States are enriched and most are lower in fiber than their wheat-containing counterparts.[184] In fact, adult and adolescent patients on a GFD have been shown to have decreased fiber intake.[193,194] Mean daily intakes of folate and vitamin B12 were significantly lower in adults with CD on a GFD as compared to healthy controls.[195] Children on a GFD were also found to consume only 60% of the recommended daily allowance of iron.[196] Another nutritional study of children with CD found that those children on a strict diet were more likely to have a nutritionally unbalanced diet and were more likely to be overweight than children who were not adherent to the diet.[197] A study in adult celiac patients after 8–12 years of GFD with biopsy-proven remission showed that 56% showed signs of poor vitamin status, specifically with lower plasma levels of folate, vitamin B6 and elevated levels of homocysteine (a metabolic marker of folate, vitamin B6 and vitamin B12 deficiency).[195] Thus the use of a daily gluten-free multivitamin supplement is often recommended.[184]

Please refer to Chapter 72, Special Diets, for additional information about a gluten-restricted diet and celiac resources and support groups.

BEYOND THE GFD

While highly effective, a GFD is not an ideal therapeutic option for many individuals with CD because of the challenges associated with diet adherence and the negative impact on quality of life. Developing grains, through selective breeding and transgenic technology, that have low or nontoxic peptide sequences and acceptable baking qualities is technically challenging. Fortunately, as our understanding of the pathophysiology of CD has grown, several potential targets for new treatments have been identified. Alternatives to the GFD are currently being investigated.

Intraluminal therapies in the form of endoproteolytic enzymes, such as ALV003 or AN-PEP, may help degrade gluten peptides in the intestinal tract thereby rendering them nontoxic. Larazotide acetate affects tight junctions and acts to strengthen the intestinal epithelial barrier and reduce the passage of toxic gluten peptides into the lamina propria. Evidence suggests that larazotide reduces symptoms and gluten-induced immune reactivity in patients with CD on a gluten challenge.[198] Development of a desensitizing vaccine is also underway.[199] Other potential strategies target recognition and presentation of the offending gluten antigens via blockade of dendritic cells and other antigen presenting cells, specific antagonization of HLA-DQ peptide binding or by inhibition of TTG. Interfering with the subsequent inflammatory response by cytokine therapy and selective adhesion molecule inhibition is another potential intervention that is currently being explored in other disease processes.[200]

Many of these potential new treatments, while promising, are in the early phases of investigation.

Ideally, a safe and effective treatment will be developed that can replace the GFD and allow patients with CD to eat freely. However, a more realistic goal may be to develop therapies that allow patients with CD increased flexibility with their diet. A treatment that allows individuals to tolerate small or moderate amounts of gluten in their diets would clearly have a positive impact on the lives of people with CD.

Food Allergies

54

Julie Wang, MD, Jennifer M. Maloney, MD, and Hugh A. Sampson, MD

DEFINITION

The term “allergy” is subject to a wide range of interpretations. Many conditions are labeled as allergic disorders; however, a clear immunologic basis for disease is not present. As a result, a clear definition is necessary before delving into the subject of food allergy.

Adverse reactions to food include a wide spectrum of food allergic and nonallergic reactions (see Figure 54-1). Food allergies result from immunologic responses to foods, through either IgE or non-IgE-mediated mechanisms, that occur reproducibly on exposure to the triggering food.[1] Nonallergic adverse food reactions include intolerances that result from host factors,[1] such as enzyme deficiencies, for example, lactase deficiency, which results in the bloating, abdominal pain, and occasionally diarrhea of lactose intolerance. Toxic food reactions represent a separate category, which result from inherent toxicities or properties of the food, for example, histamine-mediated symptoms due to scromboid fish poisoning.[1]

PREVALENCE

Although 10%–50% of the population believes they have adverse reactions to foods, not all of these reactions are immune mediated.[1] Many studies have investigated the prevalence of food allergies, however, few population studies have used double-blind, placebo-controlled food challenges (DBPCFCs) to confirm the diagnosis of food allergy, which can lead to an overestimate of prevalence. Rona et al. performed a meta-analysis focusing on milk, egg, peanut, and seafood allergy, and determined the prevalence of food allergies to be approximately 3.5%.[2] The majority of the studies included in this meta-analysis used self-

reported food allergy, many used skin prick testing (SPT) and food-specific IgE levels to confirm sensitization to the food allergens, and some employed DBPCFCs. A US study that used several national health databases and health-care surveys to determine food allergy prevalence concluded that 3.9% of US children report having food allergy, which is an 18% increase in prevalence between 1997 and 2007.[3] More recently, higher estimates have been reported in the United States (8.0%, based on self-report),[4] in Canada (7.14%, based on self-report),[5] and in Australia (>10% of a general infant cohort had challenge-proven food allergy).[6]

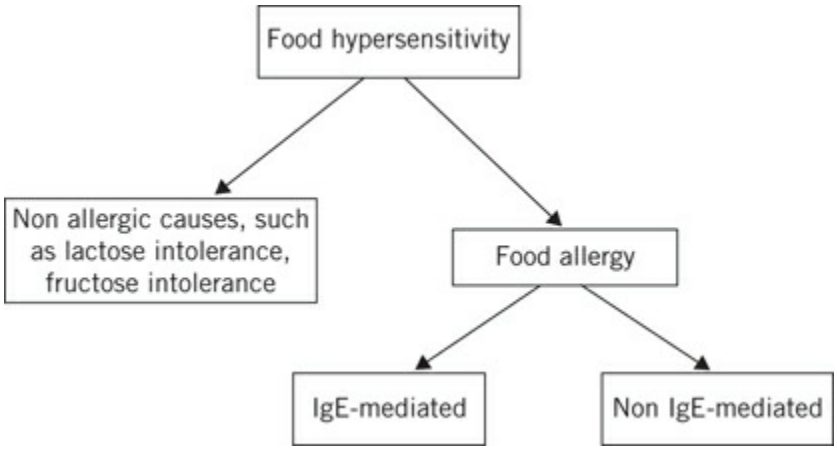

Figure 54-1 Classification of food hypersensitivities.

Cow milk allergy affects approximately 1%–2% of infants in their first year of life.[1] IgE-mediated processes account for approximately 60% of cases. Hypersensitivity to egg affects approximately 1.6% of children,[1] and peanut affects over 0.06%–5.9% of children.[1] Interestingly, over an 11-year period, the rate of peanut allergy in the United States appears to have tripled in young children.[7]

The persistence of symptomatic food allergy varies depending on the food. It used to be believed that most children outgrew their milk and egg allergies by school-age, however, more recent reports indicate that it is taking longer for children to outgrow their milk and egg allergy, with most developing tolerance by their mid-teenage years.[8,9] In contrast, only 20% of children with peanut allergy and 9% with tree nut allergy will develop tolerance.[10,11]

Pollen food allergy syndrome (PFAS, also known as oral allergy

syndrome) is a common symptom complex, which usually provokes isolated oral symptoms following exposure to heat-labile proteins in uncooked fruits and vegetables. Pollen allergic individuals are at risk due to the homology between specific pollen proteins and proteins in certain foods. Of patients with allergic rhinitis, it has been estimated that 23%–76% of patients experience oral symptoms to at least one food.[12] The cooked version of the foods is typically tolerated due to disruption of the protein conformation or tertiary structure.

Food allergy commonly presents in patients with or who will develop other atopic diseases. Approximately one-third of children and adolescents with moderate-severe atopic dermatitis have IgE-mediated food allergy.[1] In addition, the presence of food allergy increases the probability of developing allergic airway disease.[1] Despite the concomitant existence of food allergy and asthma, wheezing is rarely an isolated finding in a food allergic reaction.[13]

PATHOPHYSIOLOGY

Food allergy results from an atypical response of the mucosal immune system to orally consumed antigens. The gastrointestinal (GI) mucosa is an extensive structure responsible for digestion and absorption of nutrients as well as protection from pathogenic organisms. A nonspecific physical barrier works with immune and nonimmune cells and cytokines to maintain immunologic homeostasis.

The physical constituents of the GI mucosa comprise epithelial cells, the mucin glycoprotein lining, trefoil factors, proteolytic enzymes, and bile salts. The epithelial cells are attached by intercellular tight junctions. The mucin lining traps large particles due to its viscous nature and functions as a reservoir for secretory IgA (sIgA), which entraps bacteria and viruses. Trefoil peptides maintain barrier function by restoring its integrity if defects occur. Proteolytic enzymes, bile salts, and exposures to wide ranges of pH gradients work to eliminate pathogenic organisms and modify the immunogenicity of proteins due to proteolysis and emulsification.[14]

Furthermore, the mucosal immune system provides an active line of defense through both the innate and adaptive arms. Peyer’s patches (organized lymphoid structures of the small intestine and rectum), sIgA, dendritic cells, antigen-presenting macrophages, MHC class I and II bearing T lymphocytes, intestinal epithelia cells, as well as other cytokine-

producing cells allow for immunologic responsiveness.[15] Despite the complex interplay of the mucosal system, approximately 2% of intact food proteins are absorbed through the mature GI tract and reach the lymphatic and portal circulation. The intestinal permeability is increased during infancy, and young children's vulnerability is further augmented by the nature of their immature mucosal barrier, which has decreased gastric acid production and reduced pancreatic and intestinal enzymatic activity.[16] Consequently, there is increased absorption of intact food proteins, which may cause stimulation of the immune system and generation of IgE antibody.[16]

Oral tolerance allows individuals to encounter immense quantities of dietary protein and commensal bacteria without inciting a dynamic immune response. Antigenic factors and host factors are involved in the generation of oral tolerance, see Table 54-1. Antigenic factors, which influence oral tolerance, include the form and the dose of the antigen. Soluble antigens are more tolerogenic than particulate antigens. Antigenic dose is also a key component to tolerance development. Experiments in mice have shown that oral tolerance can be induced by the administration of a single high dose of allergen or repeated low doses.[17] High-dose oral tolerance may occur through Fas-mediated apoptosis or through the generation of anergy. Anergy occurs when T cells encounter antigens in the absence of co-stimulatory signaling. Low-dose tolerance develops as a result of regulatory T cell activation. The best categorized regulatory T cells are CD4+ cells (TH3 via TGF-β, TR1 via IL10, CD4+CD25+ cells possibly via surface bound TGF-β), CD8+ suppressor cells, and NK1.1+T cells.[15,18]

TABLE 54-1 Factors Influencing the Development of Oral Tolerance

Antigenic Factors

- Form – soluble antigens are more tolerogenic than particulate antigens
- Dose – tolerance is induced by single high dose or repeated low doses

Host Factors

- Age – ability to generate oral tolerance increases with age
- Genetics – genetic composition influence oral tolerance
- Gut Flora – contributes to the development of oral tolerance

Alternate routes of exposure (i.e., via skin or respiratory tract) can lead to loss of oral tolerance. Peanut exposure via the epicutaneous or epidermal routes in a murine model with slight inflammation of the skin induces Th2 immune responses and promotes allergic sensitization.[19] In humans, increased rates of peanut allergy were found in children with atopic dermatitis, who used topical creams containing peanut oil (OR 6.8).[20] Specific aeroallergen exposure through the respiratory route leads to PFAS.[12]

HOST FACTORS

Host factors involved in the generation of oral tolerance include age, genetics, and GI flora. The ability to become tolerant to food antigens appears to become more effective with age. Neonates develop a stronger immunologic response to dietary proteins in their first few months of life, as demonstrated by rapid increases in circulating antibodies when fed milk or soy formulas,[21] and prevalence of food allergies is higher in young children as compared to adults.[4] However, a few recent studies suggest early introduction of foods may be beneficial in some cases. A comparative study of Jewish children in Israel and the United Kingdom found a 10-fold lower incidence of peanut allergy in Israel where infants are fed peanut proteins [Bamba®, Osem Corporation, Israel] starting at an early age as compared to the United Kingdom where peanut is not introduced until children are much older.[22] The Learning Early About Peanut Allergies (LEAP) study is currently exploring the effect of early peanut allergen exposure on the development of peanut allergy. Similarly, introduction of cow's milk in the first two weeks of life was associated with the lowest incidence of cow's milk allergy in a large cohort of Israeli children.[23]

Host genetic composition influences the development of oral tolerance or food hypersensitivity, as demonstrated in murine models and human disease. Induction of oral tolerance in mice differs depending on the strain of mouse.[24] In humans, a higher frequency of three HLA class II genotypes has been found in peanut allergic patients.[25] In addition, monozygotic twins have been shown to have a high concordance rate of peanut allergy,[26] supporting the interplay of genetic influence on oral tolerance and food hypersensitivity.

Commensal gut flora take residence in the GI tract within 24 hours

after birth at a concentration that has been estimated to be between 10^{12} and 10^{14} bacteria per gram of colon tissue.[14] The impact of gut flora on oral tolerance is supported by the finding that mice raised in germfree environments following birth are unable to develop tolerance to orally administered OVA.[27] Furthermore, both mice with TLR 4 deficiency plus normal GI flora and mice who have intact TLR 4 signaling but are raised in germfree conditions are susceptible to the induction of allergy,[28] suggesting that cooperation between the innate immune system and the gut flora is essential for oral tolerance induction. A recent study demonstrated that mice with food allergy have a microbiota signature that is distinct from congenic, but food allergy-resistant wild-type control mice.[29] Transfer of microbiota from food allergic mice to naïve, germfree mice resulted in transmission of food allergy susceptibility. Furthermore, the study demonstrated that the microbiota signature could be reprogrammed to a tolerance-associated signature after treatment with allergen-specific T regulatory cells. Therefore, the potential for probiotics in the prevention and treatment of human allergic disease has generated great interest. Results from several studies have demonstrated effectiveness of probiotics in the prevention of eczema in certain populations; however, benefits for food allergy prevention have not yet been reported.[30–32]

Other factors that can influence the clinical response of food allergy include comorbid asthma, exercise, viral infections, and concurrent use of alcohol or medications. Asthma is known to be a risk factor for more severe anaphylaxis.[33] Exercise, use of alcohol, or medications (aspirin, beta-blockers, angiotensin converting enzyme inhibitors, monoamine oxidase inhibitors, tricyclic antidepressants), and concurrent infection may increase the severity of anaphylactic reactions or diminish the efficacy of epinephrine.[34]

FOOD ALLERGEN FACTORS

Despite the wide range of foods that humans consume, surprisingly few foods account for the majority of food allergies. Milk, egg, peanut, wheat, and soy are responsible for most food-induced reactions in children, whereas peanut, tree nuts, fish, and shellfish cause most reactions in adults.[1]

Two forms of IgE-mediated food allergy have been proposed. Class 1 food allergy results from sensitization through the GI tract.[35] The class 1 food allergens are generally 10–70 kd in size and highly stable when

subjected to heat, acid, or proteases.[16] Examples of class 1 food allergens include milk (caseins), peanut (vicilins), egg (ovomucoid), and nonspecific lipid transfer proteins.

Class 2 food allergy results from sensitization to inhalant allergens that are partially homologous to proteins in certain fruits and vegetables, and principally occurs in adolescents and adults. Class 2 allergens are heat labile and susceptible to digestive processes.[35] Consequently, symptoms occur when the food is ingested in the raw form, but not when cooked. For example, Bet v 1, a major allergen of birch pollen, shares homology with class 2 allergens in various fruits and vegetables (e.g., apple, Mal d 1; carrot, and Dau c 1). A similarity in the three-dimensional structures (rather than the overall sequence identity) between birch pollen epitopes and the epitopes of specific foods has been demonstrated.[36] IgE antibody recognition of structurally related epitopes among pollens and foods likely results in PFAS.

Different phenotypes of food allergy may be distinguished by the presence of specific IgE to sequential or conformational epitopes. Transient allergy to milk and egg is primarily due to IgE antibody binding to conformational epitopes whereas persistent allergy to milk and egg is characterized by significant binding to sequential epitopes.[37,38] Recent studies show that most milk and egg allergic individuals are able to tolerate extensively heated or baked forms of these foods,[39,40] suggesting that these individuals have specific IgE to conformational epitopes that are disrupted by heating. In addition, different patterns of epitope recognition or epitope diversity may provide additional insight on the clinical manifestations of allergic reactions to peanut and milk.[41,42] Although heating can reduce the allergenicity of milk and egg proteins, it is important to know that heating peanut proteins at high temperatures (i.e., roasting) increases the allergenicity of peanut allergens.[43]

REACTION MECHANISMS

IgE-Mediated Reactions

Food allergic reactions involving IgE antibodies occur when IgE binds to and cross-links the high affinity IgE receptor (FcεRI) on mast cells and basophils. Following mast cell and basophil activation, preformed and newly synthesized mediators are released. The mediators include histamine, leukotrienes, numerous cytokines, chemokines, and proteases.[44]

Perivascular mast cells are present in significant concentrations in

areas that border the external environment, such as skin and the respiratory and GI tracts. When activated, mediator release produces vasodilation, bronchoconstriction, and mucus production, which leads to the symptoms of an immediate hypersensitivity reaction. Six to 24 hours after the initial allergen encounter, a late-phase reaction may occur which is characterized by edema and an inflammatory cell influx.[44]

IgE-mediated reactions usually occur within minutes to one hour following ingestion of the causal food. Multiple organ systems may be involved including the skin, respiratory tract, GI tract, and cardiovascular system.

Non IgE-Mediated Reactions

Several food hypersensitivity disorders exist that are not solely IgE-mediated. Cell-mediated hypersensitivity reactions, orchestrated by antigen-sensitized T cells, may be responsible for the manifestations of certain conditions. A few diseases are thought to result from a combination of cell-mediated and IgE-mediated mechanisms, for example, atopic dermatitis, allergic eosinophilic esophagitis.[1]

CLINICAL FOOD ALLERGIC DISORDERS

Food-Induced Anaphylaxis

Food-induced anaphylaxis is a severe, potentially fatal, systemic allergic reaction that occurs rapidly after exposure to an allergy-causing food.[45] The majority of anaphylactic events are characterized by cutaneous symptoms, such as urticaria, angioedema, and flushing, although the absence of skin involvement does not exclude the diagnosis. For example, cardiovascular collapse with resultant shock may occur without cutaneous symptoms due to decreased blood supply to the skin.[34] In fact, in a report of six food-induced, fatal and seven near-fatal, anaphylactic reactions, 38% of reactions were not accompanied by cutaneous symptoms.[33]

As with any IgE-mediated reaction, there may be a late-phase response associated with anaphylaxis. The incidence of such reactions is described to occur in up to 20% of food-induced events.[45] The only published series of anaphylactic episodes in a pediatric population, reports the incidence of biphasic reactions to be 6%.[46] With biphasic reactions, a period of recovery after the initial reaction is followed by a recurrence of symptoms. Late-phase reactions are variable, may be severe and severity cannot be predicted based on earlier symptoms.

Food-associated exercise-induced anaphylaxis usually occurs when exercise follows the ingestion of a specific food (such as wheat, shellfish, celery) by approximately 2–4 hours.[1] A less common form of food-associated exercise-induced anaphylaxis occurs with the ingestion of any food prior to exercise. The pathogenesis of food-dependent exercise-induced anaphylaxis is unclear.

Cutaneous Food Hypersensitivity Reactions

Acute urticaria and angioedema are the most common manifestations of food-induced allergic reactions (Table 54-2).[1] The onset of symptoms may occur minutes after ingestion. Urticaria also frequently develops as a result of direct skin contact with food allergens. Contact reactions are typically localized to areas of direct exposure and are unlikely to provoke systemic reactions, unless inadvertent ingestion occurs.[47] Chronic urticaria and angioedema are defined as the presence of symptoms for more than six weeks and are infrequently due to food allergy.

Atopic dermatitis is a mixed IgE-mediated and non-IgE-mediated disorder. It is a chronic skin condition that often starts in childhood and is characterized by a relapsing and remitting course. Acute lesions are intensely pruritic and appear as erythematous macular and papulovesicular lesions. Scratching results in excoriation with crusting and exudation. The rash may progress to a subacute form with erythematous, scaling papules and further advances with the chronic changes of skin thickening or lichenification.[48]

The cutaneous lesions of atopic dermatitis usually occur on the face, scalp, and extensor surfaces in young infants. The distribution tends to shift as children get older, affecting the flexural surfaces of the extremities.[48] Atopic dermatitis skin lesions are characterized by a Th2 cytokine profile (acute lesions—IL-4, IL-5, IL-13; chronic lesions—IL-5, IL-13). These cytokines result in an inflammatory state with upregulation of adhesion molecules on vascular endothelial cells, upregulation of the high-affinity IgE receptor on Langerhan's cells and other antigen presenting cells, recruitment of inflammatory cells to the skin, and local production of IgE.

TABLE 54-2 Cutaneous Hypersensitivity Disorders

Cutaneous manifestations of food allergy
IgE mediated
Urticaria and angioedema, skin erythema, morbilliform rash

Mixed IgE and cell mediated
Atopic dermatitis
Cell mediated
Contact dermatitis, dermatitis herpetiformis

Approximately one-third of children and adolescents with moderate to severe atopic dermatitis have IgE-mediated food hypersensitivity.[1] When patients with food allergy-related atopic dermatitis undergo food challenges, positive challenges are usually hallmarked by cutaneous symptoms such as pruritic, morbilliform, or macular eruptions with a tendency to occur in skin areas affected by atopic dermatitis. In addition to affecting the skin, the majority of positive food challenges trigger other organ system involvement (GI or respiratory). Egg, milk, wheat, peanut, tree nuts, and soy are the most frequent foods to which patients are clinically reactive,[1] with egg affecting approximately two-thirds of patients with food allergy and atopic dermatitis.[49] If the history reveals food-related symptoms and tests for specific IgE to the food are positive, elimination is the best initial approach. However, caution is needed because although removal of a causal food may improve the skin disease, the patient develops an increased probability of an acute allergic reaction, even anaphylaxis, with reintroduction of the food.[50]

Dermatitis herpetiformis is a polymorphous, pruritic rash characterized by erythematous, urticarial plaques, papules, and vesicles. It develops as a result of gluten sensitivity, usually in association with gluten-sensitive enteropathy (celiac disease). Patients with dermatitis herpetiformis have serum IgA autoantibodies to epidermal transglutaminase.[51]

Contact dermatitis is a non-IgE-mediated skin condition, which may be provoked by food exposures.[1]

Respiratory Food Hypersensitivity Reactions

Food-induced respiratory symptoms usually occur in conjunction with other organ system reactions (Table 54-3).[13] Respiratory symptoms consist of rhinoconjunctivitis, laryngeal edema, cough, and/or bronchospasm. Comorbid asthma is a risk factor for more severe food allergic reactions, including fatal and near-fatal anaphylaxis.[33] In addition, having a food allergy has been shown to be associated with life-threatening asthma. In a case-control study, it was demonstrated that children requiring intubation at the time of asthma exacerbation were 5.9 times more likely to have a food allergy compared with matched children who had milder asthma

exacerbations.[52]

TABLE 54-3 Respiratory Hypersensitivity Disorders

Respiratory manifestations of food allergy
IgE mediated
Bronchospasm, cough, rhinitis, congestion, rhinorrhea, sneeze
Mixed IgE and cell mediated
Asthma
Cell mediated
Heiner's syndrome

Rhinitis and nasal symptoms are commonly seen in patients who have reactions during food challenges. Just as it is uncommon to have isolated food-induced asthmatic symptoms, it is very unusual to have nasal symptoms as the only manifestation of an acute food-allergic reaction.[53]

Allergic reactions can develop as a result of inhalation of airborne food proteins. This modality of exposure is more significant when vapors or steams (from foods such as fish or eggs) are being emitted during the cooking process.[54] Inhalation reactions secondary to peanuts, such as particulate matter from peanut dust when shells are opened, have also been reported.[55] In contrast, exposure of peanut allergic patients to the smell of peanut butter, due to aromatic pyrazines, has not been shown to result in systemic or respiratory symptoms.[47]

Food-induced pulmonary hemosiderosis (Heiner's syndrome) is a rare non-IgE-mediated hypersensitivity reaction primarily to milk, which results in the development of recurrent pneumonia, hemosiderosis, GI blood loss, iron deficiency anemia, and failure to thrive. Removal of milk from the diet results in symptom resolution.[1]

Gastrointestinal Food Hypersensitivity Disorders

Food-induced reactions affecting the GI tract may be IgE-mediated, non-IgE-mediated, or due to an interplay of IgE and non-IgE-mediated reactivity (Table 54-4). GI anaphylaxis is an IgE-mediated reaction that includes symptoms of acute nausea, abdominal pain, colic, vomiting, and/or diarrhea. More indolent symptoms may occur in infants with atopic dermatitis and food allergy who are chronically ingesting the allergen. In these patients, intermittent vomiting and failure to thrive may be part of the symptom constellation.[16]

PFAS, also known as oral allergy syndrome, is also an IgE-mediated reaction that occurs in pollen allergic individuals due to homologous proteins shared between foods and specific airborne pollens.[12] Patients with birch pollen allergy may develop oropharyngeal symptoms with raw apple, carrot, potato, celery, pear, kiwi, stone fruits, hazelnut, almond, and peanut; patients with ragweed pollen allergy may be sensitive to various melons and banana; patients with grass pollen allergy might become symptomatic with tomato, melons, and kiwi; and patients with mugwort pollen allergy may develop symptoms with celery, carrots, and spices. Symptoms of PFAS are usually confined to the oropharyngeal cavity, and the foods are usually tolerated in the cooked form because the allergens do not retain their tertiary structure at high temperatures.

TABLE 54-4 Gastrointestinal Hypersensitivity Disorders

Gastrointestinal manifestations of food allergy
IgE mediated
Nausea, abdominal pain, colic, vomiting, diarrhea
Pollen food allergy syndrome ⇒ usually only oropharygeal symptoms
Mixed IgE and cell mediated
Allergic eosinophilic esophagitis, eosinophilic gastroenteritis
Cell mediated
Food protein induced enterocolitis, proctocolitis, celiac disease

Eosinophilic esophagitis (EoE) and gastroenteritis are disorders believed to be due to Th2-mediated mechanisms. Eosinophils infiltrate the walls of the esophagus, stomach, and small intestine. Peripheral eosinophilia is found in approximately half of the patients.[56] When evaluating these patients, other known causes of eosinophilia must be excluded, such as GI reflux, drug reactions, parasitic infections, and malignancy. Patients with GI eosinophilic disorders have a high incidence of concomitant atopy, with many having sensitizations to foods and environmental allergens.

In a disease-free state, eosinophils are usually not present in the esophagus. EoE may occur at any age from infancy through adolescence and into adulthood. Symptoms include abdominal pain, spitting-up or vomiting, food refusal, and gastroesophageal reflux symptoms in younger patients, and midsternal chest pain, dysphagia, and food impaction in adolescents and adults. Diagnosis is defined by multiple criteria: evidence

of esophageal dysmotility, histology showing at least 15 esophageal intraepithelial eosinophils per 40× high power field, persistence of esophageal eosinophilia despite proton pump inhibitor therapy, and remission of disease with dietary intervention or topical corticosteroid therapy.[57] Histological features include eosinophils in the proximal and distal esophagus, thickened esophageal mucosa, papillary elongation, and basal zone hyperplasia. Endoscopic findings include furrowing (vertical, linear creases), mucosal rings, strictures, ulcerations, and whitish papules that are secondary pockets of subepithelial eosinophils.[57]

Allergic eosinophilic gastroenteritis is much less common than EoE and may occur at any age. Most notably, patients frequently present with weight loss and failure to thrive.[56] Additional symptoms include abdominal pain, emesis, nausea, and diarrhea. Especially in young infants, presentation may consist of gastric outlet obstruction or symptoms resembling pyloric stenosis. Diagnosis is made through biopsies, which reveal significant eosinophilic infiltration of the gastric and/or duodenal mucosa, with no other identifiable medical cause (i.e., infection, inflammatory bowel disease, drug reaction). A subgroup of patients develop anemia and hypoalbuminemia, secondary to fecal loss of blood and a protein-losing enteropathy.[58]

Allergic proctocolitis is a non-IgE-mediated, eosinophilic disorder that typically presents in the first few weeks to months of life.[1] Infants appear in good health; however, they have blood and mucus in the stool, which increases in frequency unless the causal allergen is removed from the diet. Growth delay and poor weight gain are not usual presenting features.

Proctocolitis commonly occurs in breast-fed infants (as many as 60% of cases), with milk and soy formulas being the causative foods in the majority of the remaining cases.[1] For infants who develop proctocolitis while breast-feeding, it is believed that cow's milk proteins consumed by the mother are the triggering agents in breast milk, and it has been demonstrated that β-lactoglobulin (one of the major allergens in milk) is detectable in the majority of breast milk samples following maternal cow milk consumption.[59] Elimination of cow's milk from the mother's diet usually will bring about gradual resolution of symptoms; however, if cessation of bleeding does not occur with maternal dietary manipulation, a casein hydrolysate formula, or in rare instances, an amino acid–based formula[60] eliminates gross symptoms, typically within 48–72 hours. For formula-fed infants drinking cow milk formula, a large percentage who have milk-induced proctocolitis, will also become symptomatic to other

foods if introduced in the first six months of life, for example, soy ingestion.[1] A casein hydrolysate or amino acid formula is the recommended treatment.

Food protein-induced enterocolitis syndrome (FPIES) is a non-IgE-mediated food allergy, which usually occurs in formula-fed infants, although it has been reported to a variety of foods (especially cereal grains) in older infants, and is characterized by irritability, excessive, vigorous vomiting, and diarrhea.[1] Diarrhea may have occult blood and stool smears may reveal leukocytes and eosinophils. The stool may also be positive for reducing substances. Depending on the severity of symptoms, patients may develop dehydration with accompanying hypotension and lethargy. Metabolic derangements such as acidosis and hyponatremia can occur as does leukocytosis and a "left-shift." In severe cases, children may even present with methemoglobinemia.

Symptoms may follow a more indolent course for children who are fed the causal food from birth or shortly thereafter. Failure to thrive and hypoalbuminemia in conjunction with chronic emesis and diarrhea may be presenting features. When the causal food is removed and later reintroduced, repetitive vomiting within 2–3 hours and late-onset diarrhea occur.[1] Milk and soy are most frequently the causative foods in food-protein–induced enterocolitis; however, solid foods (such as oat, barley, rice, chicken, and turkey) may be responsible.[61] Approximately 50% of patients reactive to milk also develop reactivity to soy, necessitating treatment with a casein hydrolysate formula or, in rare instances, an amino acid–based formula.[62]

Celiac disease is a chronic inflammatory disorder of the small intestine. An interplay between genetic risk factors and dietary triggers are thought to result in the manifestations of this disease, which include intestinal villus atrophy, malabsorption, and chronic inflammation of the small intestinal mucosa. The major associated haplotypes are HLA-DQ2 and HLA-DQ8, with approximately 95% of patients having HLA-DQ2. Celiac disease is strongly associated with dermatitis herpetiformis, and patients with celiac disease are at increased risk for other autoimmune conditions, such as type 1A diabetes mellitus and autoimmune thyroiditis.[63]

As a result of the immunologic imbalance, patients with celiac disease react to peptide sequences of gluten proteins. Responsible gluten proteins are present in wheat, rye, and barley. Unlike IgE-mediated allergy to wheat, barley, or rye, the T cell cytokine profile from patients with celiac

disease has a T_H1 bias. Removal of gluten from the diet leads to symptom resolution. Patients with untreated disease are at increased risk for T cell non-Hodgkin's lymphoma.[63]

The diagnostic gold standard for celiac disease is the intestinal biopsy, which demonstrates a loss of villi, lymphocytic, and plasma cell infiltration of the lamina propria and intraepithelial compartments and crypt lengthening. Detection of IgA anti-endomysial and transglutaminase-2 antibodies are accurate for the diagnosis of celiac disease.[64] Importantly, testing for celiac disease, either by biopsy or through serologic studies, must be performed while the patient has a diet that includes gluten; otherwise, false-negative results may occur.

DIAGNOSIS

The diagnosis of food allergies requires a comprehensive history, specifically focusing on adverse reactions to particular foods, the time frame of such reactions, whether other contributing factors were present (i.e., exercise), the extent of organ system involvement, and required treatment.[1] Attention to accompanying atopic conditions in the patient and family history of allergy are important. Diet diaries may be helpful in recognizing patterns of reactivity, in identifying commonly consumed allergens, and in identifying foods that may have "hidden allergens," which have provoked the reaction.

The history may be more helpful in situations when food ingestions are causally linked to a reaction, such as the development of urticaria and cough immediately after cashew consumption. For chronic disorders, such an atopic dermatitis, asthma, and GI disorders, the history has a poor predictive value. This point is highlighted by a study in which double-blind placebo-controlled food challenges were conducted in 38 children with severe persistent asthma, where the asthma symptoms were attributed to food allergy. Only 20% of the food challenges (70 challenges conducted) resulted in symptoms. Furthermore, the challenges elicited symptoms predominantly affecting the GI tract despite the chronic respiratory complaints.[65]

Diagnostic Modalities for IgE-Mediated Disorders

SPT is a rapid screening method for IgE-mediated food hypersensitivity. A small amount of food allergen extract is placed on the skin and then subjected to a prick or puncture, which break the skin integrity. A negative

control (saline) and a positive control (histamine) are also placed on the skin. Wheals which are 3 mm larger than the negative control are considered positive.

Unfortunately, the positive predictive value of a positive SPT is less than 50% when compared to results of double-blind placebo-controlled food challenges.[1] Therefore, the medical history remains important because SPTs must be interpreted in the context of the clinical situation. Positive SPTs may be helpful especially when a clear cut history of food reactivity is present. In addition, when hypersensitivity is suspected to milk, egg, or peanut, "diagnostic SPT mean wheal diameters" have been defined (cow milk ≥8 mm, egg ≥7 mm, peanut ≥8 mm; for children ≤2 years of age, cow milk ≥6 mm, egg ≥5 mm, peanut ≥4 mm).[66] However, test results are highly dependent on reagents used (which are not standardized), application technique, and interpretation by the physician. Negative skin tests essentially exclude IgE-mediated allergy.

Intradermal skin testing has no place in the diagnosis of food allergy (Table 54-5).[1] In addition to having poor specificity and positive predictive value, fatalities have been reported with the use of this diagnostic modality.

Detection of food-specific IgE antibodies (i.e., ImmunoCAP, Thermo Fisher Scientific; Waltham, MA) has been shown to be predictive in symptomatic IgE-mediated food allergy.[67] The ImmunoCAP system contrasts with qualitative radioallergosorbent test (RAST) assays because standardized allergens are used, the dose response curve is calibrated against the World Health Organization IgE standard and the matrix binds more antigen, which provides a steep dose response curve. Diagnostic "decision points" have been generated for common food allergens, namely milk, egg, peanut, and fish (see Figure 54-2). The decision points indicate reaction likelihood (a >95% probability of reaction), but do not predict reaction severity. As serum-specific IgE levels decrease to undetectable, the likelihood of reaction decreases. However, reactions may still occur for a small subset of patients when serum-specific IgE levels are undetectable.

TABLE 54-5 Methods of Diagnosing Food Allergy

Diagnosis of Food Allergy

Oral food challenge
IgE mediated and mixed disease
Prick skin testing

Serum specific IgE testing

Cell mediated and mixed disease

± Patch testing

Whereas SPT and serum-specific IgE tests are instrumental in the diagnosis of IgE-mediated food allergy, for non-IgE-mediated and mixed disorders, their diagnostic utility has little or no value. Patch testing is a modality being considered for diagnosing delayed contact hypersensitivity reactions where T lymphocytes are the major effector cell. For testing, the food allergen is placed on a small area of the skin under an occlusive dressing. The patch is removed after 48 hours, and the area is examined at 48 hours and again at 72 hours. Positive tests demonstrate erythema, edema, papules, vesicles, and/or bullae, and are graded based on severity of reactivity. Although patch testing is a common diagnostic practice for cutaneous contact allergy due to chemicals, its use is not typically used for the diagnosis of food-related conditions.[1] Patch testing may have some utility in the evaluation of food allergy in those with atopic dermatitis or EoE, but this remains to be established with further studies.[1]

The DBPCFC remains the gold standard for diagnosing food hypersensitivities.[1] For the DBPCFC, neither the patient nor the physician knows whether the challenge material is the allergen or the placebo. This approach reduces both patient and observer bias. Single-blind challenges and open challenges are other options best utilized for foods that are unlikely to produce a reaction. For single-blind challenges, the physician knows the content of the challenge material and the patient is blinded, and for open challenges, all participants know the challenge content. The decision to pursue a food challenge should be based on the clinical history in conjunction with SPT and serum-specific IgE results. Food challenges are not benign procedures. Positive challenges may produce mild, moderate, or severe symptoms, and often require treatment[68]; therefore, a properly equipped environment is essential.

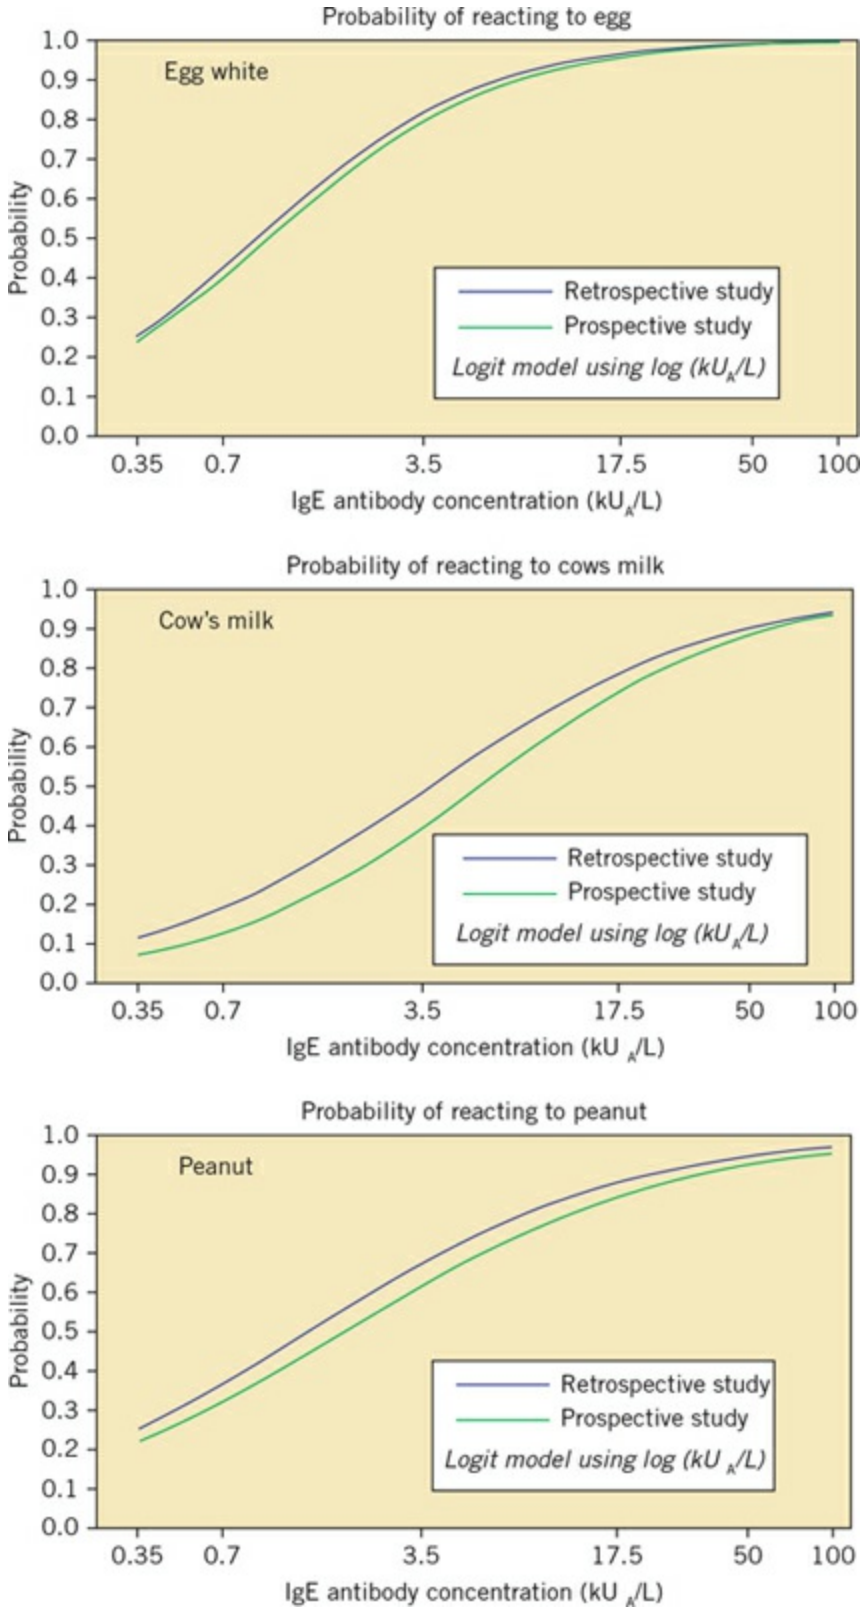

Figure 54-2 Diagnostic decision points for specific foods. (Reproduced with authorization from Sampson HA, Utility of food-

specific IgE concentrations in predicting symptomatic food allergy. *J Allergy Clin Immunol*. 2001;107(5):891–896.)

Prior to food challenges, patients should be instructed to avoid medications that may interfere with interpretation of results, such as antihistamines and beta-adrenergic bronchodilators. For IgE-mediated food allergies, the aim is for the patient to eat the equivalent of approximately 8–10 g of dry (dehydrated) food mixed within a vehicle.[68] A negative-blinded challenge must be followed by an open challenge to assure that the patient can ingest the food safely in natural, meal-sized portions.

For non-IgE-mediated food protein–induced enterocolitis, 0.15–0.3 mg protein/kg body weight, up to a maximum of 10 g is administered in three doses.[68] A reaction typically occurs 1–3 hours later, but when symptoms occur, they may be severe with excessive vomiting and possibly result in hypotension; therefore, intravenous access is recommended prior to the start of the challenge. For other conditions such as the eosinophilic GI disorders, several feedings of the food over a few days may be necessary to induce symptoms.

MANAGEMENT OF FOOD ALLERGY

Dietary avoidance of the causal food allergen is the key element for management of food hypersensitivity at this time (Table 54-6).[1] To practice strict avoidance, patients and their caregivers must be supplied with appropriate education materials to prevent ingestion of foods that may have had inadvertent cross-contact with allergens or foods that have hidden allergens. One study illustrated that for 156 reactions to peanut and tree nuts, 50% of accidental ingestions in food establishments were due to "hidden ingredients," such as an ingredient in a sauce or dressing.[69] Although just one study, it illustrates the difficulties that food allergic patients face with daily experiences, such as purchasing prepared foods or eating in restaurants. The Food Allergen Labeling and Consumer Protection Act (FALCPA) in the United States requires food manufacturers to clearly label their products that contain any of the eight major food allergens (milk, egg, peanut, tree nuts, wheat, soy, shell fish, and fish). This benefits patients allergic to these foods; however, the labeling does not necessarily include labeling for all other food allergens. An excellent educational resource for patients and families affected by

food allergies is the Food Allergy Resource and Education organization (www.foodallergy.org).

For patients with IgE-mediated food allergy, accidental ingestions may trigger potentially life-threatening allergic reactions. Therefore, patients and caregivers must be prepared to respond in case of an allergic reaction. Written anaphylaxis action plans should explicitly state the symptoms of anaphylaxis and when self-injectable epinephrine should be administered. Antihistamines are useful in treating mild symptoms, particularly cutaneous and oral symptoms, but will not reverse systemic reactions. Epinephrine is the treatment of choice for acute anaphylaxis (1:1000 dilution, 0.01 mg/kg with a maximum of 0.3 mg). Fatalities from anaphylactic events often appear to result from the late administration of epinephrine and subsequent irreversible cardiopulmonary complications.[34]

The treatment of eosinophilic disorders requires allergen avoidance.[56,57] Frequently, multiple foods must be eliminated from the diet. Many patients with eosinophilic GI disorders have evidence of sensitization to foods (by skin prick tests and/or serum-specific IgE assays); however, immediate reactions to foods are infrequently reported. Dietary elimination based on SPT and serum-specific IgE results alone is generally insufficient to promote disease resolution of eosinophilic disorders. Multiple foods may be causative in the same patient, with the most common ones including milk, soy, egg, and wheat.[56,57] A six food elimination diet has been proposed for the initial evaluation of food-induced symptoms; resolution of symptoms reportedly occurs in about two-thirds of patients. Another approach is to place the patient on an elemental (L-amino acid) formula and slowly add foods back into the diet when symptoms have resolved. Several weeks on an elemental formula is usually required for diminution of symptoms and for regression of the GI eosinophilic infiltrate. Open challenges with the causative foods, following elimination, have been shown to frequently provoke symptoms indistinguishable to those experienced before the elimination diet.

In cases where dietary intervention is not feasible or effective, administration of anti-inflammatory drugs (systemic or topical corticosteroids) can result in clinical and histopathologic improvement[56,57]; however, the side effects that accompany prolonged corticosteroid therapy is unacceptable, and the disease typically returns with discontinuation of the medication.

For proctocolitis, progression to a normal diet, including the eliminated allergen, is usually possible by 1–2 years of age.[1] If the prick skin tests and serum-specific IgE levels are negative, gradual introduction typically takes

place at home. For FPIES, action plans must be in place in the event of accidental ingestions. First-line treatment is fluid resuscitation rather than epinephrine and antihistamines (although these medications should be administered if there is concomitant IgE-mediated disease).[70] Corticosteroids should be considered, especially when past history reveals serious reactions. Corticosteroids likely suppress a presumed T cell immune response. When food reintroduction is considered, challenges in a properly equipped environment are necessary. The high risk of developing FPIES to multiple foods, for example, milk and soy, multiple cereal grains, often necessitates multiple food challenges. Up to 50% of patients reactive to milk may react to soy; up to 65% of patients reactive to grains may react to milk or soy; up to 50% of patients reactive to one grain may react to another grain.[70] More than half of the patients with FPIES due to milk become tolerant by age 3 years. Resolution of FPIES varies by age and is influenced by the primary causative food and the presence of concomitant IgE-mediated disease.[70]

NOVEL THERAPIES

Much recent attention has focused on means of altering the immune system to either eliminate food allergy or increase tolerance to allergenic food. A very limited number double-blind, randomized, placebo-controlled studies of oral immunotherapy (OIT) performed indicated that desensitization was induced in the majority of patients treated and a state of "sustained unresponsiveness" in a subset of subjects.[71–73] However, it is unclear why certain subjects benefit from this therapy whereas others do not, what the duration of sustained unresponsiveness is for those who do experience it, long-term consequences of this therapy, and the underlying mechanisms responsible for these outcomes. Furthermore, adverse reactions during OIT are common. Reactions have ranged from mild localized reactions to systemic reactions requiring epinephrine.[74,75] There are also reports of subjects developing GI symptoms similar to EoE while undergoing OIT.[74,76] At this time, OIT is not approved by regulatory bodies and must be considered experimental.

Sublingual immunotherapy (SLIT)[77] and epicutaneous immunotherapy (EPIT)[78] are alternate routes of administration that are currently being explored.

The type of allergen used can also play a role in the safety and efficacy of immunotherapy. OIT with heat-denatured proteins may accelerate the

development of tolerance to regular milk and egg in those who are allergic, but can tolerate baked milk or egg products in their diet.[79,80] In these studies, the addition of the baked milk and egg products into the diets was safe and well-tolerated. Modified recombinant vaccines with altered IgE-binding epitopes, peptide immunotherapy containing T cell epitopes, use of immunostimulatory sequences as adjuvants, and allergen gene immunization are other potential therapies that are under investigation for peanut allergy.[81]

TABLE 54-6 Treatment Approach to Food Allergy

Treatment of Food Allergy
Food avoidance
Anaphylaxis action plan—epinephrine, anti-histamines, corticosteroids
FPIES action plan—intravenous fluids, ± corticosteroids
Possible Future Therapies
Immunotherapy—oral, sublingual, epicutaneous, heated denatured proteins, recombinant proteins
Monoclonal anti-IgE
Traditional Chinese medicine

Allergen nonspecific forms of treatment for food allergy include anti-IgE therapy and traditional Chinese medicine. Humanized IgG_1 monoclonal antibody against IgE (TNX-901) was tested in peanut-allergic subjects and was shown to enable subjects to tolerate increased quantities of peanut following therapy. Although not a cure for food allergy, the medication offered protection in the event of inadvertent ingestion.[82] Investigation of another anti-IgE preparation, omalizumab (Xolair®, Genentech), for the treatment of peanut allergy was initiated, but discontinued for safety concerns related to the pretreatment oral peanut challenge.[83] Based on the limited data from 14 subjects who completed the study, the omalizumab-treated subjects were able to tolerate increased amounts of peanut as compared to the placebo group. Anti-IgE therapy is now being explored in combination with OIT. A pilot study for milk allergy demonstrated that combination therapy resulted in desensitization within 7–11 weeks.[84]

The potential value of traditional Chinese medicine, which has been used in Asia for centuries, as an effective form of treatment for allergic disease is being explored. Experiments administering a Chinese herbal medicine formula have been able to block anaphylaxis in a murine model

of peanut allergy and multiple food allergy.[85] Phase 1 clinical trials have demonstrated the formula to be safe and well-tolerated by food allergic individuals.[85] A phase 2 clinical trial is currently underway.

SUMMARY

Food allergy is a general term that includes a wide range of conditions. The pathogenesis involves IgE-mediated and/or non-IgE-mediated processes with varying manifestations depending on the mechanisms of disease. Diagnosis requires a skillful history, physical exam, and targeted diagnostic testing. Treatment requires avoidance of the causal allergen(s). Hopefully in the future, diagnostic modalities will be more fine-tuned and additional treatment options will be available.

Exocrine Pancreas

55

Kevin Gaskin, MD, FRACP

EXOCRINE PANCREATIC DISEASE

There are a variety of childhood exocrine pancreatic disorders (EPDs) of an inherited or acquired nature in terms of their etiology. The acquired disorders include primary protein energy malnutrition, tropical calcific pancreatitis, and nongenetic chronic pancreatitis. From a global perspective, primary protein energy malnutrition is possibly the commonest EPD, but not surprisingly there is a dearth of evidence-based pancreatic studies in such populations as compared to the far less commonly inherited/genetic diseases described in the western world. The present chapter will discuss the clinical phenotypes and the molecular basis/pathophysiology of the genetic disorders, highlight the mechanisms of fat and protein maldigestion and malabsorption common to all patients with severe exocrine pancreatic dysfunction, and the nutritional consequences and management of children with exocrine pancreatic dysfunction.

Molecular Basis and Clinical Features of Inherited Exocrine Pancreatic Disorders

The inherited genetic disorders are uncommon or rare and are summarized in Table 55-1, according to the molecular defects and functional effects thereof. The commonest, cystic fibrosis (CF), occurs in 1:2500–1:4000 live births in Western countries.[1] The second commonest, Shwachman–Diamond syndrome (SDS),[2] has a much lower incidence of 1:76,000 globally, approximately 3% of the CF population.[3] The remaining disorders, including Pearson's Marrow Pancreas syndrome (PMPS),[4] Johanson–Blizzard syndrome (JBS),[5] and pancreatic agenesis (PA),[6] are rare, with less than 100, 30, and 50 cases, respectively, reported

worldwide. There are only anecdotal reports of enzyme deficiency syndromes, but although very rare their recognition has emphasized the important role these enzymes/coenzymes have in fat and protein digestion.

TABLE 55-1 Hereditary Exocrine Pancreatic Disorders

Disorder	Genetics Mutations of	Functional Defect
Cystic fibrosis	CFTR gene 7q31	Impaired anion transport via CFTR
Shwachman–Diamond syndrome	Shwachman, Bodian, Diamond syndrome gene 7q11	Possible defects in ribosomal maturation structure, function
Pearson's Marrow Pancreas syndrome	Mitochondrial DNA deletion	Abnormal oxidative phosphorylation, severe sideroblastic anemia, pancreatic insufficiency
Johanson–Blizzard syndrome	UBR-1 gene chromosome 15q13	Impaired synthesis of ubiquitin ligase with dysregulation of protein degradation, progressive inflammation, fibrous tissue proliferation
Pancreatic agenesis	i. PDX1 gene at 13q12, which encodes IPF-1 transcription factor ii. PTF-1a gene 10p12 iii. GATA-binding factor on 18q11	Interference with protein transcription factors, formation and function
Hereditary pancreatitis	Protease serine-1 gene 7q34	Premature activation of trypsinogen in pancreas
Congenital enteropeptidase (enterokinase) deficiency	Proenteropeptidase, PRSS-7 gene 21q21	Failure to produce enteropeptidase and lack of trypsinogen activation to trypsin
Isolated lipase colipase deficiency	No mutations described	Fat malabsorption

The molecular basis of the genetic disorders has been elucidated over the last 20 years and particularly in CF has provided insight into the pathophysiology of the disorder. Each of these conditions will be discussed in terms of their pathophysiology and clinical manifestations.

Cystic Fibrosis

The molecular/genetic basis of CF was unraveled in 1989 with the discovery of the cystic fibrosis transmembrane conductance regulator (CFTR) gene[7,8] and the subsequent recognition that CFTR protein is a cyclic adenosine monophosphate (c-AMP)- dependent anion transport channel in epithelial cell membranes.[9] Mutations of CFTR cause a multiplicity of electrolyte transport defects as, for instance, poor reabsorption of Cl^- from the sweat duct resorptive epithelium[10] and poor Cl^- and HCO_3^- secretion from both respiratory and pancreatic duct epithelium.[11,12] In vivo, the poor reabsorption of sweat duct Cl^- leads to excessive sweat losses of Cl^- and is the basis of sweat Cl^- testing as the gold standard diagnostic marker of CF. The in vitro work on CF pancreatic cell lines demonstrating the impairment of pancreatic duct Cl^- and HCO_3^- secretion[11,12] also confirms the earlier in vivo work on CF patients using pancreatic stimulation tests.[13,14] These studies demonstrated that CF patients had significantly impaired Cl^- and HCO_3^- secretion in comparison with normal and disease controls, irrespective of the degree of destruction or lack of development of pancreatic acinar tissue.

CFTR/c-AMP-dependent HCO_3^- secretion has more recently been found, in vitro, to be impaired in a variety of epithelial CF tissues in addition to the above, including biliary tract, gut, and uterine/cervical epithelia, with a coimpairment of mucin secretion.[12] Mucin appears to aggregate in glandular structures and an inflammatory, fibrotic process ensues. Even impairing HCO_3^- secretion in the absence of CFTR mutations can induce a similar process. In a similar vein, in a CF mouse model,[15] poor alkalinization of pancreatic fluid leads to intraduct aggregation of glycoprotein-2 obstructing small ductules consistent with postmortem studies on CF infants and children, and at least in part contributing to the fibrotic process observed so characteristically in this disease.

To date, over 1900 CF-causing mutations have been recognized. Considering this large number, over the last 15 years these mutations have been classified into five classes according to their biosynthetic defects and dysfunction,[16,17] as per Table 55-2. In terms of pancreatic disease, Classes I, II, and III mutations are associated with severe pancreatic disease with fat malabsorption, the pancreatic insufficient (PI) phenotype, whereas Classes IV and V mutations are associated with less severe impairment of

and even normal pancreatic enzyme secretion with normal fat absorption, the pancreatic sufficient (PS) phenotype (see the section *Maldigestion and Malabsorption*). The two phenotypes, PI and PS, are regarded as classic forms of CF with sweat chloride levels over 60 mmol/L and characterized by multisystem involvement as outlined in Table 55-3. PS patients also have milder lung disease and longer survival, a lower sweat chloride, and compared to their PI counterparts experience less liver or gut disease.[18] Although rare reports of meconium ileus, distal intestinal obstruction syndrome, or cholelithiasis have occurred in PS patients, along with fibrosing colonopathy (FC) and intussusception, these complications almost exclusively occur in the PI phenotype.

TABLE 55-2 Classification of CFTR Mutations Reflecting Biosynthetic Defects and Function

Class I	• Defective protein production • Frameshift and nonsense mutations • Unstable messenger RNA
Class II	• Defective CFTR processing (includes ΔF508 as most common mutation)
Class III	• Defective regulation of CFTR gene • Mutations can dramatically impair channel function, G551D
Class IV	• Defective channel conduction, e.g., R117H
Class V	• Abnormal splicing of CFTR gene • Reduction in normally functioning channels

In those patients with classical CF, particularly the 85%–90% with the PI phenotype, over 95% of the mortality is related to the inexorable progression of the lung disease. Early colonization with *Pseudomonas* and *Staphylococcus aureus*, bronchiectasis, and obstructive respiratory disease ultimately lead to respiratory failure and the need for lung transplantation. Recent studies suggest survival has improved dramatically over the last 30 years.[19–21] In the early 1980s, the best median survival was up to 30 years. This has now improved to over 45 years and over 90% of patients are expected to survive into adulthood. Although the improvement is multifactorial, delivery of care in specialist multidisciplinary CF clinics,[22] early diagnosis through neonatal screening[23] and protocol-driven antibiotic regimens, segregation of patients with lung *Pseudomonas* colonization to

prevent early lung damage, and maintenance of normal nutrition have no doubt contributed. In one of the Australian newborn screening programs there was a definite survival advantage to the screened population. CF infants in the first 3 years of the program were compared to a retrospective nonscreened group for the 3 years prior to the commencement of screening. The screened infants maintained a significant average advantage of a 10% higher forced expiratory volume in 1 second (FEV_1) percent predicted at 10[23] and 15[24] years of age, increasing to 16% at 18 years.[25] The mortality in the nonscreened group (66%) was over twice the mortality of the screened group (32%) by 25 years of age,[25] confirming two U.S. CF Database reports of longer survival in those diagnosed and treated from early in life.[26a,26b]

In non-neonatal CF patients, general genotyping for the commonest mutations (ΔF508, a Class II mutation) in patients of Northern European ethnicity reveals approximately 50% are ΔF508 homozygotes, 40%–45% are ΔF508 compound heterozygotes (with ΔF508 mutation and a non-ΔF508 mutation), and 5%–10% have two non-ΔF508 mutations.[27] Virtually all ΔF508 homozygotes, 70% of ΔF508 compound heterozygotes, but only 30%–35% with two non-ΔF508 mutations, were PI. Those with PS have at least one Class IV or V non-ΔF508 mutation. In patients of Southern European (SE) ethnicity, ΔF508 homozygotes represent less than 30% of their total CF population[28] but, again, in non-neonatal populations, there is a similar proportion of PI and PS, approximately 85% and 15%, respectively, indicating the Classes I–III (severe pancreatic mutations) are still predominant in these older SE populations.

Neonatal screening provides a different perspective on the pancreatic phenotype/genotype relationship as, at the time of neonatal diagnosis, the PS proportion has varied from 25%[29] to 37%[30] of the population. Over the first 10 years of life 25% of these PS patients developed PI and to date patients in this category have had two Class I–III mutations. Some 10% of patients with at least one Class IV or V mutation are at risk from recurrent pancreatitis, which may lead to the patient becoming PI during their adult years.

TABLE 55-3 Clinical Manifestations of Cystic Fibrosis

Pulmonary disease	• Recurrent infections: – *Staphylococcus*

	– *Pseudomonas* – *Burkholderia* – Fungal • Bronchiectasis • Lung fibrosis • Pneumothorax • Pulmonary hemorrhage • Emphysema • Respiratory failure
Pancreatic disease	• Pancreatic insufficiency • Pancreatic sufficiency ± pancreatitis
Gut disease	• Gastroesophageal reflux • Esophagitis • Giardiasis • Celiac disease • Neonatal meconium ileus • Distal intestinal obstruction syndrome • Intussusception • Appendicitis • Appendiceal mucocoele ± abscess • Fibrosing colonopathy • Crohn's disease • Fecal retention, megacolon • Rectal prolapse
Biliary tract/liver disease	• Microgallbladder • Nonfunctioning gallbladder • Obstructed cystic duct • Cholelithiasis • Common bile duct stenosis • Common bile duct stones • Hepatosteatosis • Focal biliary fibrosis • Multilobular biliary cirrhosis ± portal hypertension ± liver failure
Dermatological	• Salt wasting • Hyponatremic dehydration

Some CF mutations are associated with minimal organ involvement or mono organ presentations, including sinusitis, pancreatitis, and congenital bilateral or unilateral absence of the vas deferens. Other mutations have been found through population research studies or neonatal screening and appear unassociated with any disease to date, but many in this category

have only had limited follow-up. They are sometimes referred to as having CFTR disease, but this title may prove inappropriate, with longer follow-up studies.

Shwachman–Diamond Syndrome

SDS is a multisystem autosomal recessive disease[2,3,31] associated with mutations of the SBDS (Shwachman, Bodian, Diamond Syndrome) gene with a pericentrometric location on 7q.[3] It has 5 exons and spans less than 9 Kb encoding for a protein of 250 amino acid residues. The function of this protein is currently unknown, but it is suspected to be involved with fundamental aspects of RNA maturation, metabolism, and/or ribosomal structure and function. The SBDS gene is the only one currently associated with SDS. In patients with SDS over 90% have at least one of the mutant SBDS alleles caused by gene conversion. The three most common gene conversions on exon 2 account for over 76% of the disease alleles and for over 62% of affected individuals for the two predominant disease causing mutations.[32]

Classical clinical features of SDS include pancreatic hypoplasia with PI from infancy, bone marrow dysfunction, particularly neutropenia, metaphyseal dysostosis, and short stature, as outlined in Table 55-4, and a normal sweat chloride test. The EPD is associated with severe lipomatosis replacing acinar tissue of the exocrine pancreas, as can be delineated by ultrasound, computed tomography, or magnetic resonance imaging studies, but, as opposed to CF, maintaining normal ductal function in terms of water and electrolyte secretion and normal islet function in terms of insulin secretion. It is also evident that pancreatic function may improve with age, with up to 50% of patients becoming PS in the first 5–10 years of life.[33] Morbidity is related to severe neutropenia with associated sepsis, thrombocytopenia, and red cell aplasia. Mortality in early childhood is associated with severe sepsis and in older children/young adults to acute myeloid leukemia which appears 15%–22% higher in SDS compared to the general population,[34] leading to the recommendation for regular 1–3 yearly bone marrow examinations for SDS patients. Nearly all SDS patients with proven SBDS mutations have bony metaphyseal dysplasia,[35] which likely contributes to the short stature and is a useful diagnostic aid if overtly present.

Pearson's Marrow Pancreas Syndrome

PMPS is a rare, multisystem mitochondrial DNA deletion syndrome

belonging to the group of mitochondrial cytopathies.[4] A common mutation is a 4.9 Kb deletion, but the deletion size can extend up to 14 Kb.[36] The size of the deletion does not correlate with clinical features or severity, particularly the development of the Kearns-Sayre neurodegenerative syndrome in those who survive postinfancy. The disease is characterized by a severe transfusion-dependent macrocytic anemia with bone marrow features of megaloblastosis and vacuolation of bone marrow cells, and the presence of ringed sideroblasts. The pancreas, in comparison with SDS, is fibrotic and small.

TABLE 55-4 Non-cystic Fibrosis Pancreatic Diseases

Shwachman–Diamond syndrome	• Pancreatic acinar cell hypoplasia with lipomatosis • Bone marrow dysfunction: – Neutropenia – Thrombocytopenia – Red cell hypoplasia – Myelodysplastic syndrome – Acute myeloid leukemia • Bone disease: – Metaphyseal dysplasia – Shortened splayed ribs – Short stature • Miscellaneous: – Developmental delay – Eczematous skin lesions – Hepatosteatosis – Renal tubular dysfunction
Pearson's Marrow Pancreas Syndrome	• Pancreatic fibrosis with pancreatic insufficiency • Severe macrocytic anemia (often transfusion dependent) • Vacuolated cells, megaloblastosis and ringed sideroblasts in bone marrow aspirates • Variable neutropenia and thrombocytopenia • Developmental delay • Kearns-Sayre disease in later life • Pigmenting retinopathy • Ophthalmoplegia
Johanson–Blizzard syndrome	• Pancreatic lipomatosis with pancreatic insufficiency • Aplasia or hypoplasia of alae nasi • Congenital sensorineural deafness • Hypothyroidism • Short stature + growth hormone deficiency

	• Imperforate anus • “Upsweep” frontal hair pattern • Scalp defect/cutis aplasia • Absence of permanent teeth • Congenital heart disease • Intellectual disability • Lacrimal duct anomalies
Pancreatic Agenesis	• Pancreatic insufficiency • Diabetes mellitus • Cerebellar agenesis • Polysplenia

Johanson–Blizzard syndrome

JBS is the rarest of the multisystem-inherited EPDs[5] and is an autosomal recessive disease caused by mutations of the ubiquitin protein ligase E3 component n-recognin-1 (UBR-1) gene located on chromosome 15 at position q13.[37] Ubiquitin is a universally expressed protein in all cells and plays a normal role of tagging other proteins that are mismatched, damaged, dysfunctional, or unneeded for degradation. Ubiquitin ligase commences this process by attaching ubiquitin to the lysine side chain of the tagged protein. This process is fundamental for the normal cellular processes: cell division, surface receptor function, signaling, apoptosis, quality control of proteins, and inflammatory cascades. Mutations of the UBR-1 gene lead to the progressive congenital damage due to a deranged inflammatory response, failure of normal apoptosis, and persistence of abnormal protein leading to the skeletal and other structural or functional abnormalities seen in JBS. Of the various missense, nonsense, and splice site mutations identified to date no specific genotype/phenotype have been found.

Similar to SDS, JBS patients have severe lipomatosis of their exocrine pancreas and PI from early infancy. Very few of these patients have undergone formal pancreatic stimulation tests. Prognosis is poor if the PI is not recognized. Diagnosis of the disorder is facilitated by the combination of features as per Table 55-4, including flaring of the alae nasi, deafness, imperforate anus, PI, and short stature.

Hereditary Pancreatitis (HP)

The autosomal dominant form of inherited pancreatitis is caused by mutations of the protease serine-1 (PRSS-1)[38] gene, which normally

produces cationic trypsinogen. The latter is inactive in the pancreas and is transported to the duodenum where it undergoes cleavage by enterokinase to form the active enzyme, trypsin. PRSS-1 is located at 7q34. Over 40 mutations have now been found to cause HP and the commonest, R122H, is a point mutation exchanging the amino acid arginine with histidine. It remains uncertain as to how these mutations cause premature intrapancreatic trypsinogen activation, but of recent interest is the role of chymotrypsin C (CTRC).[39] CTRC promotes degradation of wild-type trypsinogens and trypsin. However, trypsinogen mutants causing classic HP, in the presence of CTRC, are autoactivated at increased rates and produce greater active trypsin concentrations than the wild type trypsinogens, suggesting there is a CTRC dysregulation involved with trypsinogens mutations and the occurrence of HP. It is noted that the average PRSS-1 gene mutation frequency in over 1000 patients with idiopathic pancreatitis was only 1.9%, although it has been reported in up to 10% in smaller studies.[40] The major clinical manifestations include recurrent acute pancreatitis commencing in childhood, and complications thereof, including intrapancreatic stones, cysts and strictures, and the early occurrence of pancreatic adenocarcinoma. Endoscopic retrograde cholangiopancreatography techniques for removing duct stones, and dilating and stenting strictures can markedly improve the patient's quality of life, but surgery using Peustow procedures or similar operations may have to be undertaken. Debate continues about the need for total pancreatectomy to prevent the occurrence of pancreatic cancer after the age of 50.

Pancreatic Agenesis

This rare autosomal recessively inherited disorder has typically been found in neonates[6] and is associated with mutations in the PDX1 gene at 13q12, which encodes for the insulin-promoting factor-1 transcription factor.[41] A variant disorder, also inherited as an autosomal recessive disorder associated with cerebellar agenesis, is caused by missense mutations of the PTF-1a gene at 10p12.[42] Recently, 15/27 (56%) of patients with PA were reported as having heterozygous mutations of GATA6, a gene that produces a protein—the transcription factor known as GATA-binding factor 6—and is located on 18q11.[43] Clinically, PA presents in the neonatal period with diabetes mellitus and pancreatic insufficiency.

Congenital Enteropeptidase (Enterokinase) Deficiency

(CED)

CED is a rare autosomal recessive disorder. Enteropeptidase, a serine protease, is a duodenal brush border enzyme required for cleaving of the proenzyme pancreatic trypsinogen to form active trypsin. Enteropeptidase is in fact secreted as a proenzyme, proenteropeptidase, which requires cleavage by a recently discovered enzyme “duodenase” also expressed in the duodenum.[44]

The human gene for proenteropeptidase, PRSS-7, has been mapped to 21q21. Of the 13 or more families with recognized CED, at least two have undergone molecular analysis.[45] In one family, patients demonstrated nonsense mutations in exons 18 and 22 and the parents were heterozygous for one or other of these mutations. In the second family, the index patient had a nonsense mutation in exon 8 and a frameshift mutation in exon 23. Clinically, CED presents in early infancy with severe diarrhea, failure to thrive, and associated severe hypoalbuminemia and edema. Diagnosis is confirmed by obtaining duodenal juice from a pancreatic stimulation test and measuring trypsin before and after adding exogenous enterokinase.

Fat and protein maldigestion/malabsorption occurs in CED and the fat maldigestion has been attributed to the lack of conversion of procolipase to active colipase in the absence of trypsin activation. Patients require pancreatic enzyme replacement therapy (PERT) and this appears very efficacious in correcting the deficiency as many of the original patients diagnosed over 25 years ago are still alive today. However, considering the standard pancreatic enzyme powder does not contain enterokinase (a small bowel mucosal enzyme), it is likely that at least some of the trypsinogens has been activated during the manufacturing process from pork pancreas. Moreover, some adult patients who were diagnosed in early infancy and who still have persistently low enterokinase levels seem to be able to cease their enzyme replacement therapy, leading to the hypothesis that they are able to autoactivate their endogenous trypsinogen.

Although there were earlier papers during the 1960–1970s on congenital isolated trypsinogen deficiency, there have been no subsequent papers and no further molecular analysis.

Congenital Lipase/Colipase Deficiency

There are a limited number of reports on isolated lipase/colipase deficiencies reported in five children up until 1990. Although the genes for pancreatic lipase at 10q24 and colipase at 6p21 have been found, no further work on the above patients has been published to confirm the

presence of specific mutations of either gene to explain these deficiencies. They present with oily stools in early infancy and in the few cases observed fecal fat averaged 50% of oral fat intake. One case had a quantitative pancreatic stimulation test showing both lipase and colipase secretion values were less than 2% of average normal values, but had normal protease and amylase secretion.[46] Other cases have had absent lipase[47] or colipase secretion.[48] Patients thrive well on oral enzyme replacement therapy, but there are no recent data published attesting to their well-being as adults.

FAT AND PROTEIN MALDIGESTION AND MALABSORPTION IN EPD

Normal Fat Digestion

Over 95% of fat ingested by humans is in the chemical form of triglycerides and, except for coconut oil, 98%–100% are long-chain triglycerides (LCTs) with 14 or more carbon atoms per fatty acid ester side chains. Medium-chain triglycerides (MCTs) as, for example, in natural coconut oil, contain 6–12 carbon atoms per fatty acid side chain. Both LCT and MCT require digestion by pancreatic lipase before absorption occurs, but medium-chain fatty acid esters are water soluble and do not require micellar solubilization which is an essential part of the process in transferring insoluble long-chain fatty acids to the enterocyte. The process of fat digestion is complex given there are two major pancreatic lipases—lipase and phospholipase A_2 (PLA_2)—and the lipase cofactor, colipase. Although phospholipids comprise less than 2% of dietary fat (2 g in a diet of 100 g of triglyceride daily), at least 12–15 g are cosecreted with bile acids from the liver on a daily basis. The role of the enzymes and colipase in digesting triglycerides and their interaction with bile acids and phospholipids is shown in the figure 55-1a. In vivo, in the small intestine, the long-chain fatty acids are insoluble in water and can only pass through the unstirred water layer covering the enterocyte if solubilized by incorporation into mixed micelles comprised of bile acids and phospholipids. In Figure 55-1b, in an in vitro experiment with buffer and the SCT, with a simple micelle with a bile acid concentration above the critical micellar concentration, the bile acids prevent adsorption of the lipase to the lipid surface, thus effectively completely inhibiting lipase activity. As per Figure 55-1c, this inhibition can be relieved by adding the smaller and less charged molecule, colipase, which can interdigitate

between the bile acids and then with its specific affinity for lipase bring that molecule into apposition with the surface of the lipid droplet and allow lipolysis to occur.[49–51] Although this concept readily explains the role of colipase in relieving the inhibition of pancreatic lipase activity by bile acids, it does not account for what happens with a mixed micelle with both bile acids and phospholipids present. Figures 55-1d and 55-e depict that the mixed micelles containing bile acid and phosphatidylcholine (PC) actually prevent apposition of colipase with the lipid droplet, completely inhibiting lipolysis.[52] However, as shown in Figure 55-1f, following hydrolysis of the common phospholipid in bile, PC, by PLA_2 to lysoPC, which is water soluble and enters the aqueous phase of the medium, colipase can then gain access to the lipid droplet surface and then activate triglyceride hydrolysis by pancreatic lipase.

Fat Digestion and Absorption in EPDs

How do these concepts apply to EPDs? In congenital lipase/colipase deficiency near absent lipase and colipase secretion during pancreatic stimulation tests was associated with up to 50% fat malabsorption.[46] However, to date, there has not been a report of congenital pancreatic PLA_2 deficiency to confirm its role in triglyceride hydrolysis. In this regard, two novel enzyme replacement preparations, the recombinant breast milk bile salt stimulated lipase (BSSL) and the recombinant microbial lipase have both demonstrated limited efficacy in relieving steatorrhea in CF patients, noting breast-fed CF PI infants at diagnosis, prior to enzyme supplements, have similar fat excretions to bottle-fed infants[29] and those older patients receiving the microbial lipase[53] had an average fat excretion near 40%, which was very similar to the 39% fat excretion documented previously in CF PI patients when not receiving enzyme supplements.[54] Both the new preparations lack PLA_2 present in the conventional microspheric pork pancreas replacement therapy which on average reduces fecal fat to 12%–15% of fat intake. PLA_2 supplementation is essential for the action of pancreatic lipase in the presence of mixed micelles containing PC and one has to question whether the same principle applies to the above nonpancreatic lipases.

Classical pancreatic phenotypes of both CF and SDS include those who are PI with fat malabsorption (fecal fat >7% of oral fat intake) and those who are PS (fecal fat ≤7% of oral fat intake). These definitions have arisen out of a study[55] assessing lipase and colipase secretion rates

measured during quantitative marker perfusion based pancreatic stimulation tests and comparing them with fecal fat excretion. Not surprisingly, colipase secretion matched closely with fecal fat excretion as, in the presence of bile acids, lipase activity is solely dependent on the amount of colipase activity present. Patients with colipase activity in excess of 100 U/kg/h (or 1% of average normal values ≈10,000 U/kg/h) had normal fecal fats, ≤7% of daily fat intake, that is, these patients had sufficient endogenous colipase/lipase activity to maintain normal fat absorption. In contrast, those with colipase secretion less than 100 U/kg/h had insufficient colipase/lipase secretion resulting in fat malabsorption.

It is evident from these data PS patients have varying degrees of pancreatic dysfunction in terms of enzyme/coenzyme secretion from above 1% to 100% of average normal values, identifying the large reserve of exocrine pancreatic function in humans of all ages. Of further interest, among PI patients there are varying degrees of fat malabsorption from over 7% and up to 80% of daily fat intake. Although some of this variation could be attributed to residual pancreatic enzyme secretion, others have proposed that variable secretion of pregastric or lingual lipases could also contribute to this finding. Others have proposed that inadequate bile acid levels from bile acid malabsorption, bacterial contamination of the small intestine, and decreased enterocyte fatty acid uptake and transport are impaired. Although the latter has been attributed to a defect in fatty acid transport related to CFTR dysfunction, it is obviously not present in PS patients who maintain normal fat absorption.

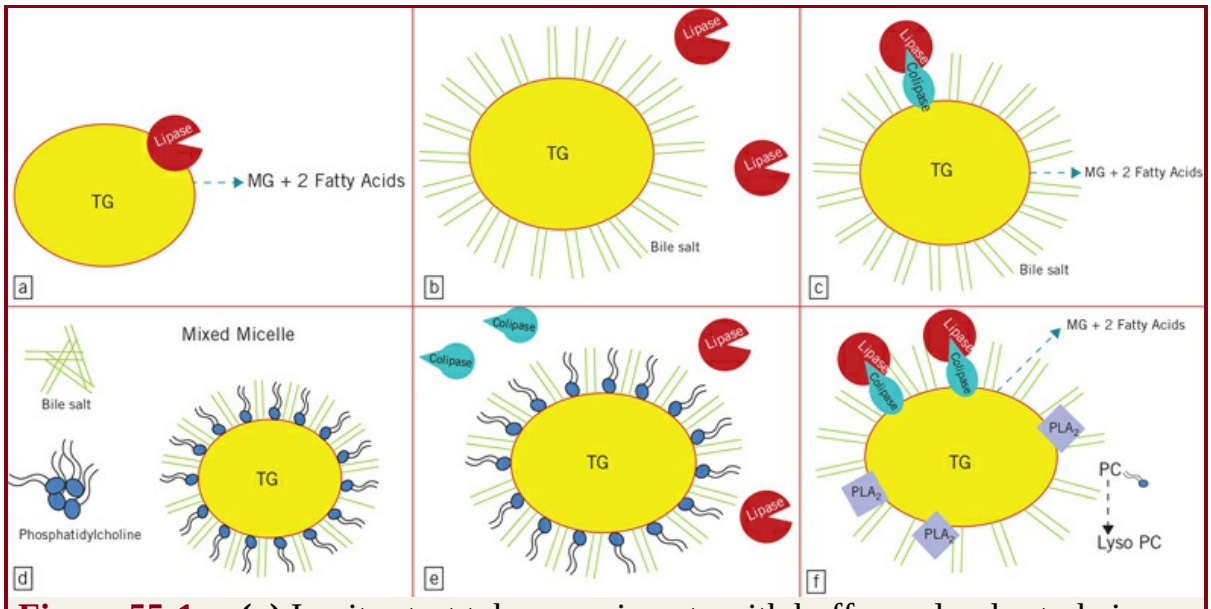

Figure 55-1 **(a)** In vitro test tube experiments with buffer and a short-chain triglyceride (SCT): pancreatic lipase comes into apposition with the lipid droplet and as hydrolysis of the triglyceride ensues, a monoglyceride and two fatty acids

are released into the medium. **(b)** In an in vitro experiment with buffer and the SCT, with a simple micelle with a bile acid concentration above the critical micellar concentration, the bile acids prevent adsorption of the lipase to the lipid surface, thus effectively completely inhibiting lipase activity. **(c)** This inhibition can be relieved by adding the smaller and less-charged molecule, colipase, which can interdigitate between the bile acids and then with its specific affinity for lipase bring that molecule into apposition with the surface of the lipid droplet and allow lipolysis to occur. **(d** and **e)** The mixed micelles containing bile acid and phosphatidylcholine (PC) actually prevent apposition of colipase with the lipid droplet, completely inhibiting lipolysis. **(f)** Following hydrolysis of PC by phospholipase A^2 (PLA^2) to lysoPC, which is water soluble and enters the aqueous phase of the medium, colipase can then gain access to the lipid droplet surface and then activate triglyceride hydrolysis by pancreatic lipase.

Normal Protein Digestion

Ingested protein consists of polypeptide chains composed of covalently bonded amino acid residues folded into quaternary structures with specific spatial arrangements and held together by noncovalent and disulfide bonds. Average recommended daily allowance (RDA) of protein vary according to age and weight from 13 g/d in toddlers 1–3 years of age up to 46–52 g/d in females and males of 14–18 year olds, to 46–56 g/d in adult females and males. In general, over 90% of the protein is absorbed through the small intestine and similar to fat, up to 5% of nitrogen is malabsorbed in normal human subjects.

Dietary protein is digested partially by pepsin in gastric juice, but mainly in the upper small intestine by pancreatic proteases, and enterocyte aminopeptidases, to amino acids and di- and tripeptides. Inactive pepsinogen is released from gastric chief cells and activated by hydrochloric acid, which allows the pepsinogen to unfold and undergo autocatalysis to form active pepsin which preferentially cleaves the aromatic amino acids, phenylalanine, tryptophan, and tyrosine. Pancreatic proteases in general are secreted as a mixture of proenzymes/zymogens, for example, trypsinogens, chymotrypsinogen, and procarboxypeptidase, avoiding activation in pancreatic tissue, which could lead to pancreatitis. Enteropeptidase, a brush border enzyme, is itself formed as a proenzyme and requires cleavage by duodenase to form the active enzyme.[44,45] The activated enterokinase, in turn, cleaves trypsinogens to trypsin which, in turn, cleaves chymotrypsinogen and procarboxypeptidase to the active chymotrypsin and carboxypeptidase. Chymotrypsin hydrolyzes protein to small di- and tripeptides and carboxypeptidase specifically hydrolyzes

amino acids from the carboxyl end of the peptide chain to produce free amino acids for absorption. The process is enhanced by trypsin autocatalysis which culminates in the production of the "proteolytic cascade." Residual di- and tri-peptides which have avoided luminal proteolysis are hydrolyzed to amino acid residues by brush border– and transmembrane–located aminopeptidases.

Protein Digestion and Absorption in EPD

Primary intestinal enterokinase deficiency has provided evidence for the important step of pancreatic proenzymes/zymogen activation necessary for the commencement of intestinal proteolysis by pancreatic proteases.[44,45] Nitrogen balance studies (as a surrogate for protein absorption) of patients with EPDs have virtually been confined to the disorder CF and, specifically, those patients with PI. Patients demonstrate nitrogen malabsorption of 5% to over 50% of ingested nitrogen, that is, a similar range to that of fat malabsorption,[56] but considering the complexities of nitrogen balances they are not as well utilized as fat balance studies in the studies of exocrine pancreatic insufficiency.

NUTRITION IN EXOCRINE PANCREATIC DISORDERS

Each of the EPDs, particularly CF and SDS, and the isolated pancreatic colipase/lipase and enterokinase deficiency (although not a pancreatic disorder, it effectively is, as its deficiency prevents intestinal activation of pancreatic proteases), have helped to elucidate the underlying pathophysiology of pancreatic maldigestion and subsequent malabsorption in human pancreatic diseases. The consequences of pancreatic insufficiency are common to the inherited disorders, in terms of maldigestion and malabsorption, growth, and fat-soluble vitamin deficiencies. These consequences have been best described in the CF population considering the rarity of the other disorders, and the remaining part of the chapter will focus on the nutritional aspects of CF, with reference to the other disorders where relevant.

Consequences of Maldigestion/Malabsorption

A classical feature of pancreatic insufficiency in children is the passing of bulky, malodorous stools which contain oil variably described as melted butter, cheese, or bacon fat. Stool microscopy readily demonstrates the

presence of oil droplets, confirming the clinical suspicion of an EPD. Beyond infancy, fat maldigestion and malabsorption have been well documented in 85%–90% of CF patients,[18] averaging near 40% and up to 80% of fat intake in 3–5 day fat balance studies.[54] Nitrogen losses are less impressive, varying up to 50% of nitrogen intake.[56] Similar fecal fat excretions have been evident in SDS patients and in patients with isolated lipase and colipase deficiency. Exceptions to these findings are seen in CF patients at the time of neonatal diagnosis as some 25%–40% have normal fat excretion.[29,30] A variable 20%–50% of these PS patients will develop PI in the first 10 years of life, likely related to the presence of two Class I–III mutations, as opposed to those who remain PS with at least one Class IV or V mutation.[29] In contrast, in SDS, while most are PI when diagnosed in the first year of life, up to 50% of these improve their exocrine function and develop normal fat excretion by at least 5 years of age.[33]

Prediagnosis and postdiagnosis if noncompliant to PERT, all PI patients are at risk of the complications outlined in Table 55-5. These include the obvious effects of poor weight gain with wasting and hypoproteinemia and edema akin to primary protein energy malnutrition or Kwashiorkor. Prolonged malnutrition, in turn, will impair linear growth as also seen in non-CF populations. Patients with PI are at ongoing risk of fat-soluble vitamin deficiencies prediagnosis and postdiagnosis if noncompliant to oral vitamin therapy and/or PERT. The classical clinical features of these deficiencies, as per Table 55-5,[57–66] are now rarely seen in infants diagnosed by neonatal screening. However, subclinical biochemical deficiencies are apparent and if untreated will eventually result in clinical deficiencies, for instance vitamin D deficient rickets, particularly in northern hemisphere winters.

Current treatment guidelines aim at keeping serum vitamin levels above the lower limit of normal, that is, vitamin A levels >0.7 μmol/L, 25-hydroxyvitamin D (25-OH-D) levels >50 nmol/L, vitamin E levels >7 μg/ml, and the maintenance of a normal international normalized ratio (INR) <1.4 as a surrogate marker for vitamin K deficiency. However, while intuitively a valid approach, these threshold levels have not been completely validated against functional effects of the deficiency.

A cross-sectional study of electroretinograms in CF PI patients showed that they remained normal in those with serum vitamin A levels above 0.6 μmol/L, indicating adequate function,[67] but whether those with persistent borderline levels suffer retinal degeneration in the long term is unknown. Subnormal levels of 25-OH-D of between 25 and 50 nmol/L are common

during Northern hemisphere winters with low sunlight exposure,[61] and rickets and osteomalacia have occurred. Recently we are seeing a similar phenomenon in the Southern hemisphere in spite of sunlight exposure throughout the year, but likely this relates to recent Public Health measures to reduce sun exposure to prevent skin cancer, which is prevalent in these populations. Clinical rickets/osteomalacia due to vitamin D deficiency are, in the main, associated with 25-OH-D levels <20 nmol/L, and those with vitamin D insufficiency without rickets are associated with 25-OH-D levels in the borderline range of 25–50 nmol/L. Maintenance of levels >50 nmol/L would appear appropriate. In regard to vitamin E levels, patients with abetalipoproteinemia or cholestasis develop peripheral neuropathy with persistently low or absent serum levels, but in CF populations a threshold of vitamin E, below which nerve conduction is impaired, has not been defined.[63,64] Vitamin K deficiency has traditionally been evaluated by measurement of prothrombin levels on INR, but they appear less sensitive than two other markers, PIVKA-II or osteocalcin, which are currently undergoing further evaluation.

TABLE 55-5 Consequences of Malabsorption

Gut
- Oily malodorous bowel movements
- Diarrhea
- Bile acid losses
- Risk of gallstones

Systemic
- Nutritional:
  - General:
    - Poor weight gain and subcutaneous fat and muscle wasting
    - Impaired linear growth with stunting
    - Hypoproteinemia with edema, ascites, hydrothorax
  - Fat-soluble vitamins:
    - Vitamin A deficiency:
      - → Raised intracranial pressure, with bulging fontanelle in infants
      - → Impaired dark adaptation with night blindness
      - → Xerophthalmia
      - → Bitot spots
    - Vitamin D deficiency:
      - → Rickets, osteomalacia
    - Vitamin E deficiencies:
      - → Loss of deep tendon reflexes with peripheral neuropathy
      - → Spinocerebellar tract degeneration

- → External ophthalmoplegia
- Vitamin K deficiency:
  - → Coagulopathy
- Essential fatty acid deficiency:
  - → Seborrheic dermatitis

In general, PS patients should not require routine fat-soluble vitamin supplementation. Considering vitamin A toxicity has occurred in PI patients with excessive use of vitamin A, theoretically this could be even more evident in PS patients who have normal absorption.[68] However, PS patients in northern winter climates could become vitamin D deficient, as occurs in normal absorbing non-CF normal populations. Ideally, all PS patients require annual monitoring of serum vitamin levels as, not only will this detect the occurrence of subclinical deficiency but also it has the potential to detect PS patients who become PI and develop subsequent fat-soluble vitamin deficiencies. Similarly, essential fatty acid deficiency, which occurs in PI patients, could be a marker for PS patients becoming PI. Of recent interest, an increased arachidonic acid to docosahexaenoic acid (DHA) ratio has been demonstrated in lung, pancreas, and intestine from a CF knockout mouse and supplementation with DHA has reversed the early pancreatic ductal dilatation.[15] Similar findings have occurred in human CF patients in circulating monocytes[69] and currently the outcome of a North American randomized controlled trial on the effect of DHA is awaited.

PI patients are at risk of vitamin B-12 malabsorption if noncompliant to PERT. The B-12 intrinsic factor complex is bound to R proteins in the stomach and prior to binding to the specific terminal ileal receptors, R proteins are cleaved from the complex by pancreatic proteases. Inadequate PERT theoretically could, therefore, be associated with poor uptake and subsequent cobalamine deficiency. Ileal resection associated with complex neonatal meconium ileus or other surgical complications, for example, intussusception, could also interfere with B-12 absorption mandating regular 3–6 monthly monitoring of serum B-12 levels.

Other Contributing Factors to Malnutrition and Growth Failure in CF

In addition to maldigestion/malabsorption, other factors, including inadequate nutritional intake and excessive energy expenditure, can contribute to the occurrence of malnutrition with concomitant wasting and stunting and CF-related bone disease (CFRBD), as summarized in Table

55-6.

Inadequate Intake

Up until 1980 poor growth was a recognized feature in CF clinics globally, with nearly 50% of patients in early adolescence being below the third percentile for height and weight.[70,71] These findings were attributed to the then undiscovered cause of the underlying disease process and the lack of efficacy of the nonmicrospheric PERT preparations used in that era. However, in 1980, Corey[72] published near normal height percentile distributions in both males and females from the Toronto, Canada, clinic and observed males also approached normal weight percentiles. Females over 8 years of age were more wasted although still only 16% were below the third percentile, as opposed to 42% of those from another similarly sized clinic.[73] The much improved average growth figures from the Toronto clinic suggested that neither the underlying disease nor the use of the less efficacious PERT were major factors to the globally observed growth failure in CF populations. Bell et al.[74] later published dietary intakes on patients from Toronto demonstrating that on a high-fat diet regimen they achieved an average energy intake of 113% of recommended dietary intake (RDI), well in excess of the average 80%–90% RDI reported from clinics utilizing low-fat diets.[73] "Low-fat diets" were used in virtually every clinic during the 1960s and 1970s to control steatorrhea in the absence of efficacious PERT preparations, but the Toronto clinic did not adhere to this policy. Instead, they advised a high-fat diet with LCT comprising 40%–50% of energy intake[74] on the basis that if one increased dietary fat intake both the fat absorbed and the fecal fat in absolute terms would increase concomitantly. In effect, the dietary fat intake increase was replacing fat malabsorbed. This difference in dietary policy was later shown to be the most important single factor of the era in improving nutritional status and growth, but also was a major factor impacting on survival. The latter was best demonstrated by a retrospective epidemiological study comparing growth and survival between the Toronto clinic and the low-fat diet clinic in Boston.[75] Growth was superior in the Toronto clinic, and although average FEV_1% at age 20 was similar, median survival was significantly better with a near 10-year survival advantage to the Toronto clinic (≈30 years vs. 20 years). Nutrition and maintenance of normal diet has now become a major focus for CF clinics given the increasing amount of supportive data and the recognized median survival improvement to the mid-40s in some North American and

Canadian clinics.[21]

TABLE 55-6 Contributing Factors to Malnutrition in Cystic Fibrosis

Inadequate Intake:

- Inappropriate therapy with low-fat diets
- Anorexia:
  - Lung infections
  - Lung disease
  - Antibiotics
  - Malnutrition
  - Esophagitis
  - Gut/biliary tract disease:
    - Celiac disease
    - Persistent DIOS
    - Giardia
    - Crohn's disease
    - Biliary tract stones or strictures
    - Multilobular biliary cirrhosis

Malabsorption (see Table 55-5)

Excessive Energy Expenditure:

- Lung disease
- Lung infections
- Gene defect
- Female gender

DIOS, distal intestinal obstruction syndrome.

Currently, most clinics globally adhere to relatively high-fat diets and the microspheric PERT preparations available from the early 1980s have helped in this process. However, 20% or more patients have difficulties in maintaining their growth and dietary intervention is required if intakes are suboptimal and/or if patients fail to respond to changes in PERT including improvement of compliance and adjuvant therapy to their PERT regimen. Some patients are clearly anorexic, related to their disease complications including lung disease, antibiotics used, esophagitis, gut (celiac disease) and biliary disease (gallstones, bile duct strictures), psychosocial factors, micronutrient deficiencies, and, in temperate climates, salt deficiency. Although investigation and treatment of these complications, including intensification of lung and psychosocial therapy, may improve appetite and growth in some patients, others may continue to deteriorate and more invasive feeding techniques may be required to correct the nutritional

deficits.

Increased Energy Expenditure in CF

This phenomenon has been considered since at least the early 1980s to explain the lack of weight gain in some CF patients regardless of their excellent intake and energy consumption often in excess of 120% of RDI, and appropriate control of fecal fat excretion to less than 20% of dietary fat intake.[76] Similar findings occurred in undernourished CF patients undergoing nutritional rehabilitation, demonstrating energy requirements could be in excess of 150% RDI to achieve weight gain.[77,78] These studies further postulated as most subjects had moderate to severe lung disease the latter was the major contributing factor to the increased resting energy expenditure (REE).

However, in vitro experiments assessing tissue oxygen consumption had in fact demonstrated this occurrence in both cultured CF fibroblasts with a doubling of oxygen consumption,[79] and 6 years later, to a lesser degree, in CF nasal epithelium.[80] These findings indicated that at least a component of the increased energy expenditure was related to the intrinsic disease and independent of lung disease.

Consistent with this hypothesis, Shepherd et al.[81] demonstrated total energy expenditure (TEE) measured by doubly labeled water in CF infants with assumed minimal lung disease averaged 123% of control values suggesting if lung disease was minimal the major factor contributing was the underlying disease. Questions remained regarding the undefined minimal lung disease and the accuracy of the doubly labeled water technique measuring TEE in these infants. Using another approach, O'Rawe et al.[82] measured REE in three genotypic groups: ΔF508 homozygotes, ΔF508 compound heterozygotes, and non-ΔF508 compound heterozygotes and demonstrated an average REE of 121%, 109%, and 104% predicted, respectively, further supporting the contention that REE was related to the severity of genotypic disease. However, average FEV_1% was 56% predictive in the ΔF508/ΔF508 group, 63% in ΔF508/other groups, and near normal in non-ΔF508 groups, demonstrating an effect of lung disease in these three genotypic groups. Fried et al.[83] later demonstrated, retrospectively, a curvilinear effect of lung disease exponentially increasing REE as FEV_1% dropped below 75% predicted, confirming a major effect of deteriorating lung disease escalating energy expenditure.

Having established the deleterious effect of deteriorating lung disease

on energy expenditure, the question still remained as to whether the underlying gene defect contributed to increasing EE, as suggested by the in vitro work above, and whether there was any gender effect given the female survival disadvantage in this disorder. In a large study[84] of 104 CF patients with near normal lung function (average FEV_1% predicted in males 87% and females 83%), PI patients (Class I–III mutations) had an average REE of 110% of that seen in the PS patients (mild Class IV and V mutations) adjusting for lean body mass, thus identifying a very significant effect of those with the severe PI mutations, in spite of the similarity of lung dysfunction in these patients and linking the effect to the intrinsic gene defect. Moreover, in comparison with age-matched controls CF females had very significantly elevated average REE adjusted for lean mass of 111% of controls, whereas CF males had only 104% of their controls. These differences persisted in a subsequent longitudinal study[85] identifying a female disadvantage, which others suggested may contribute to the female survival disadvantage.[86] Overall, although the increase in EE in CF females remains enigmatic, in combination with the EE related to the intrinsic disease and deterioration of lung function into the moderate and severe ranges, one could expect to observe energy requirements escalating over 120% of RDA in many of these patients.

CF-Related Bone Disease (CFRBD)

With improved survival in CF, an increasingly large number of publications[87–92] have reported high clinical fracture rates and decreased bone mineral density (BMD) in the patient population. Fracture rates were twice as high in CF females (16–34 years old) compared with CF males (25–45 years old) with vertebral and rib fractures 100× and 10×, respectively, more common than in control populations. High vertebral fracture rates of 41% historically and 19% radiologically in one adult study, and overall in 34% of adults in another study suggest this is an ever-increasing problem with advancing age and prolonged survival. BMD studies emphasize the extent of the problem, noting impaired BMD [below −1 standard deviation (SD)] in up to 85% of adult patients, and 20%–34% having scores below −2 SD. High fracture rates and BMD scores below −1 SD are observed in patients with low FEV_1% (30%) and BMD scores averaging −2 SD, and alarmingly high fractures rates of up to 42% have been reported in patients post-lung transplantation.[89]

Bone histomorphometric studies demonstrate severe osteopenia and decreased intratrabecular and cortical bone formation with reduced

osteoblastic and increased osteoclastic activity, but surprisingly minimal, if any, evidence for osteomalacia.[93] Clinical BMD studies indicate that the peak BMD accrual that occurs in normal adolescence is impaired in CF populations. The resultant osteopenia and osteoporosis is seemingly independent of country of origin and is in keeping with the concept above that CFRBD is not usually related to vitamin D deficiency and osteomalacia. Bone turnover studies demonstrate, similar to the CFTR-null mouse,[94] bone resorption is in excess of bone formation, as evident by high urinary hydroproline levels and the more recent isotopic calcium kinetic studies showing decreased calcium deposition.

Irrespective of the histological and turnover studies, vitamin D insufficiency (25-OH-D levels of >25–50 nmol/L) is common and deficiency occurs in 5%–10%. CF adults are often in this deficient range and in end stage lung disease may affect up to 33% of patients. The deficiency is likely due to malabsorption, as noted in studies where CF patients absorbed 50% less of vitamin D than controls and had an absence of rise of their serum 25-OH-D levels. Of considerable interest, 1,25-dihydroxyvitamin D levels are usually similar to controls and as it is the most active vitamin D metabolite this may explain the minimal effects of vitamin D deficiency on bone histology and turnover.

Other contributing factors to the development of CFRBD include vitamin K deficiency, CF-related diabetes, physical inactivity and lack of weight-bearing exercise, delayed puberty with gonadal failure, chronic infection with release of inflammatory cytokines [tumor necrosis factor-α, interleukin (IL)-1, IL-6], parathormone, vascular growth factors, and the use of glucocorticoids.

Considering the frequency and severity of CFRBD particularly in the adult population, it is essential that CF children achieve their peak BMD accrual in their adolescent years.[93] In this regard, a consensus committee has recommended a baseline BMD assessment [dual-energy X-ray absorptiometry (DXA)] for all patients ≥18 years of age. In those 8 years and older, a BMD should be performed if ideal weight is <90%, FEV_1% predicted <50% or glucocorticoids ≥5 mg/kg/d for ≥90 d/yr, delayed puberty, and/or fractures. If BMD is ≥−1.0 T or Z score, DXA should be repeated 5 yearly; if T or Z score is −1.0 to −2.0, 2–4 yearly; and ≤ −2.0, yearly, as listed in Table 55-7.

NUTRITIONAL ASSESSMENT

Most CF clinics worldwide would undertake a baseline nutritional assessment at diagnosis with at least an annual review of the same parameters. As most patients are reviewed 3–6 monthly in-between annual visits, more limited evaluation with anthropometry and physical examination can be assessed and, if anomalies occur, further investigations at that time may be required. Baseline and annual reviews require height, weight, ideal weight for height and BMI, and head circumference measurements, with percentiles or Z scores and examination for micronutrient deficiencies. Blood work should include hemoglobin, coagulation profile, serum albumin, liver function tests, U&E (urea and electrolytes), serum fat-soluble vitamins and 25-OH-D levels, and serum essential fatty acids. Iron and trace metals, zinc and selenium levels may be required depending on clinical findings or geographic location and serum vitamin B-12 if patients are noncompliant to PERT. Fasting blood glucose is recommended annually after 5 years of age or sooner if diabetic symptoms occur (polyuria, polydipsia). After neonatal screening diagnosis, a formal three-day fecal fat study is essential to determine if the infant is PI or PS as neither fecal elastase (FE-1) nor the mixed triglyceride breath test (MTBT) have been fully evaluated in this population. A three-day fecal fat result in full-term babies of ≥10% of fat intake is indicative of fat malabsorption in bottle-fed infants and ≥2 g/d in breast-fed babies.[30] In nonscreened populations with children presenting for diagnosis at over 1 year of age, either FE-1 or MTBT can be used reliably to evaluate the pancreatic phenotype (PI or PS). The latter tests can also be used in later childhood to determine if a PS patient has become PI because of symptoms suggesting PI, for example, weight loss, oily stools, night blindness, absence of deep tendon reflexes, rickets and coagulation problems, or low-serum fat-soluble vitamin levels. If fresh symptoms of malabsorption occur in spite of compliance to an adequate dose of PERT, a formal fecal fat may be required to assess the failure of the medication. Prior to doing so it is worth considering intercurrent illness, for example, giardiasis or cryptosporidiosis and to perform celiac serology to exclude celiac disease. Annual food diaries to assess macro- and micronutrient intakes are undertaken at many clinics, particularly in patients with evidence of growth or nutritional deficits. However, in patients maintaining normal growth who are asymptomatic with normal blood profiles, the use of food diaries is questionable.

TABLE 55-7 Guidelines for the Management of CF-

Related Bone Disease
Regular/Routine Therapy • Maintain serum 25-OH vitamin D levels >50 ng/mL • Vitamin K supplements 0.3–0.5 mg/d • Calcium intake up to 1500 mg/d • Weight-bearing exercise • Intensification of treatment of lung infections • Cessation of oral corticosteroids • Treat diabetes • Endocrine referral for the management of delayed puberty
For T or Z scores for bone mineral density of −1.0 to −2.0—oral bisphosphonates. For T or Z scores for bone mineral density below −2.0—oral bisphosphonates, and if not tolerated, intravenous bisphosphonates.

In the absence of symptoms of malabsorption, growth failure can signal a number of significant problems, particularly exacerbation of pulmonary disease. However, if adequate respiratory therapy is given and the growth problems continue one has to consider poor intake related to esophagitis, liver, and biliary tract disease, and celiac disease, all of which require further investigation. Moreover, if the growth failure continues despite negative investigations, they may have excessive energy expenditure as seen in pubertal PI females colonized with *Pseudomonas* either with or without significant lung disease. Such patients, if unable to increase their nutrient intake orally, should then be considered for enteral tube feeding.

Nutritional Management

Nutrient requirements for EPD patients with PI are summarized in Table 55-8, including a salt supplement regimen for CF patients. EPD patients with PS should grow normally on an average normal diet without macro- or micronutrient supplements with the exception that CF patients still require salt supplements. In terms of macronutrients, average protein intake in CF PI patients is well in excess of requirements when consuming a liberal relatively high-fat diet, where LCT constitutes over 40% of the energy intake. However, energy requirements vary considerably depending on residual fat malabsorption, excessive energy expenditure, and the degree of physical activity undertaken. Maintenance of normal height and weight percentiles with patients tracking on the best previously achieved percentiles is the appropriate evidence of an adequate energy intake. Deviation below the achieved percentile is indicative of a negative energy balance related to decreased appetite, increased malabsorption or excessive

utilization, or some combination of these factors, and requires appropriate investigation.

Micronutrient balance is best monitored as above measuring serum levels of fat-soluble vitamins and trace metals, and maintenance of these levels within a range of normal defined by a clinic's local laboratory. Subnormal levels may be related to noncompliance and if not, an increase in vitamin dose would be appropriate, but with the caution that vitamin A toxicity has occurred in CF PI individuals.

TABLE 55-8 Nutrient Requirements in PI Including CF

Nutrient	Requirement	
Protein	>120% of RDI	
Energy	Variable, depending on disease status, but in PI patient should average near 120% RDI, with 40% as LCT and 3%–5% as EFA	
Vitamins:		
A	5,000 IU/d[a]	1–3 years of age
	10,000 IU/d[a]	>3 years of age
D	400–800 IU/d[b]	
E	200–400 IU/d[a]	
K	5 mg twice weekly[a]	
Salt intake[c]		
Age:		
0–6 months	0.5 g/d	
6–12 months	1 g/d	
1–5 years	2 g/d	
>5 years	3–5 g/d	

CF, cystic fibrosis; EFA, essential fatty acid; LCT, long-chain triglyceride; PI, pancreatic insufficiency; RDI, recommended dietary intake.
Can use vitamins A, D, E, and K (Scandipharm) or vitamins A, B, D, E, and K (Technipro): 4–10 years, one cap daily; >10 years, two caps daily; 0–1 year, 1 mL daily; 1–3 years, 2 mL daily; or Micelle A&E, 1–2 mL daily, or Aquasol E (Rover Pharmaceutical, Fort Washington, PA), 1 mL daily.
[a]If serum levels and coagulation profile are normal, patients may not need supplement.
[b]Not required if exposed to sunlight throughout the year.
[c]Double salt dose in hot weather or during strenuous exercise.

CF patients living in warm to hot climates in subtropical/tropical zones are at constant risk of salt depletion. The average sweat chloride in CF is

in the region of 100 mmol/L and is the equivalent concentration of a solution of 2/3 N saline or 6 g/L. During prolonged exercise on a hot day, an older child could easily lose a liter or more of sweat and replacement electrolyte solution or salt tablets are required during the exercise. The proportionally large body surface area of small CF infants leads to a more rapid salt depletion in hot enclosed areas, and they may present in shock with a hyponatremic, hypokalemic, hypochloridemic metabolic alkalosis requiring emergency resuscitation with normal saline boluses 10–20 mL/kg intravenously or intraosseously if intravenous cannulation is not possible.

Malabsorption is currently managed with microspheric PERT. Many different regimes have been developed based on dosage per kilogram of body weight per day or dosage per gram of fat per meal. In the 1980s when microspheric preparations were first used, a number of studies were conducted in older children and adolescents (in general, over 30 kg in weight) using a standard capsule containing 5000 IU of lipase. In each study, 3-day fecal fat balance studies on and off PERT preparations were performed, but with each new study a higher number of capsules and therefore a higher dose of lipase were used.[76,95,96] Studies using 25–30 capsules/d showed average fecal fat as a percent of fat intake had decreased from near 40% off PERT to 12%–15% on PERT, suggesting there was a plateau effect on fat excretion when the dose averaged between 20 and 30 capsules/d. Using a dose of one capsule of 5000 U of lipase per kilogram per day to a maximum of 30 per day ensured normal growth of infants associated with a newborn screening program,[30] and in older children near 40% had normal fat absorption (<10% of fat intake) in fat balance studies.[76] However, a variable number of patients (<20%) maintained fat excretions in excess of 20% of fat intake. Others had also observed this phenomenon and suggested it was related to poor pancreatic HCO_3^- secretion and subsequent failure to elevate the duodenal pH above 6,[96] which was required for the microsphere dissolution. Initial studies using H_2 receptor antagonists to suppress gastric acid secretion in fact demonstrated marked improvement in fat excretion in these patients[96] and have led to the use of proton pump inhibitors in patients with excessive steatorrhea in spite of compliance to PERT.

During the late 1980s and early 1990s, manufacturers of PERT increased the lipase dosage per capsule so that a variety of capsules with lipase levels ranging from 5,000 IU and up to 25,000 IU became available, on the basis that the lesser number of capsules required would improve

compliance. However, many units worldwide permitted patients to self-modulate their doses and they ended up taking as many or more capsules per day of the high-dose preparations, giving them a lipase dose of 50,000 U/kg/d, that is, up to 10 times higher than their previous dose. Contemporaneously, the first descriptions of FC appeared suggesting a link between the excessive use of high-dose lipase capsules and the occurrence of FC.[97] Two subsequent epidemiological studies[98,99] confirmed this association leading to the recommendation that the lipase dose should not exceed more than 10,000 U/kg/d. Subsequently, FC has been virtually nonexistent.

In order to improve fat absorption in patients on conventional microspheric PERT, other investigators have trialed a recombinant breast milk lipase and a recombinant microbial lipase. Breast milk lipase is a BSSL and based on in vitro work has been shown to digest LCT similar to pancreatic lipase. However, at diagnosis in a newborn screening program, breast-fed PI CF infants pre-PERT have virtually identical ranges of fat excretion as those PI CF infants who were bottle fed pre-PERT indicating the BSSL had minimal, if any, effect.[29] Similarly, in older children, the microbial lipase had a minimal effect when studying fecal fats on and off the preparation.[53] As per the Figure, the pancreatic lipase/colipase complex can only gain access to the lipid droplet incorporated into the complex bile salt/phospholipid micelles if the phospholipid has been hydrolyzed by pancreatic PLA_2. The capsules trialed for either the recombinant BSSL or the microbial lipase did not have PLA_2 and one is left to assume the unhydrolyzed phospholipids which have remained in the micelle have prevented access of the lipase/colipase complex to the lipid droplet. It would be worth reevaluating the combined effect of these two new lipases in combination with a minimal dose of conventional microspheric PERT, which contains PLA_2.

Infant Nutrition

Prior to neonatal screening programs for early diagnosis of CF, CF infants often presented clinically with a history of fatty diarrhea and associated hypoproteinaemia, edema, ascites, and/or hydrothorax, with evidence of fat-soluble vitamin deficiencies. The hypoproteinemia could be attributed to the lack of proteolytic enzymes, but it was also more common in breast-fed CF infants, related to the lower protein content of human milk. Moreover, after diagnosis, the nonmicrospheric enzyme preparations used in the 1960s and 1970s were problematic as they could not be used in an

encapsulated form for infants. Mixing with milk or fruit gels and sauces provided a vehicle for ingestion, but when given orally infants often experienced mouth ulceration because of the premature activation of the enzymes by the more alkaline salivary secretions.

To overcome these problems in the early 1970s, the newly marketed hydrolyzed protein and MCT-containing semielemental formulae were trialed for use in CF infants. Fat balance studies showed near normal or normal fecal fat excretion, and the hydrolyzed protein overcame the problem of lack of pancreatic proteolytic enzymes.[100] However, long-term studies demonstrated poor growth of these infants so treated.[101] In addition, a further study[102] indicated that the Van de Kamer method for measuring the fecal fat in the original study was incorrect as it only measured LCT and not MCT. Thus, the fecal fat was seriously underestimated and no doubt the ongoing malabsorption contributed to the poor growth of this cohort.

An advantage of neonatal screening for diagnosis of CF has been the early recognition of infants with PI and commencement of PERT. This has enabled reevaluation of breast-feeding of CF infants[103] and demonstrated that exclusive breast-feeding, for at least 4 months and up to 12 months, is associated with average normal height and weight percentiles at 12 and 24 months, without the occurrence of hypoalbuminemia. These infants still require fat-soluble vitamin supplementation. Non-breast-fed PI infants also grew normally on regular cow's milk formulae with appropriate PERT supplements. These studies clearly indicate that specialized semielemental formulae as used in some clinics[101,104] are unnecessary for normal growth in CF infants with the exception of those with postsurgical short gut syndrome which these days is a rare occurrence.

Enteral Tube Feeding

Multiple studies[105–108] have been published on the efficacy of nocturnal gastrostomy feeding regimens for nutritional rehabilitation and restoration of normal growth in malnourished CF patients. Definitions for considering such therapy have varied, but center around the premise that if a patient has fallen below the third percentile for weight and/or height, and more recently below the third percentile for BMI, and the patient does not respond to oral supplements over a 3–6 months' duration, then tube feeding is an optional therapy. However, tube feeding is very demanding and may prove to be overburdening for families considering the multitude of other patient requirements. Some cope well, embracing the therapy and

ensuring its success. Those who express reluctance to have enteral feeding, who have psychosocial problems, and/or not coping with regular therapy are very unlikely to achieve nutritional rehabilitation. Thus, before embarking on this line of treatment, families require a thorough psychosocial evaluation and/or education program, including discussions with patients who have successful gastrostomies to ensure this type of therapy is appropriate for individual patients and their families.[109] Motivation and compliance are particularly important factors and it is imperative that teams guiding such programs bear this in mind both before commencing the therapy and throughout its duration, which may extend for many months or even years. Nutritional rehabilitation with enteral feeding prelung transplant intuitively is appropriate and in some units it is a prerequisite to lung transplant. However, such recommendations have yet to be completely evaluated.

CONCLUSION

The EPDs, except for isolated pancreatic enzyme deficiencies and enteropeptidase deficiency, are multisystem disorders and require a multidisciplinary team to achieve optimal care. These teams should include medical personnel with specific expertise in diagnosing and managing exocrine pancreatic disease, and expert nutritional support teams for managing the nutritional problems associated with pancreatic insufficiency. Optimal dietary management, ensuring adequate macro- and micronutrient intake and PERT control of malabsorption provides the best possible chance of achieving normal growth and ensuring normal bone development with adolescent accrual of peak BMD. Likewise, regular monitoring is necessary to detect deviations, particularly decline in growth or bone health, to ensure intensification of therapy and prevent further decline, and to restore growth and bone parameters to normal.

Acute and Chronic Liver Disease

56

Deirdre A. Kelly, MD, FRCP, FRCPI, FRCPCH, Susan Protheroe, MD, MRCP, FRCPCH, and Sara Clarke, BSc (Hons)

The liver has a central role in energy metabolism, nutritional homeostasis, and absorption of nutrients. Severe liver disease, whether acute or chronic, leads to multiorgan failure, which can have significant effects on growth and development in the long term. The pathophysiology of malnutrition in liver disease is complex and multifactorial and has extensive implications (Table 56-1). It is most severe in infants with chronic cholestatic liver disease, who are particularly vulnerable to the effects of malnutrition because of their high energy and growth requirements.[1] Insufficient dietary intake is often a crucial factor that can be rectified. This chapter reviews the pathophysiology of malnutrition in pediatric liver disease and current treatment strategies, including liver transplantation.

PATHOPHYSIOLOGY OF MALNUTRITION IN LIVER DISEASE

Prevalence of Malnutrition

Malnutrition is common in children with chronic liver disease. Estimates vary from 50% to 80% in studies from North America and Europe.[1–4] In general, children who present with acute liver disease such as viral hepatitis or fulminant hepatitis are not malnourished at presentation but

can become so as a result of their illness.[5]

TABLE 56-1 Pathophysiology of Malnutrition in Liver Disease

Reduced calorie intake
Anorexia
Fat malabsorption
Use of bile salt resins
Portal hypertension
Unpalatable feeds
Inappropriate substrate use
Abnormal nitrogen metabolism
Reduction in glycogen stores
Negative protein balance
Increased metabolic needs
Energy expenditure
Calorie requirements
Hormonal dysregulation GH/IGF-I
Insulin resistance

Protein energy malnutrition (PEM) used to be inevitable in chronic liver disease, particularly in the developing infant. Severe malnutrition (weight and/or height less than 2 standard deviations below the mean) with loss of fat stores and muscle wasting used to affect 60% of infants with liver disease[1]; but with modern management with early referral, diagnosis, and intensive nutrition, less children in the developed world develop this problem today. Both morbidity and mortality post liver transplantation are related to the degree of pretransplant malnutrition, and thus nutritional status is an important risk factor for survival.[1]

Reduced Energy Intake

Anorexia is a common symptom in children with either acute or chronic liver disease. Due to ill health or anorexia, children may take less than the recommended requirements or less than is appropriate for their increased energy requirements due to excess energy expenditure.[6] The consequent reduction in enteral intake may lead to considerable loss of body stores or lean body mass, which alters body composition as determined by anthropometry.[7]

In children with chronic liver disease, the complications of portal hypertension, such as ascites and hepatosplenomegaly, can lead to malabsorption of nutrients. The treatment of ascites, which includes fluid restriction, prescription of unpalatable feeds, or both, can exacerbate

anorexia and reduce energy intake further.[2]

Carbohydrate Metabolism

Under normal circumstances, the liver receives portal vein blood rich in absorbed glucose, which can be stored in the liver as glycogen or circulated to extrahepatic tissues, especially muscle, where lactate, pyruvate, and alanine are generated by glycolysis.[8,9] In children with liver disease, this substrate supply and use can be abnormal. The loss of glycogen stores in chronic liver disease leads to fasting hypoglycemia and an inability to meet energy demands. In addition, any significant hepatocyte loss, especially in acute liver failure,[10] has an immediate effect on glucose metabolism, leading to hypoglycemia.

In cirrhotic adults, the pancreas secretes increased amounts of insulin, which is not metabolized, either because of portosystemic shunting around the liver or because of reduced degradation owing to hepatic dysfunction[11] or reduced glucose uptake by hepatocytes.[12] Although there is increased circulation of insulin, glucose uptake in the peripheral tissues, especially muscles, is reduced as a result of insulin resistance. Adult studies suggest that this could be attributable to impaired glycogen synthesis in the muscle, because of either abnormal insulin receptor numbers or affinity.[13,14] These data have not been confirmed in children; but it is possible that similar mechanisms occur, although a few children (apart from those with cystic fibrosis) develop overt diabetes mellitus unlike adults.[13]

Protein Metabolism

Amino acids are absorbed by the intestine directly into the portal vein and transferred to the liver, where they are synthesized into protein or used for energy. The liver is responsible for approximately 10% of plasma protein synthesis; thus, amino acids are constantly recycled.[9,15] Nonessential amino acids are oxidized in both liver and muscle. The seven essential aromatic amino acids (AAAs) (arginine, histidine, lysine, methionine, phenylalanine, tryptophan, and threonine) are metabolized in the liver, whereas the three essential branched-chain amino acids (BCAAs) (leucine, isoleucine, and valine) are metabolized predominantly in muscle and pass unaltered through the liver to the periphery, where their uptake is regulated by insulin.[16] The liver detoxifies nitrogenous wastes via the urea cycle, leading to the production of ammonia—hence the rise of plasma ammonia in both acute and chronic liver failure.[17]

Reduced hepatic and muscle glycogen stores lead to early recruitment of fat and increased dependence on amino acids as an alternative fuel.[18] Abnormal protein use by the liver leads to a rise in AAAs and a reduction in BCAAs, which are metabolized in muscle in both children and adults.[19–21] An abnormal ratio of BCAAs to AAAs correlates with histologic damage and encephalopathy in adults[22] and children.[20,23]

Studies in adults demonstrating abnormalities in BCAA metabolism using studies of BCAA fluxes and protein turnover have given conflicting results. It is possible that the hyperinsulinemia detected in cirrhosis could cause decreased BCAA levels by increasing BCAA uptake in muscle or adipose tissue. Alternatively, it is possible that there is an increase in liver transamination of BCAAs in addition to abnormal protein turnover.[24] Three adult studies demonstrated that protein synthesis can be increased or decreased depending on clinical condition and that muscle wasting is attributable to a relative increase in protein breakdown.[25–27] Those patients who had more efficient protein retention were less malnourished.

A study of protein metabolism in infants with liver disease, which used a whole-body leucine turnover model, demonstrated that muscle protein degradation and protein oxidation were increased, possibly as a result of a reduction in carbohydrate metabolism and the use of protein as an energy supply.[27] In contrast to normal children, muscle protein degradation continued in these children even when they were fed, suggesting that this could be a factor in the muscle loss common in infants with chronic liver disease. A study in cholestatic children also documented increased leucine oxidation in the postabsorptive state but not in the fed state, but these children had less severe liver disease than in the aforementioned study.[23]

In addition to protein synthesis and degradation, the liver is the site of synthesis of all of the coagulation factors except factor VIII, von Willebrand's factor, which is synthesized by vascular endothelial cells.[28–30] Thus, coagulopathy is an early sign of significant acute or chronic liver failure.

In chronic liver disease, these metabolic changes result in muscle wasting, hyperammonemia, hypoalbuminemia, hypoglycemia, hypolipidemia, and reduced circulating triglyceride levels secondary to increased fat oxidation. Hypoalbuminemia is associated with a reduction in plasma oncotic pressure, exacerbating the development of ascites and peripheral edema. In acute liver failure, the main effects of deranged protein metabolism are hyperammonemia and abnormal coagulation.[30]

Fat Metabolism

Most dietary fat is in the form of long-chain triglycerides (LCTs), which are a high-energy source.[31] The first step in fat digestion is emulsification in the stomach; it is followed by hydrolysis of triglycerides by pancreatic lipase in the intestinal lumen and then micellar solubilization of di- and monoglycerides by bile acids, which are then transported into enterocytes. Once they are in the enterocytes, fatty acids are reesterified and chylomicrons are formed and removed via the lymphatics through the portal system to the liver and other tissues.[31]

In contrast, medium-chain triglycerides (MCTs) do not depend on micellar solubilization for absorption and can be transferred directly from the enterocytes to the portal circulation without reesterification.[31,32] In the liver, free fatty acids are metabolized into triglycerides or oxidized for energy. The very-low-density lipoproteins and high-density lipoproteins are synthesized in the liver, as is cholesterol, which is the precursor for many hormones, vitamins, and bile acids.

In all forms of chronic liver disease, there is reduction in the synthesis and secretion of bile salts, although this is more severe in cholestatic diseases such as biliary atresia and in children with progressive familial cholestasis who have a bile salt transport defect. Up to 50% of LCTs, fat-soluble vitamins, and essential polyunsaturated fatty acids (PUFAs) might not be absorbed because of reduced biliary secretion and reduction in intraluminal bile concentration.[33–35] In contrast, 95% of water-soluble lipids, such as MCTs, which do not depend on bile solubility, are absorbed even in cholestatic infants[36] and form the basis for nutritional replacement.[37]

Fat malabsorption can also be affected by portal hypertension, which leads to congested gastric and intestinal mucosa, and by small bowel overgrowth in the Roux-en-Y blind loop created by a Kasai portoenterostomy. In addition, therapies such as cholestyramine to reduce pruritus can exacerbate steatorrhea because it binds bile salts, decreasing micellar solubilization.

Pancreatic function is usually normal except in children with Alagille syndrome, in whom pancreatic lipase can be reduced.[36,38,39]

Long-Chain Polyunsaturated Fatty Acids

Long-chain polyunsaturated fatty acids (LCPs) such as arachidonic acid and docosahexaenoic acid (DHA) are essential nutrients in neonates and infants. LCPs, in particular DHA, play a major role in the development of

visual acuity and mental development in the first year of life, particularly in preterm infants.[40–42] The main source of LCPs is maternal, in the last trimester of pregnancy and through breast-feeding, because breast milk is a rich source of LCPs and contains both arachidonic acid and DHA in a combination of phospholipid and triglyceride forms.

Studies in adults have demonstrated that LCP deficiency can develop either from malabsorption of long-chain fat and essential fatty acids or from reduced synthesis or function of the A-6-desaturase enzyme required for the de novo synthesis of very-long-chain[20–22] carbon PUFAs from their essential fatty acid 18-carbon dietary precursors.[43,44]

A recent study that compared plasma and liver levels of very-long-chain PUFAs in adults undergoing liver transplantation with controls undergoing hepatic resection demonstrated low plasma but normal liver levels in cirrhotic adults, suggesting that tissue stores were not affected.[45] It is unclear how this would compare with infants who are growing rapidly, and certainly deficiencies have been described in pretransplant infants.[46]

Children with cholestatic liver disease have normal LCP and DHA levels at birth but can become deficient within 8–12 weeks[47] from malabsorption of LCTs, from prescription of formula feeds rich in MCTs, or as a result of inadequate liver desaturase enzyme activity.[43,48,49]

Fat-Soluble Vitamin Deficiency

Chronic liver disease affects vitamin absorption, metabolism, and storage. Reduction in bile salt secretion leads to malabsorption of the fat-soluble vitamins A, D, E, and K. Fat-soluble vitamin deficiency can develop within 6–12 weeks of birth, depending on body stores and availability of vitamin supplementation. Vitamin A deficiency can also develop secondary to reduction in protein synthesis or depletion of hepatic stores. Vitamin D deficiency can occur either from fat malabsorption or from reduction in hepatic 25-hydroxylation. Vitamin K deficiency arises partly from fat malabsorption and partly from a reduction in intake, particularly in breast-fed infants. Deficiency in all fat-soluble vitamins is as high as 30% despite supplementation in severely cholestatic children.[50,51]

Because the liver has a central role in lipoprotein metabolism and cholesterol synthesis, hypercholesterolemia and hypertriglyceridemia are common in chronic liver disease. There can be increased synthesis of cholesterol esters as a result of loss of hepatic lecithin cholesterol acyltransferase, which can alter lipoprotein fractions. In cholestatic liver

disease such as Alagille syndrome, unusual lipoproteins, such as lipoprotein X, are produced with cutaneous xanthomata and hemolysis from alterations in red cell and platelet membranes.[52]

In terminal liver disease, however, the reduction in cholesterol synthesis leads to hypocholesterolemia, which is a poor prognostic sign, now usually seen only in the developing world.[53]

Endocrine Dysfunction

Growth failure in chronic liver disease can be exacerbated by an impaired growth hormone (GH)/insulin-like growth factor (IGF-I) axis[54,55] because IGF-I and its major circulating binding protein, IGF-BP3, are synthesized in the liver. It seems that IGF-I is nutritionally regulated[56] because there is animal evidence that nutrients influence synthesis and action of IGF-I and its binding proteins at many levels, including defects in pre- and posttranslational expression. Thus, protein malnutrition not only decreases the IGF-I production rate but also can increase serum clearance and degradation. Evaluation of GH, GH-binding proteins, and IGF-I in children with protein-energy malnutrition before and after nutritional rehabilitation has confirmed the role of malnutrition in these hormones.[57]

Children with chronic liver disease have GH resistance due to downregulation of GH receptor expression resulting in low IGF-I levels[58–64], despite elevated levels of GH, which could be a result of diminished hepatic synthesis or malnutrition or related to end-organ insensitivity to IGF-I.[60,63,64] Additional reductions (50%-68%) in IGF binding protein 3 (IGF BP3) and acid-label subunit (ALS), as seen in adult cirrhosis,[65] are likely but have not been investigated in children. Reductions in these transport proteins lead to rapid clearance of IGF-I from the circulation resulting in growth failure.

Increased Energy Expenditure

Adult studies have produced conflicting data on energy expenditure, but the situation is different in a growing child. A number of studies have indicated an increase in energy requirements of up to 140% in children with both acute and chronic liver disease.[66–68] Mechanisms implicated include portosystemic shunting and ascites; abnormal intermediate metabolism; and energy demands of specific complications, such as sepsis and variceal hemorrhage. A study has confirmed that children with end-stage liver disease have a hypermetabolic state with increased metabolic activity in the body cell mass with excess lipid oxidation during fasting

and at rest, once again confirming the necessity for appropriate nutrition and the avoidance of prolonged fasting in these children.[69] In contrast, children with stable liver disease such as Alagille syndrome did not have increased energy expenditure, suggesting that abnormal energy expenditure is related to severity of liver disease.[70] Children with acute liver failure also have excess energy expenditure and requirements because of multiorgan failure and may also develop electrolyte loss such as hypomagnesmia.

Trace Elements and Metals

Biochemical deficiencies of water-soluble vitamins such as thiamin and pyridoxine can occur and lead to nutritional cardiomyopathy and peripheral neuropathy.[71] Trace metal deficiencies include iron deficiency secondary to gastrointestinal bleeding or diminished intake and zinc and selenium deficiencies caused by reduced enteral intake, malabsorption, or increased losses.[72]

Consequences of Malnutrition

Many different nutrient deficiencies occur in children with chronic liver disease (Table 56-2), and malnutrition per se can increase liver dysfunction because of the energy required for synthesis, storage, and detoxification. Children with progressive cholestasis, such as those with biliary atresia or Alagille syndrome, develop significant fat malabsorption, which leads to steatorrhea, fat-soluble vitamin deficiency, essential fatty acid deficiency, loss of fat stores, and a reduction in growth[51,73,74] (Tables 56-2 and 56-3). Essential fatty acid deficiency can present with a rash,[48] whereas DHA deficiency is associated with abnormalities in visual function, as demonstrated by electroretinograms in cholestatic infants.[47]

TABLE 56-2 Clinical Manifestations of Malnutrition in Liver Disease

Nutritional Deficit	Clinical Manifestation
Protein-energy malnutrition	Stunting, muscle wasting, motor, developmental delay
Fat malabsorption	Steatorrhea, loss of fat stores
Essential fatty acid deficiency	Peeling rash
Vitamin A deficiency	Conjunctival and corneal drying, night blindness

Vitamin E deficiency	Peripheral neuropathy, ophthalmoplegia, ataxia, hemolysis
Vitamin D deficiency	Osteopenia, rickets, fractures, reduced bone density
Vitamin K deficiency	Bruising, epistaxis, coagulopathy
Zinc deficiency	Acrodermatitis, anorexia, poor growth
Hypercholesterolemia	Xanthomata
Immunosuppression	Systemic infections secondary to reduced cell-mediated immunity

TABLE 56-3 Anthropometric Definitions in Children with Liver Disease

Acute malnutrition	Decreased weight for height Decreased triceps skinfold or midarm muscle area
Chronic malnutrition	Decreased height for age
Severe malnutrition	<2 SDSs below the mean <3rd percentile

Abbreviation: SDS, standard deviation score (z-score), 0 = 50th percentile.

Fat-soluble vitamin deficiency is more common and can be detected biochemically before clinical symptoms, or severe deficiencies.[51,73,74] Clinical signs and symptoms of vitamin A deficiency are rare but include night blindness, xerophthalmia, and keratomalacia.[75] Vitamin D deficiency leads to hypocalcemia, hypophosphatemia, rickets, and pathologic fractures, particularly in infants who are rarely exposed to sunlight or who have inherited metabolic liver disease and a renal tubular disorder.[63] Deficiency of vitamin E leads to hemolysis, peripheral neuropathy, and occasionally visual loss.[76,77] Vitamin K deficiency can present as hemorrhagic disease of the newborn, particularly in breast-fed babies who are given insufficient vitamin K at birth.[78] It leads to coagulopathy, which is exacerbated by decreased synthesis of liver-dependent clotting factors. In vitamin K deficiency secondary to fat malabsorption, parenteral vitamin K will improve the coagulation profile, whereas it will be ineffective in parenchymal liver disease.

Metabolic bone disease with reduced bone density is usually observed in end-stage liver disease[63] and has been related to fat absorption rather than dietary intake.[79] Although malabsorption of vitamin D is a factor, the etiology is more complex as normal levels of vitamin D do not prevent bone demineralization.[63] Children with liver disease have a higher incidence of dental caries and enamel hypoplastic defects, which could be

related to nutritional deficiency or to bone disease. They also have discolored teeth as a result of hyperbilirubinemia.[80]

Trace element and mineral deficiencies include iron deficiency with anemia and zinc deficiency, which leads to acrodermatitis, immunodeficiency, and altered protein metabolism; both zinc and selenium deficiencies can exacerbate growth failure and poor protein synthesis.[1,72] Recently, the development of scurvy was reported in a child awaiting combined liver and kidney transplantation.[81]

In the course of chronic liver failure, fat malnutrition develops first, as demonstrated by the loss of fat stores. Protein malnutrition is a late development and is associated with a reduction in muscle bulk, stunting, and significant motor developmental delay. In time, children with significant malnutrition will have impaired growth and psychosocial development[82–84]; thus, malnutrition is an important indication for liver transplantation Severe malnutrition has a significant effect on mortality and morbidity and correlates with prolonged hospital stay[85] and is one of the most important prognostic factors[83] for survival post liver transplantation.[4,83,86,87]

NUTRITIONAL ASSESSMENT

Accurate nutritional assessment is essential to the management of children with acute or chronic liver disease. It is important to start with a comprehensive clinical history, feeding history, and careful physical examination. Serial anthropometric examination is critical and can identify early malnutrition. Standard weight and height ratios are of little value in children with liver disease because of misinterpretation caused by fluid overload, ascites, and visceromegaly. Many researchers, using sophisticated methods such as whole-body potassium and dual-energy X-ray absorptiometry (DXA) scanning, have demonstrated that body weight underestimated the incidence of malnutrition by 50% in both adults and children[2] and, for this reason, simple methods of measuring body composition, such as body impedance analysis, are not reliable in children with liver disease.[87,88]

Thus, the assessment of malnutrition should be performed using a number of parameters, such as triceps or subscapular skinfolds, midarm circumference, and arm muscle measurements (midarm muscle area).[7,89] Triceps, skinfolds, and midarm circumference are useful indicators of body fat and protein and serial recordings demonstrate early loss of fat

stores before weight and height changes become obvious.[7,89] Although linear growth is a sensitive parameter, it is a late sign of growth failure in infancy; stunting (or negative height velocity) might not be apparent until 1 year of age (Table 56-3).[90]

A number of evidence-based tools are under evaluation to assess nutrition in seriously ill children and may be of future relevance for liver disease.[91]

Growth data are best expressed as standard deviation scores (or z-scores) related to the median value for the child's age and sex in which the z-score of 0 = 50th percentile. This is particularly useful for comparisons between centers and for evaluation of new feeds.

Biochemical evaluation of vitamin deficiency is a useful adjunct to nutritional assessment. Plasma vitamin A levels can be measured but might not reflect hepatic stores.[92] Vitamin E deficiency is monitored by serum vitamin E levels or the ratio of vitamin E to total lipids. Vitamin D deficiency is evaluated by measuring serum levels of vitamin D, parathyroid hormone, calcium, phosphate, and alkaline phosphatase, whereas the diagnosis of rickets is confirmed by radiographic examination of the wrist or knee.[63] Vitamin K deficiency is identified by measuring coagulation times and monitoring the response to parenteral vitamin K, but a more accurate assessment can be obtained by measuring plasma PIVKA-II (protein induced in vitamin K absence).[50]

Acute malnutrition is evidenced by loss of weight compared to height and loss of fat stores, whereas chronic malnutrition is documented by stunting and reduction in the height-for-age index (Table 56-3).

INDICATIONS FOR NUTRITIONAL THERAPY

The aim of nutritional therapy is to prevent or treat malnutrition by providing adequate calories for energy and sufficient nitrogen for protein synthesis, restore plasma amino acid imbalance, prevent vitamin and trace element deficiency, and achieve normal growth and activity. The need for nutritional support is often underestimated particularly in infants with liver disease, who might have an increased appetite in the first few months of life.

Children who are at particular risk for developing malnutrition include the following:

- Children under 2 years of age who have severe cholestasis (serum bilirubin > 70 mmol/L [4 mg/dL])

- Those with progressive liver disease such as biliary atresia or severe familial intrahepatic cholestasis
- Those with end-stage liver failure awaiting liver transplantation
- Children with recurrent hepatic complications such as ascites and bleeding varices

STRATEGIES FOR NUTRITIONAL SUPPORT

Increased energy intake: because the resting energy requirements of infants and children with liver disease are increased,[66] it is important to increase the energy intake to 140%–200% of estimated average requirements (EARs). Cholestatic infants in the early stages of disease will compensate for malabsorption and increased energy requirements by increasing their intake, often consuming 120%–200% more formula than the recommended intake for age. In ongoing cholestasis, energy intakes often fall due to associated symptoms of progressive liver disease and strategies to increase the nutrient density of feeds must be employed. This can be achieved by using recently available ready to feed nutrient-dense MCT-containing formula (Infatrini Peptisorb, Nutricia Advanced Medical Nutrition), which provides enhanced protein and energy intakes (100 kcal/100 mL, 10% energy from protein). Alternatively, where this formula is unavailable MCT-containing formula can be concentrated from 13% standard dilution to 15%–19% dilution. This increases the energy density from 67 to 80-100 kcal/100 mL and protein from 1.9 g/100 mL to 2.24–2.84 g/protein/100 mL. Concentrating infant formula feeds increases the intake of all nutrients and maintains the delicate balance between energy, protein, and micronutrients. The practice of concentrating formula should only be undertaken by an experienced pediatric dietitian who can ensure appropriate monitoring of intake and growth (Table 56-4). There are many high-calorie, nutrient-dense supplement drinks available (Fortini—Nutricia Advanced Medical Nutrition, Paediasure Plus, and Abbott Nutrition), some containing MCT fat (Paediasure Pepdite—Abbott Nutrition, Peptamen Vanilla Bottle—Nestle Healthcare Nutrition), which can be effective for older children to enhance nutritional intake; however, compliance in taking these supplements over the long term is poor. If there is no response to an increase in energy intake alone, enteral feeding by nasogastric tube as either daytime bolus feeds or continuous overnight feeds is beneficial (Figure 56-1).

MCTs: because fat is an important calorie source, with an energy value of 8 to 9 kcal/g, it is a major source of energy for infants. Because

absorption is deranged in liver disease, the fat content of the diet needs careful consideration. Low-fat diets are no longer considered appropriate, but an increase in MCT content will reduce steatorrhea.[34,37,48] For infants, a whole protein formula such as Caprilon (SHS Nutrition) containing 75% fat as MCT or hydrolyzed-protein infant formulas, such as Peptijunior (Cow & Gate), Pregestimil (Mead Johnson), or Infatrini Peptisorb, (Nutricia Advanced Medical Nutrition), which contain 50% MCTs, will maximize fat absorption and improve steatorrhea,[48] but formulas with more than 80% MCTs can lead to essential fatty acid deficiency.[48] Although MCTs are a useful energy source, there is no evidence that growth improves with formulas having a high MCT content,[93,94] so it is necessary to increase the total fat intake with both LCTs and MCTs. This will increase the overall amount of fat absorbed and improve growth despite increasing steatorrhea.[37] In older children, MCT oil or emulsions (Liquigen—SHS Nutrition) can be added to meals and should be balanced by fats with high LCP content.

LCPs: the malabsorption of long-chain fats in chronic liver disease means that it is important to ensure adequate intake of LCPs. The minimal intake of linoleic acid recommended for infants is 1% to 2% of energy in a ratio of linoleic to linolenic acid of 5:15.1.[41]

TABLE 56-4 Formulas for Children with Liver Disease[a]

Formula	kcal/kj	Protein (g)	Fat (% MCT)	Sodium (mmol)	Essential Fatty Acids (omega-6: omega-3)
Pregestimil[b]	68/285	1.9	55	1.26	10:1
Peptijunior[c]	67/280	1.8	50	0.9	7:1
Caprilon[d]	66/276	1.5	75	0.8	7.5:1
Generaid Plus[d]	102/428	2.4	32%	0.7	4:1

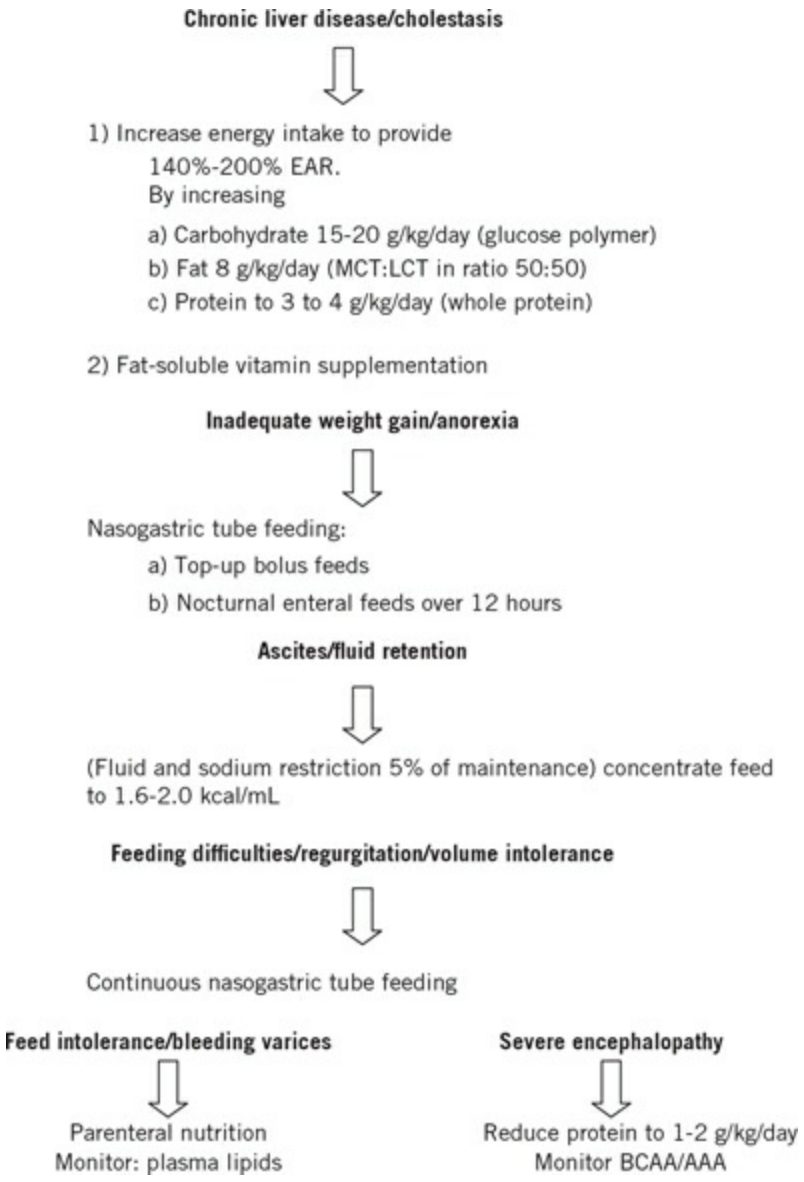

Figure 56-1 Nutritional support for chronic liver disease.

The LCPs, or PUFAs, can be supplemented by the addition of walnut oil to provide 1% to 2% of total energy, whereas LCP supplementation is provided in dietary products such as egg yolk (which is rich in arachidonic acid) or fish oil (which is rich in DHA). Alternatively, infants can be given conventional LCP-supplemented formulas, which are commercially available.[95]

Structured lipids: recently, chemically defined structured lipids have been developed to increase absorption of both medium-chain and long-

chain and essential fatty acids.[96] These lipids combine pure MCTs with LCTs, resulting in a triglyceride that contains combinations of short-, medium-, and long-chain fatty acids on a single glycerol backbone, which should be absorbed like MCTs. To date, clinical studies in adults have evaluated structured lipids in postoperative patients receiving parenteral nutrition and demonstrated that they are safe and effective compared to LCP emulsion.[97] Although clinical studies of these modified lipids in children are currently in the preliminary stages,[98] studies in rats have demonstrated improved fat absorption and reversal of essential fatty acid deficiency in vitro in caco-2 cells.[99,100] If successful, there might be considerable benefit for cholestatic infants.

Carbohydrate: carbohydrate is a major source of energy and is particularly useful for increasing calorie intake. It can be given as a monomer, a short-chain polymer, or starch, but complex carbohydrates such as maltodextrin or glucose polymer restrict the osmolality of feed while maintaining a high energy density of more than 1 kcal/mL. This allows fluid restriction if necessary while providing up to 20 g/kg/day of carbohydrate. In infants, glucose polymers are best added to milk feeds; in older children, they can be added to drinks, mixed in with foods, or given as a supplemental drink.

PROTEIN INTAKE

Historical advice, which restricted protein in advanced end-stage liver disease, is now considered inappropriate in both children and adults.[101] Children with end-stage liver disease require minimal protein intakes of approximately 2 to 3 g/kg/day but will tolerate up to 4 g/kg/day without developing encephalopathy or a significant increase in plasma amino abnormalities.[102] Severe protein restriction (less than 2 g/kg/day) might be required for acute, severe encephalopathy but should be avoided in the long term as it can lead to endogenous muscle protein consumption.[66] There is no necessity to use semielemental diets or protein hydrolysates because there is no evidence of protein malabsorption.

In view of the abnormal aromatic acid to BCAA ratio, there has been considerable interest in the use of a modified amino acid formulation designed to improve this imbalance. Numerous studies in adults have not demonstrated a clear benefit for BCAA nutritional supplementation, despite the evidence that BCAAs did improve nitrogen retention and protein synthesis; their effect on patient outcome was not proved.[103]

The necessity for BCAA supplementation may persist post transplantation, as demonstrated in a recent study in five clinically stable children, although the requirement was less than before transplantation.[104]

There is both animal and clinical evidence that suggests that BCAA-enriched formulas can have significant nutritional benefit in children. BCAAs increased weight gain, protein and muscle mass, body composition, and bone mineral density in an animal model of biliary obstruction.[105] A study that compared a feed containing 32% BCAAs with a standard feed demonstrated improved lean body mass in children awaiting liver transplantation but no improvement in amino acid levels.[106] In another study in infants with liver disease, the effect of a modified amino acid feed containing 50% BCAAs was compared with an isonitrogenous formula containing 22% BCAAs by measuring whole-body protein turnover.[67] The BCAA-supplemented feed improved protein retention compared with the standard formula by suppressing endogenous protein catabolism and normalizing the plasma amino acid profile. Formulas rich in BCAAs, complete with MCTs and vitamin and mineral supplements, have been developed for use in infants, and oral supplements rich in BCAAs are available for older children, but both are particularly unpalatable.

VITAMIN AND MINERAL SUPPLEMENTATION

Both water- and fat-soluble vitamins should be supplemented in children with chronic liver disease. Supplementation should be based on plasma levels of selenium, zinc, calcium, and magnesium. Iron supplementation might be required in children with chronic blood loss.

Fat-soluble vitamins are required in all children with prolonged or cholestatic liver disease (Table 56-5). Most children will be maintained adequately on oral fat-soluble vitamin administration, but monthly intramuscular administration is occasionally required for children with severe cholestasis.

MODE OF DELIVERY

Nutritional supplementation should be provided enterally for as long as possible because it has a number of advantages over parenteral feeding. It not only is cheaper and more physiologic but also maintains gastrointestinal tract immunity, reduces bacterial overgrowth, and maintains the integrity of the gut barrier to microorganisms. It is also

essential to maintain normal feeding behavior. Many children with progressive liver disease will not be able to consume the prescribed increase in nutritional intake necessary to prevent or reverse malnutrition orally; thus, early nasogastric tube feeding is indicated for children who have a poor response to an increase in nutritional intake or who become anorexic.

Despite anxiety about using nasogastric feeding in children with esophageal varices, there is no evidence that the use of modern soft Silastic™ nasogastric tubes is harmful. Nocturnal feeding is the method of choice because it allows nutritional supplementation while supporting normal oral feeding during the day. For infants with severe liver disease, nocturnal feeding can be beneficial because it will prevent fasting hypoglycemia and reduce protein catabolism. Continuous enteral infusion might be required in children with severe malabsorption or feed intolerance. Intensive enteral nasogastric feeding has effectively reversed malnutrition in infants and children with liver disease, and it can relieve parental anxiety and may induce a transformation in the child's affect and increase voluntary intake.[37,102,107] Under normal circumstances, it should be possible to provide nocturnal or continuous nasogastric feeding at home with appropriate support from a nutritional care team including a dietitian, a liaison nurse, pediatric community nurses, and clinicians.

Gastrostomy tube placements might be preferable in older children but should be avoided in children with severe portal hypertension because of the development of stomal varices. In children with stable compensated liver disease (e.g., cystic fibrosis), percutaneous endoscopic gastrostomy might be beneficial.

GROWTH HORMONE THERAPY

In view of the disruption of the GH/IGF-I axis, it is tempting to prescribe GH therapy for children with significant growth failure, but this has not been proved beneficial in children with end-stage liver disease.[60,63]

PARENTERAL NUTRITION

In view of the well-recognized hepatobiliary complications that occur in premature infants with short-gut syndrome or intestinal failure, parenteral nutrition has been used cautiously in children with liver disease. Particular concern has been focused on whether the potentially toxic components of parenteral nutrition could be exacerbated in children with established

chronic liver disease or cholestasis. There is no evidence that amino acids, carbohydrates, or lipid emulsions are any more toxic in children with established liver disease, although amino acid levels and plasma lipids need careful monitoring.

Although aluminum toxicity is well recognized in parenteral nutrition and can lead to bone disease, there is no evidence that it is implicated in parenteral nutrition liver disease or that it exacerbates the metabolic bone disease associated with chronic liver disease.[108] In contrast, chromium toxicity has been reported in animals on parenteral nutrition. Although both serum and urine chromium levels are higher in children on long-term parenteral nutrition, there is no correlation with liver disease.[109]

However, manganese toxicity in children on long-term parenteral nutrition has recently been reported.[110,111] Although 79% of children on long-term parenteral nutrition had whole-blood manganese concentrations above the reference range, children with impaired liver function had the highest manganese levels. Although manganese is toxic to both brain and liver, it is not clear whether the high manganese levels led to cholestasis or were secondary to it because manganese is excreted in the bile. Nevertheless, it is likely that manganese toxicity exacerbates cholestasis in children with established liver disease; thus, monitoring of manganese levels is particularly important in this group.

TABLE 56-5 Assessment and Management of Nutritional Deficiency in Pediatric Liver Disease

Deficit	Investigation	Management
Energy	Calorie intake, energy expenditure, anthropometry (body cell mass [TBK], DXA)	Increase calorie intake, achieve 130%–150% EAR, nocturnal enteral nutrition, continuous enteral nutrition
Protein	Plasma proteins (albumin), BCAA/AAA ratio, protein stores (muscle mass, TBN)	Provide adequate protein, (3 to 4 g/kg/d), BCAA-enriched protein (32%), albumin infusion (if serum albumin < 25 g/L)
Fat	Triceps skinfolds, body composition, EFA deficiency, plasma lipid profile	Improve fat absorption (MCT:LCT, 50:50), provide saturated fats high in EFA, ? supplement DHA
Fat-	Plasma 25-OH-D (skeletal	Light exposure, vitamin D-1-a (50

soluble Vitamins	X-rays, DXA), prothrombin time ([<138 c] INR = 1), plasma vitamins E and A	ng/kg), vitamin K (2.5–5 mg/d), vitamin E (50–400 IU/day as TPGS), vitamin A (5,000–10,000 IU/d)
Water-soluble count vitamins	Specific levels, blood	Supplement as requested
Minerals	Specific levels, cardiac evaluation	Supplement as requested

Abbreviations: EFA, essential fatty acid; INR, international normalized ratio; LCT, long-chain triglyceride; MCT, medium-chain triglyceride; TBK, total body potassium; TBN, total body nitrogen; TPGS, tocopherol polyethylene glycol-1000 succinate.

In general, the use of parenteral nutrition in children with established liver disease is for short-term purposes only; thus, they are unlikely to develop the complications seen in children on long-term parenteral nutrition,[112] although prescription of ursodeoxycholic acid (15–20 mg/kg) might be of value.[113]

Parenteral nutrition should be considered in children with chronic liver disease only if they cannot be enterally fed because of feed intolerance or secondary to complications such as recurrent variceal bleeding or abdominal sepsis. As stated earlier, there is no evidence that short-term parenteral nutrition is associated with hepatobiliary dysfunction or an increase in cholestasis; it can improve nutritional status in the short term. Standard amino acid and lipid solutions are well tolerated in stable patients, and lipids can be particularly beneficial in achieving adequate calorie intake. If encephalopathy develops, the amino acid content of the feed can be reduced to 1 to 2 g/kg/day; lipid administration requires careful monitoring in children with severe liver dysfunction, hepatic encephalopathy, or sepsis. Parenteral structural lipid emulsions have not yet been evaluated in children.

The use of parenteral nutrition is particularly important for children with acute fulminant hepatitis who are awaiting liver transplantation because they are hypercatabolic. Standard formulas should be used, although the volume needs to be restricted to 75% of maintenance and the concentration should be increased to maintain glucose levels (less than 4 mmol/L). There is no need to reduce protein content, particularly if the patient is electively ventilated. As indicated earlier, intravenous use of BCAAs for the treatment of hepatic encephalopathy or coma has not been evaluated in children, although they can be of value in adults.

BEHAVIORAL FEEDING PROBLEMS

Behavioral feeding problems are common in this group of children, particularly in infants who have had long-term nasogastric feeding. Feeding problems are compounded by the use of unpalatable feeds, medications, and excess parental anxiety about feeding and growth.

Strategies to prevent behavior problems include promoting daytime feeding to provide oral stimulation and encouraging children to experiment with flavors and textures appropriate to their age. The success of these techniques is dependent on a multidisciplinary approach involving a clinician, nurse specialist, dietitian, clinical psychologist, speech therapist, and play therapist.[37]

SPECIFIC DISEASE STATES

Acute Liver Disease

Most children with acute viral or autoimmune hepatitis require no nutritional supplementation, although recent studies indicate that their energy intake, body composition, and vitamin status may be altered.[68,73] Fulminant hepatic failure requires careful management of protein to prevent hepatic encephalopathy and reduce excess protein catabolism. Protein should be restricted only for short periods to treat severe encephalopathy (see earlier). Fluid volume can be reduced to prevent or treat cerebral edema; it is critical to maintain adequate glucose levels by infusing 6–8 mg/kg/min of glucose to prevent hypoglycemia. Enteral nutrition should be continued as long as the child is conscious and in the early stages of elective ventilation. Once the requirement for liver transplantation becomes obvious, parenteral nutrition may be required to provide sufficient calories to prevent additional protein catabolism should enteral feeding fail to be tolerated (see earlier).

Chronic Liver Disease

The majority of children with chronic liver disease will have cholestasis, from biliary atresia, Alagille syndrome, or familial intrahepatic cholestasis, and should be managed as indicated earlier.[3,114,115] Children who are not jaundiced require similar support, although their requirement for fat-soluble vitamin supplementation will be less.

Problems can arise with children who have ascites and fluid retention; fluid and sodium restriction might be required. In these circumstances when commercial feeds may not deliver appropriate nutrition, a modular

feeding system may be of benefit. The modular feeding system is extremely flexible in its composition and allows individual prescription of protein, sodium, and water to which complex carbohydrate polymers, fats, vitamins, and minerals are added to produce a highly energy-dense/nutrient-dense feed to suit the child's specific nutritional requirements.

Inborn Errors of Metabolism

A number of inborn errors of metabolism rely on dietary modification as part of therapy. These include galactosemia, hereditary fructose intolerance, and tyrosinemia type I.

Galactosemia is an autosomal recessive disorder in which there is a reduction in the enzyme activity of galactose-1-phosphate uridyl transferase, which prevents the conversion of galactose to glucose. Dietary treatment includes removing all products containing galactose (i.e., milk and milk products).[116]

Hereditary fructose intolerance is an autosomal recessive disorder caused by a deficiency or the absence of the enzyme aldolase B, which leads to cirrhosis and renal tubular disorders. Dietary management consists of elimination of fructose, sucrose, and sorbitol from the diet; this must be maintained for life. This means that all fruit and fruit juices are eliminated from the diet and only certain vegetables are permitted. Commercial products such as breads and cereals can also contain small amounts of sucrose, as can medications and toothpaste.[116]

Tyrosinemia type I is an autosomal recessive disorder caused by a defect in the enzyme fumarylacetoacetase, which leads to hypertrophic cardiomyopathy, cirrhosis, and renal tubular acidosis. For many years, dietary treatment was the only method of therapy and included restriction of phenylalanine, tyrosine, and methionine. Although restriction of these amino acids was effective in normalizing plasma amino acids, it did not prevent the progression of liver failure or the development of metabolic crises. The development of Nitosone (2-[2-nitro-4-trifluoromethylbenzoyl]-1,3-cyclohexenedione) in association with dietary treatment has altered the natural history and outcome of the disease.[117]

Glycogen Storage Disease

Hepatic glycogen storage disorders are a group of autosomal recessive inherited disorders that lead to defects in the metabolism of glycogen. Liver and skeletal muscle are usually affected, but heart, kidney, bones,

and brain can also be involved. The presentation and biochemical features depend on the precise enzyme deficiency. Nevertheless, the treatment is dietary: provide a continuous supply of exogenous glucose, either intravenously or enterally; maintain normal glucose; and suppress counterregulatory responses. In infants, this is best achieved by frequent daytime feedings or continuous nocturnal enteral glucose feeding. In older children, the oral feeding of uncooked cornstarch (1 to 2 g/kg every four hours), which is hydrolyzed in the gut to release glucose slowly, can reduce the need for frequent daytime feedings or continuous nocturnal feeding.[118] Glycogen storage disease type III requires similar treatment but with a higher protein intake (3 g/kg). In most instances, dietary management is successful and can prevent the long-term complications of these diseases.

PREPARATION FOR LIVER TRANSPLANTATION

Liver transplantation is indicated for both acute and chronic liver failure. Nutritional support is of particular importance for children with chronic liver failure because malnutrition is a significant risk factor for mortality and morbidity related to liver transplantation.[83,86,87]

Children awaiting liver transplantation require intensive nutritional support, depending on the etiology of their liver failure, as documented earlier, but the main principle is to provide a sufficient nutrient intake (Table 56-6).

TABLE 56-6 Nutritional Support in Children Before and After Liver Transplantation

Requirement	Preoperative	Postoperative
Carbohydrate	Glucose polymer 15–20	Glucose polymer 6–8 (g/kg/day)
Protein (g/kg/d)	Low-salt protein 3–4	Whole protein 2.5–3
Fat (g/kg/d)	50%–70% MCT 8	LCT 5–6
Energy intake	130%–150%	120% (EAR)

EFFECT OF LIVER TRANSPLANTATION ON NUTRITIONAL STATUS

Many recent studies have documented the nutritional rehabilitation achieved by successful liver transplantation.[4,90,119] Following liver

transplantation, surviving children experience a rapid return to normal midarm muscle area and midarm fat within three to six months.[92,119] Initial weight gain can be rapid because of the effects of corticosteroids on appetite and salt and water retention, but most children return to a normal weight once corticosteroids are reduced or discontinued. Linear growth is often delayed by 6–24 months depending on the rate of hepatic complications and the withdrawal or reduction of corticosteroids.[83]

Preoperative nutritional status has a strong influence on posttransplantation growth. Children who were less stunted at transplantation grew slowly initially but finally achieved normal growth velocity, whereas older children who were more stunted (height standard deviation score [SDS] > –2) grew more quickly initially post transplantation but did not achieve normal height.[120] There are no differences in catch-up growth between the sexes or with pretransplantation disease, apart from Alagille syndrome, which is associated with growth failure before and after transplantation in 50% of patients.[121,122]

Although successful liver transplantation reverses most aspects of malnutrition, it can take some months or years before bone density returns to normal. Persistent osteoporosis and bone fractures have been described at three to six months following transplantation[63] and were exacerbated by the effects of corticosteroid therapy.

Likewise, it may take some time before long-chain PUFA and BCAA metabolism return to normal[46,103] and these factors should be taken into consideration when planning posttransplant nutrition.

EFFECT OF GROWTH HORMONE AND IGF-I

As indicated earlier, both GH and IGF-I are necessary for normal growth, and it has been shown that plasma IGF-I levels are low in children with chronic liver disease despite elevated serum GH. Although posttransplantation IGF-I and IGF-BP3 rise significantly and IGF levels return to normal, abnormalities in the IGF-binding proteins BP1, BP2, and BP3 remain for some months.[55]

PREVENTION OF GROWTH FAILURE AFTER TRANSPLANTATION

The nutritional strategy for prevention of growth failure before and after

liver transplantation begins with intensive nutritional support preoperatively. Children who are malnourished before transplantation should be maintained with parenteral nutrition perioperatively until normal nutrition is resumed, whereas children with normal nutritional status should start enteral feeding with a rapid buildup of calorie intake 3–5 days following transplantation.

It is important to ensure sufficient energy intake (at least 120% of EAR) following the operation. This can be provided as a high-energy pediatric enteral feed, a high-energy infant formula, or a modular feed taken either orally or enterally via a nasogastric tube for infants and children who have poor oral intake. Nasogastric tube feeds alongside additional supplements of fat and carbohydrate may be required for some time to maintain growth while establishing normal oral intake. The energy intake should include 2.5 to 3 g protein/d and glucose polymer (6–8 g/kg/d), but fat can now be provided entirely as long-chain fat (5 to 6 g/kg/d) unless cholestasis secondary to chronic rejection is a complication (Table 56-6).[123]

Glucocorticoids, used to prevent organ rejection, interfere with GH excretion. As GH, IGF-I, IGF-BP1, IGF-BP2, and IGF-BP3 remain abnormal following transplantation, it is rational to consider whether GH therapy might be helpful. Recombinant human GH has been evaluated in eight growth-retarded children following liver transplantation.[124] The median growth rate increased from 3.2 to 7.1 cm/year (p = .025) and height SDSs increased from –2.9 to –3.1 (p = .036) during the first year of GH treatment. Both IGF-I and insulin IGF-BP3 levels increased significantly during treatment. There was no effect on graft function, and no child developed rejection or any other complication, but growth velocity was not maintained beyond the first year.

THE OBESITY EPIDEMIC

Survivors of liver transplantation are not immune from the effects of the obesity epidemic, and there are reports of obesity following all forms of solid organ transplantation.[125] Likewise, the development of nonalcoholic fatty liver disease is related to a number of inherited disorders, such as Bardet-Biedl, polycystic ovary disease, and obesity,[126] but a detailed description of this new emerging chronic disease in childhood is outside the scope of this chapter.

CONCLUSION

The essential role of liver in energy and growth has particular relevance for infants and children with end-stage liver failure. Considerable progress has been made in understanding the pathophysiology of malnutrition in liver disease, and this has improved our ability to support these children. Nutritional rehabilitation has been achieved by intensive nutritional support, and mortality following liver transplantation has been reduced. Its success depends on a multidisciplinary approach based on early intervention and prevention of malnutrition. Caution about the effects of overfeeding may be relevant to the development of obesity in the long term.

Cancer Prevention

57

A. Lindsay Frazier, MD, ScM

INTRODUCTION

Cancer is undeniably a disease with an established genetic basis, but the field of epidemiology has shown that the development of cancer is the result of an interaction between genes and the environment. A simple example are migrant studies that show an increase in cancer risk in the second generation after migration but not in the first generation, theoretically after sufficient exposure to the environment of the new country has taken place. These studies strongly suggest that it is the environment that modifies underlying genetic risk. Diet has long been postulated to be one of the most important environmental factors in the etiology of cancer.[1]

Pinpointing exactly which elements of diet are implicated in the pathogenesis of cancer is complicated; diet itself is inherently complex, even one single food can simultaneously contain both cancer-promoting and cancer-preventing substances. Moreover, diet does not happen in a vacuum but takes place in the context of other human behaviors, and these other risk factors must be simultaneously taken into account. Precise measurement of diet is challenging due to the day-to-day variability in consumption; measurement is also dependent on the accurate recall and estimation by the individual (see Chapter 17, Nutritional Epidemiology for details). Finally, the critical time of the exposure may vary by type of cancer. For instance, in the case of breast cancer, the theory has been advanced that there is a critical period for carcinogenic exposures between onset of menarche and first birth. The hormone-induced proliferation occurs with each menstrual cycle prior to the differentiation of the breast that occurs at the time of pregnancy and lactation. Diet during this

adolescent period likely has different implications for breast cancer than diet in later life. Despite this substantial list of caveats, the evidence has accumulated that diet throughout the life course, beginning with in-utero exposures and extending through adult life, has an impact on the risk of malignancy, both in childhood and adulthood.

The evidence for the relationship between nutritional intake and cancer comes in several forms. The simplest line of evidence is the relationship between growth and risk of malignancy. Although studies showing a relationship between birth weight, height, or growth velocity do not help to identify a causative agent, these studies do confirm that what one eats, and therefore what fuels growth, is related to cancer. The second line of evidence attempts to identify the causative agent through the use of dietary records, either in the setting of a case-control study or in a prospective cohort study. Animal studies in which diet can be more tightly controlled, can either suggest or support observations in humans.

In this chapter, we review the evidence that childhood nutrition can impact the risk of subsequent malignancy. Using a wide lens, we examine several different aspects of nutrition. The first principle will be to examine the impact of diet over the entire span of childhood, beginning with in utero exposures through adolescence. Second, we consider the impact of childhood diet on the incidence of both childhood and adult malignancies. To do so, we review the evidence linking childhood growth and cancer, making the argument that growth is a proxy for nutrition. In addition, using case-control studies, we review the specific associations between childhood diet and cancer. Finally, we review the evidence that for breast cancer at least, the period of childhood and adolescence may be the critical period for exposures that ultimately determines risk of disease as an adult (see Figure 57-1).

The Connection Between Growth and Cancer

Cancer, simply put, is uncontrolled growth. Where does the uncoupling occur between controlled and uncontrolled growth? In pediatrics, there are a set of clinical syndromes notable for “overgrowth,” or excessive growth in the pre- and postnatal periods that occur at a frequency of approximately 1/10,000 children. Over 20 pediatric overgrowth syndromes have been described, each with the shared feature of excessive growth, but also with unique abnormalities due to the specific underlying genetic cause. Most of these syndromes are also associated with an increased risk of cancer, principally embryonal tumors. These syndromes are provocative paradigms of the malignant hazards of excessive growth.

The most widely recognized of pre- and postnatal growth syndromes is Beckwith–Wiedemann syndrome (BWS). BWS is often associated with advanced bone age, macroglossia, hemihypertrophy, neonatal hypoglycemia, and umbilical hernia or omphalocele. Approximately 1%–8% of children with BWS will present with Wilms' tumor and less commonly, hepatoblastoma. Genetic abnormalities have been located primarily to the short arm of chromosome 11(11p15), known as the WT2 locus. This region is heavily imprinted; the paternal gene for insulin-like growth factor 2 (IGF-2) is normally constitutively activated. The presence of not just one but two active copies of the IGF-2 gene, due to paternal uniparental disomy, which is demonstrable in 10%–20% of BWS patients, is hypothesized to be one of the molecular causes of the syndrome.

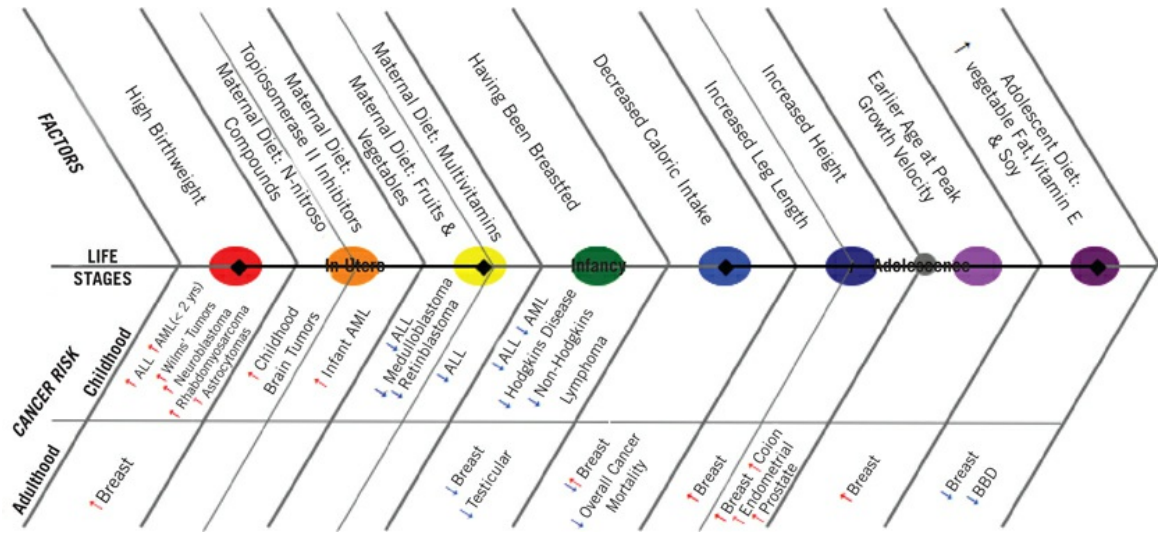

Figure 57-1 Nutritional factors in childhood and lifetime prevention of cancer.

Simpson–Golabi–Behmel syndrome (SGBS) is an X-linked disorder that has many of the same clinical features as BWS: pre- and postnatal overgrowth, macroglossia, cleft plate, advanced bone age, and umbilical hernia. Approximately 5%–20% of patients with SGBS will present with Wilms' tumor. SGBS patients often have other features including coarse facies, down-slanting palpebrae, polydactyly, syndactyly, intracardiac defects, and cardiac conduction defects. SBGS is caused by a deletion in the glypican 3 gene on the X chromosome. Glypican 3 is a heparan sulfate proteoglycan that is attached to the cell surface via a glycosyl-

phosphatidylinositol anchor. Its role in the cell is to regulate the growth and differentiation of predominately mesodermal cells through modulating the interaction of growth factors, particularly IGF-2, with their receptors. Glypican 3 is usually expressed in embryonic tissues and downregulated in adult tissues. Glypican 3 is found to be overexpressed in Wilms' tumor, hepatocellular carcinoma, and neuroblastoma. It is interesting that IGF-2 is implicated in two of the most common pediatric overgrowth syndromes: BWS and SBGS. Understanding the molecular basis for these overgrowth syndromes will likely highlight genes critical for the proper balance of growth during childhood and may help us to understand the link between the genetics of growth and the genetics of cancer and the environmental influences, such as diet, that can tip the balance in favor of malignant growth.

IN-UTERO EXPOSURES AND INFANT LEUKEMIAS AND OTHER CHILDHOOD CANCERS

When does cancer begin? The genetic evidence is now quite compelling that infant leukemias are initiated in utero. Infant leukemias have certain pathognomonic translocations such as t(12;21), t(4,11), or t(8:21). Among infants who developed leukemia in the first 2 years of life, scientists used neonatal blood spots collected to neonatal screening purposes at birth to get a picture of the chromosomal makeup of the child at birth. They have been able to identify the leukemia-causing translocation clone present at birth, even though the leukemia itself did not become manifest for several months or years.[2,3] Epidemiologic evidence supports the notion that in utero exposures are etiologic in cancer causation. For instance, there is strong association between birth weight and childhood cancer, especially leukemia. Other environmental factors, particularly maternal—or in utero—diet have also been shown to influence the risk of certain childhood cancers, particularly leukemia, and central nervous system tumors in children.

Birth Weight and Pediatric Malignancies

The most straightforward marker of intrauterine growth, birth weight, is in large part determined by levels of maternal insulin-like growth factor-1, which has both mitotic and anti-apoptotic functions. These same functions of IGF may be the link between larger birth weight and the observed

associations with several types of childhood cancers including acute lymphoblastic leukemia (ALL), acute myelogenous leukemia (AML), Wilms' tumor, neuroblastoma, rhabdomyosarcoma, and astrocytomas (but not other forms of childhood brain tumors).[4–8] The results of some studies have been inconsistent but some of the variability in results is likely due to the fact that the association between birth weight and cancer may operate for only for one gender and not the other, or only for certain histologic subtypes, or only for earlier age at diagnosis, depending on the underlying mechanism responsible for the association. Reviewing the adequacy of stratified analyses is imperative in interpreting the findings.

The data linking higher birth weight and childhood malignancy are most consistent for childhood leukemias. A meta-analysis of 18 studies of birth weight and childhood leukemia,[9] estimated that for each one kilogram (kg) increase in birth weight, risk of ALL increased by 14% (95% CI 1.08–1.20) and risk of AML increases by 29% (95% CI 0.73–2.20).[9] There was evidence of a dose-response relationship for both types of leukemia, although it was stronger for ALL (likely because ALL is more prevalent than AML and hence there is more power to detect an association). The association is strongest in children under the age of 2 years; in fact, for AML, the association appears to be limited to children diagnosed before age 2.[10] Indeed, for children under age 2, risk of leukemia may increase by as much as 100% for children who weigh > 4,000 g at birth.[11] In a pooled analysis of three case-controls studies from the United States, United Kingdom and Germany that comprised 4,075, the estimated excess risk per kg of bodyweight was similar, however, in this analysis, the authors showed that case children were on average heavier at every gestational age. The authors also noted a paucity of cases in the very low birth weight group (<1500 g) and speculate that if indeed ALL is initiated in utero but not manifest at birth, that it may still predispose these "occult" cases to increased perinatal mortality.[12] Interestingly, both the prevalence of children who are large for gestational age (birth weight > 90th percentile) as well as the incidence of childhood leukemia and brain tumors have been increasing in parallel in the United States over the past several decades.[4]

Several studies report no relationship between birth weight and soft tissue sarcoma, but soft tissue sarcoma encompasses a very wide range of histologies and subgroup analysis is important. For instance, in a case-control study that linked state cancer registry and birth registry data, the authors showed that larger birth weight was associated with risk of

rhabdomyosarcoma, but only the embryonal histology. This makes intuitive sense in that embryonal rhabdomyosarcoma is diagnosed at a much younger age than alveolar, usually within the first 5 years of life, suggesting that perinatal exposures may be more relevant.[13] Moreover, the authors showed that it was not just birth weight but increased fetal growth that was specifically associated with embryonal rhabdomyosarcoma because the association was replicated for babies large for gestational age, not just those who met a certain birth weight cut-off.

A case-control study of the risk of osteosarcoma was conducted in orthopedic surgery departments in 10 US medical centers between 1994 and 2000. Controls (n = 151) were from the same departments as cases (n = 158) and the study included both children and adults. The study found that a higher birth weight was associated with an increased risk of osteosarcoma and the odds were greater for females. However, these results were inconsistent with two prior studies, which found no association, though these results were primarily conducted in children.

High birth weight and Wilms' tumor has been examined in 12 studies to date, including three prospective birth cohorts. Results of a meta-analysis show that a high birth weight is associated with a significantly increased risk of Wilms' tumor (RR = 1.08 (95% CI: 1.04–1.12).[14] Additionally in the National Wilms Tumor Study, a high percentage of cases had birth weights higher than the national median.

The results may vary by gender as well. Two studies have reported that the association between birth weight and Wilms' tumor was only observed for girls but not for boys.[15] Dorak et al. reported that the association for birth weight and ALL was present only for boys but not for girls.[16]

Several biologic explanations for the association between birth weight and childhood cancer have been suggested. One hypothesis has focused on the possibility that higher birth weight is a simple proxy for a greater number of cells proliferating at any one time and therefore greater absolute number of cells that are at potential risk for malignant transformation. Another possible mechanism may be a surfeit of IGF-1, which is known to be associated with higher birth weight. Others have suggested that excess of iron, which has also been linked to both increased birth weight as well as enhanced cancer cell growth, may explain the relationship between birth weight and childhood cancer. The major hemochromatosis allele, HFE C282Y, which is associated with increased serum iron levels in 15%–25% of heterozygotes, is also present in higher frequency among boys diagnosed with childhood ALL than controls.[17]

It should be noted that a variety of studies have also reported an

association between birth weight and cardiovascular disease, but in the opposite direction as that observed for cancer. Low birth weight has been associated with an increased risk of ischemic heart disease, as well as many of the intermediate markers of cardiovascular disease, such as blood pressure, body mass index, waist/hip ratio, serum lipids, plasma clotting factors, and impaired glucose tolerance.[18] Adverse conditions in utero, whether it is a surfeit of growth (linked to cancer) or a paucity of growth (linked to cardiovascular disease), appear to have long lasting implications on the human for risk of subsequent disease (see Chapter 26, Human Growth and Disease in Later Life for details).

IN-UTERO DIET (MATERNAL DIET) AND CHILDHOOD CANCER

Topoisomerase II Inhibitors and Infant Leukemias

Infant leukemias, although rare, clearly represent a unique subset of childhood leukemia because of their high resistance to standard chemotherapy (20% survival), in contrast to leukemias that occur later in childhood (80% survival). The majority of infant leukemias display a gene rearrangement at 11q23 in the MLL gene. This gene has been shown to play a major role in normal hematopoiesis.

The same gene, MLL, is implicated in secondary leukemias that result from treatment with a class of drugs—epipodophyllotoxins—that inhibit the function of DNA topoisomerase II (DNAt2). DNAt2 first relaxes the supercoiled DNA double helix by cleaving the bonds between the strands and then religates the two strands. Epipodophyllotoxins act by inhibiting religation by the enzyme, thereby triggering apoptosis. Topoisomerase inhibitors have wide activity against a number of different types of malignancies, but a small percent of treated patients will develop secondary leukemia, usually AML, with a characteristic cytogenetic marker of an 11q23 abnormality.

The de novo presence of the MLL abnormalities in infant leukemias led Ross et al. to propose in 1994 that there might be a link between in-utero exposure to DNAt2 inhibitors and infant leukemias.[19] The principal source of DNAt2 inhibitors in the environment is diet, primarily flavonoids, genistein, and catechins. Flavonoids, such as quercetin, are found in citrus fruits, apples, onions, parsley, tea, red wine, and dark berries such as blueberries and blackberries; genistein is found in soy products and catechins are found in green and black tea, cocoa, and red

wine. In the largest case-control study to date (n = 240), an increase in the odds of infant AML but not infant ALL was observed.[20] The effect was limited to in infants who were MLL+. Mothers in the top quartile of consumption of DNAt2-containing foods during pregnancy had 3.2 times (95% CI: 0.9–11.9) the odds of having an infant with AML (MLL+); however, the P value for the test for trend was .10 likely due to the fact that the study was based only on 29 patients in this subgroup.

N-Nitroso Compounds and Brain Tumors

Animal experiments have definitively shown that feeding pregnant animals nitrosamines causes nervous system tumors in the offspring. In the human diet, cured meats are the major source of nitrites and vegetables a major source of nitrates. Cured meats are treated with nitrites to prevent spoilage and unappealing changes in the color of the meat. The most common types of cured meats consumed include hot dogs, bacon, sausage, cured ham, and packaged lunch meats. In the acid environment of the stomach, nitrates and nitrites are converted to *N*-nitroso compounds, which can cause the formation of DNA adducts. Vitamins C and E block the nitrosation reactions in the intestines and have been shown in animals to protect against the carcinogenic effect of *N*-nitroso compounds.

Numerous case-control studies have examined the relationship between maternal consumption of nitrate and nitrite containing foods and childhood brain tumors; a consistent relationship has been seen for cured meats but not for vegetables.[21,22] In a meta-analysis of maternal cured meat consumption during pregnancy and the risk of childhood brain tumors that included seven observational studies, the pooled RR was 1.68.[23] As part of the US West Coast Childhood Brain Tumor Study, Preston-Martin et al. examined the mitigating effects of vitamin supplementation on risk of childhood brain tumors among women who consumed cured meat.[24] Risk of diagnosis of a brain tumor in her offspring was greater among women who did not take supplemental prenatal vitamins than among women who did take vitamins (OR = 2.4 vs. 1.3). In the group overall, daily use of prenatal vitamins decreased risk of childhood brain tumors by nearly 50% (OR = 0.54).

Multivitamins Supplementation During Pregnancy and Childhood Cancer

Numerous studies have examined how the use of multivitamins periconceptually and during pregnancy affect cancer risk in offspring.[25] In

a meta-analysis,[26] prenatal vitamin use was associated with a reduced risk of brain tumors (OR = 0.73; 95% CI 0.60–0.88), ALL (OR = 0.61; 95% CI 0.50–0.74), neuroblastoma (OR = 0.53; 95% CI 0.42–0.68). One study of retinoblastoma has also shown a reverse association. Studies have consistently have shown a decreased risk of childhood ALL, but not AML, among the offspring of women who took vitamins at time of pregnancy. In a case-control study of children with Down syndrome, chosen as the study population because of their 20-fold increase in risk of leukemia, vitamin use by the mother in the periconceptual period was associated with a reduced risk of ALL (OR = 0.63; 95% CI 0.39–1.00) whereas vitamin use later in pregnancy was associated with an increase in risk.[27]

Because of the evidence that adequate preconceptual levels of folate prevent neural tube defects and other congenital anomalies, both the US and Canada mandated universal fortification of flour products with folate in the mid 1990s. Two ecological studies of the effect of flour fortification with folic acid on rates of childhood malignancy have been reported. The first study from Canada showed that the incidence rate ratios of both neuroblastoma and Wilms' tumor decreased after universal flour fortification with folic acid.[28] The second study examined the impact of universal fortification in the United States.[29] Using SEER data, the incidence of both Wilms tumor and possibly primitive neuroectodermal tumors sharply declined after fortification. There was no observed effect on the rates of neuroblastoma in the United States postfortification.

Fruit and Vegetable Intake During Pregnancy and Childhood Cancers

Two studies have examined the relationship between fruit and vegetable consumption of the mother during pregnancy and risk of childhood ALL and both have shown an inverse association.[30] Another study has shown a moderate association between maternal consumption of fruits and vitamin C and a decreased risk of medulloblastoma/PNET in the offspring.[31] An additional case-control study from Mexico City has shown that incidence of sporadic retinoblastoma in the offspring is associated with lower maternal intake of fruits and vegetables, in particular folate and lutein/zeaxanthin.[32]

Birth Weight and Adult Malignancies

The association between birth weight and breast cancer is the most studied (Figure 57-2); evidence for other adult malignancies is limited. The

hypothesis that the roots of breast cancer could originate in utero was proposed by Trichopoulos in 1990.[33] He suggested that higher levels of maternal estrogens and other intrauterine growth factors could produce higher birth weight[34] and simultaneously affect the developing fetal breast tissue.[35,36] both of which might contribute to a higher risk of breast cancer.

There is a strong relationship between high birth weight and increased risk of premenopausal cancer. Evidence is remarkably consistent across study types (i.e., case-control versus cohort), exposure ascertainment (birth records versus self-reported birth weight), and even countries including populations in Scandinavia, United Kingdom, and the United States.[35] To date, 12 of the 15 studies provide supportive evidence of a relation between premenopausal breast cancer and high birthweight.[35] In meta-analyses of birth weight and premenopausal breast cancer, cohort studies showed a 20% (95% CI: 1.07–1.35I) increase whereas case-control studies showed a 36% (95% CI: 1.15–1.61) increase in risk with each 1,000 g increase in birth weight.[35] In an analysis that combined data from the Nurses' Health Study (NHS) and NHS II (*n* = 152,608 women), women with low birth weights (<5.5 lbs) had a 34% reduction in risk of premenopausal breast cancer incidence (95% CI: 0.47–0.93) compared with high birth weight (>8.5 lbs).[37] The association of birth weight was stronger in estrogen-receptor positive (ER+) and progesterone-receptor positive (PR+) tumors, indicating steroid hormones as a possible mediator between birth weight and breast cancer.[37] Finally, the association of birth weight and future risk of premenopausal breast cancer was independent of other factors later in life (i.e., age of menarche, family history of breast cancer), with the exception of adult height,[37] another risk factor for breast cancer that is established during childhood (see Figure 57-2).[35]

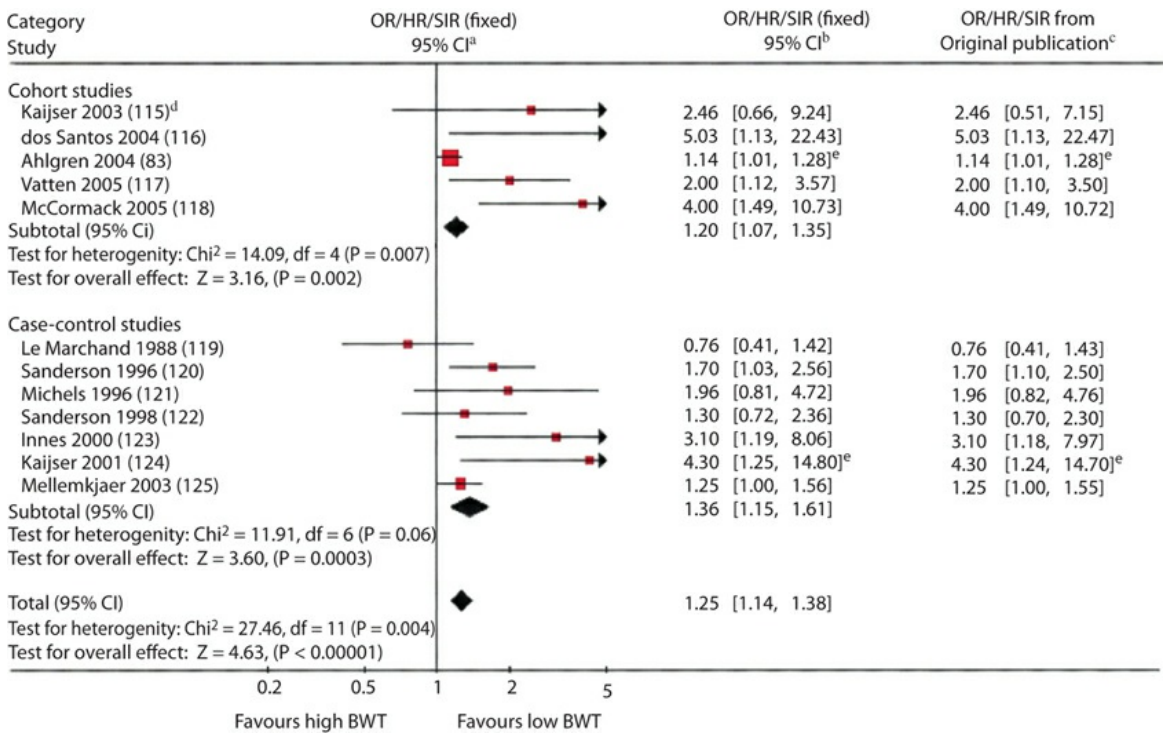

Figure 57-2 Studies on birthweight and the risk of breast cancer among premenopausal women. [a]OR, odds ratio; HR, hazard ratio; SIR, standardized incidence ratio; CI, confidence interval. The square indicates the odds ratio, hazard ratio, or standardized incidence ratio; the size of the square indicates the statistical weight each study contributes to the overall estimate; the line indicates the 95% confidence intervals. [b]Odds ratios, hazard ratios, standardized incidence rate ratios, and 95% confidence intervals generated by Revman through the generic inverse variance method and used in the analysis. [c]Odds ratios, hazard ratios, standardized incidence rate ratios, and 95% confidence intervals from original publication. [d]The number following the last name of the first author indicates the year of publication; the number in parenthesis indicates the reference number of the publication. [e]Effect estimate associated with each 1,000 g increase in birthweight.

In contrast, all but one study to date report no association between birth weight and postmenopausal cancer.[35] The pooled analysis of birth weight and postmenopausal breast cancer reported a relative risk of 1.04 (95% CI: 0.91–1.19) in cohort studies and a RR of 1.04 in (95% CI: 0.66–1.64) case-control studies.[35] The data from the combined NHS cohorts also support this meta-analysis, reporting a RR of 0.97 (CI: 0.08–1.16) of

postmenopausal breast cancer comparing women with a birth weight >8.5 lbs. compared with those <5.5 lbs.[37]

The relationship between birth weight and other cancers have been investigated, although the studies are sparse. Several studies have investigated the relationship between prostate cancer and birth weight but results are inconclusive. In a large Norwegian cohort (n = 19,681), a weak positive association was found between birth weight and risk of prostate cancer comparing the highest quartile of birth weight (>3,925 g) and the lowest quartile (<3,260 g), (RR 1.3; 95% CI: 0.8–2.0).[38] However, the study also reported a significant positive association between birth length comparing the highest (>53 cm) to lowest (<51 cm) quartile and risk for metastatic prostate cancer (n = 33). Also, men in the highest quartiles for both birth weight and birth length had nearly a 4-fold increase in metastatic prostate cancer (RR: 3.8; 95% CI: 1.2–2.0). These findings are consistent with a small Swedish cohort study[39] and the health professionals follow-up study which reported a weak positive association between birth weight and risk of advanced prostate cancer.[40] However, to date, the health and professionals follow-up study and two other studies reported no association of birth weight and risk of total prostate cancer.[40–42]

The association of birth weight and testicular cancer is also unclear. A large cohort study of Swedish men (n = 337,249) found no association between birth weight and total testicular cancer (n = 144) nor in a subset of nonseminomatous testicular cancer (n = 120),[43] although three previous case-control studies had reported a positive association.[44–46]

Two case-control studies have been conducted regarding birth weight and colorectal cancer.[47] Of note, in one case-control study, lower birth weight was associated with increased risk, though the trend across categories was not consistent.[47] Another prior study reported a J-shaped relationship between birth weight and colorectal cancer; the study was based only a few cases and included both men and women in analyses.[48]

Breastfeeding and Childhood Malignancy

Breastfeeding already has many proven benefits for the mother and child, including potentially decreasing the mothers' own risk for ovarian and breast cancer.[49,50] Breastfeeding likely also reduces risk of hematologic malignancy in the offspring.[51,52] Children who have been breastfed for at least six months have approximately a 30% lower likelihood of developing ALL and AML.[53] The effect appears restricted to pre-B cell ALL and M0,

M1, and M2 subtypes of AML. Other studies have suggested a reduction in risk for non-Hodgkin's lymphoma, although not all studies have reached statistical significance due to small number of cases.[51,54,55] The risk of Hodgkin's Lymphoma also appears reduced in two studies[54,56] but inference is limited in other studies due to small sample size.[53,55] The mechanism by which breastfeeding protects against hematologic malignancies in children is postulated to be immunomodulatory, protecting against an inappropriate lymphoproliferative response to an infection or other antigen challenge, rather than due to the nutritive components of breast milk.

Having Been Breastfed and Adult Malignancies

The anticarcinogenic effects of having been breastfed during infancy may persist into adulthood. The most studied relationship is the association of having been breastfed and risk of breast cancer, although the relationship between having been breastfed and site-specific cancers including gastric, colorectal, prostate, and testicular, has also been investigated.[57]

Several hypotheses have been advanced to explain the link between having been breastfed and subsequent risk of breast cancer.

- Early research (1930s) focused on breast milk as a deleterious exposure. The theory was that an "oncogenic" virus could be transmitted from the mother to infant via breast milk, increasing risk of breast cancer later in life for offspring. This hypothesis was first supported in animal models where particular strains of mice could be infected with a tumor virus via breast milk inducing mammary carcinogenesis.[58] Additionally, there is evidence of viral DNA, RNA, and antigen in human breast tissue and milk, and thus there has been continued interest in the possible viral etiology of breast cancer.[59–62]
- Organochlorines, such as polychlorinated biphenyls (PCBs) and Dichloro-Diphenyl-Trichloroethane (DDT), are carcinogenic substances preferentially secreted into breast milk.[63] It has been postulated that breastfeeding is a method used by the body to reduce the mother's burden of these chemicals; and women with higher levels of these chemicals are associated with decreased lactation,[64] thereby possibly reducing breast cancer risk for the mother.[65] However, the infant is exposed to these carcinogenic substances which are implicated in increasing risk of cancer

(including breast) in adulthood. This physiologic situation raises the question as to the optimal duration of breastfeeding, balancing the positive attributes of breast milk against possible extended exposure to carcinogens secreted into the breast milk.[66] At present, the World Health Organization recommends exclusive breastfeeding for the first 6 months of life because of well-documented benefits to both the mother and child.[67]

- Breast milk contains many bioactive components not present in formula such as prostaglandins, hormones, and cytokines, present at especially high levels in colostrum[68] that may affect the offspring's normal breast development but in addition reduce overall child morbidity.[67] Breastfed children may have altered patterns of growth which may impact subsequent risk of breast cancer risk later in life, as reviewed later in this chapter.[60]
- A protein fraction of breast milk, MAL (multimeric alpha-lactalbumin), is a potent agent inducing apoptosis in tumor and immature cells, while sparing mature cells. This unique property of MAL has been proposed as possibly guiding the breast epithelium of the infant toward healthy maturation and away from neoplasm.[69]

The Boyd Orr cohort is one of the few cohort studies with prospective data (rather than recalled data) on breastfeeding and subsequent risk of cancer. The Boyd Orr cohort is comprised of 4,999 children who were ages 0–19 when enrolled as part of Carnegie survey of family diet and health in prewar Britain (1937–1939). In 1988, the children who had been part of the study were recontacted by a team of researchers who were then able to link their childhood experiences with adult disease outcomes. Using data from the National Health Services Central Registry, cancer outcomes from 1948 to 2003 were available on 88% of the original cohort. Martin et al. reported the association of having been breastfed with risk of total cancer, smoking-related and nonrelated cancers, as well as site-specific cancers including breast, prostate, testicular, colorectal, and gastric cancers. For each cancer site, Martin et al. also conducted a meta-analysis of data on breastfeeding and cancer using data available from other cohort and case-control studies.[57]

Analysis of cases from the Boyd Orr cohort itself showed no association between having been breastfed and total cancer incidence nor any of the individual cancers (prostate, breast, colorectal, gastric). In the meta-analyses using data pooled from other studies, there was an 18%

reduction in risk for testicular cancer and having been breastfed, though the association failed to reach statistical significance (95% CI = 0.62–1.10).[57] This result was consistent with one of the individual case-control studies included in the meta-analysis which found that men who had been breastfed greater than 6 months compared with those never breastfed had a reduction in risk of 55% of borderline statistical significance in a dose-responsive manner (95% CI: 0.41–1.04, p-trend = 0.05).[70]

Having been breastfed is associated with a lower risk of premenopausal cancer. The Boyd Orr meta-analysis of breastfeeding and premenopausal breast cancer which included nine studies and a total of 3,346 premenopausal breast cancer incident cases, showed a 12% reduction in risk for premenopausal breast cancer (95% CI: 0.79–0.98).[57] This is consistent with the majority of case-control studies, although the prospective NHS and NHS II cohorts reported a nonsignificant reduction in risk of having been breastfed and premenopausal breast cancer.[57,60,71] In contrast, the Boyd Orr meta-analysis that focused solely on postmenopausal breast cancer showed reported no association (RR: 1.0; 95% CI: 0.86–1.16) (n = 5,069)[57] and is consistent with individual studies.

There are several limitations to the research of having been breastfeeding and later risk of cancer in adulthood. First, in meta-analyses described above, subjects were born in 1874–1972 when alternatives to breastfeeding were primarily unmodified cow's milk. Preparations of infant formula have changed dramatically over time. Rates of breastfeeding have decreased as depicted in NHS cohort, in which 82% of women were breastfed as infants as compared with the younger cohort of women in NHS II, among whom only 31% report having been breastfed as an infant; there was also a decrease in exclusive breastfeeding, likely resulting in mixed feeding.[60] This raises a concern of generalizability of past research to modern day populations worldwide. Second, ascertainment of breastfeeding exposure was generally a simple yes/no question, a rather crude estimate and breastfeeding duration was ascertained in only three studies.[34] Third, timing of breastfeeding initiation is a possible important question since colostrum is dense with immunological factors, a possible mechanism of protection in childhood cancers with possible implications for disease in adulthood. Lastly, residual confounding is possible since infant feeding practices are associated with social, educational, and economical factors.

Adolescence and Breast Cancer: Critical Time Period for

Breast Carcinogenesis

Data from both animal and human studies suggest strongly that the breast is particularly sensitive to carcinogenic exposures that occur after menarche and prior to first pregnancy. In the rat, Russo and Russo have elegantly studied the underlying biology of mammary gland development that explains the phenomenon of this time-sensitive window for exposure.[72,73] The mammary gland, a specialized accessory organ of the skin, is unusual in that, unlike most other organs in the body, it develops entirely postnatally. It is the terminal end of the duct, farthest from the nipple, or terminal end bud (TEB) that undergoes growth and differentiation at the time of puberty. With the advent of menarche and the monthly surges in progesterone and estrogen, the TEB undergoes further cleavage into alveolar buds (AB). At the time of pregnancy, these AB differentiate into lobules that are capable of lactation. Pregnancy permanently alters the architecture of the mammary gland; the multiparous rat's mammary gland has virtually no TEBs and the number of lobules is four times that seen in an age-matched virgin rat.[72,73]

This change in structure is important in terms of carcinogenesis because of the concomitant change that has occurred within the epithelial cells that line these three developmentally distinct structures. The epithelial cells that line the TEB likely represent a pluripotent stem cell that can differentiate into either a myoepithelial cell or a ductal cell. Cell kinetics of TEB are quite different than their more differentiated counterparts. Compared with cells that line the AB, cells in the TEB have much higher DNA labeling index, as measured by incorporation of ^{3}H thymidine, and fewer cells in the G_0 portion of the cell cycle.[72,73] Higher rates of cell proliferation, and less time in the G_0 phase of the cell cycle allow less time for DNA repair, which may be one reason that TEB are more susceptible to carcinogenic exposures than the more differentiated structure of the AB or lobule.

In animals, one of the most reproducible ways to decrease cancer incidence is to restrict calories. The effect of caloric restriction is most pronounced for hormone-sensitive cancers. The effect of reducing calories during different age periods of the rat has been tested and restricting the peripubertal diet of the rat, as compared with the adult diet, is the most potent inhibitor of future cancer risk.[72,73] If the caloric intake of the rats is restricted early in life, the architecture of the mammary gland is permanently altered, with more terminal end buds and lower rates of proliferation in the gland overall.[74] These structural changes remain

evident into the adulthood of the rat, and persist even after pregnancy-induced differentiation. Some insight into the mechanism by which a reduction in calories also reduces risk of cancer is evident from experiments in the worm *Caenorhabditis elegans.* In *C. elegans,* reduced food induces a decrease in an IGF-1–like compound, *daf,* that results in the induction of "diapause," a hibernation-like state of the larva between the juvenile state and adulthood. The breast may also be undergoing a similar developmental arrest.[75]

Few human studies exist on the effect childhood caloric intake and risk of cancer as it is rare to have a study that has data on both childhood diet and adult cancer risk. Analysis of the data from the Boyd Orr cohort did show that for each one megajoule increase in total calories during childhood, there was a 20% increase in nonsmoking related cancers observed as an adult.[76]

Sadly, the Second World War has provided another mechanism to study the effect of war-induced famine on human health. The residents of Norway experienced a chronic reduction in calories due to rationing over the entire timeperiod of the war. Females who were adolescents during the war subsequently had a 13% reduction in risk of breast cancer.[77] A famine in the Netherlands at the end of the war, known as "the Hunger Winter," was more abrupt and severe.[78] The Dutch government in exile ordered a railroad strike to try to cripple the German army; the Nazis retaliated with a transport embargo that severely limited the transport of all food and fuel. Average caloric intake dropped to 600 kcal/d. Women exposed to the famine as children had, as expected, a later age at menarche, reduced height and earlier age at menopause, three factors shown to reduce risk of breast cancer. The effects were strongest for prepubertal children who were 2–9 years old during the Hunger Winter. However, Dutch scientists found that paradoxically the risk of breast cancer was increased, not decreased, among childhood survivors of the famine. Consistent with this increased risk of breast cancer, scientists showed that hormone levels of estrone sulfate were higher in the women exposed to the famine as children, measured 60 years postexposure. Likewise, IGF-1 was also higher among the women who had been exposed to the famine. The authors propose the immediate effects of the famine were as predicted, but that the effect of severe deprivation followed by refeeding reset hypothalamic set points, resulting in lifelong elevations in IGF-1 and steroid hormones. This resetting overrode the short-term results of famine that should have reduced risk of breast cancer and resulted in higher observed rates of breast cancer among the famine-exposed. These two

experiences of famine point out the complexity of the human organism's response to environmental exposures and how the response can modulated by dose (severity of the famine) and by susceptibility of the organism (age at exposure).

Other animal experiments, and human experiences, have highlighted how the age at which exposure occurs can influence the risk of subsequent breast cancer. For instance, chemical induction of tumors in the rat is most potent when the carcinogen is administered *after* 30 weeks of age and *before* 60 weeks of age, the time period analogous to the window between menarche and first pregnancy.[79] In humans, women who survived the atomic bombs in Japan have an elevated risk of breast cancer, but increase in risk is inversely proportional to age at the time of the bombing. Interestingly, no increase in risk at all was observed among women 35 years and older at the time of the bombing. Effects of the treatment for Hodgkin's disease is another example of the importance of age of exposure to radiation in determining subsequent risk of breast cancer. When the mediastinal lymph nodes are involved with lymphoma, Hodgkin's disease patients receive what is known as "mantle irradiation," a radiation field that includes the breast. Women who survive Hodgkin's disease have a markedly increased risk of developing breast cancer, but again, risk is dependent on age at exposure to the ionizing radiation.[80] Similar to the experience of women who were exposed in Japan to the radiation fall out of the atomic bomb, no increase in risk of breast cancer is observed among women who were over age 30 at the time of treatment, but risk rises exponentially the younger the woman was at the time of her mantle irradiation for Hodgkin's disease.

Migrant studies are another indicator of the importance of age at exposure. Migrant studies examine how risk of disease changes when an individual migrates from a country with a low incidence of disease to a country with a high incidence of disease. In the case of breast cancer, studies of Japanese immigrants (low incidence) to Hawaii (higher incidence), rates of breast cancer did not approximate those of US citizens for the immigrants themselves but only for their children and grandchildren.[81] The interpretation of this data is that the immigrant must grow up in the adopted country to "inherit" the cancer risk of the country, pinpointing again the importance of early life and adolescent exposures in breast cancer risk induction.

Childhood and Adolescent Growth and Breast Cancer

Adult height has been correlated with several adult-onset cancers, including colon, prostate, and endometrial cancer, but the association between tall stature and cancer has been most consistently observed in terms of risk of breast cancer, primarily postmenopausal breast cancer. A review of 24 prospective studies[82] found a positive relationship in all but one and since the publication of that review several more studies have confirmed the relationship.[83,84] On average, risk of breast cancer increases by 11% for each 5 cm increase in height.[83,85]

Height is the composite of leg length plus trunk length. Interestingly, leg length and trunk length, though both strongly correlated with total height, are poorly correlated with one another (r = 0.1–0.2)[84,86] and appear to be determined by different factors during childhood and at different times during childhood growth.[87] Growth immediately after birth is due in larger part to leg length than trunk growth. This is demonstrated by the changing ratio of trunk length: height over time. At birth, the ratio is around 0.66 but by puberty, this ratio has declined to 0.50.[87] After puberty, linear growth occurs proportionately in the trunk and the leg. It has been suggested therefore that separate analysis of these two components of height may help elucidate the biologic connections between growth and breast cancer.

Insight on the determinants of leg and trunk height has been gleaned from the 1946 National Birth Cohort study[86] (n = 5,362), a social-class stratified sample of all legitimate births in England, Scotland, and Wales from March 3–9, 1946 who have been followed up on 21 separate occasions between birth and age 53. Adult leg and trunk height were measured by a research nurse at home visit when the subjects were 43 years old. The most important predictor of leg length was early childhood nutrition: having been breastfed (reported at age 2) and total energy intake (reported at age 4).[86] Not living in an “overcrowded” home, a proxy for socioeconomic conditions, was also associated with longer leg length. The determinants of trunk length are less clear than those of leg length. Prolonged childhood illness (> three months or requiring hospital admission) were associated with shorter trunk length as was parental separation, whereas childhood nutrition was not associated with trunk length.

Using data from the Boyd Orr cohort, Gunnell et al. argue that the effect of stature on cancer risk is more strongly correlated with leg length; in fact, the authors report no association was observed between trunk length and risk.[88] Overall, Gunnell reports an 80% increase in risk of non-

smoking related cancers with each one z-score increase (approximately 3–4 mm) in leg length; this effect was even more pronounced in sex-hormone–dependent cancers, such as breast cancer. The association between longer leg length and breast cancer was confirmed in the French E3N cohort.[89] Further elucidation of the separate contributions of trunk length and leg length to the overall association of height and breast cancer may provide insight into the key developmental periods for induction of breast cancer risk.

Earlier age at onset of peak growth velocity and more total growth during puberty have also been associated with increased risk of breast cancer, independent of total stature.[83] A study from Denmark linked school health records in Copenhagen from 1930 to 1975 to the Danish Cancer Registry, resulting in a cohort of 117,415 women, among whom 3340 cases of breast cancer had been diagnosed. Age at peak growth was divided into quintiles. Girls whose peak growth occurred in the oldest quintile (median age 13.5 years) had a decreased risk of breast cancer (RR 0.84) compared with those whose peak growth occurred in the youngest quintile (median age: 10.4 years). Earlier age at peak growth velocity is associated with earlier onset of menarche and therefore more prolonged exposure of the never-pregnant and thus undifferentiated breast to the higher levels of estrogens postpuberty. In the Danish study, age at menarche was a significant predictor of subsequent risk of breast cancer in univariate analysis but not when age at peak growth velocity was also included in the model, indicating that although both are likely a measure of onset of puberty, it is rapid early growth that appears to confer risk. Larger increases in height during puberty (between ages 8 and 14) conferred an increased risk of breast cancer; whereas total height accrued prior to age 8 was not significantly associated with risk of breast cancer.

Adolescent Diet and Breast Cancer

Concern that the period of adolescence is a key and critical period for the induction of breast cancer has lead investigators to also study adolescent diet and breast cancer. The study of adolescent diet and breast cancer is challenging in that it is usually based on recall of diet from the past, which undermines its accuracy due to measurement error.[90] In addition, in the situation where the recall of adolescent diet is collected after the diagnosis of breast cancer, there is the potential for recall bias.

In the NHS and the NHS II, the reproducibility of the recall of adolescent diet has been assessed and effort made to estimate validity of

diet recalled from 15 to 30 years previously.[91,92] In NHS, a short 24-item food frequency questionnaire (FFQ) was added to the main questionnaire in 1986. In NHS II, participants were asked on the main questionnaire if they would be willing to fill out a supplemental questionnaire on adolescent diet. The 124-item supplemental adolescent diet FFQ was completed by 45,947 NHS II participants in 1998. In both cohorts, a subset of the nurse participants who had completed the initial FFQ on adolescent diet were asked to complete a second survey 4–8 years later. In both cohorts, the reproducibility of recall of both foods and nutrients was reasonable (r = 0.5–0.6 [NHS] and r = 0.6–0.7 [NHS II]). The mothers of the participants from the NHS II were also asked to recall their daughters' diets as adolescents. The correlation between the report of the mother versus the daughter was moderate (r = 0.4) but implies some modicum of validity especially when one acknowledges that the mother of an adolescent no longer has the control over diet that a mother would have had at an earlier age, and therefore she may have been unaware of what the daughter was eating outside the home. As an additional approach to assessing the validity of the report, the basal metabolic rate of the NHS II participant as an adolescent was calculated on the basis of her reported weight at age 18. This predicted basal metabolic rate was then used to calculate expected total energy intake. The expected energy intake was compared with the reported energy intake. Participants were categorized as under-, over-, or acceptable reporters. Correlation between the two reports of adolescent diet did not differ by reporter status. In addition, in both cohorts, current adult diet was minimally correlated (r = 0.2) with report of adolescent diet which implies minimal confounding by the content of the current diet. Finally, foods and nutrients were ranked into quintiles. 80% of the reports on the two surveys of adolescent diet were within one quintile of each other. These data in sum show that recall of adolescent diet using a FFQ provides a reasonable estimate, given the many limitations of the method.

In the NHS II, vegetable fat was also observed to be protective to the development of breast cancer (RR 0.58; 95% CI 0.38–0.86) as was Vitamin E (RR 0.61; 95% CI 0.42–0.89).[91] Vitamin E is a fat-soluble vitamin, and vegetable fat (principally peanut butter) is the major source of vitamin E in the adolescent diet of the NHS II participant. In addition, in the analysis of the adolescent diet of the NHS II participant, foods with a higher glycemic index, which are foods that invoke a steeper rise in blood sugar and therefore a compensatory rise in insulin and insulin-like growth factors, were associated with an increase in risk of breast cancer (RR 1.47;

95% CI 1.04–2.08). In the NHS, a significant protective effect was also observed for higher dietary intake of vegetable fat (RR 0.85) and risk of breast cancer.[93]

Red Meat Consumption in Adolescence and Risk of Breast Cancer.

Several case-control studies have examined the issue of adolescent red meat consumption and breast cancer. In a case-control study using cases identified through the SEER registry in three sites, Potischman et al. found a borderline effect for high-fat meats.[94] Hislop et al. conducted a case-control study in British Columbia among 846 incident cases of breast cancer between 1980 and 1982.[95] Women were asked to recall dietary intake of 31 foods during early childhood (up to age 13). Among premenopausal women, consumption of meat with visible fat during childhood was associated with increased risk of breast cancer (RR for "three or more times per week" compared with "less than once per month" = 2.69; 95% CI 1.26–5.80). A more recent analysis of premenopausal women in NHS II showed that increased levels of red meat consumed during adolescence was associated with a significant linear trend for premenopausal breast cancer risk; this risk was most pronounced for estrogen-positive tumors.[96] Supporting the possible role of red meat in breast cancer etiology, a case-control study of Chinese immigrant women reported that high consumption of red meat during adolescence, but not during adulthood, was associated with a significantly higher adult mammographic breast density.[97]

In another case-control study that used a limited version of the Bloch FFQ to assess only foods high in fat and fiber, Pryor et al. reported that higher intake of fat from dairy sources was associated with decreased risk of breast cancer for both pre- and postmenopausal women.[98] In the same study, higher intake of fiber decreased risk among premenopausal women, whereas higher intake of fiber was associated with an increased risk of breast cancer among postmenopausal women. Consumption of vegetable oils was associated with reduced risk among premenopausal women (RR = 0.48; 95% CI 0.25–0.89), analogous to the findings from the NHS and NHS II.

Adolescent Soy Intake and Breast Cancer

Several recent studies have focused on adolescent soy intake and breast cancer. Phytoestrogens have been shown in animal models to promote

differentiation of the mammary gland by enhancing the transition from terminal end buds to AB or lobules.[99] All four case-control studies to date have shown a protective effect for adolescent soy intake,[100–103] which was especially pronounced in the two studies that compared adolescent versus adult intake. In one study those individuals who indicated high intake in both time periods had 50% reduction in risk of breast cancer,[101] whereas in the other study, the greatest reduction in risk was associated with consumption during childhood (OR = 0.42; 95% CI 0.20–0.90).[102]

Adolescent Diet and Benign Breast Disease

Benign breast disease (BBD) is catch-all phrase that includes several different types of pathologic lesions, some with no relation to breast cancer and some that dramatically heighten risk. Non-proliferative BBD has no bearing on subsequent risk of breast cancer, whereas women with proliferative lesions without atypia have 1.5- to 2-fold great risk; women who have proliferative lesions with atypia have a 3.5- to 5-fold greater risk of breast cancer.[104] A mathematical model of breast cancer also has shown that BBD confers an increased risk of breast cancer, even when adult risk factors are included in the model, suggesting that it is early life events that determine risk. Therefore, proliferative BBD is considered an intermediate marker of risk for breast cancer. That reflects adolescent exposures in particular.

In an analysis from the NHS, a retrospective analysis of diet during adolescence and subsequent risk of proliferative BBD showed that higher intakes of vegetable fat, vitamin E and fiber during adolescence were inversely related to risk. In addition, it was shown that whereas recent alcohol did not affect risk of BBD, remote consumption of alcohol between ages 18 and 22 increased risk for both proliferative and nonproliferative BBD.[105]

Childhood Diet and Age at Menarche

Earlier age at menarche is a strong risk factor for breast cancer. In fact, it has been estimated that risk of breast cancer increases by 4% for each yearly decrease in age at menarche.[106] Earlier age at menarche is also a risk factor for endometrial cancer. Examinations of the dietary predictors of age at menarche have been sparse. Most dietary hypotheses have had null results.[107–109] A study in Germany showed that energy-adjusted fat intake was associated with accelerated menarche,[110] but this finding was not replicated in a study in Canada.[110] In fact, the Canadian study reported

that higher intake of monounsaturated fat was associated with a delay in menarche. Several studies have shown an association between higher intakes of dietary fiber and later age at menarche.[111–114]

SUMMARY

Data from a variety of sources support the notion that diet during childhood, beginning in utero and extending through adolescence, has an impact on the incidence of childhood as well as adult malignancies. Some of the evidence is based on the relationship between childhood growth and cancer; both abnormal growth patterns as in the Beckwith–Wiedemann syndrome, and "normal" growth, for instance, the relationship between birth weight and childhood ALL or height and breast cancer. Other studies have been able to pinpoint foods or nutrients that may impact risk of cancer, such as nitrate-containing meats and pediatric brain tumors, periconceptual folate and Wilms' tumor, or topoisomerase II inhibitors and infant AML. Timing of the exposure is a key variable; for instance, topoisomerase II inhibitors are not implicated in the genesis of AML that develops later in childhood and vegetable oil has not been found to have an effect on rates of breast cancer when consumed in the adult diet, only in the adolescent diet. The availability of validated tools such as the FFQ that allow diet to be measured efficiently and accurately in prospective large-scale, population-based studies will allow for the ascertainment of further relationships between diet and cancer, avoiding the inherent recall bias of case-control studies. Finally, the interaction between nutrition, genes, and cancer will become more interesting as the inter-relationships are elucidated and we understand more about how diet interacts with genetic susceptibility.

Cancer Treatment

58

Lori J. Bechard, PhD, MEd, RD, LDN and Christopher Duggan, MD, MPH

INTRODUCTION

Nutritional care for children with cancer is an essential component of treatment. Changes in nutrient metabolism, dietary intake, and body composition[1] occur in pediatric cancer patients as a result of disease and subsequent treatment. These changes can obscure nutritional deficits for growing children. Nutritional assessment of the child with cancer is important for identifying and treating malnutrition, and for ensuring the appropriate provision of nutrients to promote recovery and long-term health. Deviations in normal growth patterns may occur as a result of the disease, treatment, or other underlying causes. Being overweight or underweight has been associated with greater treatment-related mortality.[2]

Chronic health conditions, many of which have a relationship with nutritional intake, are common among survivors of pediatric cancer.[3] Obesity, hyperlipidemia, and diabetes combined with risk for subsequent cancers reveal the importance of nutrition beyond the acute stages of treatment. Families of children with cancer may be especially concerned with weight[4] and nutritional therapy, for both the important psychosocial aspects of eating and the potential for synergistic intervention with immediate and long-term medical therapies. We review the metabolic effects of pediatric cancers and their treatment, highlighting the nutritional conditions and interventions encountered by children from diagnosis to long-term survival. The role of nutrition in the prevention of cancer is described in Chapter 57.

PREVALENCE OF MALNUTRITION IN

PEDIATRIC CANCER

Among children from infancy to age 14, cancer is the leading cause of death by disease in the United States.[5] The incidence of childhood cancer in the United States during 2007-2009 was 17.2 cases per 100,000 children under the age of 20 years; the most common pediatric malignancy was acute lymphocytic leukemia (ALL), followed by brain and other central nervous system (CNS) tumors.[5] Although US pediatric cancer incidence has increased slightly over the past 30 years, mortality rates have declined by more than 50% for many childhood cancers, and the five-year survival rate for all pediatric cancers has increased from 63% in the 1970s to 83% in 2012.[5]

Malnutrition prevalence at presentation and during treatment varies with underlying history, host susceptibility, tumor type and location, and treatment regimen.[1] Relapsed malignant disease, hematopoietic stem cell transplantation (HSCT); tumors of the abdomen, head, or neck; and other advanced-stage solid tumors are clinically associated with poorer nutritional status than lower risk diseases. In general, children with solid tumors have a greater incidence of malnutrition.[6] Malnutrition is more prevalent among children with cancer in developing countries, which may impact survival rates in these areas.[7] High rates of obesity have been observed during and following treatment for acute leukemia.[8] A variety of pediatric cancer diagnoses can be grouped according to their nutritional risk (Table 58-1).

Weight loss may be considered the final step in a long process of nutritional perturbation in patients with cancer, and as such it may not be a useful indicator of malnutrition. The use of body mass index (BMI) as a marker of nutritional status may be inaccurate due to its inability to distinguish changes in lean body mass. Children undergoing treatment for cancer have reduced body cell mass and increased fat mass compared to control subjects, and these changes do not correlate well with BMI.[9] Overt signs of malnutrition do not typically present at diagnosis with leukemia, although elevations in cytokine antagonists and reductions in plasma proteins, compared to controls, have been observed, suggestive of an early malnourished state.[10] Although measures of body weight are commonly used to identify nutritional problems, the weight of tumor masses may obscure changes in lean body mass. A study of Canadian children diagnosed with cancer found that measurements of midarm circumference correlated better with lean body mass, as assessed by dual-energy X-ray absorptiometry (DXA), than BMI.[11] Lean body mass declines substantially

with the use of chemotherapy.[12] Assessment of the nutritional status of children with cancer should include consideration of changes in body composition that may result from disease, treatment, or both.

TABLE 58-1 Nutritional Risk Groupings of Pediatric Malignancies and Associated Conditions

- High risk
  - Relapsed disease
  - High-risk ALL
  - Acute myelogenous leukemia
  - Advanced-stage solid tumors
    - Neuroblastoma
    - Wilm's tumor
    - Lymphoma (Hodgkin's and non-Hodgkin's)
    - Hepatoblastoma
    - Medulloblastoma
    - Ewing's sarcoma
    - Osteosarcoma
  - Tumors involving the head, neck, or abdomen
  - Hemophagocytic lymphohistiocytosis
  - HSCT
- Low risk
  - Standard-risk leukemia
  - Early-stage solid tumors
- Obesity risk
  - ALL
  - Brain tumors with hypothalamic damage
  - Treatment including extended courses of corticosteroids

Cancer Cachexia

Wasting is defined as involuntary weight loss and is found in many patients with chronic disease, including cancer, kidney disease, cardiac disease, and advanced HIV infection. Overall loss of body weight, including fat and fat-free mass, occurs as a result of the energy imbalance caused by disease. Cachexia, in contrast with wasting, is defined as involuntary loss of lean body mass with or without overall weight loss. In this scenario, patients of normal or even excessive weight can still be malnourished due to diminished lean body mass. This loss of muscle is known to negatively influence recovery and reduce survival in patients with cardiac disease and cancer.[13] Because this decline in lean body mass has much functional and prognostic significance, this type of malnutrition is important to identify.

Differential loss of body fat versus fat-free mass implies a different

etiology and prognosis of malnutrition than simple starvation. Prolonged fasting typically leads to a predictable decrement first in body fat and then in body protein stores. In this case, energy repletion is usually successful with the careful provision of adequate energy, protein, and micronutrients.

In contrast, children with cancer experience reductions in fat-free mass both at diagnosis and during treatment, and some have concomitant increases in fat mass.[1] These changes are significant, because loss of lean body mass is associated with important functional changes including loss of strength, decreased immune function, decreased pulmonary function, increased disability, and death.

METABOLIC EFFECTS OF CANCER

The presence of malignancy results in several important changes in macronutrient metabolism, and these metabolic alterations can in turn affect energy balance. Metabolic effects of cancer are variable and depend in part on tumor types and sizes, chemotherapies used in treatment, as well as several host factors, including nutritional status. However, a general understanding of these aberrations is useful in anticipating potential metabolic complications as well as planning nutritional therapy.

Carbohydrate

Multiple metabolic shifts in glucose homeostasis tend to increase blood concentrations of glucose in cancer. These include increased gluconeogenesis (conversion of amino acid carbon skeletons to glucose) and increased Cori cycling (hepatic conversion of lactate to glucose). Increased conversion of lactate to glucose may be due in part to increased lactate production by selected tumors. Combined with insulin resistance, the enhanced production of glucose provides the tumor with ample substrate that is readily metabolized under both aerobic and anaerobic conditions.

Lipid

Multiple changes in lipid metabolism in cancer include increased free fatty acid turnover, increased free fatty acid oxidation, increased glycerol turnover, greater lipolysis, and lower rates of lipogenesis. A lipid mobilizing factor has been isolated from the urine of cachectic cancer patients and shows bioactivity with isolated murine adipocytes.[14] In addition, there can be a marked loss of body fat that can occur early in the

evolution of malignancy. Hypertriglyceridemia can be observed among children with acute lymphoblastic leukemia, those with widespread solid tumors, and patients treated with L-asparaginase.[15] The provision of glucose does not seem to resolve the high rates of fatty acid and glycerol turnover evident in weight-losing cancer patients.[16] Treatment with chemotherapy is associated with decreased fat utilization in children newly diagnosed with acute lymphoblastic leukemia.[17]

Protein

Cancer is often associated with an acute-phase response blood profile, with low synthesis rates of albumin, prealbumin, and transferrin and increased synthesis rates of C-reactive protein, fibrinogen, and ferritin.[18] Some tumors such as hepatocellular cancer exhibit very high rates of protein turnover and increased protein degradation.[19] A net loss of skeletal muscle protein is a common finding with malignancy and is particularly problematic in the growing child. An increase in muscle protein breakdown mobilizes amino acids that may assist tumor growth as well as fuel gluconeogenesis. This increased protein breakdown in pediatric cancer patients may be related to falling levels of insulin-like growth factor (IGF-1) and insulin-like growth factor binding proteins[20] and decreased skeletal muscle protein synthesis.

Cytokines

Proinflammatory cytokines commonly associated with cancer cachexia include tumor necrosis factor-α (TNF-α), interleukin-6 (IL-6), interleukin-1 (IL-1), and interferon-γ (INF-γ). These cytokines are secreted by macrophages and lymphocytes and may represent the host response to cancer. Administering TNF-α to humans produces effects associated with cancer cachexia including increased fatty acid turnover, elevated glycerol turnover, and increased whole-body protein turnover.[21] Not all patients with cancer cachexia have detectable levels of TNF-α; hence, a paracrine or autocrine mechanism of action may be responsible. Other factors also seem to be involved with the catabolic response to cancer. Circulating IL-6 levels are generally elevated in cancer patients, supporting its role in causing cachexia. As with TNF-α, the precise mechanism of action of IL-6 is unknown. The metabolic roles of IL-1 and INF-γ are less well characterized in tumor models; however, like TNF-α and IL-6, they appear to inhibit lipoprotein lipase and hence facilitate lipolysis.

Energy Balance

Energy expenditure measurements of children with cancer have been observed in a variety of clinical scenarios. Stallings and others measured resting energy expenditure (REE) in nine patients with ALL and found that patients with a higher tumor burden (elevated white blood cell count, organomegaly) had an increased REE.[17] On the contrary, a study of 26 patients with ALL or solid tumors in remission showed no elevations in REE compared to age- and sex-matched healthy controls.[22] Reilly and others[23] studied 20 preadolescent children with ALL with doubly labeled water. Compared to healthy controls matched for age, sex, and body composition, children with ALL had significantly lower total energy expenditures than controls by an average of 282 kcal/d. Most of this reduction was due to reduced physical activity. Any deviation in energy expenditure can result in energy imbalance and potentially undesirable weight loss or gain; thus, a careful look at changes in expenditure is worthwhile.

Lean body mass is the primary predictor of energy expenditure, so it follows that reductions in lean body mass related to cancer treatment could affect energy expenditure. Patients with head and neck cancer experienced changes in REE, as measured by indirect calorimetry, when prospectively evaluated prior to treatment; at weeks 2, 4, and 6 during treatment; at the end of treatment; and at two weeks following completion of treatment. Whereas REE was higher than that predicted by standardized equations in this small group of adults, REE declined significantly over time and followed a U-shaped curve from pretreatment to posttreatment.[24] Studies of children undergoing HSCT have implicated a relationship between changes in REE and reductions in lean body mass during this medically intense treatment. Ringwald-Smith and others compared weekly measured REE in 34 children undergoing autologous or allogeneic stem cell transplantation to standardized equations and found that REE was significantly less than predicted except at 14 days after transplant.[25] A prospective study of 37 children undergoing allogeneic transplantation described a significant decline in REE from baseline to week 3 after HSCT.[26] Moreover, a second study of children undergoing HSCT demonstrated significant reductions in REE over the course of transplant, which correlated with reductions in lean body mass.[27] These changes appeared to be unaffected by the level of energy provision.[28] Studies suggest that treatment-related changes in REE occur, which may be related to reductions in lean body mass. Further explorations of REE as it relates

to changes in body composition in children with cancer are needed.

METABOLIC EFFECTS OF TREATMENT

Treatments used in pediatric cancer cause systemic side effects that exacerbate the symptoms of the tumor itself. A combination of agents, including radiotherapy, chemotherapeutic drugs, and surgery, is commonly used to treat pediatric cancers, particularly high-risk diseases. Radiation therapy, widely used in the treatment of leukemia and brain tumors, is known to cause localized end-organ damage. Diarrhea and malabsorption with fluid and electrolyte losses may result when the abdomen or pelvis is radiated. Radiation to the head and neck areas may similarly cause damage to taste, chewing, and swallowing functions. Nutritional status may be affected by surgical interventions depending on the site of the tumor and the extent of the resection. The efficient digestion, ingestion, absorption, and utilization of food are complex processes. Surgical disruption with impaired swallowing, decreased gastric reserve, or reduction in intestinal length can result in decreased oral intake as well as absorption of nutrients.

Many chemotherapeutic agents are known to cause anorexia, with or without nausea and vomiting; enteritis with malabsorption and diarrhea; mucositis; and constipation. Taste perception is often altered in cancer patients receiving chemotherapy; this phenomenon further contributes to anorexia and reduced food intake. Mucosal damage is generally dose related, with increased risk of mucosal toxicity with high-dose induction therapy, escalating dosage patterns, continuous infusion (versus bolus doses), and combination chemotherapy treatments. Oral and gastrointestinal mucositis represent major complications of cytotoxic chemotherapy and radiotherapy, which lead to significant morbidity, pain, odynophagia, and poor intake as well as nausea and vomiting. Examples of commonly used chemotherapies and applicable nutrition-related toxicities are presented in Table 58-2.

Myeloablative HSCT is typically reserved for those cases having no other reasonable options, because it is known to be a high-risk, highly toxic intervention (Table 58-3). High-dose chemotherapy and total-body irradiation as conditioning for HSCT frequently cause prolonged oral and gastrointestinal mucositis that can reduce nutritional intake for days to weeks. Another adverse effect of HSCT is hepatic veno-occlusive disease (VOD), a syndrome of hepatomegaly, jaundice, and fluid retention, which in its severe form, may cause renal and respiratory failure. The cholestasis and fluid management of hepatic VOD has nutritional implications in that

it will almost certainly impact available volume for nutrient and fluid provision. Graft-versus-host disease (GVHD), a condition involving the attack of newly engrafted cells on the host recipient, can occur following allogeneic HSCT. Acute gastrointestinal GVHD can cause symptoms ranging from mild nausea and anorexia to profuse, bloody diarrhea. Acute skin GVHD can similarly manifest as a mild rash or progress to severe epithelial sloughing, akin to a burn injury. Other organ systems may also be affected. Most children with severe acute GVHD will require intensive, individualized nutrition support while high-dose immunosuppression is used to treat the disease process.

Chronic GVHD typically occurs more than 100 days following transplant and while its initial presentation tends to be less severe than acute GVHD, it is associated with significant long-term morbidity and mortality.[31] Skin, liver, mouth, and eyes are the most commonly affected sites.[32] Multiorgan disease often affects the skin and oral cavity, as well as the lung and liver, while single-organ disease is more frequently found in the liver or skin.[33] The incidence of chronic GVHD is lower in children than in adults; however, its manifestations are uniquely problematic to children. Malnutrition and accompanying growth failure is common, but poorly understood.[33] Other complications include bone loss, steroid-induced weight gain, dysphagia, and depression. Treatment of chronic GVHD typically employs therapy beyond first-line immunosuppression with steroids and calcineurin inhibitors.

TABLE 58-2 Nutrition-Related Side Effects of Commonly Used Chemotherapies in Childhood Cancer

Chemotherapeutic Drug	Diseases Targeted	Toxicities
Alkylating agents		
Mechlorethamine (nitrogen mustard)	Hodgkin's disease	N&V, phlebitis, mucositis
Cyclosphosphamide	Lymphomas, leukemias, sarcomas, neuroblastoma	N&V, cystitis, water retention, cardiac (HD)
Ifosfamide	Sarcomas, germ cell	N&V, cystitis, renal, cardiac (HD)
Melphalan	Rhabdomyosarcoma, sarcomas, neuroblastoma,	N&V, mucositis, diarrhea (HD)

	leukemias (HD)	
Lomustine, carmustine (CCNU, BCNU)	Brain tumors, lymphoma, Hodgkin's disease	N&V, renal, pulmonary
Busulfan	CML, leukemias (HSCT)	Pulmonary, N&V, mucositis, hepatic (HD)
Cisplatin	Testicular, other germ cell, brain tumors, osteosarcoma, neuroblastoma	N&V, renal
Carboplatin	Brain tumors, germ cell, neuroblastoma, sarcomas	N&V, hepatic
Dacarbazine	Neuroblastoma, sarcomas, Hodgkin's disease	N&V, flu-like syndrome, hepatic
Temozolomide	Brain tumors	N&V
Procarbazine	Hodgkin's disease, brain tumors	N&V, rash, mucositis
Antimetabolites		
Methotrexate	Leukemia, lymphoma, osteosarcoma	Mucositis, rash, hepatic, renal
Mercaptopurine (6MP)	Leukemia (ALL, CML)	Hepatic, mucositis
Thioguanine	Leukemia (ALL, AML)	N&V, mucositis, hepatic (VOD)
Fludarabine, cladribine	Leukemia, lymphoma	Opportunistic infections, renal
Clofarabine	Leukemia	Hepatic, hypokalemia, inflammation
Nelarabine	T-cell leukemia	Somnolence, peripheral neuropathy
Gemcitabine	Hodgkin's, sarcomas	N&V, hepatic, mucositis, flu-like syndrome, edema, rash
Cytarabine (Ara-C)	Leukemia, lymphoma	N&V, mucositis, GI, flu-like syndrome, ocular, skin (HD)
Fluorouracil (5FU)	Carcinomas, hepatic tumors	Mucositis, N&V, diarrhea, skin, ocular, cardiac
Antitumor antibiotics		
Doxorubicin (adriamycin), daunomycin, idarubicin	Leukemia (ALL, ANLL), lymphomas, solid tumors	Mucositis, N&V, diarrhea, cardiac
Mitoxantrone	Leukemia (ALL, ANLL), lymphomas	Mucositis, N&V, bluish color to urine, veins, sclerae, nails

Bleomycin	Lymphoma, testicular, other germ cell	Lung, skin, fever, mucositis, Raynaud's, N&V
Dactinomycin (actinomycin-D)	Wilm's, sarcomas	N&V, mucositis, hepatic (VOD)
Plant products		
Vincristine	Leukemia (ALL), lymphomas, solid tumors	SIADH, hypotension, constipation
Vinblastine	Histiocytosis, Hodgkin's disease, testicular	Mucositis
Etoposide	Leukemias (ALL, ANLL), lymphomas, neuroblastoma, sarcomas, brain tumors	N&V, mucositis, hypotension, secondary leukemia, diarrhea (PO dosing)
Teniposide	Leukemia (ALL)	N&V, mucositis, hypotension
Topotecan	Neuroblastoma, rhabdomyosarcoma	Diarrhea, mucositis, N&V, rash, hepatic
Chemotherapeutic Drug	Diseases Targeted	Toxicities
Irinotecan	Rhabdomyosarcoma	Diarrhea, N&V, hepatic, dehydration, ileus
Kinase inhibitors		
Imatinib mesylate (Gleevec®)	Ph chromosome + CML	N&V, fatigue, GI, hepatic
Dasatinib	Ph chromosome + ALL, CML	Fluid retention, rash, nausea, bleeding, diarrhea
Sorafenib	Renal cell carcinoma, hepatocellular carcinoma	Rash, hypertension, diarrhea, N&V, bleeding
Sunitinib	GI stromal tumors, renal cell carcinoma	Cardiac, hypertension, diarrhea, N&V, GI, mucositis, bleeding, rash
Bevacizumab	Carcinomas, glioblastoma	Infusional reaction, rash, proteinuria
Erlotinib, gefitinib,	Carcinomas	Rash, diarrhea
Other agents		
Corticosteroids (prednisone, methylprednisolone, dexamethasone, decadron)	Leukemia, lymphomas, brain tumors	Increased appetite, centripetal obesity, myopathy, osteoporosis, pancreatitis, hypertension, diabetes, growth failure, impaired wound healing

Asparaginase (L-ASP, PEG-ASP)	Leukemia (ALL), lymphoma	Pancreatitis, hepatic
All-trans-retinoic acid (ATRA, tretinoin)	Acute promyelocytic leukemia	Retinoic acid syndrome (weight gain, respiratory distress, cardiac & renal failure), cheilitis, dry skin, η-triglycerides
13-*cis*-Retinoic acid (isotretinoin, accutane)	Minimal residual disease neuroblastoma	Cheilitis, dry mouth, bone & joint pain, η-triglycerides, η-Ca^{++}

Abbreviations: N&V, nausea and vomiting; HD, high dose; CML, chronic myelocytic leukemia; AML, acute myelogenous leukemia; CLL, chronic lymphocytic leukemia; GI, gastrointestinal; ANLL, acute nonlymphoblastic leukemia; SIADH, syndrome of inappropriate antidiuretic drug hormone secretion; ↑, increased.

ETIOLOGY OF ANOREXIA IN CANCER TREATMENT

As indicated in earlier sections, malignancies and their treatment can have a considerable effect on a child's nutritional status. Frequently occurring nutritional problems with cancer treatment are depicted in Figure 58-1.

Anorexia can be a side effect of any disease. Food aversion and anorexia may be linked with nausea and vomiting. While the pathophysiology of cancer and its treatment undoubtedly cause nutritional risk, eating problems are multifactorial in nature. Psychological factors are also important to consider in evaluating the reasons for inadequate dietary intake. Depression-related anorexia is probably underappreciated as a cause.

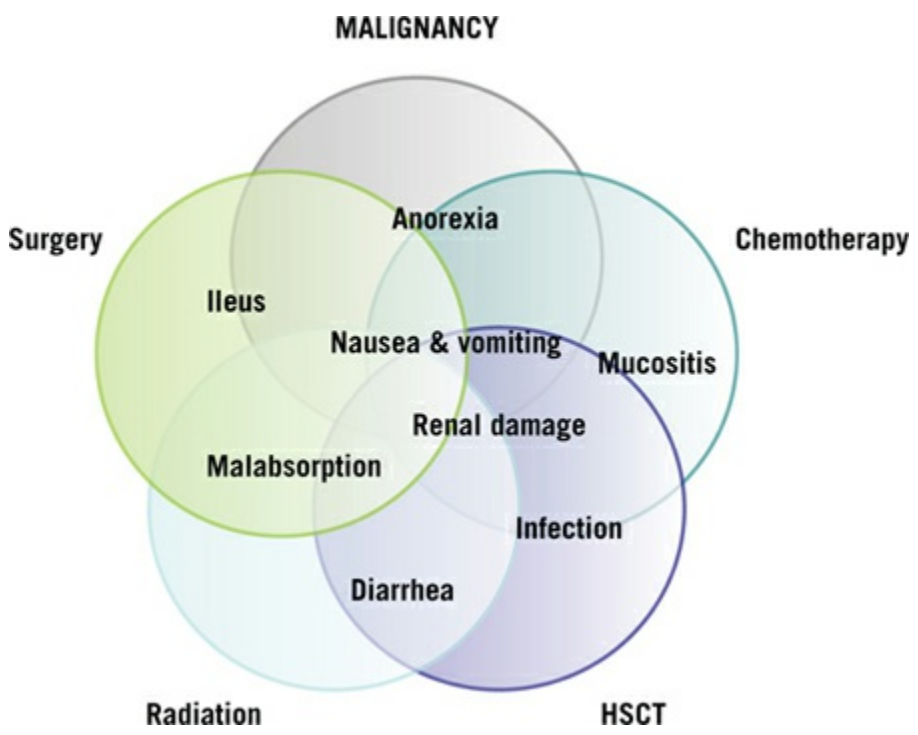

Figure 58-1 Nutrition-related problems in pediatric cancer treatment

The ability of children to eat at their appropriate developmental level may affect the nutritional adequacy of their diet. Anorexia, mucositis, and other effects of cancer treatment may interrupt the normal progression of feeding skills in infants and young children. Once arrested, the development of these skills may be difficult to restore. The resumption of eating can be a lengthy and difficult process and may extend the time frame of cancer recovery. Poor swallowing and chewing abilities will lengthen the time required to complete a meal and thus may lead to inadequate consumption of many required nutrients. Children may refuse to eat their preferred foods due to adverse associations or other impairments and thus may self-restrict their intake.

The impact of a cancer diagnosis on family dynamics and related behaviors should not be overlooked. Relationships between patients and caregivers influence nutritional intake, both positively and negatively. Appetite and feeding behaviors are inherently complicated activities of all children, and this behavior can obviously be affected by the onset of illness, its treatment, as well as the psychosocial impact that cancer has on the child and family. The nature of cancer medical care is such that parents often feel that they are relinquishing much of their usual caregiving behavior to the medical and nursing staff. Some parents understandably cling to the provision of food and nutrients as a critical part of parenting. Occasionally, such strong feelings concerning food and dietary intake can cause conflict between parent and child and be counterproductive to the goal of optimal nutrition. Discord among family members can lead to further negative consequences to the feeding relationship.

NUTRITIONAL ASSESSMENT OF THE CHILD WITH CANCER

The assessment of a child with cancer includes the standard elements of a nutritional evaluation: history of past and present illness, review of dietary intake and nutritional history, physical examination, and anthropometric measurements. Inquiry for suspected or measureable body composition changes should also be considered, as well as a review of pertinent laboratory measures.

History

A detailed medical history is essential to the nutritional evaluation of a patient. Important oncologic history includes the type and stage of the tumor, intensity of the antitumor therapy, presence or absence of remission, and timing and type of future treatment. Nutritional history entails (1) current symptoms of cancer and its therapy and their effect on nutrient intake, absorption, and retention; (2) growth history, previous antitumor therapy and its effects on nutritional status; (3) developmental status, with special attention to milestones of feeding skills and swallowing function; (4) known or perceived food allergies or intolerances; (5) medications, with special attention to those with gastrointestinal and metabolic side effects; (6) family history, parental heights, and sibling growth patterns; (7) social history, food preferences/beliefs, and food availability; and (8) a thorough diet history

obtained from the patient and/or caregivers.

Physical Examination

The physical characteristics of a child with cancer may suggest the presence of nutritional problems. Indeed, the predisposition of chemotherapy to affect tissues of rapid turnover (e.g., hair and gastrointestinal mucosa) parallels the symptoms of deficiency of several nutrients (e.g., stomatitis with some B vitamins and alopecia with biotin deficiency). Careful inspection and palpation of subcutaneous fat and muscle stores are particularly important in the physical examination, because deficits of these two components of body stores are common in malnutrition.

The general physical examination may show edema as a result of low concentrations of circulating albumin. This can be a subtle finding with only mild hypoalbuminemia. Edema may actually mask progressive muscle wasting and loss of lean body mass. Hypoalbuminemia may be due to poor liver function related to tumor or treatment, inadequate protein intake, or nutrient losses in excess of intake. Painful mouth or esophageal sores caused by mucositis can reduce a child's ability to eat and thus be a reason to consider nutritional support. Children who have limited mobility due to impairment by disease or treatment side effects may experience changes in appetite or satiety. Recognition of these aspects of the physical examination is a valuable component of the overall nutritional assessment of the child with cancer.

Anthropometry

Weight and height measured over time are the foundation of nutritional monitoring and evaluation. These objective measures of nutritional status provide the most information with the least inconvenience and cost. Weight should be measured daily in the hospital setting and at each office visit for outpatients. Height/length measurements should be recorded monthly. Accurate technique is critical to the validity of the measures; detailed methodologies are reviewed in Chapter 2.

The incidence of weight and height deficits in children with cancer has been reported to be quite high, depending on the severity and type of cancer and its treatment.[1,34] However, with the increased incidence of obesity in children, and the predisposition of some pediatric cancer patients to become obese,[8] it is also important to screen for overweight. For children under the age of 2 years, this can be done by examining the

weight for height z scores using the World Health Organization (WHO) 2006 growth curves. For older children, BMI is a more suitable measure of body fatness. Children with BMIs greater than the 85th percentile for age and sex are termed overweight, and those with BMIs greater than the 95th percentile are obese.[35] Growth curves for BMIs are included with the National Center for Health Statistics 2000 growth curves as well as the WHO 2007 growth reference. See Appendix I.

Arm Anthropometrics

Arm anthropometrics are an inexpensive, noninvasive, and widely accepted technique for estimating body composition against established normal values (see Chapter 2). Triceps skinfold, mid-upper arm circumference, and computed values of midarm muscle area and midarm fat area correlate well with more accurate and sensitive measures of body composition.[36] Percentiles and standards for comparisons for triceps skinfolds and midarm muscle area are available[37] and may indicate the presence of malnutrition when weight or height is unavailable or unreliable, as in the case of a growing tumor mass.

In a convenience sample of children undergoing treatment for cancer in Australia, skinfold measurements were more closely correlated with percentage body fat measured by air displacement plethysmography than weight, height or BMI z scores.[38] Midarm circumference was significantly correlated with lean body mass as measured by DXA in a study of children newly diagnosed with cancer.[11] These studies suggest that arm anthropometrics may be reasonable surrogates for precise measures of body composition and likely better indicators of nutritional status in children with malignancy than weight and height alone.

Other Measures of Body Composition

Anthropometric measurements may be confounded by technique, inaccuracy of equipment, lack of patient cooperation, and poor interindividual reliability. Because lean body mass is considered the most metabolically active component of the body, it would be preferable, therefore, to characterize nutritional status by an accurate and dependable measure of lean body mass. Patients with solid tumors prior to reduction or excision and patients with fluid imbalances are particularly susceptible to inaccurate nutrition assessment based on anthropometric measurements.

DXA is becoming increasingly available for clinical use. A whole-body DXA assessment measures total-body bone mineral content, nonbone

lean tissue, and fat, as well as bone mineral density, thereby providing body composition information using a three-compartment model. Elevations in body fat mass measured by DXA without a concomitant rise in BMI (kilogram per square meter) have been reported in several studies of cancer survivors.[39,40] Others have shown similar trends in body fat mass measurements. Warner and others found that a group of children treated for ALL with chemotherapy and cranial radiation had a significantly greater percent of body fat, as measured by DXA, than age-matched groups with other malignancies or healthy controls.[41] When combining the DXA measurements of fat-free mass with measures of total-body water and total-body potassium, children with ALL in this cohort had a significantly lower hydration and potassium state of their fat-free mass than those with other malignancies and controls. Conversely, a cross-sectional study of children in remission from ALL showed a significantly higher hydration fraction of fat-free mass compared to healthy age- and sex-matched controls, using DXA and a four-component model of body composition assessment.[42] Another study of 25 children who had undergone allogeneic HSCT at least four years previously showed that their mean BMI was 0.45 z scores lower ($p < .05$) but that percent body fat as measured by DXA was 1.1 z scores higher than controls ($p < .001$).[43] Furthermore, deficits in lean mass exceed overall BMI declines in survivors of childhood malignancy and HSCT.[44] These studies confirm the utility of assessing body composition in children with cancer to reveal clinically important changes relevant to nutrient provision. While the ultimate applicability of DXA scanning to nutritional assessment is still evolving, it is now widely used as a reasonable method to evaluate body composition in both clinical and research settings.

Laboratory Evaluation

Although laboratory evaluation of the pediatric cancer patient is commonly performed to assess the hematologic and metabolic response to cancer and its treatment, nutritional status should also be monitored with select biochemical parameters. Serum electrolytes and mineral concentrations are commonly deranged during treatment of cancer, especially when nephrotoxic agents are employed. A specific metabolic emergency termed “tumor lysis syndrome” occurs in the early stages of tumor diagnosis and treatment as a result of tumor cell breakdown. Massive cell lysis can lead to life-threatening electrolyte abnormalities, including hyperphosphatemia, hyperkalemia, hyperuricemia, and resultant

renal failure.

Visceral proteins synthesized by the liver are often used to assess nutritional status, because decreased levels presumably reflect a reduced supply of amino acid precursors and/or decreased hepatic and other visceral protein mass. Blood concentrations of these proteins, however, are dependent on their rates of synthesis, degradation, and escape from the circulatory system. Serum proteins are also affected by infectious or catabolic processes. The concentrations of positive acute-phase proteins (e.g., C-reactive protein, ferritin, and ceruloplasmin) are increased in infectious or other catabolic illnesses, whereas negative acute-phase proteins (e.g., albumin, prealbumin, transferrin, and retinol-binding protein) are decreased in these circumstances.

Albumin is a relatively insensitive marker of nutritional status owing to its long half-life of 20 days and its ability to be mobilized from extravascular stores even in the presence of prolonged energy and protein deficiency. Hypoalbuminemia can occur in situations of decreased synthesis (e.g., liver disease, age over 70 years, and malignancy), increased losses (e.g., nephrosis, protein-losing enteropathy, and burn injuries), or displacement to extravascular spaces (e.g., acute catabolic stress with capillary leak syndrome) and is not necessarily related to the presence of malnutrition. Fluid overload, a condition common to acutely ill cancer patients, can also dilute albumin concentrations.

Prealbumin is a more sensitive measure of visceral protein status than albumin because of its short half-life (two days) and high ratio of essential to nonessential amino acids. A small study of children with solid tumors correlated disease status and treatment intensity with changes in prealbumin levels, suggesting that it is likely the best available serum marker of nutritional status.[45] Like albumin, its concentration falls with an acute-phase protein response or liver disease. Levels increase with renal failure.

In a study of 170 children with an assortment of cancers, albumin and prealbumin levels were significantly lower on presentation in patients than in controls, whereas the acute-phase indicator C-reactive protein was elevated. After six months of chemotherapy, however, the C-reactive protein levels were comparable in the groups but the visceral protein levels were still lower in those with cancer.[46] This suggests that even though acute-phase response is responsible for some alterations in visceral protein levels cancer patients still have poorer visceral protein nutrition than controls.

Assessment of vitamin and mineral nutriture, particularly in the patient

on total enteral or parenteral nutritional support, may also be helpful. At the time of diagnosis, the effect of tumor burden on metabolic processes may be profound, as demonstrated by laboratory analysis. Vitamin D insufficiency in survivors of childhood cancer is common[47] and may predispose them to low bone mineral density and fractures.[48] Whether vitamin D status might be associated with cancer-related outcomes remains unknown.

Antioxidant nutrients, including vitamins A and E, β-carotene, zinc, and selenium have also been studied. Children newly diagnosed with a variety of cancers had lower concentrations of retinol, β-carotene, vitamin E, and zinc prior to treatment compared to healthy controls in a multicenter French study. After six months of treatment, most of these parameters were largely unchanged; however, zinc concentrations in patients with CNS tumors and malignant bone tumors showed significant decline, suggesting the possibility of losses related to therapy, or a reduction in intake.[46] Zinc deficiency was also found to be common in children following stem cell transplantation. Nineteen of 28 children developed biochemical zinc deficiency at a median of seven days post transplantation. Zinc blood levels were positively correlated with serum concentrations of alkaline phosphatase, a zinc-dependent enzyme.[49] Another study of 103 children with ALL examined plasma antioxidant levels and chemotherapy side effects at diagnosis and three months and six months after diagnosis. After adjustment for multiple comparisons, there was a significant relationship between shorter length of hospital stay and higher total carotenoid to total cholesterol ratio at diagnosis. Additionally, subjects were more likely to experience a treatment-related toxicity if they had a low plasma total carotenoid level.[50] More research is needed to further elucidate the relationship of nutrient levels with clinical outcomes in cancer.

NUTRITION INTERVENTION

Food Safety

Because cancer and its treatment inherently cause immunosuppression to varying degrees, low microbial diets have historically been used in an effort to minimize risk of illness from foodborne pathogens. Although there is little evidence to support the efficacy of these regimens in preventing clinical infections,[51] it is intuitive to rule out possible causes when little potential harm might be involved. Versions of the neutropenic

or low microbial diet continue to be used widely in pediatric cancer treatment centers, although the impact of diet adherence and quality of life must be considered when comparing this more regimented approach to general food safety guidelines.[52] Table 58.4 summarizes the prudent principles recommended for HSCT recipients.

TABLE 58-4 Food Safety Recommendations for HSCT recipients[a]

- Avoid raw or undercooked meat, including beef, poultry, pork, lamb, venison, sweetbreads, other game meat
- Avoid any foods containing undercooked meat, including sausages and casseroles
- Avoid raw or undercooked eggs or foods that contain them, such as hollandaise sauce, homemade eggnog, homemade mayonnaise or salad dressing
- Avoid raw or undercooked seafood, such as clams, oysters, sushi
- Avoid raw fruits and vegetables from developing countries
- Drink only tap water that has been treated and tested, or bottled water
- Avoid unpasteurized milk or other dairy products
- Avoid unpasteurized fruit juices
- Avoid food and drinks from street vendors

[a]In addition to careful attention to food safety guidelines recommended for all children, those who have undergone HSCT should adhere to the recommendations in this table for three months, or until immunosuppresive medications have been discontinued.

MMWR. Vol 49;RR-10: Centers for Disease Control and Prevention; 2000:50–52.[53]

Indications for Feeding Modalities

The method of nutrition support selected for the child with cancer is determined by a timely clinical assessment and estimation of the child's nutrient requirements.[54] Some children may thrive well on volitional oral intake, whereas others may require specialized enteral or parenteral support. Available evidence suggests that enteral nutrition is a less expensive, safer, and more effective way of nourishing the child with cancer than parenteral nutrition.[54] However, there is no standardized approach to nutrition intervention in pediatric oncology.[55] It is axiomatic that enteral feeding should be considered prior to the initiation of parenteral nutrition and that oral supplements should be offered before

considering tube feeding. The most appropriate feeding method for the child with cancer is that which provides complete nutrient requirements with least risk. Patients and their family members should of course be included in the discussion of nutrition options, with discussion of the risks and benefits of appropriate and available methods for the patient's current situation.

In the case of malnutrition, it is imperative to consider the manifestations of refeeding the body in a starved or cachectic state. A profound hypophosphatemia, in particular, can characterize the rapid cellular influx of nutrients during the anabolic phase following starvation. The risk of this complication is especially present with parenteral nutrition. Severe metabolic complications may be avoided by cautious advancement of macronutrients over a period of days to weeks combined with close laboratory monitoring of electrolytes, glucose, and minerals.

Oral Diet

Because painful oral mucositis is a common side effect of chemotherapy with few effective treatments, a soft diet is often better tolerated. A diet high in magnesium or potassium may be useful for the child with excessive urinary losses of minerals due to chemotherapies or antibiotics. Other diet alterations may be indicated for a variety of comorbidities, for example, a reduced sodium diet for hypertension and a bland, low-residue diet for gastrointestinal GVHD.[56] Most commonly, however, calorie enhancement is the primary manipulation in an effort to promote weight gain or weight maintenance during treatment-associated anorexia. This can be accomplished with usual foods, or in combination with commercial supplemental drinks, bars, or calorie additives. See Chapter 70 for further specifications of the high-calorie diet. The use of appetite-enhancing medications such as cyproheptadine hydrochloride and megestrol acetate has been associated with weight gain and increases in leptin levels in children with cancer cachexia,[57] although megestrol acetate has also been linked to adrenal suppression and is therefore not recommended for routine use.[58] Some children, including those with standard-risk ALL and long-term survivors of cancer with activity limitations, may be aided by calorie moderation when excessive weight gain is a concern.

Enteral Feeding

If children are unable to meet their nutrient needs orally, tube feedings should be considered to preserve or achieve optimal nutritional status.

Nasogastric tubes have been used with success in many pediatric oncology patients. In 21 children newly diagnosed with cancer, nasogastric tube feedings were given in addition to volitional oral intake. After 16 weeks of feedings, weights increased significantly.[59] Several studies have reported the use of nasogastric feedings in children after stem cell transplantation with varying results. One group demonstrated improved weight gain in 21 patients, compared to 8 children receiving dietary counseling alone. There was a positive correlation between increases in weight and midarm circumference and the duration of enteral feedings. However, 8 of the 21 patients stopped feedings after 10 days due to vomiting or diarrhea. Six of these patients were then switched to parenteral nutrition support.[60] Langdana and others retrospectively analyzed their intensive enteral feeding protocol for children undergoing HSCT, which included routine insertion of nasogastric tubes during conditioning or when oral intake had decreased. Of their 49 evaluable patients, 86% (42) were maintained on enteral nutrition alone, including 8% who took adequate oral intake.[61] Another study compared tube feeding to parenteral nutrition in a group of children undergoing allogeneic HSCT, with just 3 of 34 patients supported exclusively by tube feeding; the remainder required partial or total parenteral nutrition. Cholestasis occurred significantly less often in children who received at least some tube feeding compared to children who were exclusively parenterally fed; nutritional costs were also less in children receiving tube feeding.[62]

These studies suggest the feasibility of nasogastric feeding as a method of nutrition support for pediatric cancer and HSCT patients, although clearly some patients will be unable to tolerate the adequate volumes to support their nutritional needs. Gastrostomy tube feedings are generally considered to be more cosmetically acceptable and comfortable than nasogastric feedings while still providing the same advantages over parenteral nutrition. In a number of studies, significant weight gain in pediatric cancer patients has been demonstrated with the use of surgically placed or percutaneous endoscopic gastrostomy (PEG) feedings.[63–66] Although some patients may ultimately require parenteral support due to gastrointestinal intolerance, the use of enteral nutrition substantially reduces the amount and duration of parenteral nutrition required, thus reducing the risks and costs with which it is associated.[62–65] Further studies assessing the effect of proactive enteral feeding in this population are needed.

Nutritionally complete formulas for oral supplementation or tube

feeding are available for a variety of ages and conditions (see Appendix III). Most pediatric cancer patients will tolerate intact protein, 1 or 1.5 kcal/mL, formulas either orally or via tube feeding. On rare occasions, a specialized formula for tube feeding may be indicated. Formulas with elemental (free amino acids) or semielemental (small peptides) protein are available, primarily for the purpose of allergy or intolerance. Medium-chain triglycerides are also used in many formulas intended for patients with fat malabsorption. An abundance of defined formula diets are available for varying conditions and ages.

Parenteral Feeding

When the gastrointestinal tract is nonfunctional or unavailable, nutrients may be infused via central venous catheters. Peripheral venous lines may also be used temporarily to provide a nutrient solution with less than 900 mOsm/L, usually 10% dextrose and 1.5%-2% amino acids. Parenteral nutrition has been widely used in the oncology population due to the cytotoxic effects of many treatment regimens. Most chemotherapies commonly cause some degree of nausea and vomiting. Radiation therapy, when directed to gastrointestinal organs, also causes cell damage that may impair digestive or absorptive function. High-dose chemotherapeutic regimens and total-body irradiation, used in preparation for stem cell transplantation, may cause severe mucositis and enteritis, making significant oral or enteral intake difficult for many patients to achieve for several weeks. Gastrointestinal GVHD, a complication of allogeneic stem cell transplantation, typically causes impaired absorption of nutrients, either due to anorexia and diminished oral intake in its mildest cases or as profuse, bloody diarrhea in its more severe cases.

The value of parenteral nutrition in cancer patients has been questioned; in fact, its routine use in cancer treatment has been discouraged due to the risks of infectious complications.[67] A small study of pediatric cancer patients with severe chemotherapy-induced mucositis failed to demonstrate a significant benefit of parenteral nutrition over standard intravenous fluid. This prospective, randomized trial compared body composition measurements (bioelectrical impedance analysis), laboratory parameters, and other clinical outcomes after 10 days of therapy. Only total weight gain was greater in the parenteral nutrition group, with similar measures of fat-free mass, thus implying exclusive accumulation of body fat in the parenteral nutrition group.[68] HSCT, however, is one of the few clinical situations where parenteral nutrition has

historically demonstrated benefit.[69] A few well-designed trials have further advanced the science of nutrition support in children with cancer. A study of 20 children receiving parenteral nutrition during HSCT attempted to clarify a relationship between changes in parenteral energy intake and clinical outcomes. A greater difference between expected and actual parenteral energy intakes was associated with longer time to engraftment in this retrospective analysis. Actual energy expenditure and oral intake were not reported.[70] A randomized controlled trial designed to compare parenteral energy intake titrated to measured REE with standard energy intake, typically 130%-150% of REE, found significant declines in lean body mass in both groups, with a trend toward higher body fat in the standard energy group.[28] These results raise concern for overfeeding when parenteral nutrition energy intake exceeds REE. More research examining the specific regimens and components of nutrition support is warranted for children with cancer.

When clearly indicated, parenteral nutrition should be initiated according to standard recommendations (see Chapter 68). Goals for parenteral nutrition infusions will be based on estimated nutrient requirements, fluid requirements, and available venous access. Electrolytes are added to promote metabolic homeostasis; pediatric multivitamin and trace element preparations are generally used as well. Attention should also be directed to concomitant and expected medication use, particularly those with known nutritional interactions.

The risks of parenteral nutrition can be significant and include infections, hepatotoxicity, suppression of oral intake, and metabolic abnormalities. Most children undergoing aggressive cancer treatment will require indwelling central venous catheters for chemotherapy, but the use of parenteral nutrition has been associated with a 2.4-fold increase in the risk of infection in children receiving chemotherapy who have central access devices in place.[71] A specific role for intravenous fats in increasing infectious complications is not supported in the literature.[72]

Many of the medicines used in oncologic treatment can cause liver injury. The use of parenteral nutrition, singly or in combination with these medicines, may cause biliary dysfunction or steatosis.[73] Another potential risk of parenteral nutrition administration is the generation of peroxide compounds, which may have harmful effects in neonates and others with immune dysfunction and/or reduced antioxidant defenses.[74] Covering parenteral nutrition bags and intravenous tubing with opaque plastic coloring may reduce this effect.[75]

Parenteral nutrition may also cause early satiety and decreased oral intake. In a randomized controlled trial of children and young adults following marrow transplantation, outpatient parenteral nutrition delayed resumption of oral intake by six days compared to 5% dextrose hydration. The clinical outcome of both groups was not significantly different.[76] Metabolic derangements are also associated with parenteral nutrition. Over- or underhydration, electrolyte imbalance, hyperglycemia, and hypoglycemia are among the most common concerns. While there remains a role for parenteral nutrition in selected pediatric cancer patients, close monitoring of laboratory values, clinical condition, and ability to enterally or orally feed are important to minimize risks associated with long-term parenteral nutrition.

The significant metabolic and nutritional ramifications of cancer and its therapy have led investigators to evaluate whether the addition of various nutrients may improve clinical outcomes. Glutamine, an important amino acid for rapidly turning over cells, has a documented role in ameliorating the mucosal atrophy seen in prolonged states of parenteral nutrition,[77] the healing of gastrointestinal mucosa after damage from radio- or chemotherapy,[78,79] and reducing episodes of clinical sepsis.[80] Evidence supporting its use in cancer treatment has been conflicting, however, and pediatric data are minimal. ω-3 Fatty acids, derived from the essential fatty acid α-linolenic acid, have also been under consideration, owing to the antiangiogenic and antitumoral properties observed in animal models, and the anticachectic effect seen in a small number of clinical studies.[81] One small study suggested that supplementation with a formula containing ω-3 fatty acids may reduce weight loss associated with pediatric cancer treatment, although the effect may have been a result of additional energy rather than a specific effect of the fatty acids.[82] Further research is needed to advance this science as it pertains to the nutritional therapy of pediatric cancer.

NUTRITIONAL CONCERNS OF CHILDHOOD CANCER SURVIVORS

Many nutritional issues during childhood cancer treatment are associated with weight loss or poor growth, but more recently the risk of obesity and excess body fat accumulation has been elucidated. The Childhood Cancer Survivor Study, a multicenter, retrospective cohort study of adults who survived pediatric cancer greater than five years, described a greater

prevalence of overweight and obesity in cancer survivors who received high-dose cranial radiation (>20 Gy), compared to their healthy siblings.[83] Survivors of ALL were more likely to be obese, whereas survivors of other cancer types were more likely to be underweight, suggesting an overall abnormal growth pattern resulting from pediatric cancer treatment.[84] A study using a combination of indirect calorimetry and ambulatory heart rate monitoring to measure basal metabolic rate and total energy expenditure concluded that ALL survivors have lower levels of energy expenditure for activity.[85] Percent body fat, as measured by DXA, was significantly higher among ALL survivors, whereas their BMI remained similar to controls,[86] suggesting the need for body composition measurements to elucidate changes in body fat. These changes in growth and body composition may be subsequent risk factors for cardiovascular disease and other chronic illnesses as this population ages.[84]

The impact of cancer treatment on linear growth has also been examined. A cohort of HSCT survivors, engrafted before or at the onset of puberty, had a significant decrease in final height compared to pretransplant height standard deviation scores. However, most of the patients achieved a height considered to be normal.[87] Similarly, another study of HSCT survivors, who were treated with total-body irradiation, found a reduction in peak height velocity following transplantation.[88] Again, radiation therapy seems to be the common element. A reduction in linear growth has also been described in survivors of ALL and brain tumors.[84] Nutritional intervention may play a key role in limiting the extent of growth faltering, though the primary cause is likely a deficiency of growth hormone caused by radiation damage. Although the clinical significance of this growth stunting is as yet unclear, the relationship of height to nutrient intake, body weight, and body composition is certainly worthy of consideration when planning nutritional therapy.

Conflicting reports of a greater prevalence of osteopenia in childhood cancer survivors have been published,[89–92] perhaps related to differences in treatment, time of follow-up, or variability in measurements. Bone loss has been described in adult HSCT survivors,[93] likely related to steroid treatment post transplantation. Declines in bone mineral density z scores have also been observed in children following HSCT. One study demonstrated an increasing incidence of osteopenia (defined as a z score between 1 and 2 SD below the mean) and osteoporosis (defined as a z score >2 SD below the mean) in a prospective evaluation of bone mineral density at the time of HSCT and 100 days, six months, and one year after

HSCT.[94] These changes in bone mass have yet to be correlated with clinical findings, such as fractures; however, their relationship to the overall health of the growing group of childhood cancer survivors may be substantial.

A significant incidence of insulin resistance and dyslipidemia among survivors of HSCT has been reported.[95] Likewise, features of the metabolic syndrome have been found in ALL survivors[96]; however, the findings appear to be most pronounced in those receiving HSCT. Unquestionably, complications of oncologic treatment, including obesity and insulin resistance, need further evaluation and attention. Dietary intake among long-term survivors may fall short of recommendations for optimal health and chronic disease prevention.[97] Children undergoing cancer treatment should be taught healthy diet principles and acceptable activity options for weight maintenance.

CONCLUSION

From the time of diagnosis, nutrition is an important aspect of the care and recovery of the pediatric cancer patient. The effects of cancer and its treatment have lifelong implications. Age-appropriate growth and development should be the goal during extended treatment courses as well as following the completion of therapy. Serial nutritional assessments should be performed regularly with appropriate interventions and follow-up. Malnutrition should not be accepted as an inevitable consequence of cancer and/or its treatment. Similarly, effort should be made to prevent obesity and other nutrition-related chronic diseases in long-term cancer survivors. Effective supportive care of the pediatric cancer patient involves nutritional intervention and counseling with a multidisciplinary approach, emphasizing the quality of life of each child.

MEDICAL NUTRITION THERAPY

Meal planning is a cornerstone of diabetes management, and nutrition education is an essential component of a comprehensive program of diabetes education for patients and their families.[1] Recommendations for medical nutrition therapy (MNT) of diabetes mellitus have continued to evolve since the advent of insulin therapy in 1922. In this chapter, we briefly review the history of MNT, the scientific basis on which the general principles are founded, and recent investigations that implicate dietary factors in the etiology of immune-mediated or type 1a diabetes mellitus. Thereafter, we discuss the goals of treatment, principles of meal planning, and formulation of an individualized meal plan based on current evidence as recommended by the Food and Nutrition Committee of the American Diabetes Association (ADA).[2]

PREVALENCE, DEFINITION, AND CLINICAL DESCRIPTION OF DIABETES MELLITUS

Diabetes mellitus is one of the most common chronic diseases in children and adolescents. Diabetes is not a single entity but a group of metabolic diseases characterized by hyperglycemia that is caused by defects in insulin secretion, defects in insulin action, or both.[3] Type 1 diabetes, caused by absolute deficiency of insulin secretion, is the most common form in children and adolescents. Its incidence widely varies among geographic regions, from 0.1/100,000 per year in China and Venezuela to

64/100,000 per year in Finland. In the United States in 2010, an estimated 215,000 people below 20 years had diabetes (type 1 or type 2), which represents 0.26% of all people in this age group.[4] The estimated crude prevalence rate was 1.82 cases per 1000 youth, being lower for children 0–9 years of age (0.79 cases per 1000 youth) than for those 10–19 years of age (2.80 cases per 1000 youth).

Type 2 diabetes occurs when insulin secretion is inadequate to meet the increased demand caused by insulin resistance. Until recently, immune-mediated type 1 diabetes was by far the most prevalent form of diabetes in children and adolescents in the United States; only 1% to 2% of children had type 2 or other, rare, forms of diabetes. In the past two decades, the prevalence of type 2 diabetes in youth has increased at an alarming rate throughout the developed world, and recent reports indicate that 8%–45% of children with newly diagnosed diabetes have nonimmune-mediated diabetes.[5] Among younger children type 1 diabetes accounts for at least 80% of diabetes, whereas among older youth the proportion of type 2 diabetes ranges from 6% for non-Hispanic white youth to 76% for American Indian youth.[6] The variation in incidence depends on age, race/ethnicity, and sampling strategy. Most children and adolescents who do not have immune-mediated diabetes have type 2 diabetes; however, other types, especially monogenic diabetes (formerly referred to as maturity-onset diabetes of youth), are being increasingly identified in adolescents and young adults and account for 1% to 2% of youth with diabetes.[7]

Type 1a diabetes occurs in genetically predisposed individuals as a consequence of immune-mediated destruction of the insulin-secreting β-cells of the pancreatic islets.[8] The onset of clinically overt diabetes represents a late stage in the process of chronic progressive immune-mediated β-cell destruction. The resulting absolute deficiency of insulin leads to hyperglycemia (the result of decreased uptake and utilization of glucose by liver, muscle, and adipose tissue and uncontrolled hepatic gluconeogenesis), unregulated release of free fatty acids from adipose tissue, and increased ketogenesis. The disease typically presents with polyuria, polydipsia, and weight loss.

Patients with type 1 diabetes depend on exogenous insulin to survive. Insulin is normally secreted in an oscillatory fashion at a low basal rate with periodic increases in secretion in response to ingestion of food. In contrast, when insulin is injected subcutaneously it is absorbed from the injection site in a somewhat predictable fashion depending on the specific types of insulin used. Each type of insulin has a characteristic time of onset

of action and maximum effect, duration of peak effect, and total duration of action (Table 59-1). When short- or intermediate-acting insulins are used, meals and snacks have to be timed to match the pharmacodynamics of insulin. Rapid-acting insulin analogs, delivered by injection or via continuous subcutaneous insulin infusion (CSII) (insulin pump), significantly reduce the variation in absorption of insulin and permit greater flexibility and accuracy with respect to matching insulin delivery to glucose absorption after meals and snacks.

Children with idiopathic or nonimmune-mediated type 1 diabetes may be difficult to distinguish from those with immune-mediated diabetes. In the United States, most patients with idiopathic type 1 diabetes are African-American and have so-called atypical diabetes mellitus or Flatbush diabetes.[9] They typically have a positive family history of early-onset diabetes in several relatives and in multiple generations. Although insulin may not be required for survival after the episode of acute metabolic deterioration resolves, without insulin therapy blood glucose control is usually poor and ketoacidosis may recur.

TABLE 59-1 Insulin Preparations Classified According to Their Pharmacodynamic Profiles

	Onset of Action	Peak Action	Duration of Action
Rapid acting[a]		30–90 min	3–5 h
Insulin lispro (Humalog®)[b]	5–15 min	30–90 min	3–5 h
Insulin aspart (Novolog®)[b]	5–15 min	30–90 min	3–5 h
Insulin glulisine (Apidra®)[b]	5–15 min		
Short acting[a] Regular (soluble)	30–60 min	2 to 3 h	5–8 h
Intermediate acting[a] NPH (isophane)	2–4 h	4–10 h	10–16 h
Long acting	2–4 h	Peakless	20–24 h
Insulin glargine (Lantus®)[b]	2–4 h	6–14 h	16–20 h
Insulin detemir (Levemir®)[b]			

[a]Premixed combinations of intermediate-acting and either rapid- or short-acting insulins are available whose pharmacodynamic profiles have a bimodal pattern reflecting the two insulin components.

[b]Insulin analog developed by modifying the amino acid sequence of the human insulin molecule.

Type 2 diabetes is characterized by decreased insulin sensitivity and inadequate insulin secretion and is commonly associated with other features of the insulin resistance syndrome (hyperlipidemia, hypertension, acanthosis nigricans, ovarian hyperandrogenism, and nonalcoholic fatty liver disease).[10] Changes in energy intake and expenditure have resulted in an epidemic of obesity in children and adolescents in the United States, and in the past two decades there has been an alarming increase in the prevalence of type 2 diabetes in children and adolescents, especially in minority populations.[10] Almost 95% of youth with type 2 diabetes are either overweight or frankly obese.[11] Body composition is a major determinant of insulin sensitivity in children. Adiposity accounts for 55% of the variance in insulin sensitivity in white children,[12] and an inverse relationship between increasing adiposity and insulin sensitivity has also been shown in black children. As adiposity and body mass index (BMI) increase, insulin sensitivity decreases and serum insulin levels increase.[13]

Monogenic forms of diabetes are caused by defects in β-cell function and are inherited in an autosomal dominant pattern.[7] Monogenic diabetes occurs in all racial and ethnic groups and has a broad clinical spectrum ranging from asymptomatic hyperglycemia to a severe acute presentation. Genetic testing is required to confirm specific diagnoses.[7]

Individuals with nonimmune-mediated diabetes may have clinical presentations indistinguishable from those of patients with immune-mediated type 1 diabetes. This is especially relevant because as the number of children with type 2 diabetes increases it is important to determine correctly the cause of a child's diabetes to be able to institute appropriate therapy. When the type of diabetes is uncertain, initial stabilization and management with insulin therapy should be the default approach to management.

The initial classification is usually based on the clinical and laboratory assessment at presentation. Children with immune-mediated type 1a diabetes are typically not overweight, have a short duration of symptoms, and frequently have ketosis, and approximately 15%–70% of newly diagnosed patients in North America and Europe present with ketoacidosis. However, as the childhood population in the United States has become increasingly overweight the percentage of children with immune-mediated type 1 diabetes who are coincidentally overweight, or obese, has increased. After metabolic stabilization, they may have an initial period of reduced insulin requirement (the honeymoon period); thereafter, they require daily insulin replacement for survival and are

always at risk for ketoacidosis. In contrast, approximately 95% of children with type 2 diabetes are either overweight or obese at the time of diagnosis and typically present with glucosuria, absent or mild polyuria and polydipsia, and little or no weight loss. In contrast to new-onset type 1 diabetes, only one-third of children diagnosed with type 2 diabetes have ketonuria at diagnosis, and 5%–25% present with ketoacidosis. Children with type 2 diabetes are usually more than 10 years old and are in middle to late puberty; 45%–80% have at least one parent with type 2 diabetes, and 74%–100% have a first- or second-degree relative with type 2 diabetes. Children and adolescents of African-American, Hispanic, Asian, American Indian, and Pacific Islander descent are disproportionately affected.[6]

Acute, life-threatening consequences of diabetes are hyperglycemia with ketoacidosis or the hyperglycemic hyperosmolar state syndrome from inadequate insulin, and severe hypoglycemia from excess insulin administration or, in the case of type 2 diabetes, oral antihyperglycemic medications. Long-term complications of chronic hyperglycemia include retinopathy with potential loss of vision; nephropathy leading to hypertension and renal failure; and peripheral and autonomic neuropathy with associated risk of foot ulcers and limb amputation and gastrointestinal, genitourinary, and cardiovascular symptoms.[14] Glycation of tissue proteins and other macromolecules and excess production of polyol compounds are among the mechanisms whereby chronic hyperglycemia produces tissue damage.[15]

HISTORY OF MEDICAL NUTRITION THERAPY FOR TYPE 1 DIABETES MELLITUS

Until the advent of insulin therapy in 1922, the only available treatment was diet and exercise. Meal plans severely restricted total energy intake and were low in carbohydrate and high in fat. Nutrition recommendations were often based on dogma and a limited understanding of pathophysiology. After the introduction of insulin, nutrition recommendations changed but generally involved restriction of carbohydrate to a maximum of 40% of total energy because this was thought to reduce the severity of hyperglycemia. Several studies early in the 20th century showed that a high-carbohydrate meal plan, provided it was restricted in total energy, had beneficial metabolic effects. Nonetheless, change was slow and, despite evidence to the contrary,

patients continued to be indoctrinated to use a low-carbohydrate, high-fat meal plan until 1971 when the Food and Nutrition Committee of the ADA formally recommended liberalizing the consumption of carbohydrate. Sucrose was not permitted in the meal plans of people with diabetes mellitus. Considerable scientific evidence since then has shown that sucrose as part of the meal plan does not impair blood glucose control in people with either type 1 or type 2 diabetes (see the section Nutritive Sweeteners).

In 1950, the ADA, American Dietetic Association, and US Public Health Service introduced the "exchange system" for meal planning to assist patients in choosing foods consistent with current nutrition recommendations.[16] The exchange system established portion sizes and grouped foods with similar macronutrient contents. The goal of the system was to enable individuals with diabetes to have greater flexibility in food choices by allowing them to exchange foods within a group and still consume comparable amounts of macro- and micronutrients. This was an important advance because it antedated the current widespread availability of standardized food composition analysis. Legislation mandating food labeling was not introduced in the United States until 1974. The exchange system has undergone four revisions. The 1976 revision improved the accuracy of the calorie content of foods within exchange lists and stratified foods by their fat content. The 1986 revision developed a database for nutrient composition and increased the carbohydrate content of fruits from 10 to 15 g, which is closer to their actual carbohydrate content. The 1995 revision grouped carbohydrate-containing foods into a single category to allow greater flexibility in meal planning. This revision also added many new food items (e.g., fat-modified, vegetarian, and fast foods) to reflect the US population's changing dietary habits and food choices. The most recent revision, in 2003, liberalized the use of sugar in the diet by establishing a food list entitled "Sweets, Desserts and Other Carbohydrates that could be exchanged for Grains, Fruits and Dairy." Another new category, "Combination foods," was added in response to the increased availability of processed foods.

Changes in food manufacturing and societal dietary habits, including increases in the consumption of prepared foods, access to international cuisines, eating meals outside the home, and modification of natural foods to lower their fat and carbohydrate content, have resulted in added complexity when teaching the exchange diet. For example, historically, bread contained 15 g of carbohydrate per ounce and presliced bread was generally sold in 1-oz. portions. Currently, some bread recipes are

formulated to provide 4 g of carbohydrate per ounce; thus, it has become important to understand the "evolution" of carbohydrate content in bread in order to explain why multiple bread slices may need to be consumed in order to satisfy the historical "15 gram" expectation within the exchange diet. Therefore, teaching patients and families how to perform carbohydrate counting will enable them to avoid problems with the exchange diet that are the result of altered manufacturing and consumption practices. It is also important to recognize that the portion size on food labels may differ from the portion size and carbohydrate content listed in the exchange system. Most food manufacturers do not list diabetes exchanges on their products. Since the introduction of mandatory food labeling, the general public is becoming more accustomed to reading nutrition facts on food labels. It is no longer essential, therefore, for people with diabetes to rely on the exchange system as the sole source of information regarding macronutrients for dietary planning.

In 1993, the landmark Diabetes Control and Complications Trial (DCCT) showed that a system of intensive diabetes management aimed at near-normal glycemic control dramatically reduces the risk of microvascular complications and favorably affects the risk of macrovascular complications.[17] Intensive insulin therapy using multiple daily injections (basal-bolus or flexible insulin regimen) or an insulin pump has become the standard of care for type 1 diabetes. Flexible insulin regimens in conjunction with carbohydrate counting (estimating the carbohydrate content of foods based on information available from food labels, reference books, and software) allow patients with type 1 diabetes to have a wide variety of dietary choices and to live more normal lifestyles without compromising glycemic control. Carbohydrate counting is discussed in more detail later in this chapter.

DIETARY FACTORS IN THE PATHOGENESIS OF TYPE 1 DIABETES MELLITUS

The increasing incidence of type 1 diabetes in recent decades[18] and the concordance rate of less than 50% in monozygotic twins suggest a role for environmental factors in the development of type 1 diabetes. The relatively greater increase in incidence in children below 5 years suggests that environmental exposures early in life could play an important pathogenetic role.[19] However, the contributions of genetic, environmental, and immunologic factors and their interactions in the pathogenesis of type 1a

diabetes are poorly understood.

Early nutrition is one of the first environmental determinants to which an infant is exposed, and evidence suggests that components of the diet may predispose to or protect against type 1 diabetes. Short duration of breast-feeding and early exposure to complex foreign proteins have been implicated as risk candidates. Other possible diet-related factors that have been implicated include fruits, berries, root vegetables, lack of vitamin D supplementation, heavy birth weight, and rapid weight gain in infancy.[20] It has been suggested that a dietary antigen may play a role as the factor driving the disease process toward clinical type 1 diabetes.

Changes in food, particularly its protein content, influence the onset of diabetes in rodent models of autoimmune diabetes, and these observations have been invoked as evidence that complex natural ingredients in human and rodent diets may be involved in the immune-mediated destruction of β-cells. Antibodies reactive against a peptide sequence contained within bovine serum albumin occur in humans, BB rats, and NOD mice, which cross-react with an islet antigen designated p69. Together with suggestive epidemiological data, these observations have given rise to the controversial theory that dietary cow's milk may contribute to the pathogenesis of type 1a diabetes in susceptible individuals. Removal of bovine proteins from the diet prevents diabetes in NOD mice. Some investigators have also shown that diets containing cow's milk are diabetogenic in the BB rat, but other investigators have not confirmed this. Although diet clearly has a major diabetogenic effect in BB rats and NOD mice, the exact chemical identity of the food diabetogens is still unclear.

Insulin is an important autoantigen in type 1a diabetes and is the only β-cell-specific autoantigen in postnatal life.[8] Insulin autoantibodies are the first or among the first autoantibodies to appear when the disease process leading to type 1a diabetes is initiated in young children. Because cow's milk formulas are generally the first and most common dietary source of foreign complex proteins to which infants are exposed in developed countries, the question has been asked whether early exposure to cow's milk formula results in an immune response to bovine insulin (which differs from human insulin in three amino acids) present in infant formulas. Bovine insulin is thought to be an attractive candidate because an immune response, initially induced by bovine insulin, cross-reacts with and may target human insulin in the β-cell.[21] Infants exclusively breast-fed up to the age of 3 months had substantially lower IgG class antibodies to bovine insulin than those exposed to formula before 3 months of age.[22] The IgG class insulin antibodies started to decrease slowly after the age of

3 months as a sign of the development of oral tolerance in those infants who were given formula before the age of 3 months. In contrast, antibody levels increased up to the age of 12 months before titers leveled off in infants exclusively breast-fed to the age of at least 3 months. It has been suggested that young children who present early signs of β-cell autoimmunity lack the capacity to develop oral tolerance to bovine insulin.[21] In these individuals, the initial immune response to bovine insulin appears to be diverted to a response targeting human insulin.

Data from three population-based case-control studies on cow's milk intake before the diagnosis of type 1 diabetes have yielded conflicting results. In New South Wales, Australia, cow's milk intake was higher in children who subsequently developed diabetes than in control children,[23] and in Finland a high consumption of cow's milk in childhood was associated with more frequent appearance of diabetes-associated autoantibodies and type 1 diabetes in a prospective cohort of initially unaffected siblings of children with type 1 diabetes.[24,25] In contrast, a Swedish retrospective survey showed that the frequency of cow's milk consumption was modestly lower among children who presented with type 1 diabetes than among unaffected children.[26] If confirmed, the increased risk of diabetes associated with formula feeding could reflect early exposure to a variety of cow's milk proteins, modification of the gut microflora,[27] and increased weight gain early in life.[28] A recent pooled analysis of data from 43 observational studies (9874 participants) suggests that exclusive breast-feeding in the early weeks of life (for more than two or three weeks) can reduce the risk of childhood-onset type 1 diabetes by 15%. There is little evidence, however, that longer exclusive or nonexclusive breast-feeding has a protective effect.[19] Knip et al.[27] have speculated that breast-feeding could protect against type 1 diabetes risk by causing a more rapid decrease in gut permeability or by reducing the risk of enteroviral infections, which have been associated with increased type 1 diabetes risk.[29]

A pilot intervention study sought to determine whether weaning to hydrolyzed formula over the first six to eight months of life decreased the cumulative incidence of diabetes-associated autoantibodies. Preliminary evidence has shown a decreased frequency of at least one diabetes-associated autoantibody including, specifically, islet cell antibody by the age of 6 years. In 2002, a randomized double-blind trial (Trial to Reduce IDDM in the Genetically at Risk) was initiated to determine whether it is possible to reduce the frequency of diabetes-associated autoantibodies

and/or clinical type 1 diabetes by the age of 6 years and the cumulative incidence of type 1 diabetes by the age of 10 years by weaning to a highly hydrolyzed formula over the first six to eight months of life.[27] During a median observation period of 10 years, weaning to a casein hydrolysate formula during infancy was associated with a lower risk of developing β-cell autoimmunity markers compared to weaning to cow's milk formula.[30]

Gluten or other cereal-derived proteins have also been implicated as potential driving antigens in type 1 diabetes. Dietary gliadin, a component of gluten found in wheat and other grains, may trigger intestinal inflammation in subjects with type 1 diabetes, independent of the presence of the human leukocyte antigen (HLA) DQ2/DQ8 haplotype known to confer risk for celiac disease. It has been suggested that gliadin could affect the immune activation stage of the gut immune system in individuals at genetic risk for type 1 diabetes and modify the autoimmune process involved in β-cell destruction.[21] Two prospective studies have reported an association between the introduction of cereals in infancy and the emergence of early β-cell autoimmunity. A study conducted in the United States suggested that both early (<4 months) and late (≥7 months) exposures to cereals, either gluten- or non-gluten-containing cereals, were associated with an increased risk of β-cell autoimmunity.[31] A similar study in Germany suggested that an increased risk of β-cell autoimmunity was related to exposure to cereals before age 3 months.[32] In contrast, a prospective analysis of data from the DIPP study conducted in Finland showed no relation between early or late introduction of cereals and emergence of advanced β-cell autoimmunity.[33] In small intervention studies performed in family members already positive for pancreatic autoantibodies, gluten elimination from the diet did not significantly affect autoantibody titers nor did titers change when gluten was reintroduced into the diet. A gluten-free diet does not appear to influence β-cell autoimmunity in first-degree relatives of affected patients.

There is seasonal variation in the initial appearance of pancreatic autoantibodies in young children with increased HLA-conferred susceptibility to type 1 diabetes. Seasonal viral infections have been implicated but not proved. There is marked seasonal variation in the amount of daylight and hours of sunshine, especially in Northern Europe, which has the highest incidence of type 1 diabetes in the world. Sun exposure may affect the immune system, possibly mediated by vitamin D. In 2003, Stene and Joner reported that the use of cod liver oil (containing high concentrations of vitamin D and ω-3-polyunsaturated fatty acids)

during the first year of life was related to a decreased risk of type 1 diabetes,[34] but the observation was not confirmed in a later study.[35] A lack of oral vitamin D supplementation in infancy may increase the subsequent risk of type 1 diabetes, and a recent meta-analysis based on five studies concluded that vitamin D supplementation in early childhood may provide protection against the development of type 1 diabetes.[36] There is countervailing evidence, however, arguing against a role of vitamin D deficiency as a trigger of β-cell autoimmunity. About 80% of all young children in Northern Europe receive a daily vitamin D supplement at least up to the age of 1 year. Furthermore, there were no significant differences in the circulating vitamin D concentrations in pregnant women and schoolchildren between the Karelian Republic of Russia, where the incidence is approximately one-sixth that of neighboring Finland, and Finland despite similar HLA-conferred genetic susceptibility.[37]

Increased weight gain in infancy is also a risk factor for developing type 1 diabetes.[38] Children with type 1 diabetes are both heavier and taller in infancy (despite no differences in birth weight or length) compared to unaffected children.[39] Individuals who develop type 1 diabetes between 15 and 39 years of age have a faster gain in BMI during infancy than unaffected individuals.[40] Accelerated linear growth and weight gain result in increased β-cell load and insulin resistance, and rapid growth and weight gain may induce β-cell stress. Indeed, compared to resting cells active β-cells are more prone to cytokine-induced damage.[41] According to Wilkin's accelerator hypothesis, rapid weight gain is an important factor accounting for the rising incidence of both type 1 and type 2 diabetes, but mediation through insulin resistance has yet to be established.[42,43]

Although no specific dietary factor or nutrient in infancy has, unequivocally, been shown to play a role in the development of type 1 diabetes, dietary components may predispose to or protect against type 1 diabetes.[27] Therefore, at the present time no definitive nutrition recommendations can be made for preventing type 1 diabetes. However, increasing BMI is associated with a younger age at diagnosis of type 1 diabetes in youth with reduced β-cell function,[44] and excessive weight gain during childhood should be avoided.

GOALS OF MEDICAL NUTRITION THERAPY

Medical nutrition therapy (MNT) is the process by which the nutrition prescription is tailored for the individual with diabetes based on medical,

lifestyle, and personal factors and is an integral component of diabetes management and diabetes self-management education.[45] The goals of MNT for children and adolescents are shown in Table 59-2.

TABLE 59-2 Goals of MNT for Diabetes Mellitus

Goals that apply to all persons with diabetes	Attain and maintain optimal metabolic outcomes including:
	Blood glucose levels in the normal range or as close to normal as is safely possible
	A lipid and lipoprotein profile that reduces the risk for vascular disease
	Blood pressure levels in the normal range or as close to normal as is safely possible
	To prevent, or at least slow, the rate of development of the chronic complications of diabetes by modifying nutrient intake and lifestyle.
	To address individual nutrition needs, taking into account personal and cultural preferences and willingness to change
	To maintain the pleasure of eating by only limiting food choices when indicated by scientific evidence
Goals specific to type 1 diabetes	To provide adequate energy to ensure normal growth and development and integrate insulin regimens into usual eating and physical activity habits
Goals specific to type 2 diabetes	To facilitate changes in eating and physical activity habits that reduce weight and insulin resistance, and improve metabolic control
Goals specific to patients treated with insulin or insulin secretagogues	To provide self-management education for prevention and treatment of hypoglycemia, acute illnesses, and exercise-related blood glucose problems.

Nutrition recommendations and interventions for diabetes—2006: a position statement of the American Diabetes Association. *Diabetes Care*. Sep 2006;29(9):2140–2157[74]; Franz MJ, Bantle JP, Beebe CA, et al. Nutrition principles and recommendations in diabetes. *Diabetes Care*. Jan 2004;27(Suppl 1):S36–S46.[119]

TABLE 59-3 ADA-Recommended Glycemic Targets for Type 1 Diabetes Across all Pediatric Age Groups

Blood glucose goal range		
Before meals	**Bedtime/overnight**	**A1c**
90–130 mg/dL	90–150 mg/dL	<7.5%*

*A lower goal (<7%) is reasonable if it can be achieved without excessive hypoglycemia.

Key concepts in setting glycemic goals:

- Goals should be individualized, and lower goals may be reasonable based on benefit-risk assessment.
- Blood glucose goals should be modified in children with frequent hypoglycemia or hypoglycemia unawareness.
- Postprandial blood glucose values should be measured when there is a discrepancy between preprandial blood glucose values and A1c levels and to help assess glycemia in those on basal-bolus regimens.

The DCCT and the observational follow-up study of the DCCT cohort, the Epidemiology of Diabetes Interventions and Complications (EDIC) study, confirmed that long-term maintenance of blood glucose at levels near to normal delays or prevents the microvascular complications of type 1 diabetes[17] and the benefits of intensive treatment extend well beyond the period of its most vigorous implementation.[46] The DCCT also demonstrated that intensive management of type 1 diabetes is associated with an increased risk of severe hypoglycemia and a tendency to gain weight. Weight gain in intensively treated patients with type 1 diabetes has been primarily attributed to the elimination of glucosuria (70% of the weight gain) and a 5% reduction in daily energy expenditure (30% of the weight gain). Recurrent symptomatic hypoglycemia requiring oral carbohydrate to restore normal blood glucose levels also contributes to the tendency to gain weight in some intensively treated patients.

Our ability to help most patients achieve optimal glycemic control is limited by the imperfection of insulin replacement, which does not mimic normal physiology; inability to continuously monitor blood glucose concentrations; and risk of severe hypoglycemia when glucose levels are near to normal. In the future, insulin delivery regulated by a closed-loop feedback system will likely improve our ability to tightly control blood glucose and hemoglobin A1c levels for all individuals with diabetes.

The child with diabetes and his or her family have to assume primary responsibility for daily management, whereas the role of the health-care professional is that of educator, advisor, and motivator. Even modest

objectives are not achievable in all patients because educational, psychosocial, and economic factors make it impossible for some children and their families to perform daily all the tasks that comprise a comprehensive treatment program. Nonetheless, the goals of therapy can be accomplished in a substantial number of patients by using flexible insulin regimens and insulin dosage algorithms in conjunction with frequent self-monitoring of blood glucose (supplemented by continuous glucose monitoring), individualized meal planning, and educating and motivating older children and adolescents. The ultimate goal is to empower patients and enable them to independently make appropriate decisions about their day-to-day diabetes management.

GENERAL PRINCIPLES OF NUTRITION MANAGEMENT

There is little or no research on the unique nutrient requirements of children and adolescents with either type 1 or type 2 diabetes nor is there evidence that their nutritional needs differ from those of children without diabetes. Therefore, nutrient recommendations are based on requirements of the general pediatric population. Meal plans for children with diabetes should begin with the key recommendations outlined in Dietary Guidelines for Healthy Americans 2010.[47] This document provides guidelines that should serve as the foundation for nutrition management in each of the following areas: balancing calories to manage weight, foods and food components to optimize food safety, and the rationale and process for developing healthy eating patterns. The guidelines address issues specific to children and may require further definition as they relate to diabetes management. For example, the guidelines suggest that carbohydrate choices should include fiber-rich fruits, vegetables, and whole grains, and added sugar should be minimized.[47] People with diabetes treated with insulin or insulin secretagogues must be aware of the total amount of carbohydrate eaten at a meal and have a form of oral glucose available at all times to treat hypoglycemia.

ENERGY

It is important to assess a child’s usual dietary intake before the onset of diabetes to assist with the formulation of the initial meal plan. Clinical dietitians frequently use equations such as the Schofield, World Health

Organization (WHO), Harris-Benedict, or estimated energy requirements for age to calculate energy requirements (see Appendix II). Because energy requirements change with age, physical activity, and growth rate, an assessment of height, weight, and energy intake is recommended every three to six months.[48]

Growth is an excellent indicator of the adequacy of energy intake, which should be evaluated by regularly plotting weight and stature on WHO growth charts for children less than 3 years of age and Centers for Disease Control and Prevention (CDC) pediatric growth charts (http://www.cdc.gov/growthcharts) for older children. In addition to adequate daily caloric intake, good metabolic control is essential for normal growth and development. If growth is not optimal, the diet should be reviewed and, in patients with type 1 diabetes, one should screen for evidence of inadequate insulin delivery, hypo- or hyperthyroidism, celiac disease (see later), and adrenal insufficiency. For overweight and obese youth with either type 1 or type 2 diabetes, energy consumption must be reduced to arrest weight gain while supporting normal linear growth and physical development.

DISTRIBUTION OF MACRONUTRIENTS

Many studies have attempted to determine the optimal macronutrient combination that should comprise total energy intake. The general consensus is that a single prescription does not exist. The dietary reference intake (DRI) is cited as a guideline that should be used to formulate the initial prescription. DRI reports suggest a mix of 45%–65% of calories from carbohydrate, 20%–35% from fat, and 10%–35% from protein. Once the nutrition prescription is determined, the proportion of macronutrients can be modified, as necessary, according to blood glucose and plasma lipid goals and requirements for growth and development.

CARBOHYDRATE

Control of blood glucose in an effort to maintain normal or near to normal levels is the primary goal of diabetes management. Because dietary carbohydrate is the major determinant of postprandial glucose levels, food and nutrition interventions that reduce postprandial blood glucose excursions are extremely important.[49] Blood glucose concentrations after a meal are primarily determined by the rate of appearance of glucose in the blood (digestion and absorption) and its clearance from the circulation.

Normal insulin secretory response maintains blood glucose concentrations in a narrow range. In patients with diabetes, however, defects in insulin secretion, defects in insulin action, or both impair normal regulation of postprandial blood glucose concentrations in response to dietary carbohydrate. The amount, type, and source of carbohydrate in foods, as well as the dose and time interval between administration of rapid- or short-acting insulin and consumption of the meal, influence postprandial glucose levels.

The diet should include carbohydrates from fruits, vegetables, whole grains, legumes, and low-fat dairy products. Until the 1980s, dietary dogma had been that people with diabetes should avoid simple sugars and replace them with complex carbohydrates. This belief was based on the assumption that simple sugars are more rapidly digested and absorbed than starches and, therefore, would lead to more pronounced postprandial hyperglycemia. The blood glucose responses to various carbohydrate-containing foods have been extensively investigated and there is little scientific evidence to support this notion. It is now clear that there is a wide spectrum of biologic responses to different complex and simple carbohydrates with so much overlap that they cannot be simply classified into two distinct groups.

Numerous factors influence the glycemic response to food, including the amount of carbohydrate, type of sugar (glucose, fructose, sucrose, and lactose), nature of the starch (amylose, amylopectin, and resistant starch), cooking and food processing (degree of starch gelatinization, particle size, and cellular form), and food structure, as well as other food components (fat and natural substances that slow digestion—lectins, phytates, tannins, fiber, and starch-protein and starch-lipid combinations). Furthermore, the glycemic response to a particular carbohydrate food is dependent on whether it is eaten alone or as part of a mixed meal. Fasting and preprandial blood glucose concentrations, severity of glucose intolerance, and second meal effect (the ability of a meal to diminish the glucose response to carbohydrates in the subsequent meal) are other factors that can affect the glycemic response to foods.

The glycemic index (GI), proposed in 1981 as an alternative system for classifying carbohydrate-containing food, measures the glycemic response after ingestion of carbohydrate. Carbohydrates were previously classified only on the basis of their chemical structure: sugars, starches, or fiber. GI is defined as the incremental area under the plasma glucose response curve over two hours after consumption of a standard amount (usually a 50-g portion) of carbohydrate from a test food relative to that of a control food,

either white bread or glucose.[50] In individuals without diabetes, the glycemic and hormonal responses to a large number of ingested carbohydrates have been systematically examined and their GIs defined. A low-GI food releases glucose more slowly, leading to a flatter postprandial blood glucose curve, whereas a high-GI food causes a more rapid rise in blood glucose levels.

As a result of these studies, the validity of the dogma that ingestion of simple sugars causes a rapid and pronounced rise in blood glucose whereas complex carbohydrates produce only modest increments in blood glucose concentration began to be disputed. Even a single food produces a substantially different glycemic response when it is prepared in different ways. For example, a pureed apple causes a greater increment in blood glucose than does an apple eaten whole. Similarly, ground rice or rice flour causes a greater glycemic and insulinemic response than whole cooked rice and cooking increases the glycemic response to starch. Blood glucose levels after ingesting wheat flour in the form of pasta are lower than those after an equal amount of wheat flour in bread. Thus, the form of a carbohydrate-containing food, in addition to its chemical composition, influences its glycemic effect. The effect of food form alters the rate of digestion and absorption and, therefore, affects postprandial glycemia. Fruits (e.g., apples GI 40, oranges GI 48, peaches GI 42, and pears GI 38 vs. watermelon GI 72) and milk (e.g., whole milk GI 27 and skim milk GI 32)[51,52] cause a lower glycemic response than most starches, and sucrose causes a glycemic response similar to that of bread, rice, and potatoes. In general, most refined starchy foods eaten in the United States have a high GI, whereas nonstarchy vegetables, fruits, and legumes tend to have a low GI. Although insulin- and glucose-lowering medications for type 2 diabetes can adequately control the glycemic impact of added sucrose and other sugars, their impact on total caloric intake suggests that moderation in the use of added sugars is still warranted.

Use of the GI of a food alone ignores the glycemic response if the portion is other than 50 g. The concept of glycemic load was introduced to more accurately describe the postprandial glycemic response to a food when eaten in a typical portion size. The glycemic load is determined by multiplying the GI of a food by the amount (in grams) of carbohydrate in the portion size consumed. For example, 12 medium carrots contain 50 g of carbohydrate. Although carrots have a high GI, a typical portion would not significantly increase the glycemic load of the meal. The glycemic load of a meal reflects the sum of the contributions of each food that is eaten.

The practical usefulness of low-GI diets in type 1 diabetes is beginning

to be embraced as a therapeutic option that potentially enhances overall glycemic control. In 2006, the ADA rated the evidence for use of low-GI diets as an E (evidence based on expert opinion). By 2008, the ADA increased its support to a B (evidence from controlled cohort studies). A meta-analysis of randomized controlled trials (virtually all adult studies) shows that choosing low-GI foods in preference to conventional or high-GI foods has a small (0.4% decrement in hemoglobin A1c) but clinically beneficial effect on medium-term glycemic control in patients with diabetes.[53] It should be noted that no negative effects of the low-GI diet have been documented; however, if GI and load were used as the only criteria for meal planning the results could be a diet high in fat and low in vitamins and minerals. ChooseMyPlate.gov guidelines unveiled in 2011 by the US Department of Agriculture depicts a standard plate with recommended serving sizes from grains, fruits, vegetables, and protein with dairy and fats to the side. When the concepts of GI and load are taught within the context of these nutritionally based guidelines, the result is a healthy diet. This is a useful approach to improving glycemic control, especially in patients with pronounced postprandial hyperglycemia.

Concerns about the acceptance of lower GI foods have been expressed as a reason not to introduce a low-GI diet. At a diabetes summer camp for 7- to 16-year-old children, satisfaction ratings were equal when dinner and snacks containing lower GI foods replaced standard food choices; however, they were lower (although within the acceptable range) at breakfast and lunch.[54] In a different study, 8- to 13-year-old children who received low-GI dietary advice did not report more limited food choices or compromise their macronutrient intake compared to children who planned their meals using a traditional exchange system.[55] Once patients have mastered the concept of matching carbohydrate intake to insulin (discussed later), we recommend providing additional guidance on how to lower the GI of the diet.

FIBER

Fiber refers to the indigestible portion of a plant, and previously it was thought to have no nutritive value in humans. It is now known that fiber markedly influences the digestion, absorption, and metabolism of many nutrients. The fibers (cellulose, lignins, and certain hemicelluloses) in vegetables and grains are usually insoluble in water, whereas many fruits and certain legumes are rich in water-soluble fibers such as pectins, guar, and storage polysaccharides. When carbohydrate is ingested together with

soluble fiber, the blood glucose concentration increases less than when carbohydrate is ingested alone. A large test meal containing carbohydrate, protein, and fat causes significantly less postprandial glycemia when the meal is supplemented with guar due to delayed rather than incomplete absorption of carbohydrate.

Small, short-term studies using large amounts of fiber (>30 g/d) in suboptimally controlled individuals with type 1 diabetes suggest a positive effect of fiber on glycemia; however, in participants using intensive insulin therapy 56 g of fiber had no beneficial effect on glycemic control.[56] Subjects with baseline hemoglobin A1c levels of 7%–10% receiving more than or equal to two injections per day were randomized to either a high-fiber (50 g/d), low-GI diet or a low-fiber (15 g/d), high-GI diet for 24 weeks. The high-fiber diet significantly decreased mean daily blood glucose concentrations, number of hypoglycemic events, and hemoglobin A1c levels in the subgroup of study participants who were adherent to their diet. There were no beneficial effects, however, on total cholesterol, high-density lipoprotein (HDL) cholesterol, or triglyceride concentrations.[57] A cross-sectional analysis of dietary fiber in type 1 diabetes patients in EURODIAB IDDM showed that a higher intake of soluble fiber (from fruit, vegetables, and legumes) was independently associated with higher levels of HDL cholesterol in both men and women and lower low-density lipoprotein (LDL) cholesterol levels in men but not women.[58] No substantial differences were observed between soluble and insoluble fiber intakes. These observations suggest that inclusion of plant fiber in the diet may benefit patients with diabetes by decreasing postprandial hyperglycemia.

People with diabetes are encouraged to choose a variety of fiber-containing foods, including legumes, fiber-rich cereals (≥5 g of fiber per serving), fruits, vegetables, and whole grain products and should be encouraged to achieve the fiber intake goal set for the general population: 14 g per 1000 kcal. Alternatively, children more than 2 years old should consume an amount of dietary fiber greater than or equal to their age (in years) plus 5 g daily.[59]

PROTEIN

Protein requirements are not increased when diabetes is well controlled; therefore, children with diabetes should follow the recommended daily allowance (RDA) of protein for children without diabetes. The physiologic requirement is determined by the amount of protein necessary to sustain

normal growth; is based on ideal weight for height; and varies with age, being highest in infancy and early childhood. The protein requirement (per kilogram body weight) of infants, children, and adolescents is higher than that of adults. Protein intake decreases from approximately 2 g/kg/d in early infancy to 1 g/kg/d for a 10-year-old and is 0.8–0.9 g/kg/d in later adolescence. Children and adolescents with diabetes who have normal renal function should consume the same amount of protein as unaffected children. The 2010 DRIs for children 1–3 years old is 5%–20% and for children 4–18 years of age 10%–30%, respectively, of total energy intake. The recommendation for adults with diabetes is to maintain protein intake at less than 20% of energy needs. Any ingested protein that exceeds the body's requirement for new protein synthesis enters the carbon pool and is converted into either glucose or fat.

Dietary protein can be derived from both animal and vegetable sources; however, the source of protein is not especially important provided that all the essential amino acids are available in adequate amounts. Sources of good-quality protein include meat, poultry, fish, eggs, milk, cheese, and soy. To lower the consumption of saturated fat, less protein should be derived from red meat, whole milk, and high-fat dairy foods than is customary in the United States. With the onset of nephropathy, as evidenced by persistent microalbuminuria, excessive protein intake may be detrimental and it is prudent to advise a protein intake similar to the adult RDA (0.8 g/kg body weight per day), approximately 10% of daily energy intake. With a protein intake of 0.6 g/kg/d, evidence of protein undernutrition has been reported.

FAT

The American Heart Association (AHA) categorizes children with type 1 diabetes in the highest tier for cardiovascular risk.[60] People diagnosed with type 1 diabetes in childhood have a high risk of early subclinical[61] and clinical[62] cardiovascular disease (CVD). The prevalence of CVD is increased in both type 1 and type 2 diabetes. Type 1 diabetes is associated with a greater than or equal to 10-fold increase in CVD compared with an age-matched population without diabetes.[63] Atherosclerotic vascular disease affecting the coronary, cerebral, and lower extremity large arteries is the major cause of mortality and morbidity in patients with diabetes in Westernized populations, and about 75% of patients with diabetes in Europe and North America die of coronary heart disease. This terrible toll is not inevitable. In other parts of the world, individuals with diabetes who

escape atherosclerosis have low serum cholesterol levels and live on diets that are usually high in starch and have a low content of saturated fat.

The DCCT/EDIC report on the effect of intensive diabetes therapy on CVD in type 1 diabetes shows that higher total and LDL cholesterol levels at baseline are significantly associated with the occurrence of CVD independent of treatment assignment.[64] Saturated fatty acids and *trans*–fatty acids are the principal dietary determinants of plasma LDL cholesterol concentrations. In individuals without diabetes, reducing the consumption of saturated fatty acids and *trans*–fatty acids and cholesterol decreases plasma total and LDL cholesterol levels. Reducing the consumption of saturated fatty acids may also reduce HDL cholesterol concentrations; importantly, the ratio of LDL to HDL cholesterol is not adversely affected (Table 59-4). Therefore, to reduce CVD risk consumption of saturated fat, *trans*–fatty acids, and cholesterol must be limited while increasing the intake of ω-3 fatty acids and unsaturated fat. *Trans*–fatty acids, formed when vegetable oils are processed and solidified (hydrogenation), are found in margarine, deep-frying fat, cooking fat, and some processed foods such as cookies and cakes.

Children and adolescents with well-controlled type 1 diabetes are not at high risk for developing lipid abnormalities, but they should be screened and monitored according to specific guidelines.[65] For normally growing children and adolescents with normal plasma lipid levels, less than 10% of energy from saturated fat is recommended, the daily intake of cholesterol should be less than 300 mg/d, and consumption of *trans*–fatty acids should be minimal. In the overweight or obese child, total fat should be reduced to reduce total energy consumption. Drinking less whole milk; eating less red meat and high-fat dairy foods; and eating more poultry, fish, and vegetable proteins can reduce consumption of saturated fat.

For individuals with diabetes and increased LDL cholesterol concentrations, initial therapy is with a step 2 AHA diet, which restricts saturated fat to 7% of total calories and dietary cholesterol to 200 mg/d.[60] A recent survey of a representative sample of US youth with diabetes (89% with type 1 and 11% with type 2) aged 10–19 years shows that fat represents 37% to 38% of their total energy consumption. Only 6.5% of the cohort met the ADA recommendation of less than 10% of energy from saturated fat, and less than 50% met the recommendations for total fat, vitamin E, fiber, fruits, vegetables, and grains. It is evident that there is a critical need to improve the diet of youth with diabetes.[66]

TABLE 59-4 Practical Recommendations for Implementing the AHA Dietary Guidelines

- Reduce added sugars, including sugar-sweetened drinks and juices.
- Use canola, soybean, corn, safflower oil, or other unsaturated oil in place of solid fats during food preparation.
- Use fresh, frozen, and canned vegetables and fruits and serve at every meal; be careful with added sauces and sugar.
- Introduce and regularly serve fish as an entrée.
- Remove the skin from poultry before eating.
- Use only lean cuts of meat and reduced-fat meat products.
- Limit high-calorie sauces such as Alfredo, cream sauces, cheese sauces and hollandaise
- Eat whole-grain breads and cereals rather than refined products; read labels and ensure that “whole grain” is the first ingredient on the food label of these products.
- Eat more legumes (beans) and tofu in place of meat for some entrées.

Breads, breakfast cereals, and prepared foods, including soups, may be high in salt and sodium and/or sugar; read food labels for content and choose high-fiber, low-salt/low-sugar alternatives.

SODIUM

The average consumption of salt in populations correlates with the prevalence of hypertension, and a high intake of sodium causes high blood pressure in susceptible individuals. Most processed foods contain considerably more sodium than similar foods prepared from raw ingredients. Sodium is usually present in the form of sodium chloride; but it may also be present as sodium glutamate, added to enhance flavor, or added as sodium nitrite included as a preservative. The leaders in sodium content are takeout or fast foods, which account for an ever-increasing proportion of the US diet. It has been estimated that 70% of the sodium in the US diet is derived from prepared foods.

Sodium consumption in persons with diabetes should be the same as that for the general population, between 2400 and 3000 mg daily. A reduction in salt intake lowers blood pressure in both normotensive and hypertensive individuals. In adults who do not have diabetes, a reduction

in salt consumption may lower systolic blood pressure by 4 to 5 mmHg. A reduction in salt intake to 2400 mg daily is recommended for patients with diabetes and hypertension (in children and adolescents defined as the average of three separate systolic and/or diastolic blood pressures >95th percentile for age, sex, and height). To achieve these goals, individuals with diabetes should be advised to reduce their use of table salt and decrease their consumption of convenience foods.

SWEETENERS

The preference for a sweet taste is present at birth, and for most individuals sweetness adds significant enjoyment to eating. Sweeteners are available in two varieties, nutritive and nonnutritive.[67] If a patient on a fixed carbohydrate meal plan has exceeded his carbohydrate allotment and has a preference for sweeter products, nonnutritive sweeteners (NNSs) can be used. Current recommendations do not exclude the use of nutritive sweeteners, although nutritive sweeteners should be limited to 10% of total calories. It is important to note that the Nutrition Facts label does not differentiate between carbohydrate supplied by naturally occurring sugar and added sugar. This distinction is often a source of confusion to the general public.

NUTRITIVE SWEETENERS

Nutritive sweeteners contain carbohydrate and provide energy. Whereas monosaccharides or disaccharides provide 4 kcal/g, sugar alcohols (polyols) provide 2 kcal/g. These include sucrose; fructose; sorbitol; xylitol; and corn sweeteners such as corn syrup, fruit juice or fruit juice concentrate, honey, molasses, dextrose, and maltose.

Sucrose

Several studies have shown that sucrose as part of the meal plan does not adversely affect blood glucose control in individuals with type 1 or type 2 diabetes. In children, a moderate amount of sucrose does not increase glycemia more than an isocaloric amount of starch.[68] If a patient is on a fixed meal plan, sucrose and sucrose-containing foods may be substituted for other carbohydrates but may not simply be added to the meal plan. When making such substitutions, one must consider the nutrient content of sucrose-containing foods as well as the presence of other nutrients,

especially fat, frequently ingested with sucrose. Data are conflicting, and additional research will be necessary to determine whether dietary sucrose adversely affects serum lipids in people with diabetes. Sucrose-sweetened beverage consumption has been linked to excessive weight gain, and in an intervention that reduced consumption of sugar-sweetened beverages (replacement of sucrose-sweetened beverages by the provision of noncaloric beverages at home) among overweight and obese adolescents the increase in BMI was smaller in the experimental group than in the control group after one year.[69] Consumption of sugar- sweetened beverages should be strictly curtailed in youth with type 2 diabetes.

Fructose

Fructose is a constituent of sucrose and accounts for approximately 9% of energy intake in the United States. About one-third of dietary fructose is from fruits, vegetables, and other natural dietary sources, and about two-thirds is from the addition of fructose to food and beverages. Compared to sucrose, fructose is similar in taste but 1.2–1.8 times sweeter. It is absorbed more slowly from the intestinal tract than glucose, sucrose, or maltose and is converted to glucose and glycogen in the liver. Several studies have shown reduced postprandial plasma glucose levels when isocaloric amounts of fructose replaced sucrose or starch in the diets of people with diabetes.

Any potential benefit is tempered by the concern that excessive consumption of fructose may have adverse effects on serum lipid, especially LDL cholesterol, levels.[70] Consumption of large amounts of fructose (15%–20% of daily energy intake [90th percentile of usual intake]) increases fasting total and LDL cholesterol in people with and without diabetes.[70] Because of concern about the potential adverse effect of large amounts of fructose on serum lipids, fructose may have no advantage over other nutritive sweeteners and is not recommended. There is no reason, however, to avoid fruits, vegetables, and honey, in which fructose occurs naturally. People with dyslipidemia should be advised not to consume large amounts of fructose.

Sugar Alcohols (Polyols)

Sugar alcohols are classified as hydrogenated monosaccharides. These include erythritol; sorbitol; mannitol; xylitol; hydrogenated disaccharides (e.g., isomalt, maltitol, and lactitol); and mixtures of hydrogenated mono-, di-, and oligosaccharides (e.g., hydrogenated starch hydrolysates).[71] Sugar

alcohols contain, on average, about 2 cal/g (one-half the calories of other sweeteners such as sucrose). When calculating carbohydrate content of foods containing sugar alcohols, it is appropriate to subtract half the sugar alcohol grams from total carbohydrate grams. Studies of subjects with and without diabetes have shown that sugar alcohols produce a lower postprandial glucose response than sucrose or glucose and have a lower available energy.

Sorbitol

Sorbitol is about half as sweet as sucrose and is slowly and only partially absorbed from the gut and then metabolized to fructose in the liver by sorbitol dehydrogenase. Sorbitol has been assigned an energy value of 2.6 kcal/g; however, its precise caloric value is uncertain. Its slow absorption causes blood glucose levels to rise less rapidly than after the absorption of sucrose and other carbohydrates. When the daily intake exceeds 30–50 g, sorbitol causes flatulence, intestinal cramps, and osmotic diarrhea. Isocaloric substitution of sorbitol in the diet does not appear to alter metabolic control.

Xylitol

Xylitol, a pentahydric alcohol, is as sweet as sucrose and widely distributed in fruits and vegetables. It is metabolized to glucose, pyruvate, and lactate, mainly by the liver and, to a lesser extent, by the kidneys. Xylitol is slowly converted to glucose; however, ingestion of a single 30- to 40-g dose causes diarrhea, which limits its usefulness as an isocaloric carbohydrate substitute. Scant information is available on the effect of long-term oral administration on blood glucose control of diabetes. Many so-called dietetic foods marketed for people with diabetes contain sorbitol or xylitol instead of sucrose. In general, the sugar alcohols offer no nutritional advantage over other nutritive sweeteners and are usually more expensive.

Resistant Starch

Nondigestible oligosaccharides and the starch amylose are not digested and, therefore, not absorbed as glucose in the small intestine, but they are almost completely fermented in the colon and produce about 2 kcal/g of energy. It is estimated that resistant starch and unabsorbed starch represents approximately 2%–5% of the total starch ingested in the average Western diet. Legumes are the major source of resistant starch (2

to 3 g per 100 g of cooked legumes). Uncooked cornstarch contains about 6 g resistant starch per 100 g dry weight. Single meal studies have found that meals high in resistant starch caused some reduction in postprandial glucose and insulin responses compared to meals with equivalent amounts of digestible starch. Uncooked cornstarch as part of a bedtime snack has resulted in less overnight hypoglycemia in children and adults with type 1 diabetes; however, a study in intensively treated adults with type 1 diabetes showed that a bedtime snack bar (194 kcal, 39 g carbohydrate, 4 g fat, and 4 g protein) containing 6.25 g uncooked cornstarch did not prevent nocturnal hypoglycemia.[72]

Other Nutritive Sweeteners

These include corn sweeteners such as corn syrup, fruit juice or fruit juice concentrate, honey, molasses, dextrose, and maltose. These sweeteners have the same calorie value as sucrose, and there is no evidence that they cause a less pronounced increase in blood glucose concentrations than sucrose. All nutritive sweeteners contribute calories and, like sucrose and fructose, must be accounted for in meal planning.

NONNUTRITIVE SWEETENERS (LOW-CALORIE, OR ALTERNATIVE, SWEETENERS)

NNSs are widely used in beverages and other food products such as diet soft drinks, yogurts, desserts, and gum.[67] The Food and Drug Administration (FDA) has approved six NNSs for use in the United States: saccharin, aspartame, acesulfame potassium, neotame, sucralose, and stevia. When used judiciously, NNSs can facilitate reductions in intake of added sugars, thereby resulting in decreased total energy and weight loss/weight control.

Saccharin was discovered in 1897 and until the advent of aspartame was the most commonly used artificial sweetener. It leaves a slightly bitter, metallic aftertaste. Administration of large amounts of saccharin to rats was associated with an increased occurrence of bladder tumors, which raised concerns about its carcinogenic potential and safety for use in human beings, but it is no longer on the FDA list of cancer-causing chemicals.

Aspartame has been available since the early 1980s. It is a dipeptide consisting of phenylalanine and aspartic acid and is 200 times sweeter than sugar. At one-tenth of a calorie, it has the sweetness of a teaspoon of

sugar. It rapidly gained widespread popularity as an alternative to saccharin.

Acesulfame K is a white, colorless, and crystalline sweetener approximately 200 times sweeter than sucrose. It is a derivative of acetoacetic acid and has a structure similar to that of saccharin. It was approved for use by the FDA in 1988 and is marketed in the United States under the brand name Sunette® when used as an ingredient of foods and as Sweet One® when sold as a tabletop sweetener. It is stable both in liquids and during baking and cooking.

Sucralose is made from sucrose through a process in which three hydrogen-oxygen groups are replaced with chlorine atoms. Sucralose is 600 times sweeter than sucrose. It is very stable and can be used for baking and cooking and has no effect on glucose homeostasis in diabetic subjects.

Neotame was approved by the FDA in 2002 as a sweetener for general use in foods and beverages. It is also a derivative of the dipeptide composed of aspartic acid and phenylalanine and has a clean sweet taste like sugar. It is about 8000 times sweeter than sugar on a weight basis; therefore, only very small amounts are needed to sweeten foods and beverages.[73]

Stevia: steviol glycosides, rebaudioside A and stevioside, are extracted from leaves of the plant *Stevia rebaudiana* Bertoni. In 2008, the FDA granted Generally Recognized as Safe status for purified rebaudioside A and stevioside. Steviol glycosides have a sweet, clean taste at usual amounts. They are stable in dry form and more stable than aspartame or acesulfame K in liquid form.

MEDICAL NUTRITIONAL THERAPY

A registered dietitian skilled in MNT is the diabetes team member who plays the leading role in providing nutrition care; however, it is important that all members of the diabetes team, including physicians and diabetes nurse educators, be knowledgeable about MNT and help to support its implementation.[74]

MNT begins with a nutrition assessment, taking heed of the ethnic, religious, and economic factors that pertain to the individual with diabetes and his or her family. Family eating patterns, meal preparation methods, and nutrition beliefs must be identified. The initial evaluation of eating styles and nutrition beliefs within the family assists the dietitian to determine how best to begin educating the patient and family to achieve nutrition guidelines for optimal management of the disease. The first

priority is to teach families how diet and insulin (or other antihyperglycemic medications) affect blood glucose levels and overall metabolic control. Thereafter, it is important to teach dietary principles that will help patients reduce their risk of diabetes-related complications, including CVD.

The way meals are planned should be understandable to the patient and family. A vast lay literature about diet is available to the general public; some accurately describes evidence-based research, but much does not. Families that have received and applied advice consistent with the recommendations of the AHA, American Academy of Pediatrics, and Dietary Guidelines for Americans 2010 and information available at ChooseMyPlate.gov will benefit by an approach that builds on their current practices.

Changing how we think about our food and beverage selections on a day-to-day basis is, perhaps, the most difficult aspect of diabetes management. Before discovering that a member of the family has diabetes, families may give significant thought to their food purchases, but planning when and the precise amount to be eaten at a meal is not common in the general population. Patients with both type 1 and type 2 diabetes have the same goals, namely, to achieve and maintain optimal growth and metabolic control, which includes target blood glucose and glycated hemoglobin levels (Table 59-2). The initial focus of MNT, however, differs between the two major types of diabetes.

CONSIDERATIONS WHEN FORMULATING A MEAL PLAN FOR TYPE 1 DIABETES

In the child with type 1 diabetes, the primary goal is to match insulin delivery and carbohydrate consumption while optimizing growth and physical development. Newly diagnosed children with type 1 diabetes usually present with weight loss and are hungry for the first few days to weeks after starting insulin therapy. Therefore, the child's initial dietary allowance is determined by appetite. The meal plan should be formulated to restore and then maintain an appropriate body weight and allow for normal growth and development. Energy requirements vary with age, sex, height, and weight, as well as with physical activity, season of the year, and stage of puberty. If the child's usual food intake cannot be adequately determined, the nutrition prescription can be based on a formula for estimating energy and protein allowances (see the section "Energy").

The daily eating patterns of young children generally include three

meals and two or three snacks, depending on the length of time between meals, age of the child, usual bedtime, and level of physical activity. Although their daily energy intake is relatively constant over time, young children adjust their energy intake at successive meals. Because the energy needs of children continuously change, food intake should be reevaluated at three- to six-month intervals depending on the age of the child. If a pattern of premeal hyperglycemia is identified, it should be treated by adjusting the insulin dose and not by withholding food. Trends in hunger and satiety should be tracked. The meal plan should be adjusted when an abnormal trend in growth is observed, when the child frequently complains of being too full to eat the prescribed meal or frequently complains of being hungry after meals. Occasional hunger between meals need not lead to a major dietary change because calorie-free foods can be offered. Additional servings of protein and fat-rich foods should not be routinely offered to satisfy hunger, and force-feeding carbohydrate to achieve meal plan goals is discouraged.

Dietary strategies are dependent on the patient's insulin replacement regimen (Table 59-5). The concept of total carbohydrate intake determining the premeal insulin dosage is supported by data from the DCCT. Individuals who adjusted their premeal insulin dosages based on the carbohydrate content of their meals had a 0.5% lower hemoglobin A1c level than those who did not adjust premeal insulin doses.[75]

TABLE 59-5 General Approach to Meal Management

Type 1 diabetes	Basal-bolus or flexible insulin regimen (includes insulin pump therapy)	Carbohydrate content can vary
		Must accurately estimate carbohydrate and match insulin dose using predetermined insulin to carbohydrate ratio
		Should eat at least 3 meals daily
		Should not eat less than a predetermined amount of carbohydrate per day
		Continued education and assessment of readiness to change lifestyle to achieve heart-healthy diet
	Sliding scale or fixed dose insulin regimen	Meal times consistent from day to day
		Three meals and 2 or 3 snacks daily
		Meals and snacks spaced 2 to 3 hours apart
		Consistent carbohydrate intake
		Snack before bed to decrease risk of overnight

	hypoglycemia Continued education and assessment of readiness to change lifestyle to achieve heart-healthy diet
Type 2 diabetes	Meal plan to assist with evenly spaced carbohydrate intake and increased emphasis on reducing calories to promote weight loss
Age-related issues: children's activities often differ on weekdays compared to weekends and holidays, and appropriate allowance must be made for these differences. The meal plan must take into account the child's school schedule, early or late lunches, gym classes, and after-school physical activity.	

Rapid-acting insulin combined with intermediate-acting (neutral protamine Hagedorn [NPH]) insulin may be used at the outset because glycemia can often be controlled with two or three daily injections: typically at breakfast, dinner, and/or bedtime. Such regimens may be preferred, for example, when a young child attends a school that does not employ a nurse. With this regimen, rapid- and intermediate-acting insulins are released from the subcutaneous injection site into the circulation, reaching peak effects 1 to 2 hours and 4–10 hours after injection, respectively (Table 59-1). A meal plan is formulated to provide a constant carbohydrate intake because the breakfast dose of NPH will have its peak effect between lunch and dinner, and the dose is based on the glycemic load provided by lunch and a midafternoon snack. Therefore, consuming more or less than the recommended amounts of carbohydrate at meals will result in hyper- or hypoglycemia, respectively. Whenever the quantity of carbohydrate in the meal plan is changed, the insulin dose must be reviewed. The successful use of fixed doses of rapid-acting together with intermediate-acting insulin requires consistency in the timing and carbohydrate content of meals. These fixed insulin regimens are not ideal for very young children whose appetites are highly variable and for families whose schedules are too busy or unpredictable to allow a high level of consistency with meal times and amounts.

In general, more physiologic and flexible (basal-bolus) insulin replacement strategies are preferred.[76] These employ multiple daily doses of rapid-acting insulin together with a long-acting (basal) insulin, or CSII of rapid-acting insulin using an insulin pump. Meal plans are flexible with respect to the time at which meals are eaten and the amount of carbohydrate consumed at each meal. Patients adjust the premeal rapid-acting insulin dose to match the carbohydrate content of the meal. There is a strong relationship between the premeal insulin dose and the postprandial

response; therefore, patients who use these regimens are encouraged to perform pre- and postprandial blood glucose monitoring to optimize prandial insulin doses. The patient's blood glucose level prior to the meal and the carbohydrate content of the meal are used to determine the total mealtime insulin dose. Variation in the carbohydrate content of meals does not modify the patient's basal insulin requirement. In contrast to patients receiving intermediate-acting insulin, patients who use basal-bolus insulin therapy are not obliged to eat snacks to offset excessive insulin action between meals unless they engage in strenuous or prolonged physical activity. They must, however, administer rapid-acting insulin each time they consume carbohydrate. For young children with variable appetites and unpredictable eating patterns, administering rapid-acting insulin after the meal, although not ideal, relieves the stress parents experience at meal times and provides a practical solution to the uncertainty of knowing how much insulin to administer.

CONSIDERATIONS WHEN FORMULATING A MEAL PLAN FOR TYPE 2 DIABETES

Children with type 2 diabetes are overweight or obese at presentation and there is great emphasis on weight loss, limiting caloric intake, and distributing meals evenly throughout the day. Even modest weight reduction alone increases sensitivity to insulin and improves fasting and postprandial plasma glucose levels. Studies in adults show that structured, intensive lifestyle programs involving participant education, individualized counseling, reduced energy and fat intake (~30% of total energy), regular physical activity, and frequent participant contact are necessary to produce long-term weight loss of 5%–7% of starting weight. Accordingly, lifestyle changes that lead to weight loss are the cornerstone of therapy in type 2 diabetes. It is noteworthy, however, that in the TODAY study of treatments to maintain glycemic control in children and adolescents with recent-onset type 2 diabetes the effect of an intensive lifestyle intervention program focusing on weight loss through healthful eating and activity behaviors together with metformin was not superior to metformin alone in achieving durable glycemic control.[77]

Aims of treatment for type 2 diabetes are to lose weight, normalize fasting and postprandial blood glucose and hemoglobin A1c values, identify and treat associated comorbidities such as hypertension and hyperlipidemia,[78] and minimize the risk of acute and chronic

complications associated with diabetes. The early age of onset of type 2 diabetes in children can be expected to increase their risk of microvascular complications, which are directly related to the duration of diabetes and severity of hyperglycemia. Indeed, early-onset type 2 diabetes is associated with a high incidence of diabetic nephropathy[79] and vascular disease may already be present at diagnosis.

MNT for patients with type 2 diabetes emphasizes healthy eating to optimize metabolic control while achieving sustained weight loss. The individual's usual dietary and physical exercise habits can assist in determining the best approach to formulating a meal plan. Patients and their family members should receive guidance on behavior modification strategies to change their lifestyle, decrease their consumption of high-energy/high-fat foods,[80] and incorporate daily aerobic physical activity in their lives. To increase children's physical activity, the amount of time devoted to sedentary activities and "screen time" (viewing television, playing video games, surfing the Internet, etc.) must be strictly limited.[81,82] Recommendations outlined by the AHA (Table 59-4) that include but are not limited to simple suggestions such as eliminating sugar-containing sodas and juices, and decreasing the consumption of calorie-dense fast foods and high-fat snacks, can improve blood glucose levels and achieve weight loss. Patients who do not have regularly scheduled meals and eat large amounts of food toward the end of the day can improve their glycemic control when carbohydrate intake is more evenly distributed throughout the day. If weight loss is not achieved by revising eating habits and food selections, a more structured approach to define appropriate portions and calories is warranted. These diets are based on energy requirements calculated from resting energy expenditure equations and modified based on weight change. Younger children can achieve weight loss and better glycemic control when weight is maintained or the rate of weight gain is slowed so that with linear growth their weight for height gradually returns toward normal over time. A child whose BMI exceeds the 95th percentile, however, should be encouraged to lose weight. When the diet is implemented, linear growth should be monitored to assure that the decrease in calories does not adversely affect growth velocity.

Individuals with type 2 diabetes who do not achieve satisfactory glycemic control with a combination of weight loss, portion control, and optimal meal spacing require drug therapy. The meal plan then needs to be formulated based on the prescribed medical regimen. At the time of diagnosis, patients may require glucose-lowering therapies, including

insulin, to stabilize metabolic control while lifestyle changes are implemented.

TEACHING INDIVIDUAL NUTRITION AND MEAL PLANS

The dietitian has the important task of evaluating the patient's and family's understanding of basic principles of nutrition and then providing sufficient knowledge to help clients reach their nutrition goals. The aim is to lay a foundation for lifelong, healthy eating habits for the child and family. Even the most intensive regimens of insulin administration are not successful without careful attention to meal planning and the family's eating style. Nutrition education, like all aspects of diabetes education, is an ongoing process, requiring periodic review of the meal plan and to teach the complex interactions of insulin, carbohydrates, meal composition, and exercise on glycemic response in the context of a healthy diet.

Health-care professionals must communicate their recommendations (supported by scientific evidence) in practical terms and teach individuals with diabetes how to minimize the daily burden of food calculations, maintain the pleasure of eating, and enjoy a wide variety of food choices. When implementing a nutrition plan, the distribution of educational materials and approaches will help other involved health-care providers assist in evaluating their patient's understanding of and adherence to the plan. Appreciation of a patient's or family's learning style, math and reading skills, and attention to detail are important when devising and implementing the plan.

Several different meal planning strategies are used to manage individuals with diabetes.[83,84] The primary strategies include exchange lists, carbohydrate choices, and carbohydrate counting. Additional strategies include low-GI diets and healthy food choices. Despite the great importance of dietary management, there is little evidence to support the superiority of one dietary strategy over another nor are there universally agreed on techniques for providing dietary education. Combining several meal planning approaches and teaching methods is usually necessary to ensure that patients receive all the nutrients necessary to attain normal growth and development while optimizing glycemic control.[84]

MEAL PLANNING STRATEGIES

Exchange Diet

For decades, the exchange system approach for meal planning was the most widely used strategy. This approach defines carbohydrate intake within the context of food groups, thus controlling both carbohydrate intake and by recommending sources of carbohydrate ensuring that nutritional needs are being met. It was originally developed in 1950 by a joint committee of the ADA, American Dietetic Association (now the Academy of Nutrition and Dietetics), and Diabetes-Arthritis Program of the US Public Health Service. The Exchange List for Meal Planning was designed as an education tool that placed foods into groups that could be "exchanged" or traded with another group based on macro- and micronutrients. Revisions occurred in 1986, 1995, 2003, and 2008 to meet changing nutritional recommendations and in response to the variety of foods available in the market. The 2008 revision included a name change to Choose Your Foods: Exchange Lists for Diabetes to stress self-management while alerting health-care providers that it was a revision rather than a new approach. This continues to be an excellent tool for patients on oral antihyperglycemic medications or a fixed insulin regimen and for whom a defined amount of carbohydrate is recommended for each meal and snack.

Carbohydrate choices are a simplified version of the Choose Your Foods: Exchange lists for carbohydrate counting. The approach defines carbohydrates and which foods contain carbohydrates and then identifies a Carbohydrate Choice as the amount of the food that provides about 15 g of carbohydrate.

Carbohydrate counting in total grams is taught when rapid-acting insulin is used before the upcoming meal. The dose of insulin is calculated based on the amount of carbohydrate contained in the meal using an individualized insulin to carbohydrate ratio (e.g., 1 unit rapid-acting insulin per 10 g carbohydrate). Accurate measurement of portion sizes has to be learned, and weighing and measuring foods help to achieve familiarity. Active learning is required to acquire this skill. If blood glucose control inexplicably appears to deteriorate, effort should be renewed to improve the accuracy of carbohydrate counting. A recent study showed that adults with an average diabetes duration of 21 years underestimated the carbohydrate content of 62% of their meals, and this predicted higher glycemic variability. Smart et al. examined the accuracy of carbohydrate counting in children, adolescents, and their caregivers:

larger meals were more likely to be underestimated and subjects who had been carbohydrate counting the longest made the most errors.[85] These observations suggest that maintaining visual estimation of carbohydrate counting requires ongoing evaluation to ensure that desired glycemic control is maintained. Spiegel et al. used an increased-intensity interactive approach to teach carbohydrate counting to adolescents identified as having poor carbohydrate counting skills[86]; however, the intervention did not lead to a significant improvement in glycemic control. In contrast, a similar approach significantly improved glycemic control in adults with type 1 diabetes.[87] We have yet to identify the best approach to teaching carbohydrate counting or the frequency of weighing and measuring food required to learn and maintain the visual skills for accurate carbohydrate counting.

The advantage of carbohydrate counting is the availability of food labels and ready access to reference books and electronic resources. Patients may find it easier to count grams of carbohydrate than learn exchanges or carbohydrate choices, and this allows for a wider selection of foods. Most food labels do not provide exchange values, but all provide information on their carbohydrate content. Patients must be taught how to read and interpret food labels, and it is important to review sample food labels and ensure that patients demonstrate proficiency utilizing Nutrition Facts to determine portions per container and the amount of carbohydrate in the portion that they actually consume.

Advanced Carbohydrate Counting

Advanced carbohydrate counting is encouraged for patients using flexible, basal-bolus insulin regimens, either multiple daily injections or an insulin pump. This approach attempts to more accurately count carbohydrates, and insulin doses are adjusted to match anticipated or consumed carbohydrate intake. Portion sizes should first be determined by weighing or measuring foods to help develop excellent visual estimation skills. The Nutrition Facts on food labels and nutrition composition reference guides are used to determine the carbohydrate content of the portion eaten. The total amount of carbohydrate should be adjusted for fiber and sugar alcohol content to account for their decreased impact on glycemic response. General guidelines are to subtract all of the grams of fiber if it accounts for more than 5 g of the total carbohydrate in the meal and subtract half of the grams from sugar alcohols. For practical purposes, it may be easier and provide a clearer message to subtract the entire amount of fiber, especially

if a patient usually consumes a high-fiber diet. Insulin doses are not adjusted for GI or glycemic load.

If the premeal insulin dose is correctly adjusted for the carbohydrate content of the meal and premeal blood glucose level, the glycemic response two to four hours after the meal should be within target range.[88] Although fat intake does not contribute to glycemic load, a high-fat diet can prolong hyperglycemia due to delayed digestion and absorption of the meal, and insulin pump users are encouraged to use a dual-wave or square-wave (extended) insulin bolus when consuming a meal with high fat content.[89]

Celiac Disease and Type 1 Diabetes Mellitus

Celiac disease occurs in approximately 5%–7% of patients with type 1a diabetes mellitus. Weight loss or failure to gain weight, erratic blood glucose control, and unexpected hypoglycemic episodes should alert the clinician to obtain a tissue transglutaminase determination, along with measurement of serum IgA, to screen for celiac disease. Approximately 25% of patients are asymptomatic at the time of diagnosis.[90] Definitive diagnosis requires endoscopy and a duodenal biopsy before initiating treatment with a gluten-free diet. Meal planning requires identifying and eliminating all gluten-containing foods from the diet as well as counting carbohydrates, which presents a challenge for two reasons. First, gluten-free breads and cereals are denser than their gluten-containing counterparts. Therefore, a gluten-free product that appears the same size as its gluten-containing counterpart has more carbohydrate. Affected patients must relearn portion sizes when gluten-free foods are introduced. Second, most commercially available gluten-free breads and cereals are made from highly refined, high-GI grains. Consequently, consuming gluten-free products can cause more pronounced excursions in postprandial blood glucose levels. One strategy for minimizing postprandial glucose excursions on a gluten-free diet is to incorporate naturally occurring gluten-free whole grains, such as quinoa, buckwheat, and brown rice, in the diet.

Patients should also be alerted to the probability that they will need frequent changes in their prandial insulin to carbohydrate ratios as the gastrointestinal tract heals and is able to absorb more glucose. Asymptomatic patients are more likely to be noncompliant with gluten restriction, and less than absolute compliance with gluten restriction will prevent gut healing.

OUTPATIENT NUTRITION MANAGEMENT

A single instructional session is never adequate. To be effective, nutrition education must be an ongoing process with periodic review of the meal plan and assessment of accuracy of carbohydrate estimation. The parents and patient with newly diagnosed diabetes should meet with a dietitian several times during the first few weeks after diagnosis. Because children's energy needs change with growth and variations in physical activity, food intake and overall dietary quality, ideally, should be reassessed every three to six months.

Patients should be encouraged to keep records of food, medication, blood sugar levels, and physical activity to facilitate the recognition of glycemic patterns. By measuring pre- and postprandial glucose levels with various foods, many individuals use their empirical experience to optimize insulin dosing and achieve postprandial glucose goals. Reviewing these data with their dietitian can assist patients to consume preferred foods and optimize their glycemic control.

The use of imaginative, individualized teaching methods and materials will engage the attention and cooperation of children and parents more effectively than abstract concepts of nutritional principles and detailed diet sheets that list the composition of individual foodstuffs. Incorporating visual demonstrations with exercises such as sorting pictures for their carbohydrate content and then healthier carbohydrate content will keep the patient and family involved and has the advantage of offering insight into their understanding of important nutrition concepts.

Once the family is able to accurately apply the principles of nutrition management directed toward glycemic control, focus should turn to identifying food choices and cooking methods that will be consistent with guidelines aimed at lowering the risk of CVD. If the patient's glycemic control is poor, if growth is failing, if weight gain is excessive, or if the insulin regimen is changed, the dietitian should be reconsulted to review the meal plan and to make any necessary dietary recommendations.

MEAL PLANNING AND GLYCEMIC OUTCOMES

During the DCCT, adherence to prescribed meal plans, including appropriate treatment for hypoglycemia, was associated with a significant 0.25%–1.0% absolute reduction in hemoglobin A1c among intensively treated individuals.[75] Following the DCCT, the introduction of novel insulins and greater use of insulin pumps made greater mealtime flexibility while maintaining better glycemic control possible. Over the last five

years, there has been a renewed interest in the association between meal planning strategies, particularly carbohydrate counting, and glycemic outcomes.[85, 91–93] Empirical evidence suggests that absolute accuracy is unnecessary because carbohydrate estimates within 10–15 g of the actual carbohydrate content of a meal do not adversely affect postprandial glycemic excursions[85,92,93] or hemoglobin A1c levels[91] in youth with type 1 diabetes. Conversely, inconsistent carbohydrate estimation has been associated with higher hemoglobin A1c,[91] and estimation greater and less than 20 g of the actual meal carbohydrate content[92] is associated with postprandial hypoglycemia and hyperglycemia, respectively. Despite the current focus on carbohydrate counting, there is no evidence to suggest the superiority of one meal planning strategy over another. Several, small interventions aimed at improving carbohydrate counting proficiency have failed to improve glycemic outcomes in adolescents and adults with type 1 diabetes,[86] but meal planning strategies need to be evaluated in a larger, adequately controlled population. It has been suggested that the effectiveness of carbohydrate estimates within 10–15 g is consistent with exchange-based systems[85,94] and that the emphasis should remain on formulating a healthful meal plan consistent with the preferences and abilities of the individual patient with diabetes. Indeed, the greater focus on carbohydrate estimation may negatively impact overall diet quality for youth with type 1 diabetes,[95,96] highlighting the critical importance of educating patients with diabetes about both diet quantity and diet quality.

More recently, greater attention has been given to the impact of fat and protein on postprandial glycemic responses in youth with diabetes. In nondiabetic individuals, the ingestion of protein together with carbohydrate increases postprandial glucose levels due to gluconeogenesis and changes in insulin sensitivity. The inclusion of more fat in isocaloric mixed meals is associated with attenuated peaks but prolonged, postprandial glycemic responses owing to the incretin effect of fat and delayed gastric emptying.[97] Evidence suggests that additional insulin to account for protein and fat in a meal is superior to dosing insulin based solely on carbohydrate intake.[98,99] Pankowska et al. have introduced the notion of a “fat-protein unit” in which one additional unit of rapid-acting insulin can be administered for every 100 cal derived from protein or fat in a mixed meal.[89,100] In addition to selecting a dose of insulin for anticipated carbohydrate intake, the caloric values of fat and protein are used to calculate an additional amount of insulin to be delivered over several hours as a square- or dual-wave bolus. As the relative caloric contribution to the

meal from fat and protein increases, the length of the extended bolus is increased. This investigational methodology can effectively only be used by insulin pump users. Youth who employ this insulin dosing methodology are warned not to use the bolus calculators in their insulin pumps. There are insufficient data to support the superiority of this approach in terms of safety, ease of use, and effectiveness compared to extended insulin boluses for mixed meals based on carbohydrate quantity alone. Given the complexity of advanced carbohydrate counting, additional studies are required to confirm the translation and acceptance of this novel approach in routine clinical practice.

EXERCISE

A recent report concerning the effects of regular physical activity on health and behavioral outcomes in 6- to 18-year-old youths recommends that school-age children should participate daily in at least 60 minutes of moderate to vigorous physical activity that is developmentally appropriate, enjoyable, and involves a variety of activities.[101] Regular exercise improves blood glucose control, reduces cardiovascular risk factors, and assists in reaching and maintaining healthy weight.

Patients with type 1 diabetes should check blood glucose levels before exercise to determine whether additional carbohydrate is needed to avoid hypoglycemia. The amount of supplemental carbohydrate depends on the intensity and duration of exercise. If blood glucose is less than 100 mg/dL before exercise, added carbohydrate is required. If exercise is planned and the individual is familiar with his own glycemic response to exercise, the insulin dose given at the meal preceding exercise can be reduced rather than increasing carbohydrate intake. This approach is particularly applicable to patients who are attempting to lose weight and do not want to consume additional calories to offset the energy expenditure from exercise.

HYPOGLYCEMIA

Hypoglycemia is the principal barrier to optimizing glycemic control in youth with type 1 diabetes.[102] The risk of hypoglycemia is increased for several reasons, including pharmacologic insulin therapy and impaired glucagon and epinephrine responses to hypoglycemia.[103] Mild hypoglycemia, defined as an episode of hypoglycemia that is easily recognized and managed by the affected individual, occurs several times each week in well-controlled individuals with type 1 diabetes. An

important treatment goal is to avoid severe hypoglycemia, defined as an episode requiring assistance from another individual, use of parenteral therapy (e.g., glucagon or dextrose), and/or loss of consciousness or seizure. Patients are taught to take additional precautions in situations that may increase the risk of hypoglycemia: exercise, fasting, alcohol use, and when using certain medications. In these situations, more frequent blood glucose monitoring, reducing insulin doses, and/or ingesting additional "uncovered" carbohydrate are recommended.[65]

Given the frequent occurrence of mild hypoglycemia in youth with diabetes, MNT also focuses on the prevention and appropriate treatment of hypoglycemia.[104] Treatment of hypoglycemia entails immediate ingestion of 5–15 g of rapidly available carbohydrate, depending on the child's age and current blood glucose level (Table 59-6). The patient's blood glucose level should be remeasured in 15 minutes and additional rapid-acting carbohydrate can be administered if the blood glucose level remains less than 80 mg/dL. Fat-containing foods, such as chocolate or ice cream, are not recommended as fat delays the absorption of glucose, increasing the risk of prolonged or severe hypoglycemia. Rapidly available carbohydrate derived from glucose or sucrose is more effective than fructose-based sources.[105] Following resolution of an acute, mild episode of hypoglycemia, an additional 10–20 g of complex carbohydrate with protein decreases the risk of recurrent hypoglycemia if the next meal or snack is more than one hour away. Patients should be advised not to treat based on symptoms of hypoglycemia without confirmation by measuring a fingerstick blood glucose level. However, if a patient is unable to perform a timely blood glucose measurement and/or is about to drive (or is involved in another activity that exposes the individual to risk), it is better to assume the symptoms are due to hypoglycemia and treat accordingly until a blood glucose determination can be performed. Finally, if the child with diabetes is not alert and able to swallow safely, treatment must be with glucagon or intravenous dextrose (when this is a practical option).[65,104]

TABLE 59-6 Hypoglycemia Treatment: Sources and Quantities of Rapid-Acting Carbohydrate Based on Age

Age	≤5 Years	6–9 Years	≥10 Years
Amount	4–10 g	10–15 g	15–20 g
Glucose tablets[a]	1–2 Tablets	2–3 Tablets	3–4 Tablets

Glucose gel[b]	1/3–1/2 Tube	1/2–2/3 Tube	2/3–1 Tube
Regular soda[c]	2–3 oz.	4–6 oz.	6–8 oz.
100% Fruit juice (apple, orange)[d]	2–3 oz.	4–6 oz.	6–8 oz.

Products specifically designed to treat hypoglycemia contain pure glucose. Foods and beverages contain a variety of sugars, protein, and fat, which may slow absorption of glucose. Using pure glucose instead of other foods may help to prevent consumption of more calories than are needed to restore blood glucose to normal.

[a]1 Tablet = 4 g.

[b]Amount depends on product: Dex4 Glucose Gel® and Glutose 15® 1 tube = 15 g; Insta-Glucose® 1 tube = 24 g.

[c]Carbohydrate content (grams) of 8 oz.: Pepsi 28, Coca-Cola 27, Mountain Dew 31, Sprite 26, Schweppes Ginger Ale 22, and Canada Dry Ginger Ale 24.

[d]1 oz. Contains approximately 3 g of sugar.

ADHERENCE

Adherence to a meal plan is one of the behaviors required for optimal management of type 1 diabetes and correlates with blood glucose control in children and adults.[75,106,107] In a recent study of youth primarily using a flexible insulin regimen, greater dietary adherence was associated with lower hemoglobin A1c values.[107] Achieving optimal dietary adherence, however, is challenging and requires knowledge about healthy nutrition and meal planning, proficiency in counting carbohydrates, and motivation.[91,108] Furthermore, success requires cooperation between parent and child and appropriate parent-child mealtime behaviors.[109,110] Adherence to eating behaviors in youth with type 1 diabetes varies from 21% to 95%, depending on the specific behaviors studied and whether a fixed or flexible carbohydrate regimen is used.[111]

In the United States, a self-report survey of 144 adolescents who attended a tertiary care diabetes program showed that 15% took extra insulin to cover inappropriate food intake, 73% ate inappropriate foods, and 50% missed meals and snacks.[112] Many youth with type 1 diabetes do not adhere to recommendations for intake of fruits, vegetables, and whole grains.[66,113] A recent survey of usual dietary intake among a large ethnically diverse cohort of youth with diabetes aged 10 years or older (89% type 1) showed that only 6.5% of the cohort met the ADA recommendation of less than 7% of energy from saturated fat and 40% of youth with diabetes had a BMI greater than or equal to 85th percentile. Less than 50% met recommendations for total fat, vitamin E, fiber, fruits, vegetables, and grains.[66] Many youth with type 1 diabetes in the United States struggle with dietary adherence and do not meet nutrition

guidelines.[111]

Management of diabetes is difficult for children and adolescents and, as children progress through adolescence and into young adulthood, satisfactory adherence to therapy and optimal glycemic control become increasingly difficult to achieve and maintain. To achieve better diabetes outcomes, families must remain actively involved in their child's diabetes management, regardless of the child's age, even as the primary responsibility for diabetes care shifts from parent to adolescent.[114]

Disordered eating and eating disorders are a significant health problem among adolescents and the combination of an eating disorder and type 1 diabetes has major adverse health consequences.[115] Adolescent girls and young women with type 1 diabetes frequently decrease or omit insulin doses to maintain or lose weight.[116] Family meals are an important defense against disordered eating in adolescents with diabetes. However, in persistent or extreme cases the involvement of a mental health professional is essential.

An important role of health-care professionals involved in the care of children with diabetes is to motivate their patients to overcome the barriers to adherence so that they will be able to enjoy the benefits of good diabetes control.[17,117] Empirical research shows that adherence to the meal plan can be improved by psychosocial factors such as promoting a positive attitude toward the illness and its treatment as well as supportive relationships with the patient's family, peers, and health-care team. Frequent follow-up and ongoing education is essential to individualize the meal plan, set attainable goals, and teach the patient and his or her family how to match insulin to exercise and food.[118]

SUMMARY

Nutrition recommendations for treatment of diabetes have evolved since the pre-insulin era when a starvation diet with negligible carbohydrate and 70% of calories from fat was the recommended treatment. Today, there is no diabetic diet. The recommended diet can only be defined as a meal plan based on a nutrition assessment and mutually accepted treatment goals and desired outcomes. Nutrition therapy should be individualized. Consideration must be given to usual eating habits and other lifestyle factors. Monitoring clinical and metabolic parameters including blood glucose, glycated hemoglobin (hemoglobin A1c), lipids, blood pressure, and body weight, as well as quality of life, is crucial to ensure successful

outcomes. Modern diabetes management, combining frequent self-monitoring of blood glucose (supplemented with continuous glucose monitoring) with multiple dose flexible insulin regimens, or insulin pump therapy, and mastery of carbohydrate estimation, has made it possible for children and adolescents with diabetes to have considerable dietary flexibility and achieve better glycemic control with less frequent severe hypoglycemia.

Although the introduction of insulin analogs, flexible insulin regimens, and insulin pump therapy has permitted greater flexibility in carbohydrate intake, timing of meals, variety of food choices, and overall quality of life, these therapeutic innovations may also encourage unhealthy food choices.[95] Education must continue to emphasize dietary recommendations that maintain normal body weight and improve cardiovascular risk factors, including reduction of total fat, and especially saturated and *trans*-fats, and promote consumption of cardioprotective foods such as those containing monounsaturated fats and antioxidants.

Diarrheal Diseases

60

Kerri Gosselin, MD and Christopher Duggan, MD, MPH

There exists a strong association between diarrhea and malnutrition, whereby episodes of childhood diarrhea lead to worse nutritional status, and malnutrition predisposes children to episodes of diarrhea. Diarrheal diseases are a major cause of pediatric morbidity and mortality, causing an estimated 800,000 deaths of children under 5 years of age worldwide.[1] Over the past several decades, substantial progress has been made in reducing childhood deaths due to diarrhea, with the estimated mortality dropping below one million children per year for the first time in 2012. Comparing this value to those of previous years reveals significant progress in reducing mortality due to diarrhea. For example, 2.5 million child deaths from diarrhea were estimated in 2003,[2] 3.3 million annual deaths were estimated in 1992,[3] and 4.6 million deaths from diarrhea were estimated in 1982.[4] The story underlying these statistics is the remarkable success of worldwide campaigns to treat acute diarrhea with oral rehydration therapy (ORT), as well as improved hygiene, medical care including immunizations, and access to drinking water. The development of ORT is among the most successful collaborations ever between basic and applied biomedical research and one of the most significant applications of nutritional therapy to the management of acute disease. Interestingly, it is also a case of reverse technology transfer,[5] in which work originally carried out for benefit of those in countries with less developed economies has changed the standard of practice, even in industrialized settings.

In addition to these successes worldwide, there has also been significant progress made in the United States. With the introduction of the rotavirus vaccine in 2006, the number of U.S. hospitalizations for acute

diarrhea has decreased dramatically. In 2006, before administration of the vaccine was widespread, an estimated 74 per 10,000 children under age 5 years were hospitalized for gastroenteritis or rotavirus, a figure that decreased to 50 hospitalizations per 10,000 children in 2009.[6]

However, challenges remain in the treatment of diarrhea both in the United States and abroad. It is likely that the full benefits of the fluid, electrolyte, and nutritional therapy of acute diarrhea have not been realized. Shortcomings in treatment are significant, as they result in added morbidity and costs in both developing and industrialized societies. It may be argued that the full implementation of ORT for treatment of acute diarrhea in countries with developed economies has lagged behind its use in less developed countries, perhaps because of the ingrained use of intravenous therapy or the reduced appeal of a technologically simple solution.[7] In addition, it has been difficult to establish continued feeding during diarrheal episodes as normative therapy, despite a wealth of in vitro and in vivo data supporting the role of continued nutrition in improving measurements of gastrointestinal function, as well as anthropometric, biochemical, and clinical outcomes.[8,9]

In addition, while the mortality attributed to diarrheal illness is decreasing worldwide, significant morbidity continues. Diarrheal morbidity includes dehydration, micronutrient deficiencies, altered growth, and cognitive deficits. Episodes of diarrhea predispose to stunting, with an estimated 5% increased risk of stunting for each diarrheal episode before age 2 years.[10] Diarrhea and enteric infections early in life predispose to deficits in cognitive development and result in significant burden of disability-adjusted life years, including decreased work productivity and IQ.[11] Therefore, there continues to be a great need to identify gaps in current knowledge and promote implementation research with the ultimate goal of decreasing both the morbidity and mortality of diarrheal illnesses.

This chapter reviews the historical background and scientific basis of ORT and provides a framework for assessing and treating the dehydrated patient or the patient at risk for dehydration. The discussion focuses on common clinical scenarios and traditional practices, especially with regard to feeding. The limitations of ORT are discussed, as well as areas of ongoing research.

HISTORICAL BACKGROUND

Early attempts at treating dehydration resulting from diarrhea were first described in medical literature in the 1830s, during epidemics of *Vibrio*

cholerae infections.[12] It was not until 100 years later that the use of intravenous fluids became widespread. Accurate chemical analysis of diarrheal stools eventually permitted the formulation of physiologically appropriate replacement solutions, leading to the successful treatment of cholera with intravenous fluids by the 1940s.[13] Further research into intestinal electrolyte transport led to the development of oral solutions for rehydration.[14,15] In 1971, these were put to test in the field with the large-scale treatment of refugees from the Bangladesh war of independence.[16] The remarkable success of oral solutions hastened the development of the World Health Organization (WHO) guidelines for ORT and production of standard packets of oral rehydration salts. It may be argued that the initial application of ORT to cholera epidemics in the developing world hindered the acceptance of this therapy's relevance in the United States and Europe. With time, however, ORT has become accepted as the standard of care for clinically efficacious and cost–effective management of acute diarrhea,[17,18] although it remains underused in settings in which parenteral rehydration has been the established practice. One national survey of physicians in emergency care facilities in the United States showed that many would treat mild dehydration with intravenous therapy, and half would always or almost always use intravenous therapy for a moderately (5–10%) dehydrated child under age 2.[19]

PHYSIOLOGIC BASIS FOR THE USE OF ORAL REHYDRATION SOLUTIONS

Fluid must be absorbed and reabsorbed for survival. Under the best of circumstances, the adult intestinal epithelium must handle 6,500 mL fluid per day, the combination of oral intake and salivary, gastric, pancreatic, biliary, and upper intestinal secretions. This is typically reduced to 1,500 mL by the distal ileum and is further reduced in the colon to stool output less than 250 mL/day.[20] During disease, the volume of intestinal fluid output is remarkably increased, which overwhelms reabsorptive capacity and leads to diarrhea.

Applied clinical research, first carried out among cholera patients, showed that diarrhea in cholera is not the result of a failure of intestinal reabsorption but rather a state of extreme output in which reabsorptive mechanisms remain intact.[21] Not only *V. cholerae* but many strains of *Escherichia coli, Shigella, Salmonella,* and other pathogenic bacteria have been shown to produce toxins that bind to enterocyte receptors. This

results in chloride-mediated secretion stimulated by second messengers such as cyclic adenosine monophosphate, cyclic guanosine monophosphate, and calcium.[22] Even those infectious agents typically classified as causing osmotic diarrhea may, in some cases, also increase enterocyte secretion. *Rotavirus,* for instance, damages the villous brush border, causing osmotic diarrhea, but also produces an enterotoxin that causes a Ca^{++}-mediated secretory diarrhea.[23]

Basic scientific studies of intestinal solute transport mechanisms were also crucial in outlining the processes by which solute absorption is maintained. Water passively follows the osmotic gradient generated by the transcellular transport of electrolytes and nutrients. Although three principal mechanisms of sodium absorption have been described,[20] that essential to the efficacy of oral rehydration solutions (ORSs) was shown to result from the stoichiometric co-transport of sodium and glucose molecules at the intestinal brush border.[24] Figure 60-1 provides a schematic of the cotransport process. Cotransport across the luminal membrane is facilitated by the protein SGLT1.[25] Once in the enterocyte, the transport of glucose into the blood is facilitated by GLUT 2 in the basolateral membrane. The Na^+-K^+ adenosine triphosphatase provides the gradient that drives the process. Clinical studies have demonstrated that this mechanism remains intact even in patients with severe diarrhea.[21]

In 1975, the WHO and the United Nations Children's Fund (UNICEF) agreed to promote a single solution (WHO-ORS) containing (in millimol per liter) sodium 90, potassium 20, chloride 80, base 30, and glucose 111 (2%). This composition was selected to allow a single solution to be used among diverse populations in different countries. Although this solution performed well over 25 years, subsequent clinical research, documented in numerous controlled trials and summarized in a meta-analysis,[26] has favored the adoption of a lower osmolarity standard rehydration solution. Based on these findings, UNICEF and WHO now recommend an ORS formulation with sodium concentration 75 mEq/L, glucose 75 mmol/L, and total osmolarity 245 mmol/L.[27] See Table 60-1 for a comparison of common oral solutions.

HOME MANAGEMENT OF ACUTE DIARRHEA

The simplicity of treatment with ORS makes the management of uncomplicated cases of diarrhea at home an important component of optimal care. As long as caretakers are properly instructed regarding the need for clinical assessment when children appear significantly ill or appear to be failing treatment, then it is appropriate to initiate therapy at home. Early intervention may reduce complications such as dehydration and poor nutrition. In both developed and developing settings, early administration of ORS may lead to fewer office or emergency room visits,[28] hospitalizations, or deaths.

In fact, it has frequently been the case that mothers and other caretakers begin treatment of diarrhea at home.[29] The advent of ORT allows a therapy that is more effective and less harmful than many traditional home therapies. Families should be encouraged to have a supply of ORS in the home at all times, much in the same way that acetaminophen and adhesive bandages are viewed as staples of the medicine chest. As soon as diarrhea begins, one of the commercially available products can be started at home. Although it is possible to produce a homemade solution with appropriate concentrations of glucose and sodium, possibilities for serious error in preparation exist. Therefore, standard commercial oral rehydration preparations should be recommended where they are readily available and not prohibitively expensive. Regardless of the fluid used, an age-appropriate, unrestricted diet should be encouraged.[9] The most important principles underlying home management of diarrhea is the need to give increased volumes of fluid as well as to maintain adequate energy intake. Infants should be more frequently breast-fed or bottle-fed, and children should be offered fluids frequently.

Caretakers should be educated to recognize signs of illness or

treatment failure that necessitate medical intervention. Infants with acute diarrhea are more prone to dehydration than are older children because they have a higher body surface-to-volume ratio, a higher metabolic rate, and relatively smaller fluid reserves. In addition, they depend on their caretakers for fluid provision. For this reason, parents should seek medical care promptly for infants with diarrhea, even before the first signs of dehydration are evident. Indications for prompt medical evaluation are summarized in Table 60-2. No guidelines have established a specific age under which evaluation is mandated, but, in general, infants should be evaluated by a health professional when there is risk of dehydration; in general, the smaller the child, the lower the threshold for hands-on evaluation. When fever is present, infants and children should be evaluated according to current guidelines. Naturally, underlying conditions, including history of prematurity, metabolic disorders, immune compromise, and recent recovery from surgical interventions, may prompt early evaluation, as may concurrent illnesses such as a respiratory infection. Children with dysentery (visible blood or mucus in stool) should also be evaluated by medical staff promptly.

TABLE 60-2 Indications for Medical Evaluation

Young age, with low threshold for evaluating all children under 10 kg and lowest threshold for those under 6 months
History of prematurity, underlying chronic medical conditions, or concurrent illness
Fever ≥ 38°C for infants under 3 months, ≥ 39°C for infants aged 3–36 months
Visible blood in the stools
High output, including large-volume diarrhea and persistent vomiting
Caretaker's report of signs consistent with dehydration, including sunken eyes, decreased tears, dry mucous membranes
Poor apparent response to ORT or inability to administer ORT

ORT, oral rehydration therapy.

Source: Adapted from King et al.[18]

Naturally, parents or other caretakers cannot be assumed to have skills of assessment comparable to a clinician, but their report of any of the easily recognized signs of dehydration may indicate the need for immediate evaluation. Reports of changing mental status are particularly concerning. When the child's condition is in doubt, there should be a low threshold for recommending evaluation. The hands-on visit provides an opportunity for physical assessment including vital signs, more detailed history-gathering, and family education.

CLINICAL ASSESSMENT

Diarrhea is generally defined as the passage of three or more loose or watery stools per day. The volume of fluid lost through the stools can vary from 5 mL/kg/day (near normal) to 200 mL/kg or more.[30] Dehydration and electrolyte losses follow untreated diarrhea and cause the primary morbidity of acute gastroenteritis. In addition, loose stools may be among the presenting signs of non-gastrointestinal illnesses, including meningitis, malaria, bacterial sepsis, pneumonia, otitis media, and urinary tract infection. Vomiting alone can be the first symptom of metabolic disorders, congestive heart failure, toxic ingestions, or trauma. To rule out other serious illnesses, a detailed history and physical examination should be performed in the setting of acute gastroenteritis.

History taking should include questions about the onset, frequency, quantity, and character (including the presence of bile, blood, mucous) of vomiting and diarrhea. Recent oral intake including food, fluids, and breast-feeding, as well information about urine output should be carefully noted. A recent weight measurement, if available, should be compared to the current weight to estimate total body fluid deficit. Associated symptoms, including fever or changes in mental status, should be recorded. Past medical history should include questions regarding underlying significant medical problems, history of other recent infections, and human immunodeficiency virus (HIV) status, if known. Relevant social history may include the number and nature of caretakers and their ability to return for re-evaluation, which may affect instructions regarding follow-up care.

As part of the complete physical examination, an accurate body weight must be obtained, along with temperature, heart rate, respiratory rate, and blood pressure. When premorbid weight is not known but a previous growth curve is available, an estimate of fluid loss may be obtained by subtracting current weight from expected weight based on previous weight-for-age percentile.[31] The quality of this estimate will vary, depending on the number and variability of prior data points. The general condition of the patient should be assessed, with special concern given to infants and children who appear listless, apathetic, or minimally interactive. The appearance of the eyes should be noted, including the degree to which they are sunken and the presence or absence of tears. The condition of the lips, mouth, and tongue may yield important clues as to the degree of dehydration, even if the patient has recently taken fluid. Deep respirations may be suggestive of metabolic acidosis. Faint or absent

bowel sounds may suggest ileus. Extremities should be assessed for signs of general perfusion, capillary refill, and skin turgor. Visual examination of the stool can confirm abnormal consistency and determine the presence of blood or mucus.

The clinical signs and symptoms of dehydration are outlined in Table 60-3. A comprehensive literature review found that the three most useful individual signs for predicting 5% dehydration in pediatric patients are abnormal capillary refill time, abnormal skin turgor, and an abnormal respiratory pattern.[32] The assessment of the anterior fontanel, though helpful in select instances, can be unreliable or misleading.[33] In infants and children, a fall in blood pressure is a late sign that signifies the development of uncompensated shock and may correspond to fluid deficits greater than 10%. Increases in heart rate and slowed peripheral perfusion may be more sensitive indicators of moderate dehydration, although both may be difficult to interpret as they can vary with fever. Decreased urine output is a sensitive but nonspecific sign,[31] since urine output may be difficult to assess in infants with diarrhea.

TABLE 60-3 Signs of Dehydration

	Minimal or No Dehydration	Mild to Moderate Dehydration	Severe Dehydration
Mental status	Well, alert	Normal, fatigued or restless, irritable	Apathetic, lethargic, unconscious, floppy
Thirst	Drinks normally, may refuse	Thirsty, eager to drink	Drinks poorly, unable to drink
Heart rate	Normal	Normal to increased	Tachycardia, with bradycardia in most severe cases
Quality of pulses	Normal	Normal to decreased	Weak, thready, or impalpable
Breathing	Normal	Normal, fast	Deep
Eyes	Normal	Slightly sunken	Deeply sunken
Tears	Present	Decreased	Absent
Mouth and tongue	Moist	Dry	Parched
Skin fold	Instant recoil	<two seconds	>two seconds
Capillary refill	Normal	Prolonged	Prolonged, minimal
Extremities	Warm	Cool	Cold, mottled, cyanotic

Urine output	Normal to decreased	Decreased	Minimal
Loss of body weight	<3%	3–9%	>9%

Source: Adapted from King et al.[18]

Previous guidelines, including the CDC's 2003 recommendations[18] divide patients into subgroups for mild (3–5% fluid deficit), moderate (6–9% fluid deficit), or severe dehydration (>10% shock or near shock). Other classification schemes, including 2005 WHO,[34] divide patients into those showing no signs of dehydration (<5%), some signs of dehydration (5–10%), and severe dehydration (>10%). Studies that have carefully evaluated the correlation of clinical signs of dehydration with posttreatment weight gain suggest that the first signs of dehydration are evident at 3–4% dehydration, with more numerous clinical signs evident at 5% dehydration and those signs indicating severe dehydration not evident until fluid loss of 9–10%.[31] Because of this threshold effect, it may be difficult to distinguish between mild and moderate dehydration based on clinical signs alone. For this reason, Table 60-3 groups together patients with mild to moderate dehydration and notes that these signs may be seen over a relatively wide range of fluid loss, from 3 to 9%. The magnitude of ongoing losses and the patient's oral intake will determine the success of ORT as much as current status. The goal of assessment is not to solely determine the patient's hydration status but rather to provide a starting point for treatment. In this way, the goal is to determine which patients may be safely sent home for therapy, which should remain for observation during therapy, and which should receive more immediate intensive therapy.

Supplementary laboratory studies in the assessment of the patient with acute diarrhea are usually unnecessary, including serum electrolytes.[34] Stool cultures are indicated in the case of dysentery but are generally not indicated in acute, watery diarrhea in the immunocompetent patient. However, laboratory studies should be performed where they may give important clues as to underlying or alternative causes of illness. For instance, urine cultures should be obtained when there is reason to be concerned for urinary tract infection, and blood cultures and white blood cell count with differential are indicated where the clinical presentation suggests possible sepsis. Children with severe dehydration may require serum electrolyte evaluation and monitoring.

THERAPY OF ACUTE GASTROENTERITIS BASED ON DEGREE OF DEHYDRATION

Table 60-4 provides a summary of specific treatment recommendations synthesized from CDC, WHO, and ESPGHAN guidelines.[18,34,35] Treatment of dehydration should include two phases: rehydration and maintenance. In the rehydration phase, the fluid deficit is replaced quickly, over 3–4 hours, and clinical hydration is attained. In the maintenance phase, maintenance calories and fluids are given. Rapid realimentation should follow rapid rehydration, with a goal of rapid return to an age-appropriate unrestricted diet, including solids. Gut rest is not indicated. If anything, caloric provision should be increased as soon as tolerated to make up for lost caloric intake during the acute illness. In general, lactose restriction and formula changes are not necessary. Full-strength formula is generally tolerated and allows more rapid return to full caloric intake. Breast-feeding should be continued throughout each treatment phase, including rehydration. In both phases, fluid losses from vomiting and diarrhea are replaced in an ongoing manner. No unnecessary medications should be used, and laboratory studies should be limited to those necessary to guide management.

Minimal Dehydration

For those patients with minimal or no dehydration, treatment is aimed at replacing ongoing losses. Children with diarrhea require increased fluid intake to make up for losses and to provide for maintenance needs. In principle, 1 mL of fluid should be given for each gram output. In hospital settings, soiled diapers can be weighed (without urine) and the estimated dry weight of the diaper can be subtracted. When losses are not easily measured, a reasonable rule of thumb is to provide 10 mL/kg additional fluid for each watery stool or 2 mL/kg for each episode of emesis. Nutrition should not be restricted. Instructions regarding dietary therapy are summarized in Table 60-4.

Mild to Moderate Dehydration

Children who are found on assessment to have mild to moderate dehydration should receive rapid replacement of their estimated fluid deficit, with additional fluid given for ongoing losses. Current guidelines recommend giving 50–100 mL/kg of ORS over 2–4 hours to replace estimated fluid deficit, with additional ORS given to replace ongoing losses. WHO guidelines recommend a maximum rate of 20 mL/kg/hour,[34]

but the rate may be individualized. Using a teaspoon, syringe, or medicine dropper, small volumes of fluid (e.g., one teaspoon) should be offered at first, with the amount gradually increased as tolerated. If a child appears to want more than the estimated amount of ORS, more can be offered. Although it is safe to give ORS very rapidly, vomiting may be increased with larger boluses. Frequent, small bolus feedings will generally be tolerated. Nasogastric (NG) feeding allows continuous administration of ORS at a slow, steady rate. Clinical experience supports the use of NG feedings even in vomiting patients. Rehydration via NG tube may be particularly useful in an emergency department setting where rapid correction of hydration may prevent unnecessary hospitalization. Although rapid intravenous hydration may also prevent unnecessary hospital admissions, one study showed that rapid NG rehydration was well tolerated, more cost–effective, and associated with fewer complications.[36] In addition, emergency department caregivers reported being more familiar with intravenous hydration as compared to NG rehydration when oral rehydration failed.[37]

TABLE 60-4 Summary of Treatment Plans

Degree of Dehydration	Rehydration Therapy	Replacement of Losses	Nutrition
Minimal or no dehydration	N/A	1 mL ORS for each gram lost to vomiting or diarrhea or 10 mL/kg body weight for each diarrheal stool, 2 mL/kg for each episode emesis	Continue breast-feeding; resume age-appropriate normal diet after initial hydration, including adequate caloric intake for maintenance*
Mild to moderate dehydration	ORS 50–100 mL/kg body weight over 3–4 h	Same as above	Same as above
Severe dehydration	LR or NS in 20 mL/kg IV boluses until perfusion and mental status improve. Then give 100 mL/kg ORS over 4 h or 100 mL/kg D5 ½ NS IV over 8 h	Same as above; if unable to drink, give via NG tube or give IV D5 ¼ NS with 20 mmol/L KCl/L	Begin oral or enteral feedings after initial hydration, as soon as acidosis corrected

IV, intravenous; LR, lactated Ringer's; N/A, not applicable; NS, normal saline; ORS, oral rehydration solution.

* Overly restricted diets should be avoided during acute diarrhea. Breast-fed infants should continue to nurse ad libitum even during acute rehydration. Infants too weak to eat may be given breast milk or

formula via NG tube. Full-lactose formulas are generally well tolerated. If lactose malabsorption appears clinically significant, lactose-free formulas may be used. Complex carbohydrates, fresh fruits, lean meats, yogurt, and vegetables are all recommended.

Source: Adapted from King et al.[18]

OUTPATIENT OBSERVATION

Because a certain percentage of children with mild to moderate dehydration will fail to improve with ORT, it is prudent to observe dehydrated children until signs of dehydration resolve. Similarly, children who do not show clinical signs of dehydration but who demonstrate unusually high output may be held for observation. Hydration status should be reassessed on a regular basis, with more frequent monitoring given to those patients whose status is more tenuous. This may be carried out in an emergency room, office, or other outpatient setting. Once dehydration is corrected, further management may be carried out at home if the following conditions are met: current ORT is well tolerated and the child's caretakers demonstrate comprehension of home rehydration techniques and understand indications for returning for further evaluation, and have adequate means of transportation to return to care if needed. Even among those whose illness appears uncomplicated on initial assessment, a small percentage may fail ORT and, therefore, a plan for possible reassessment must be in place. Caretakers should be encouraged to return to medical attention should they have any concerns, if they are not sure that rehydration is proceeding well, or for the development of any new or worsening symptoms.

MANAGEMENT IN THE HOSPITAL

Indications for hospital management of a dehydrated child include (1) inability of caretakers to manage ORT at home; (2) significant difficulties administering ORT, including vomiting, ORS refusal, or inadequate intake; (3) concern for possible comorbidity; (4) failure of treatment, including worsening diarrhea or dehydration despite ORT; (5) severe (>9%) dehydration; (6) social or logistical issues that may prevent return evaluation if necessary; or (7) any other factors that may indicate close observation, such as very young age of the patient, unusual irritability or drowsiness, progressive course of symptoms, or uncertainty of diagnosis.

SEVERE DEHYDRATION

Severe dehydration constitutes a medical emergency. Intravenous rehydration should begin immediately. Twenty milliliters per kilogram boluses of lactated Ringer's (LR) solution, normal saline, or a similar isotonic solution should be given until pulse, perfusion, and mental status return to normal. This may require two intravenous lines or even alternative access sites (e.g., intraosseous infusion, venous cutdown). The patient should be closely observed during this period and vital signs monitored on a regular basis. Where available, serum electrolytes, bicarbonate, blood urea nitrogen, creatinine, and serum glucose should be obtained, although it is safe to commence rehydration therapy without these results, as normal saline or LR infusion is the appropriate first step in either hyponatremic or hypernatremic dehydration. Hypotonic solutions should not be used for acute parenteral rehydration.[38]

The severely dehydrated patient may require several boluses, which may be carried out in short succession. Practically speaking, overly rapid rehydration is unlikely to occur as long as weight-based boluses are given with close observation. Errors occur most commonly in settings in which adult dosing is given to infants. For example, if a practitioner were to order "500 cc of normal saline intravenous bolus × ii," this would provide 200 mL/kg for the average 2- to 3-month-old, which would be incorrect. Edema of the eyelids and extremities may indicate overhydration. Diuretics should not be given. Once the edema has subsided, the patient may be reassessed for continued therapy. With very frail or malnourished infants, it may be prudent to proceed with 10 mL/kg boluses because of their poorer ability to increase cardiac output and because it may be especially difficult to distinguish dehydration from sepsis in these patients. The smaller boluses will also facilitate closer evaluation. Please see Chapter 14: "Protein-Energy Malnutrition: Pathophysiology, Clinical Consequences and Treatment" for details. In general, frequent reassessment of hydration status should be performed to follow the adequacy of replacement therapy. Failure to respond to fluid bolus should raise the suspicion of alternative or concurrent diagnoses, including, septic shock, as well as metabolic, cardiac, or neurologic disorders.

As soon as the patient's level of consciousness returns to normal, therapy can often be changed to the oral route, with the patient taking orally the remaining estimated deficit. An NG tube may be helpful for patients too weak to drink adequately but with normal mental status. Although no studies have specifically documented increased aspiration risk with NG tube use in obtunded patients, intravenous therapy is ordinarily favored in these patients. Although it is reasonable to leave

intravenous access in place in these patients should it be needed, early reintroduction of ORS is safer. The use of intravenous catheters is associated with frequent minor complications, including extravasation of intravenous fluid, and rare significant complications, including the inadvertent administration of inappropriate fluid such as those containing excessive potassium. In addition, early ORS will likely encourage earlier resumption of feeding, and data suggest that resolution of acidosis may be more rapid with ORS compared with intravenous fluid.[36]

DIETARY THERAPY

Recommendations for maintenance dietary therapy depend on the age and diet history of the patient. Breast-fed infants should continue nursing on demand. Those receiving formula should continue their usual formula immediately on rehydration in amounts sufficient to satisfy energy and nutrient requirements. Lactose-free or lactose-reduced formulas are usually not necessary. A meta-analysis of clinical trials shows no advantage of lactose-free formulas over lactose-containing formulas for most infants, although some infants with malnutrition or severe dehydration recover more quickly when given lactose-free formula.[39] Patients with true lactose intolerance may have exacerbation of diarrhea when a lactose-containing formula is introduced. The presence of a stool pH below 6.0 or the presence of reducing substances in the stool (>0.5%) in the absence of clinical symptoms is not diagnostic of lactose intolerance. Although medical practice has often favored beginning feeds with diluted (e.g., half or quarter strength) formula, there is insufficient evidence to justify this practice; full caloric intake should be restored as soon as possible.

Soy formulas containing soy fiber, specifically Isomil® DF, have been widely marketed to physicians and consumers in the United States. Brown et al. showed that added soy fiber reduced the duration of liquid stools without changing overall stool output.[40] This “cosmetic” effect might have some benefits with regard to diminishing diaper rash and encouraging early resumption of normal diet but is probably not sufficient to merit its use as standard of care.

Children receiving semisolid or solid foods should continue to receive their usual diet during diarrhea. Foods high in simple sugars should be avoided, as the osmotic load may worsen diarrhea. For this reason, large amounts of juice, gelatin desserts, and other highly sugared liquids should be avoided. Some guidelines have recommended avoiding fatty foods, but it is difficult to maintain adequate calories without some fat. In addition,

fat may reduce intestinal motility. The practice of withholding food for 24 hours is inappropriate. Early feeding may decrease changes in intestinal permeability brought about by infection,[41] reduce illness duration, and improve nutritional outcomes.[8,9] Highly specific diets, such as the BRAT (bananas, rice, applesauce, and toast) diet, are commonly recommended. Although one study has shown some benefit from green bananas and pectin in persistent diarrhea (PD),[42] the BRAT diet is unnecessarily restrictive and, like juice-centered diets, provides suboptimal nutrition for the patient's nourishment and recovering gut.

Many children in developing countries have multiple episodes of diarrhea in a single year. In this way, losses from diarrhea contribute to poor nutrition, which may, in turn, worsen the severity of subsequent episodes of diarrhea.[43] For this reason, WHO guidelines recommend caloric supplements following episodes of diarrhea, such as added cereal in milk, oil in cereal, and foods with high nutrient density.[34] In general, current guidelines call for age-appropriate unrestricted diets, including complex carbohydrates, meats, yogurt, fruits, and vegetables.

LIMITATIONS OF ORT

Although ORT is recommended for all age groups and for diarrhea of any etiology, some limitations exist. In children presenting in shock, the administration of oral solutions is contraindicated, as airway protective reflexes may be impaired. Likewise, patients with abdominal ileus should not be given oral fluids until bowel sounds are audible. It should be remembered that intestinal intussusception may present with diarrhea, including bloody diarrhea. Radiographic and surgical evaluations are warranted when the diagnosis is in question.

Stool output in excess of 10 mL/kg/hour has been associated with a lower rate of success of oral rehydration.[44] No patient, however, should be denied ORT simply because of a high purging rate because most patients will respond well if given adequate replacement fluid.

A small proportion of infants with acute diarrhea experience carbohydrate malabsorption, with a dramatic increase in stool output following the administration of ORS. The presence of stool-reducing substances alone is not sufficient to make the diagnosis because this is a common finding in patients with diarrhea and does not in itself predict failure of oral therapy. Patients with true glucose malabsorption will also show an immediate reduction in stool output when ORS is replaced with

intravenous therapy. The incidence of clinically significant glucose malabsorption during acute diarrhea is probably less than 1%, although rates as high as 8% have been reported in selected populations.[45]

Many patients with acute diarrhea have concomitant vomiting. Most, however, can be successfully rehydrated with oral fluids if small volumes of ORS (5 mL) are given every five minutes, with a gradual increase in the amount consumed. Administration via a spoon or syringe with close supervision helps guarantee a gradual progression in the amount administered. Often, correction of acidosis and dehydration lessens the frequency of vomiting. Continuous slow NG infusion of ORS via a feeding tube may be helpful. Even if some emesis occurs after NG administration of fluid, treatment may not be adversely affected.[36]

HYPERNATREMIC DEHYDRATION

Patients with hypernatremic dehydration respond well to ORT. Those with severe dehydration should first receive intravenous hydration, as outlined above. Subsequent hydration may be achieved with ORS.[46] As with normonatremic dehydration, ORS should be given both to replace the calculated deficit and for ongoing losses. ORS is safer than intravenous therapy because it is less likely to lead to a precipitous decline in serum sodium, which may increase intracranial pressure.

PHARMACOLOGIC THERAPY

Antibiotics

Because viral agents are the predominant cause of acute diarrhea (e.g., *Rotavirus*, astrovirus, enteric adenovirus, *Norovirus*, and *Sapovirus*), the routine use of antimicrobial agents for the treatment of diarrhea misuses resources and may lead to increased microbial resistance. Especially in the hospital setting, bacterial causes of diarrhea are unusual. A survey of stool cultures submitted over several years to the microbiology laboratory at Boston Children's Hospital revealed such infrequent occurrence of bacterial infections that the practice of sending stool cultures of patients who develop diarrhea while hospitalized has been abandoned.[47] Hospitalized patients and patients with a history of recent antibiotic use are, however, at risk for infections with *Clostridium difficile*. Infections with *C. difficile* documented by toxin assay or PCR should be treated with metronidazole 30 mg/kg divided three times daily given orally. Oral

vancomycin is also effective but should be reserved as a second-line agent, given its expense and concern over the possible emergence of vancomycin-resistant *Enterococcus.*

Even when a bacterial cause is suspected, antibiotic therapy is generally not indicated because the majority of cases of acute diarrhea are self-limited and not shortened by antibiotics. In addition, antibiotics may cause harm. There is evidence that antibiotic use may increase the risk of hemolytic uremic syndrome from *E. coli* infections.[48] There remains some concern that treatment of *Salmonella enteritis* may increase the risk of the carrier state, although patients below 3 months of age or with bacteremia should be treated.[49] Patients with underlying disorders, including immunodeficiency, provide exceptions to these rules. Detailed information regarding the appropriate use of antimicrobial therapy for infectious causes of acute diarrhea is beyond the scope of this chapter and is available in a variety of other resources. [35,50]

Non-Antibiotic Drug Therapies

The use of nonspecific antidiarrheal agents such as adsorbents (e.g., kaolin-pectin), antimotility agents (e.g., loperamide), antisecretory drugs, or toxin binders (e.g., cholestyramine) is a common practice. Few data are available to support their efficacy. The side effects of these drugs are well known, in particular among the antimotility agents, including opiate-induced ileus, drowsiness, and nausea owing to atropine effects and binding of nutrients and other drugs. One report from Pakistan detailed 18 cases of severe abdominal distention in association with use of loperamide, including at least 6 deaths.[51] Bismuth subsalicylate has shown some efficacy in traveler's diarrhea and other causes of acute gastroenteritis in children,[52] and although the side effects are less than antimotility agents, some theoretic concerns over the potential toxicity of salicylate remain. In any event, reliance on antidiarrheal agents shifts the therapeutic focus away from appropriate fluid, electrolyte, and nutritional therapy and adds unnecessarily to the economic cost of the illness.

It should be noted that none of the drugs mentioned above specifically address the underlying causes of diarrhea, specifically increased secretion by intestinal crypt cells. Racecadotril, an enkephalinase inhibitor, preserves the antisecretory activity of enkephalins, was first discovered in 1975. It does not slow intestinal transit or promote bacterial overgrowth. Its use has shown promise in two controlled clinical trials in children, significantly reducing acute watery diarrhea compared to placebo.[53] As

long as its cost is reasonable and its use does not distract from ORT and education regarding home management of diarrhea, racecadotril may prove to be a useful adjunct to the treatment of watery diarrhea.

Similarly, the use of antiemetics may be warranted in some cases. Phenothiazines can interfere with oral rehydration by causing sleepiness. Oral ondansetron, a 5HT3 receptor antagonist, has been shown to be effective in decreasing the need for intravenous hydration and hospitalization in children with actue gastroenteritis.[54] A single oral dose of ondansetron, given to pediatric emergency department patients with gastroenteritis and dehydration, significantly decreased the likelihood and frequency of vomiting. Although in this trial there was no significant reduction in the rate of hospitalization, the ondansetron group was significantly less likely to require intravenous hydration, had increased oral intake, and had a shorter mean length of stay in the emergency department.[55]

FUNCTIONAL FOODS

Functional foods may be defined as those that have an effect on physiologic processes separate from their established nutritional function.[56] Probiotics, live microorganisms found in fermented foods and intended to promote intestinal health, are the classic functional food. The mechanism of action of probiotics may include competition with pathogenic bacteria for receptor sites or intraluminal nutrients, production of antibiotic substances, and enhancement of host immune defenses.[57,58]. Chapter 12 provides a detailed discussion of this topic; the following discussion focused on the effects of functional foods solely on diarrhea.

Probiotics seem to be particularly effective in instances of diarrhea due to antibiotic use and rotavirus. In 2011, a systematic review examined 16 studies using various species of probiotics, including *Lactobacillus, Lactococcus, Saccharomyces, Bacillus, Bifidobacterium, and Leuconostoc cremoris*, for the prevention of antibiotic-associated diarrhea in children. Results indicated that probiotics prevented antibiotic-associated diarrhea in children, with higher doses of probiotics (>five billion colony forming units daily) showing a greater protective effect. There were no serious adverse events reported.[59] A second comprehensive review concluded that there is evidence for the efficacy of a wide variety of probiotics in acute gastroenteritis, especially rotavirus.[60] Probiotics may be effective in terms of prevention of diarrhea as well. A meta-analysis of studies

predominately executed in developed countries concluded that probiotics reduced the risk of acute diarrhea among children by 57% and that of antibiotic-associated diarrhea by 52%.[61] In this analysis, the protective effect did not vary significantly among the variety of probiotic strains examined.

Despite these proven benefits, there are several limitations of probiotics. First, because these products are generally not regulated, there is potential for great variability of species concentration and other aspects among different products. In addition, concerns about safety exist, such as the potential for bacterial translocation and subsequent bacteremia or endocarditis.[62] With few exceptions, however, including administration to immunocompromised patients or those with indwelling central venous catheters, the safety of probiotics for the general population has been demonstrated and may confer the benefits discussed above.

Prebiotics differ from probiotics in that they are nutrients, rather than organisms, used to preferentially stimulate the growth of health-promoting intestinal flora.[63] Oligosaccharides found in breast milk have been called the prototypic prebiotic in that they foster the growth of lactobacilli and bifidobacteria in the colon of breast-fed neonates. The prebiotic effects of inulin and fructose oligosaccharides have been studied primarily in vitro and in animal model studies.[64] Two randomized, blinded trials on prebiotic-supplemented infant cereal in an urban, economically depressed area did not demonstrate a reduced incidence of diarrheal disease.[65] Specific recommendations regarding the use of prebiotics should await further well-controlled human trials. In the meantime, it should be noted that dietary fiber may serve as both a prebiotic and a modifying agent of intestinal motility. Current guidelines recommend fiber-containing fruits and vegetables as part of the diet of children recovering from acute gastroenteritis.

SUPPLEMENTAL ZINC ADMINISTRATION

Many reports have linked diarrhea and abnormal zinc status, including increased stool zinc loss,[66] and negative zinc balance.[67] It has long been observed that diarrhea may occur with severe zinc deficiency, as in acrodermatitis enteropathica, but the broader clinical question is whether more incremental deficiencies of zinc may play a role in childhood diarrhea and whether supplementation may be of benefit for either improved outcomes in acute or chronic diarrhea or as prophylaxis against

diarrheal disease. In this way, zinc therapy can be considered both as an adjunct treatment during acute episodes of diarrhea as well as a preventive therapy for subsequent diarrheal episodes.

When given during an acute episode of diarrhea, zinc decreases the severity and duration of diarrhea.[68] In children older than 6 months of age, oral zinc supplementation has been shown to decrease the duration of acute diarrhea by 10.4 hours and reduces the probability of developing diarrhea for more than 7 days. Moreover, this effect was more pronounced in children with moderate malnutrition, whose duration of diarrhea was decreased by 27 hours.[69] There were no serious adverse effects reported, although some children experienced vomiting with oral zinc supplementation.

WHO and UNICEF now recommend that all children with acute diarrhea receive zinc supplementation for a total of 10–14 days during and after diarrhea (10 mg per day for infants under 6 months of age and 20 mg per day for children greater than or equal to 6 months of age).[34,70] Zinc supplementation in more developed settings may not be as efficacious, as has been demonstrated in trials of children (one among children with diarrhea and one among healthy children) from the United States and Poland.[71,72] Further research is needed to identify the mechanism of action and to determine optimal schemes for delivery of zinc to those populations who will gain the most benefit.

Oral zinc supplementation has also been studied as a prophylactic measure for preventing episodes of acute diarrhea. The Zinc Investigators Collaborative Group reviewed evidence that zinc supplementation is beneficial as a prophylactic supplement for decreasing the incidence of diarrheal disease and pneumonia. Among infants and young children who received supplemental zinc for 5 or 7 days per week for 12 to 54 weeks, the pooled odds ratio for diarrhea incidence was 0.82 (95% confidence interval [CI] 0.72–0.93) and that for pneumonia incidence was 0.59 (95% CI 0.41–0.83).[73]

OTHER CLINICAL SCENARIOS

Acute Bloody Diarrhea (Dysentery)

Dysentery is defined as acute bloody diarrhea caused by invasive microbial infection. This does not include occult blood (detected by guaiac card only), streaks of blood on the surface of formed stool, or melena. The reader is referred to WHO guidelines, which discuss the evaluation and

management of dysentery at length.[30,34]

The treatment of dehydration in dysentery follows the same principles as the treatment of acute watery diarrhea. The child with bloody diarrhea is at higher risk for complications, including sepsis and other systemic disease, so that the threshold for admission to the hospital for close observation is lower. Stool cultures are indicated in the setting of acute bloody diarrhea and are helpful for guiding therapy. Food should not be withheld in dysentery any more than in other cases of diarrhea. Because patients with dysentery may have significant anorexia, they should be coaxed to eat.[30] More frequent, smaller meals may be better tolerated. Children convalescing from dysentery should be given extra food to help them regain nutrition lost during the acute illness.

Cholera

Cholera differs from other causes of acute diarrhea in that (1) it may occur in large epidemics involving adults and children (as seen in the recent epidemic in Haiti); (2) it produces voluminous diarrhea, which may lead to shock and death by dehydration in a very short period; and (3) certain antibiotics may shorten the course.[34] Management of cholera may be carried out using the methods for assessment of dehydration and treatment plans outlined above and summarized in Tables 60-4 and 60-5. The health worker must be prepared to deliver prodigious quantities of fluid, either orally or intravenously, to overcome ongoing losses. These losses should be quantified so that treatment may be updated and modified under continuous close observation. Unlike diarrhea from other causes, where cereal-based ORSs are equivalent to standard ORSs, there may be some advantages in using rice-based ORS in treating cholera.[74] Traditional wisdom held that sodium concentrations of ORS used in treating cholera should be higher than those for other causes of diarrhea (based on measured stool sodium losses), but a CHOICE study group trial showed no clinical difference between those treated with the lower osmolarity solution compared with a standard solution, apart from some increased incidence of asymptomatic hyponatremia.[75] In Bangladesh, a study of over 50,000 monitored patients with uncomplicated watery diarrhea found no evidence for an increase in symptomatic hyponatremia in those treated with reduced osmolarity ORS. In fact, the incidence rate of developing symptomatic hyponatremia was significantly lower in those treated the newer, reduced osmolarity formulation.[76]

Persistent Diarrhea

Persistent diarrhea (PD) may be defined as diarrhea of acute onset that lasts more than 14 days. PD is also frequently associated with poor weight gain or weight loss.[77] Globally, PD accounts for a substantial proportion of diarrhea-related morbidity and between 36% and 54% of all diarrhea-related deaths.[78] A community-based study suggested that PD is experienced by roughly one in five young children per year in the United States, though with far less morbidity and mortality.[79]

In developing countries, the most important epidemiological risk factor for acquiring PD is malnutrition, further emphasizing the importance of aggressive nutritional therapy in the treatment of acute diarrhea. Other risk factors for PD include immune status (including HIV infection), zinc deficiency, lack of breast-feeding, male sex, and infection with enteropathogenic or enteroaggregative *Escherichia coli* or *Cryptosporidium*.[80] Malnutrition can also significantly increase mortality from PD, with a study of diarrheal deaths in Bangladesh demonstrating a 17-fold higher relative risk of death from PD in malnourished children compared to those lesser degrees of malnutrition.[81] Another study in Kenya showed that children who are hospitalized for severe acute malnutrition who have diarrhea are at an increased risk of dying compared to those hospitalized children without diarrhea.[82]

TABLE 60-5 ORS for the Severely Malnourished Child

Simple ORS for the Severely Malnourished Child	More Effective ORS for the Severely Malnourished Child
Dilute 1 L WHO-ORS to make 2 L	Dilute 1 L WHO-ORS to make 2 L
Add 45 mL KCl solution from stock solution containing 100 g KCl/L	Add the following salts:
Add and dissolve 50 g sucrose	3.6 g KCl
	1.3 g K citrate
Children given this solution should also receive:	1.2 g MgCl
2 mL 50% MgSO4 solution (4 mEq Mg/mL) IM once	130 mg Zn acetate
Zinc chloride solution (10 g/L) 1 mL/kg/d until diarrhea stops	22 mg CuSO4
	0.44 mg NaSeO4
	0.20 mg KI

	Add and dissolve 50 g sucrose

IM, intramuscularly; ORS, oral rehydration solution.

Source: Adapted from World Health Organization.[34]

The approach to the patient with PD should include prompt assessment and treatment of the diarrhea. Worldwide, the most important predisposing factor for PD is an acute diarrheal episode triggered by an enteric infection.[80] Particularly in the developing world, bacterial and parasitic infections are common and warrant aggressive diagnosis and therapy. In areas where HIV infection is endemic, chronic gastrointestinal infections with organisms such as *Cryptosporidium parvum* are even more likely.

When infection has been carefully excluded, other specific etiologies must be considered. These include food allergy and dietary protein intolerances, celiac disease, disaccharide (i.e., lactose) intolerance, cystic fibrosis and other causes of pancreatic insufficiency, and inflammatory bowel disease. For further details on the diagnosis and nutritional management of these disorders, please refer to Chapters 52 (Inflammatory Bowel Disease), 53 (Celiac Disease), 54 (Food Allergies), and 55 (Exocrine Pancreatic Disease).

In the developed world, chronic nonspecific diarrhea of childhood (or "toddler's diarrhea") is a common, nonpathologic phenomenon seen in children between the ages of 6 and 36 months. It is characterized by the passage of two or more loose, voluminous stools per day for over four weeks, in the absence of abdominal pain or growth inhibition. Diets either low in fat (which modulates intestinal motility), low in fiber (which may promote balanced intestinal flora) and/or high in high-osmolarity carbohydrate drinks, particularly sorbitol-containing fruit juice, may all contribute to PD in the developed world. In such cases, dietary modification should be attempted before undertaking an extensive diagnostic evaluation.

Attention to nutrition is critical in the treatment of PD, with restoration of a nutritious diet, including adequate calories, being a key element of therapy. As with acute diarrhea, recommended foods include age-appropriate unrestricted diets, including complex carbohydrates, meats, yogurt, fruits, and vegetables.[18] As previously discussed, zinc supplementation has been shown to be effective in reducing the duration and severity of PD and should be continued for prophylaxis against additional episodes after appropriate therapy is complete.[73] In cases of infectious etiologies, education regarding sanitation and hygiene may reduce rates of re-infection.

For details of PD in the setting of protein energy malnutrition, please refer to Chapter 14.

DIARRHEA WITH SEVERE MALNUTRITION

Assessment of diarrhea and dehydration in the malnourished child is difficult because many of the signs outlined in Table 60-3 may be unreliable. Skin turgor may appear poor owing to the absence of subcutaneous fat. Eyes may be sunken from loss of periorbital fat. Irritability or apathy from malnutrition may complicate the assessment of mental status. When possible, malnourished children with diarrhea should be referred to a hospital. A severely malnourished child with signs of dehydration but without a history of increased stool output should be treated for septic shock.[34] Because of the increased risk of bacteremia in severely malnourished children, and, in fact, in a broad range of children with diarrhea in a less developed setting,[83] the use of empiric antibiotics is not unreasonable where blood cultures cannot be obtained, although the literature regarding choice of antibiotics, doses, and duration is sparse.

Because intravenous therapy may cause overhydration and heart failure in the severely malnourished child, except for treatment of shock, slow oral rehydration is the treatment of choice. An NG tube may be used for children who drink poorly. Rehydration should begin with 10 mL/kg over 2 hours. This rate may be adjusted based on the child's thirst or ongoing stool losses. Increasing edema may be evidence of overhydration.

Full-strength WHO-ORS contains excessive sodium and inadequate potassium for the severely malnourished child. WHO guidelines recommend modified solutions such as ReSoMal, as outlined in Tables 60-1 and 60-5. Feeding should begin as soon as possible once hydration has been achieved and should continue every two to three hours day and night. Malnourished children often exhibit anorexia and require coaxing to eat. For more details, the reader is referred to Chapter 14.

CHOICE OF ORS

Table 60-1 outlines the composition of several commonly available ORSs, as well as other beverages frequently but inappropriately used for rehydration. The vast differences between the composition of the WHO ORS and beverages inappropriately recommended for rehydration should be noted. In July 2002, WHO and UNICEF recommended a significant change in ORS composition, including a reduction in sodium and glucose

to maintain a 1:1 molar ratio but to decrease total osmolarity to 245 mOsm/L. The change was prompted by clinical trials showing that this solution resulted in less use of supplemental intravenous fluid therapy as well as lower stool output and less vomiting compared with the previous WHO standard ORS.[26,84] Although the differences in measured stool output resulting from different ORS formulations may be modest, reduction in intravenous fluid use is a substantial economic and health benefit of the new solution. The composition of the new solution is also more in line with solutions more commonly used in industrialized countries.

NEW SOLUTIONS

Numerous improved ORSs have been attempted. These have generally included additional substrates for sodium cotransport (such as the amino acids glycine, alanine, and glutamine)[85,86] or, as reviewed by Fontaine and colleagues,[74] substituting complex carbohydrates for the glucose (rice and other cereal-based ORSs) to reduce osmolarity while preserving glucose-sodium cotransport. Given trials to date, the amino acid preparations do not appear to be more effective than traditional ORSs and are more costly. Rice-based ORS may be recommended where training is adequate and home preparation is preferable and appears to be particularly effective in treating diarrhea from cholera.[74,87] Nevertheless, given the simplicity and safety of ORS packets in developing countries and commercially available ORSs in developed countries, these remain the first choice for most clinicians.

Other potential additives to ORS include substances capable of liberating short-chain fatty acids. These include amylase-resistant starch derived from corn[88] and partially hydrolyzed guar gum.[89] The presumed mechanism of action is the enlistment of increased colonic sodium uptake coupled to short-chain fatty acid transport. A controlled trial of children with acute diarrhea demonstrated significantly decreased diarrhea duration in those given amylase-resistant starch-fortified ORS compared to those receiving the standard WHO ORS formulation.[90] In addition, data from adults with acute cholera-like diarrhea in India showed that duration of acute diarrhea was reduced by 55% (19 hours versus 42 hours, $P < .001$) in the cohort given ORS with amylase-resistant starch versus standard ORS.[91] Currently, guidelines do not support the routine incorporation of any potential ORS additives, including guar gum, nondigestible

carbohydrates, probiotics, zinc, glutamine, citing insufficient evidence.[35]

BARRIERS TO ORT

Barriers to the use of ORS and continued nutrition during diarrheal disease include, among patients, cultural practices[29] and lack of information[92] and, among physicians, preference for intravenous hydration, even where evidence suggests improved results from oral rehydration.[93] At the other extreme from the development of the ultimate ORS, it remains distressingly common for patients, even at times under physician supervision, to attempt rehydration with solutions bearing no resemblance to physiologically based ORS. Table 60-1 includes a number of fluids commonly used in treating diarrhea, which do not contain physiologically sound concentrations of carbohydrates and electrolytes. An informal survey of numerous hospital websites reveals outdated recommendations for the treatment of diarrhea that include nonstandard fluids. A case report of one child whose care was compromised by following advice obtained from a prominent hospital's Internet site highlights the continued gap between knowledge and practice and the ongoing need to disseminate accurate information regarding oral rehydration.[94]

CONCLUSION

The treatment of acute diarrhea has for many years been shown to rely on the simple but overwhelmingly effective therapy of oral rehydration. The important co-principle of early refeeding of children immediately on rehydration has also gained wider acceptance. The combination of oral rehydration and early nutritional support is a safe and effective treatment for the vast majority of children with diarrhea. In addition, the advances made in industrialized countries toward reducing hospitalizations for *Rotavirus*-associated gastroenteritis (due to the successful use of the rotavirus vaccine) are promising. If the principles of therapy outlined above are accepted by all levels of the medical and public health community, and if education of parents includes beginning ORT at home, then numerous unnecessary hospitalizations and deaths could be avoided. In addition, if ORT, zinc, and vaccines were combined with several other important and well-known public health interventions (exclusive breast-feeding, hand washing, improved waste disposal, and access to clean drinking water), diarrheal deaths could be drastically reduced.[95] In an age

where governments and nongovernmental organizations are dedicated to improving health outcomes in children with AIDS, tuberculosis and malaria, the world awaits strong action against a more common but often overlooked cause of child death: diarrheal diseases.

61 Intestinal Failure, Short Bowel Syndrome, and Intestinal Transplantation

Daniel Kamin, MD

Care for infants and children with intestinal failure (IF) challenges nutritional medicine fundamentally: it attempts to provide nutrition that supports normal growth and development, even while the very organ fulfilling this role has failed. Before the advent of intravenous nutrition, patients with IF often succumbed to malnutrition and dehydration. Patients are now able to grow and develop normally on long-term parenteral nutrition (PN), and methods exist to transition patients from parenteral to enteral nutrition. For those suffering severe complications, novel medical and surgical therapies increase hope for successful transition to enteral feeding. Outcomes after intestinal transplantation have substantially improved since its inception so that motivation for choosing this therapy is moving beyond a “last ditch” effort to rescue very ill children. With these points in mind, we review the etiology, complications, and medical management of pediatric IF including intestinal transplantation; elaborate on the nutritional physiologic principles motivating this management; and highlight nutritional outcomes of various management strategies.

DEFINITIONS AND DISEASES

Definitions

The term “intestinal failure” is now often used to describe a state wherein gastrointestinal function is insufficient to support normal growth in children and physiologic balance in both adults and children. Gastrointestinal function refers to the ability to absorb enteral nutrients and fluid. Although this definition is broadest, its consistent application relies on uniformity in defining normal growth or physiologic balance. Some have suggested that IF should be defined by the extent of energy loss in stool rather than the inability to provide enteral energy. Another practical approach is to identify IF when there is ongoing need (some have argued >90 days) for PN or intravenous fluids to maintain normal growth in children and physiologic balance in children and adults. For patients with short bowel syndrome (SBS), length or percentage of small bowel remaining might also figure into a definition.

Laboratory assessment has promise for helping to define IF. For instance, serum citrulline level has been proposed as a marker for functional small intestinal mass. It is a nonstructural amino acid net produced only in presumably functionally capable enterocytes.[1] Clinical studies in enteropathy and SBS support its use as a valid marker of functional enterocyte mass and absorptive function. Retrospective studies have suggested that serum levels[2,3] of 15 μmol/L or 19 μmol/L have reasonably good discriminating value for differentiating between SBS patients who will or will not become PN independent. Prospective and serial evaluation of citrulline in neonates[4] found that citrulline level distinguished necrotizing enterocolitis (NEC) (<17 μmol/L) from age-matched healthy infants and that over time rising citrulline concentration correlated with increasing amounts of enteral nutrition. Citrulline has not enjoyed uniform success[5] as a proxy for intestinal adaptation or function.

A consensus report settled on the following: “IF results from obstruction, dysmotility, surgical resection, congenital defect, or disease-associated loss of absorption and is characterized by the inability to maintain protein-energy, fluid, electrolyte, and micronutrient balance [without intravenous support].” For children, an additional criterion would be the inability to preserve normal growth.[6]

Underlying Diseases

Most cases of IF (Table 61-1) are caused by surgical resection of the small intestine. The most common conditions are necrotizing enterocolitis,

gastroschisis, and congenital intestinal atresias. Resections may be classified according to the amount of residual small intestine, as measured distal to the ligament of Treitz along the antimesenteric border. It may be appropriate to consider the remnant small bowel as a percentage of total normal small intestinal length.[7]

Congenital diarrheal diseases lead to IF because of the severe relentless electrolyte and nutrient losses, which prevent successful enteral nutrition. These diseases result from defects in enterocyte structure and/or function, and often there is villus atrophy. Microvillus inclusion disease (MVID) is an autosomal recessive condition characterized by microvillus "inclusions" in enterocytes and colonocytes when viewed with an electron microscope. Severe watery diarrhea usually begins in the newborn period, and IV support may be required from the outset. The disease is clearly inherited, as multiple siblings may be affected and ethnic clustering exists among individuals of Navajo decent. A disease-causing gene has been found (*MYO5B*), which encodes a cytoplasmic protein critical for the apical localization of membrane components.[8] The prognosis is generally unfavorable without transplantation, but case reports have described relative stability by halting progression of liver diseases and careful attention to hydration.

TABLE 61-1 Causes of Intestinal Failure in Children

Category	Disorder	
SBS	Infant	Older Child
	Gastroschisis Necrotizing enterocolitis Small intestinal atresia Malrotation with volvulus	Crohn's disease Mesenteric infarction Radiation enteritis Tumors Trauma
Motility	Hirschsprung's disease Pseudo-obstruction Neuronal intestinal dysplasia	
Mucosa	Primary Epithelial	Immune Mediated
	Microvillus inclusion disease Tufting enteropathy	Autoimmune enteropathy Immunodeficiency syndromes
Miscellaneous	Enteroendocrine cell hypoplasia

Tufting enteropathy (or intestinal epithelial dysplasia) is also an

autosomal recessive condition that presents in infancy with watery diarrhea and impaired growth. Focal epithelial “tufts” of closely packed enterocytes with rounded apical plasma membranes constitute the distinguishing features of this condition. Ethnic clustering is noted. In 2008, a gene defect was identified in epithelial adhesion molecule (EpCAM).[9] Prognosis is felt to be less dire than MVID[10]; indeed, reports are increasing of patients being weaned off PN,[11] including an adult affected woman who gave birth to a healthy infant.[12]

Severe motility disorders include long-segment Hirschprung’s disease (LSHD) and chronic idiopathic intestinal pseudo-obstruction (CIPO). LSHD refers to the characteristic aganglionosis usually isolated to the colon extending for various lengths into the small bowel. This condition causes functional SBS because the involved “paralyzed” intestine will not support aboral flow of intestinal contents. Additionally, the colon will always be affected and cannot be used for electrolyte and water recovery. Significant difficulty in weaning from PN may be expected with residual functional small bowel lengths less than 50 cm.[13]

CIPO is a heterogeneous mix of conditions sharing a common clinical presentation of apparent intestinal obstruction without surgical findings.[14] CIPO is often further classified according to histologic and manometric criteria. Myopathic CIPO refers to the primary defect localized in the smooth muscle; often, these patients have dysfunction of other smooth muscle, most commonly in the genitourinary tract (e.g., megacystis-microcolon-intestinal hypoperistalsis syndrome). This form of CIPO is generally thought to be severer, resulting in more debilitating symptoms because dysmotility is more extensive or more complete. Neuropathic CIPO indicates that the enteric nervous system is disordered, resulting in motor responses that poorly propel intestinal contents forward. In both conditions, presentation is usually in the first five years of life; patients often undergo multiple laparotomies before diagnosis; and an attempt to establish intestinal function by avoiding diseased intestine usually results in gastrostomies, jejunostomies, and diverting ileostomies. Nevertheless, the most severely affected individuals will still not be able to tolerate sufficient enteral nutrition to support growth, and long-term PN is required.

Epidemiology

IF is a relatively rare condition. Unlike rare cancers, bona fide prospective registries do not yet exist in North America to track patient numbers and

outcomes. A standard proxy is the use of home PN. Using Medicare and Oley Foundation information, Howard et al. estimated that 40,000 people were using home PN in 1992.[15] Extrapolation based on the 1994 Oley Foundation report demonstrates that roughly 40% of patients used home PN because of a primary gastrointestinal cause of IF. Children 14 years and younger accounted for approximately 25% of this group. Based on the aforementioned 40,000 estimate, approximately 4,000 US children aged 14 years and younger were on home PN because of primary gastrointestinal IF in 1992.[15] A more recent multicenter European study estimated the prevalence of pediatric home PN use at 2–6.8 children per million population.[16] Finally, a 2005 Italian survey that recorded all patients receiving artificial home nutrition reported 1.2 children/million inhabitants as using home PN.[17]

It is difficult to estimate the prevalence of individual causes of IF. Very limited published data exist for pediatrics. Certainly, SBS constitutes the majority diagnosis, and all are relatively rare. Table 61-2 displays the causes and proportions of pediatric IF from a recent multi-institutional report.[18]

TABLE 61-2 Distribution of Causes of Pediatric Intestinal Failure

Total (%)	**272**
Necrotizing enterocolitis	71 (26)
Intestinal atresia	27 (10)
Gastroschisis	44 (16)
Malrotation/volvulus	24 (9)
LSHD	11 (4)
Congenital enteropathy	3 (1)
Other single diagnoses	14 (5)
Unknown	1
Multiple single diagnoses[a]	77 (28)

PHYSIOLOGY AND PATHOPHYSIOLOGY

Normal Intestinal Growth

In utero intestinal growth is most marked during the last trimester, nearly doubling over this period of time.[19] This has obvious implications for prognosis, as acquisition of IF in early infancy or after premature birth (e.g., necrotizing enterocolitis) may lead to improved outcomes because of the growth potential of residual small intestine.

Historically, average small intestinal length (from the ligament of Treitz to the ileocecal valve) for full-term infants was estimated to be 250−300 cm,[19,20] with maximal increase in length occurring in the first year of life.[20] Normal adult small intestinal lengths ranged from[21] Generous spans are the results of variable contexts (e.g. radiologic, intra-operative, post-mortem) and/or methods used to determine intestinal length.

Recently, prospective evaluation of bowel length during laparotomy in infants and young children without gastrointestinal surgical disease identified height/length as the best predictor of extant bowel length (R^2 = 0.852; Figure 61-1), and even proposed a formula to estimate bowel length in children: ln(SBL) = 6.741 – 80.409/height.[22]

Adaptation

Intestinal adaptation refers to the gross anatomic, histologic, and functional changes that occur in the intestine that maximize digestive and absorptive capacity in the context of loss of intestinal function from either resection or disease. The phenomenon has been recognized for over a century.[23] Experimental work in dogs and clinical experience led Flint[24] to conclude in 1912 that as much as 50% of the small intestine might be removed without inexorable weight loss and death and that neither colon nor stomach could compensate for the loss. Today, while this estimate can be pushed further, the principles and observations derived from experiments conducted years ago are still apt.[21]

Adaptive changes in humans may begin 12–24 hours after massive intestinal resection and will continue for a year or longer after resection. It had once been thought that maximal adaptation occurs after 1–3 years in children and 1–4 years in adults. However, medical, surgical and nutritional innovations have extended these ranges.[18]

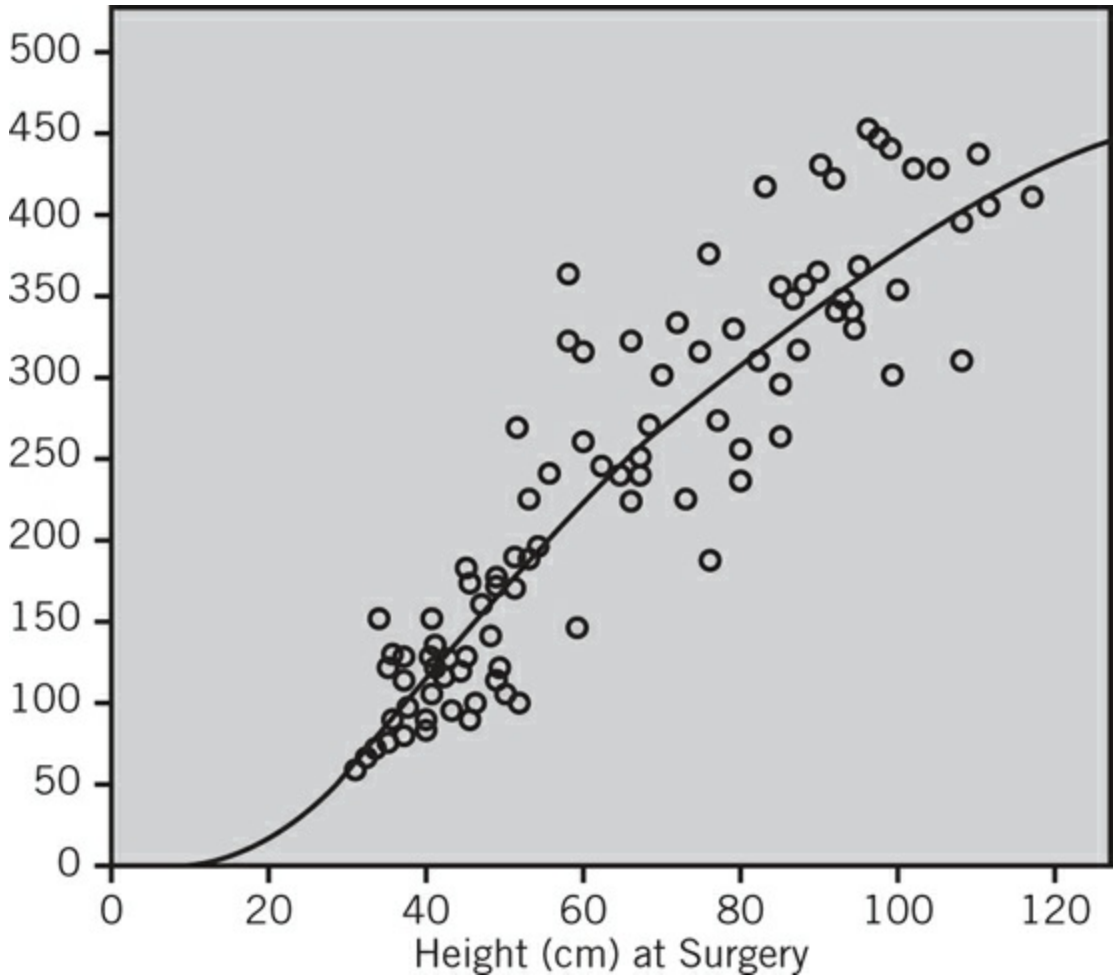

Figure 61-1 Small-intestine length versus height in 108 children without intestinal disease evaluated at laparotomy, $R^2 = 0.852$. Reproduced with permission from Struijs et al.[22]

Structural Adaptation

Laboratory data. Rodent data indicate that structural adaptation can be marked. Gross morphologic changes occur after extensive small intestinal resections (>70%) such as thickening, increase in length, and dilation.[30] Adult female Sprague-Dawley rats were examined one week after 80% small bowel resections. The wet weight of the small intestine increased fivefold, up to 70% of the preresection weight. However, there were no further increases in intestinal mass when assessed 5 and 10 weeks post resection, and there was no recovery of the preresection intestinal length (Figure 61-2). In the juvenile domestic pig, 16 weeks after surgery bowel diameter and length increased proportionally more in those that received

75% mid-small intestinal resections compared to animals who received transections.[26] Discrepancies between studies showing recovery of intestinal length may depend on species and timing. It is not clear whether intestinal length can be recovered only within species-specific "window periods."

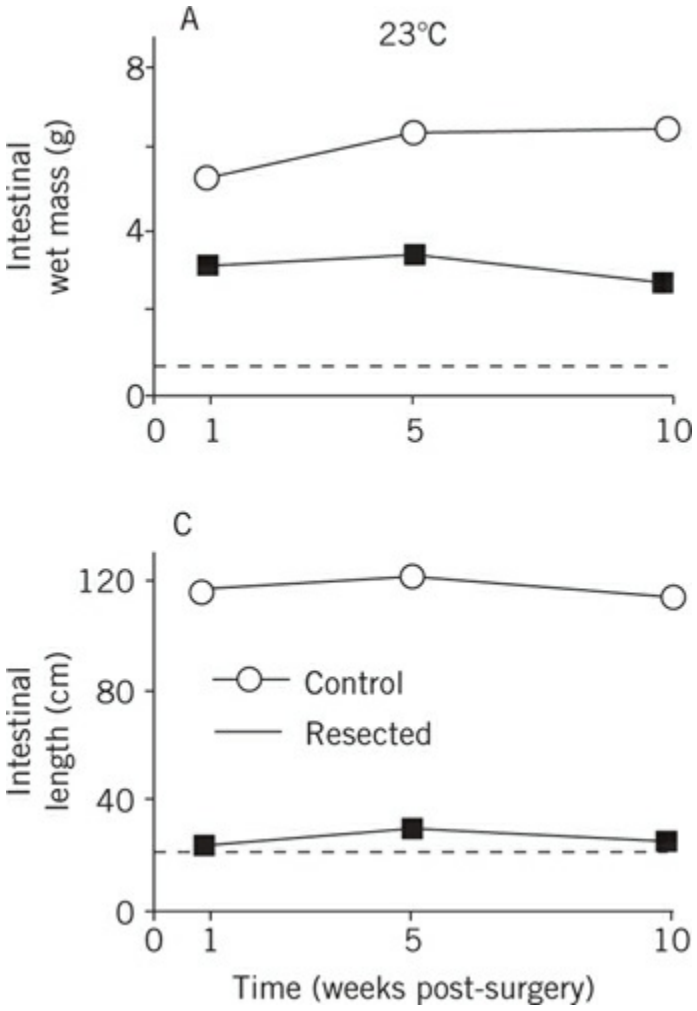

Figure 61-2 Effect of resection on wet mass (upper graph) and intestinal length (lower graph) in female Sprague-Dawley rats. Dotted line represents estimated wet mass or length immediately after resection. In this figure, 80% small intestinal resections were performed (dark squares), whereas control animals (open circles) had sham operations. (Reproduced with permission from O'Connor.[41])

Adapted rodent intestinal mucosa is characterized by elongated crypts and wider, taller villi.[27] There is increased cellularity, which is manifest by

increased DNA and protein content in adapted intestine.[28] These processes are more marked when resection is more extensive,[29] and when the residual intestine is ileum.[30,31]

Mucosal responses to adaptation likely differ between species. For instance, resection often causes crypt-villus elongation in rodents, while similar structural changes have not been routinely noted in humans.[32] The neonatal piglet model is a reasonable alternative, and has been used to show efficacy of surgical and medical therapies for intestinal failure.[33]

Human data. There is adequate documentation that human intestine can adapt to improve nutrient absorption following injury or resection.[24,34] The macroscopic changes of intestinal hypertrophy and lengthening have been observed in many case series,[32] but the crypt-villus architectural modifications observed in rodents have not been recapitulated.[34,35] For example, duodenal mucosa from an adult patient with significant SBS demonstrated hyperplasia of crypts and villi compared to specimens from normal adult humans, but cell proliferation, crypt depth, and villus height were equivalent.[36] However, a small case series of patients who received segmental small intestinal transplants found that villus length did increase by 50% over baseline at six months, suggesting that intestinal adaptation in the human may include morphologic changes in the villus that maximize surface area.[37]

Functional Adaptation

Animal data: Functional adaptation is characterized by an increase in the absorption of carbohydrate, protein, water, or electrolytes per unit length of intestine. Within six hours of intestinal resection, upregulation of the sodium-glucose cotransporter occurs in enterocytes, leading to enhanced electrolyte and water absorption.[38] Physiologic mechanisms underlying these changes may be upregulation of total available transporters, a larger number of functional enterocytes, or upregulation of efficiency of individual nutrient transporters.[39] Work using a rabbit model of SBS that examined nutrient transport across jejunal sections isolated from animals with and without significant distal small bowel resections indicates that changes in the lipid content of the brush border membrane may account for enhanced passive absorption of free fatty acids in small intestine.[40] Dowling and Booth[30] in their classic paper on rat SBS found that per unit length of remaining intestine glucose absorption was increased two weeks later and that this effect was more pronounced in ileum than jejunum.

It is worth noting that structural changes may not strictly correlate with

functional adaptations. For instance, total mucosal glucose absorption reached 33% of the pre-resection value after 80% small bowel resection in the Sprague-Dawley rat, while mucosal weight increased to an average two-thirds that of the pre-resection weight.[41]

Delayed transit through the GI tract, affording luminal nutrients more contact time with the intestinal absorptive surface, may be considered an adaptive mechanism after small intestinal resection. Few studies have documented this well,[42] while others have found transit time normal or shortened.[43] Moreover, the lack of correlation between small intestinal transit time and residual bowel length complicates generation of simple theories.[43] Transit time may even be delayed because of bowel dilation and stasis, both concerns that could contribute to maladaptive physiology.

Human data: Segmental intestinal transplant from living human donors provides some insight on the adaptive process. When 200 cm of ileum was transplanted into a human leukocyte antigen-matched sibling who suffered traumatic loss of his entire jejunum, ileum, and right colon, *d*-xylose and fat balance studies were markedly abnormal one month after transplant but were considered normal at six months.[44] Ziegler et al.[45] compared small intestinal biopsies from 13 adult SBS patients on long-term PN to those obtained from 33 adult control subjects undergoing endoscopy without histories of intestinal resection, inflammation, or infection. All 13 SBS patients were also consuming oral nutrition. Small intestinal villus height, width, and crypt depth were no different between the groups, suggesting that intestinal adaptation in humans does not depend on sheer size of the crypt-villus structure. Interestingly, Ziegler did identify upregulated expression of the peptide transporter PepT1 in colonic mucosa of SBS patients, a finding that colonic salvage not just of amino acids as well as carbohydrates (see later) in patients with small intestinal malabsorptionmay be an important component of adaptation.

Mineral absorption may adapt over an extended period of time. Gouttebel et al. investigated calcium absorption in 30 adults with SBS, comparing those whose resections were less than two years ago to those greater than two years. While *d*-xylose absorption was equivalent, calcium absorption continued to increase in the latter group, suggesting that adaptation may be a prolonged, slowly evolving process.[46]

Little information exists that characterizes intestinal adaptation with respect to motility in humans. Moreover, much of the phenotype of intestinal adaptation in humans has not been fully described (e.g., bowel flora and immunologic function). Of note, a recent paper[47] identified a

particular D/L stool lactate ratio in patients with SBS, suggesting that patients may harbor a particular microbiota that could be adaptive or maladaptive. In summary, in humans structural adaptations are less obvious than functional; adaptation may take months and possibly years; and the colon can be adapted to absorb not just fluid and electrolytes but also calories, possibly even beyond short-chain fatty acids (SCFAs).

Molecular Adaptation

Adaptation can be characterized on the molecular level.[48–50] For instance, cDNA isolated from residual ileum 48 hours after 70% resection in rats suggested significant upregulation (compared to sham-operated rats) of genes encoding proteins responsible for nutrient trafficking, cell cycle control, and protein processing.[50] Further, Stern et al.[49] used exogenous epidermal growth factor (EGF) in a similar experiment and detected upregulation of a gene product (proline-rich protein 2) not previously thought to play a role in intestinal adaptation. Current and future studies using microarray analysis and other sophisticated molecular techniques will soon offer a much more complete picture of adaptation, and possibly lead to more rational identification of therapies to promote adaptation.

Determinants of Adaptation

By far, the most powerful and consistent determinant of adaptation is provision of enteral nutrition. Directly and/or indirectly, nutrient flow through the intestinal tract promotes structural and functional integrity of the intestine; the amount of enteral nutrition that is tolerated is a robust predictor of successful adaptation and thus freedom from parenteral therapies.

Earlier Observations

There has been great interest in isolating the components linking provision of enteral nutrition with enhanced intestinal function. Observations included the effects of direct nutrient contact with the mucosa, pancreatic and hepatobiliary secretions, and circulating hormones. Ileum that is transposed into a proximal position in jejunum will develop larger villi and crypts,[51] suggesting that direct mucosal contact with richer chyme is important for maintaining mucosal structure. When the ampulla of Vater is surgically transposed to distal small intestine, mucosal hyperplasia will occur distally, highlighting the possible importance of hepatobiliary and pancreatic secretions in adaptation.[52] Finally, animal studies support the

notion that humoral factors are released secondary to enteral feeding that maintain structure and function of intestinal mucosa. Feeding an animal with a Thiry-Vella fistula, in which a portion of small intestine is removed completely from the luminal circuit while maintaining physiologic blood supply, will produce mucosal hyperplasia in the fistula when nutrients are administered enterally but not parenterally.[53] Parabiotic animal studies are also revealing. Here, two animals have blood supplies that are surgically cross-circulated, while only one animal has an intestinal resection. Both animals will then develop mucosal hyperplasia of small intestine when the resected animal is fed enterally.[54]

Nutritive Factors

Lipids: The amount, nature, and route of administration of lipids may influence the adaptive process. Studies in rats imply that both saturated and polyunsaturated fatty acids (PUFAs) have trophic effects on small intestine. Maxton[55] gave female Wistar rats four weeks of Vivonex or Vivonex with 50% of calories replaced with either saturated or essential fatty acid-substituted triglycerides and found that compared to Vivonex small bowel mucosal weight, protein, and DNA content were all higher in the supplemented groups. Alternatively, using a rat model Vanderhoof et al.[56] found that menhaden oil (a marine source of ω-3 PUFAs), compared to safflower oil, stimulated greater small bowel mucosal regeneration during recovery from mucositis induced with subcutaneous methotrexate.

Admittedly, nonresection models may have limited applicability for understanding adaptation after intestinal resection. Manipulation of dietary fat has been explored in rodents with experimental SBS. Kollman[57] investigated the effect of various combinations of docosahexaenoic acid (DHA) and arachidonic acid (AA) (major constituents of marine oil) in the diets of small bowel-resected Sprague-Dawley rats. Rats received 80% small bowel resections, leaving distal ileum and ICV intact. Rats were fed varying amounts of DHA and AA (from 5% AA and 3.3% DHA to 45% AA and 30% DHA) while energy from fat was kept constant at 30%. At 14 days, the ileal mucosa removed from rats receiving the highest amount of DHA and AA was significantly heavier (87.38 vs. 71.55 mg/cm) than the mucosa removed from animals who received normal diet (10% soy oil and 90% hydrogenated coconut oil). However, sucrase activity did not differ between the groups nor did mucosal characteristics from the duodenum.

Changes in nutrient transport have also been explored. A rat model of SBS suggests that a high-fat diet, compared to isocaloric regular chow, enhances fatty acid transport in the remaining small intestine. Three days

after 75% small intestinal resection, male Sprague-Dawley rats given a diet with saturated fat-enhanced chow had enhanced fat clearance (based on fat balance studies) versus rats that had received usual chow.[58] Earlier, Keelan et al.[59] resected the distal half of the small intestine in adult female Sprague-Dawley rats, leaving the ICV intact. Animals were fed regular chow for three weeks and then two additional weeks with isocaloric saturated fatty acid (SFA)- or PUFA-enriched chow. Glucose transport was twice as high across mucosa isolated from animals fed the SFA diet compared to that measured in tissue derived from animals fed the PUFA-enriched diet. Heterogeneity of positive findings, differing models (e.g., resection vs. chemical injury), and various protocols (e.g., age, sex, amount, and type of resection) limit the ability to draw firm conclusions. It is clear that the amount and type of enteral fat (most convincingly saturated long-chain triglycerides [LCTs] or fatty acids) can modify the nature and extent of adaptation.

Carbohydrates: Dietary carbohydrate absorption may be enhanced by altering the amount of administered carbohydrate (the functional "workload" hypothesis). This has been demonstrated carefully in nonresection rat models. Diamond et al.[60] isolated intestinal sleeves from mice and demonstrated in vitro that dietary carbohydrate significantly increased the V_{max} across the mucosa, suggesting carbohydrate induction of monosaccharide carriers in the intestine. Later, Shu et al.[61] found that increasing dietary fructose or sucrose induced a parallel higher expression of GLUT5 mRNA, sucrase activity, and brush border fructose transport. Moreover, enterocytes may acquire transport characteristics only while they are still in the crypt. Using a time-sequenced freeze fraction and transporter staining technique, Ferraris et al.[62] found that glucose-dependent regulation of Na^+/D-glucose cotransport (assessed by functional staining technique, which quantifies glucose transporter density) was possible only when cells were still in the crypts. Disaccharides may be more trophic on intestinal mucosa than equivalent amounts of monosaccharides, an effect abolished when disaccharide hydrolysis was inhibited.[63]

Other dietary constituents may influence the transport of carbohydrates. Using a rat model of ethanol mucosal injury, Thomson et al.[64] found that SFA-enriched diet protected the in vitro jejunal and ileal transport of glucose, whereas mucosa derived from rats fed PUFA-enriched diet demonstrated decrements in glucose transport when exposed to ethanol. Alternatively, fish oil seemed to have an opposite influence on

Na^+-dependent glucose transport in proximal small intestine membrane vesicles isolated from rats maintained for four weeks on menhaden oil-enriched (unsaturated fat) or butter fat (SFA)-enriched diets.[65] Compared to the SFA diet, Vmax for glucose was significantly higher in vesicles derived from rats fed the fish oil–enriched diet.

Taken together, these data do not clearly support a specific nutrient formulation to enhance carbohydrate absorption; enteral administration of nutrients in general, including a disaccharide or polysaccharide carbohydrate source, positively influences intestinal absorption of carbohydrates.

Protein: Similar to "reflexive" influence of macronutrients on their own absorption, dietary protein influences intestinal amino acid transport. Isocalorically fed mice on high-nitrogen diets will increase uptake by 77%–81% for nonessential amino acids, while only increasing uptake by 32%–61% for more toxic but essential amino acids.[66] Conversely, nitrogen-deficient diets lead to decreased uptake of nonessential amino acids while uptake for essential amino acids was maintained, a finding that suggests independent regulation of individual or groups of amino acids.[67]

The amino acid glutamine has received significant attention as a nutrient that enhances intestinal adaptation. Ziegler et al.[68] gave rats receiving 80% intestinal resections either low or glutamine-supplemented diets. Using intestinal DNA content as proxy for intestinal adaptation, Ziegler suggested that feeds supplemented with glutamine for seven days enhanced intestinal adaptation compared to rats receiving deficient diets. This is not a uniform finding, however,[69] which is corroborated by the mixed results seen in clinical trials of glutamine supplementation.[70,71] Some amino acids may in fact have detrimental effects on the adaptive response. Parenteral arginine administration led to lower proliferative and higher apoptotic indexes in 75% resected rats 15 days following resection.[72]

Miscellaneous: Pectin and other soluble fibers may facilitate intestinal adaptation. Animal studies document improved caloric and fluid absorption when diets are supplemented with soluble fiber.[73] A rodent SBS study found that the weight, DNA, and protein content of ileum and colonic sections were significantly higher in rats fed diets supplemented with 2% pectin compared to animals with similar small bowel resections consuming an unsupplemented, isocaloric diet.[74] Proposed mechanisms of action include increased lumen/nutrient contact time, "carbohydrate salvage" via colonic assimilation of SCFAs derived by fermentation of the

soluble fiber, and direct effects of SCFAs on tissue trophism and nutrient absorption.

Salvage occurs when anaerobic bacteria in the colon ferment unabsorbed carbohydrate, producing SCFAs. Studies of human subjects with SBS have shown that carbohydrate fermentation does occur.[75] SCFAs are used by the colon as a fuel source,[76] thus increasing the amount of calories assimilated from enteral nutrition.

SCFAs may also directly enhance intestinal tissue growth and function. SCFAs given intravenously prevented total parenteral nutrition (TPN)-induced small intestinal mucosal atrophy in rats.[77] Rodent work also suggests that SCFA supplementation augments intestinal assimilation of nutrients and electrolytes. Tappenden et al.[78] gave male Sprague-Dawley rats who underwent an 80% jejunoileal resection either isocaloric SCFA-supplemented or unsupplemented PN. Three or seven days later, residual small intestinal mucosal/submucosal weight and DNA content were significantly greater in the supplemented group compared to unsupplemented rats. Later, using a similar model this group found that ileal uptake of D-glucose was substantially higher in the SCFA-supplemented animals, whereas expressions of membrane glucose (GLUT2) and ion transporter (sodium-dependent glucose transporter 1) mRNA were also higher in ileal tissue from rats receiving SCFA-supplemented TPN.[79]

Intestinal trophic factor secretion could be augmented by SCFA supplementation. Tappenden et al.[78] found that ileal proglucagon mRNA was higher among SBS rats who received SCFA-supplemented versus unsupplemented TPN. More recently, a randomized SBS rodent trial found that compared to rodents fed fiber-free elemental diets rats given the same diet supplemented with 2.5% pectin had significantly increased lower intestinal weight and length (ileum, cecum, and colon), and serum samples from supplemented rats had significantly increased glucagon-like peptide 2 (GLP-2) concentrations.[80] Taken together, these data suggest that SCFAs enhance bowel adaptation via multiple mechanisms, and further work may help direct how these molecules can be harnessed most usefully in the clinical setting.

Polyamines are dietary constituents that play an important role in cellular growth and differentiation.[81] Polyamines are polycationic compounds present in all prokaryotic and eukaryotic cells, and they must be present in sufficient quantities to support cell division and differentiation. Rodent intestinal perfusion studies suggest that polyamines

enhance glucose absorption via heightened expression of *SGLT1*.[82] Moreover, experiments suggest that polyamines exert trophic effect on intestinal mucosa and muscle. Enteral diets supplemented with the polyamine precursor ornithine α-ketoglutarate lead to mucosal hyperplasia and heightened muscle glutamine repletion in rodents with 80% small intestinal resections.[83] Ornithine decarboxylase, an enzyme responsible for enterocyte polyamine synthesis, is upregulated in hyperplastic ileal mucosa isolated from 80% intestinal resected rodents given SCFA-supplemented TPN.[78] Trophic effects are seen even in nonresected animals fed polyamine-supplemented diets.[84]

These data indicate that polyamines may mediate some important elements of intestinal adaptation. Well-designed prospective clinical trials can determine the nature of their role in human adaptation, with particular attention to the possibility that polyamines may be "conditionally essential" and thus more or less helpful depending on age and underlying disease.

Clinical studies: Clinical data suggest that enteral nutrition maintains and/or promotes intestinal function. In 1975, Greene et al.[85] gave 16 infants with protracted diarrhea either PN for two to three weeks followed by semi-elemental oral formula (n = 10) or dilute PN and continuous enteral feeding with elemental formula (n = 6). After two to three weeks of treatment, sucrase and maltase activity in jejunal biopsies improved in both groups, but they improved to the normal range only in the group that received early enteral nutrition. Additionally, the enteral feeding group stayed in hospital for fewer days (mean 34 vs. 46 days; $P < .05$), suggesting that enteral nutrition brings about recovery more effectively and more quickly than regimens that rely largely on PN. Orenstein[86] later extended these findings by studying 13 infants with intractable diarrhea, malnutrition, and malabsorption. The severe group (defined as D-xylose < 10 mg/dL, n = 8) was randomized to receive continuous enteral nutrition using semi-elemental formula or PN for three to four weeks followed by enteral nutrition. Diarrhea resolved more quickly for those receiving enteral nutrition versus PN (2–4 weeks vs. 7–12 weeks; P = .02), and malabsorption, assessed by achieving D-xylose greater than 15 mg/dL, also resolved more quickly for those receiving enteral nutrition (2–4 weeks vs. 7–12 weeks; P = .02).

Early introduction of enteral nutrition influences adaptation. Sondheimer et al.[87] identified 44 neonates retrospectively with SBS on PN for at least three months. Independent predictors of PN duration included

percentage of enteral nutrition at 12 weeks after surgery, suggesting that enteral nutrition may influence outcomes. These findings were corroborated by Andorsky et al.,[88] who reported on 30 neonates who had received at least three months of PN because of SBS. A higher percentage of enteral calories at six weeks after surgery (breast milk or elemental enteral feedings) was associated with a shorter duration of PN. Although multivariate analysis found that only residual small intestinal length was an independent predictor of PN duration, these data suggest that attention to early introduction of enteral nutrition may positively influence adaptation.

Nonnutritive Factors

Patient- and organ-related factors: The age of the patient, amount of residual intestine, type of residual intestine, presence of a proximal ostomy, lack of colon in continuity, absence of ICV, and underlying disease in residual intestine have all been noted as organ- and patient-specific characteristics that can influence the success of intestinal adaptation. Many of the relationships were identified or suspected first by Wilmore in 1972.[89]

Most studies demonstrate that residual intestinal length robustly predicts the duration of PN, a proxy for the tenor of intestinal adaptation. Based on retrospective studies[7,87,90,91] and one prospective study,[92] residual small intestinal length less than 15–40 cm in an infant, especially with lack of colon in continuity, predicts inability to wean from PN. With patients living longer with ultra-short-segment SBS, exceptions to this rule are accumulating.

Ileum appears to adapt more readily than jejunum. In 1967, Dowling and Booth[30] performed 70% distal or proximal small intestinal resection in rats and then measured efficiency of glucose absorption over time as well as mucosal morphological characteristics in the residual small intestine. Ileal villus height increased on average by 53% in rats with residual ileum, whereas villi from residual jejunum increased only by 14%. At the same time, glucose absorption from residual ileum increased by 96% compared to baseline, but there was only an 18% increase in sugar absorption from residual jejunum. Human data support the notion that jejunum has at best modest adaptive capacity. Patients with jejunocolic anastomosis after extensive resections (>75% small bowel resection) did demonstrate mucosal hyperplasia in residual jejunum,[34,35] whereas others have reported no hyperplasia or in fact hypoplasia following jejunocolic anastomosis[93] or

end jejunostomy.[94]

Debate continues with respect to the importance of the ICV in continuity. Whether ICV promotes intestinal adaptation or prevents complications that impede adaptation is inescapably confounded by the usual absence of some or all colon when the ICV is removed. Clinical experience and some observational data[95] support the notion that colon in continuity decreases time to PN independence. In any case, most studies report[7,90,91] or suggest[92] that presence of ICV improves the likelihood of achieving PN independence. Some of these studies also suggest that colonic resections[90] or lack of continuity[92] predict prolonged PN courses. Corroboration comes from adult series,[96] which clearly indicate that patients lacking colon in continuity or ileum/ICV are at higher risk for requiring long-term PN.

Growth hormone (GH) and related factors: Intuition likely resulted in early consideration of GH as an adaptation-enhancing hormone. Strong animal data support its role in either promoting mucosal growth/function or preventing mucosal atrophy.[97] Intestinal mucosa atrophies when mice are hypophysectomized, and supplemental GH restores mucosal adaptation in these mice that have had intestinal resections.[98] Insulin-like growth factor-1 (IGF-1) signaling likely accounts for GH effect in small intestine. While not all studies show that GH administration causes mucosal growth,[99] the impact may be more on nutrient or ion transport.[100]

Mouse small intestinal resection models have found that GH and glutamine-supplemented diet together synergistically increase plasma IGF-1 levels, mucosal DNA content, and villus growth in the residual small intestine.[68,101] Thus, many clinical trials evaluating GH in SBS have included glutamine supplementation. The physiologic basis for this interaction may be provision of a substrate for ornithine carboxylase, an enzyme responsible for nucleotide production and polyamine synthesis, both important for tissues with rapidly diving cells.[102]

Clinical evaluation of GH has yielded variable results. Adult studies using moderate- to high-dose GH, glutamine supplementation (enterally or parenterally), and regulated diets have not been promising.[103] For example, Scolapio et al.[104] conducted a randomized, blinded, and placebo-controlled crossover trial testing the adaptive impact of GH (0.15 mg/kg/d), oral glutamine (0.63 g/kg/d), and high-carbohydrate diet on eight adult SBS patients (average small bowel length, 71 cm; mean duration of TPN, 12.9 years). Treatment with GH transiently increased total body water and electrolyte absorption but made no difference with

respect to multiple measures of nutrient transport or villus morphology. Hyperphagia and normal body composition could be important mediators of optimal adaptation; negative studies may be explained by a lack of consideration of these, and other, factors.[105]

Positive results with GH have been reported. In a randomized double-blind trial, 12 adult SBS patients (duration of PN, 7 ± 1 years; small bowel remnant length, 48 ± 11 cm) on TPN and unrestricted hyperphagic diets were given three weeks of low-dose (0.05 mg/kg/d) GH or placebo, followed by a crossover period of three additional weeks.[106] Compared to the control group, those receiving GH had improved lean body mass and significantly increased nutrient absorption. Absorption of protein increased by 15% ± 5% ($P < .002$), whereas enteral caloric absorption improved to 37% ± 16% of total parenteral energy delivery. Later, Byrne et al.[107] conducted a randomized placebo-controlled inpatient trial in 41 adult PN-dependent subjects with SBS (average duration of PN, 4.6 years; average length of small bowel, 73 cm) comparing glutamine-supplemented diets with and without GH. Compared to those receiving glutamine only, subjects who received GH plus glutamine-supplemented diet were able to wean from PN more substantially during the four-week treatment trial (mean reduction in PN volume, 7.7 L/wk ± 3.2 vs. 3.8 L/wk ± 2.4; $P < .001$); these effects were durable three months later but only for the group that received both GH and glutamine diet. It does not appear that any patient was able to completely wean off PN.

There is very limited published experience regarding the GH axis in pediatric IF. PN-dependent children with neonatal SBS received rhGH 0.14 mg/kg/d and glutamine for three months.[108] Results suggested a beneficial effect of rhGH by decreasing the need for PN but with mild effects on body composition and gut mucosa. In addition, there was no apparent benefit from glutamine treatment. More recently, an open-label trial involved eight PN-dependent children with neonatal SBS receiving more than 50% of their protein-energy requirements from PN.[109] They received 0.13 mg/kg/d of rhGH for 3 months and were followed for an additional 12 months. During treatment, plasma citrulline significantly increased (baseline 16.5 ± 14.8 μmol/L vs. on treatment 25.2 ± 18.3 μmol/L; $P < .05$), median enteral energy intake increased by 54% ($P < .001$), and net energy balance significantly increased. However, after 12 months of follow-up only two patients remained independent of PN. Guo et al.[110] recently reported on their retrospective experience in administering rhGH 0.05 mg/kg/d for three weeks; enteral glutamine for

two years; and a low-fat, high-carbohydrate diet in seven children with SBS and PN dependence. After a median follow-up of 15 months since treatment with rhGH, all but one patient were weaned from PN.

These data show that late exogenous treatment with GH and glutamine supplementation may promote intestinal adaptation. Safety concerns notwithstanding, any future prospective investigation will be more meaningful when differences in anatomy, age, dietary compliance, nutritional status, and mucosal disease processes are minimized or accounted for a priori.

IGF-1 physiology may have an important role in intestinal adaptation following resection. This has been established in animal studies. Small and large intestinal resections induce IGF-1 mRNA expression in residual colon and ileum. Compared to resection alone, exogenous IGF-1 produced heightened IGF-1 mRNA expression in residual ileum[68] and colon[111]; larger increases in small intestinal weight, DNA, and protein content[68]; and enhanced crypt cellular proliferation.[112] Administration of IGF-1 with supplemental glutamine likely has synergistic influences on these processes.[68] Interestingly, IGF-1 signaling from within the smooth muscle layers of the small intestine may exert some control over intestinal adaptation.[113]

Differential physiologic responses have been identified with respect to IGF-1 and intestinal resection. In rat models of SBS, residual colon[114] and ileum[68] underwent adaptive changes in response to intestinal resection, whereas jejunum had no response to resection alone; changes in colon and ileum correlated with tissue protein expression of IGF-1-binding protein 3. In contrast, exogenous IGF-1 produced adaptive changes in jejunum and ileum but not colon.[115] This has not been a consistent finding.[111] This complex physiology with respect to IGF-1 provides additional insight into the aforementioned heterogeneous GH findings.

Exogenous administration of IGF-1 may facilitate transition to enteral nutrition in animal models of SBS. Gillingham et al.[116] gave rats who received 60% jejunoileal resection plus cecectomy either IGF-1 or vehicle for 7 days while receiving PN and then gave 100% enteral nutrition for an additional 10 days. Rats who received IGF-1 had significantly higher amounts of lean body mass and intestinal mucosal hyperplasia compared to animals receiving vehicle.

Barksdale et al.[117] investigated the relationship between growth failure (defined as weight and length for age < 5%) and serum hormone profiles in 40 patients (29 boys; mean age, 5.3 years; range, 0.5–18.6 years) with

SBS (73% receiving PN). In the cohort, 38% (11 patients) with height measurements (n = 29) met criteria for growth failure, and significantly more children with growth failure had low IGF-1 compared to those without growth failure (64% vs. 17%; $P < .05$). GH levels were generally normal in all patients. Although patient numbers were small, Barksdale et al. speculated that these data serve as indirect evidence that in a select group of children with poorly adapted intestine inadequate IGF-1 may have caused growth failure even in the context of adequate enteral nutrition and/or PN. Larger, prospective studies accounting for confounders such as comorbid illness will be required to validate this potentially important claim.

EGFs: EGF is well recognized for its intestinal trophic properties.[118] Characterized molecular events that occur with EGF stimulation include redistribution of *SGLT1* from microsomal pools to the brush border membrane[119] and intestinal resection-induced movement of EGF receptors from basolateral to the brush border membrane.[120]

In vivo support for EGF's trophic properties mainly comes from animal models of SBS. Mice that receive sialoadenectomy (salivary gland is the major source for EGF in mice) and proximal small bowel resection, compared to mice with small bowel resection with sham sialoadenectomy, have significantly attenuated ileal villus height and tissue weight gain, differences abolished by exogenous administration of enteral or parenteral EGF.[121] Ileal brush border surface area and glucose transport were enhanced when EGF was administered to rabbits with proximal surgical SBS compared to those that received saline.[122] Conversely, compared to mice receiving saline mice receiving 50% small bowel resections who also received orogastric EGF receptor inhibitor demonstrated poor adaptation (reduced intestinal wet weight, crypt depth, and villus height) in residual small intestine.[123] Barrier function and carbohydrate absorption were enhanced in juvenile rats with surgical SBS administered recombinant human EGF compared to rats with similar operations administered saline.[124] Lastly, one human study[125] is consistent with the notion that EGF plays a role in human intestinal mucosal integrity. EGF levels in multiple body fluids from 25 infants with NEC were significantly lower than levels found in 19 gestational-age- and weight-matched neonates without NEC.

A pilot study has been conducted in five children with severe SBS (defined as <25% small bowel length predicted for age) using exogenous, enterally administered EGF. Compared to baseline, after six weeks of

therapy carbohydrate absorption was significantly higher, as was tolerance of enteral feedings. Although the trial was successful, soon after it ended three patients developed sepsis.[126] Other human observational studies suggest that EGF is important for the maintenance of adequate barrier[125] and reparative function. It is important to emphasize the role of oral feeding and subsequent salivary gland EGF release in promoting intestinal adaptation. Gastric tube feeding by shunting the oral step reduces the contribution of EGF to intestinal adaptation.

Glucagon-like peptide 2 (GLP-s): GLP-2 is a pro-glucagon-derived peptide produced in distal ileum or proximal colonic L-cells in response to luminal nutrient exposure, providing feedback information to the upper intestine so that fluid and nutrient absorption may be optimal.[127] Animal models of SBS strongly suggest that GLP-2 plays an important role in intestinal adaptation following resection or injury. Rats subjected to 70% jejunal-ileal resections followed by oral feeding sustained persistent elevation in plasma GLP-2 levels compared to those receiving transection alone, and measures of adaptive growth in the resected animals positively correlated with levels of circulating GLP-2 and proglucagon mRNA in residual ileum and colon.[128] Martin et al.[129] extended these findings in rats by demonstrating that the magnitude of GLP-2 elevation directly correlated with the extent of intestinal resection, mucosal enterocyte proliferation, and protein and fat malabsorption. This suggested that heightened GLP-2 release may induce intestinal trophism in response to nutrient exposure in distal small and large intestines. Mechanisms for enhanced tissue tropism include increasing local blood flow[130] and inducing local expression of growth factors and growth factor receptors.[131]

Heightened adaptation occurs when GLP-2 or analog is administered to animals with induced SBS[132,133] and served to motivate a number of excellent studies in humans. Jeppesen published the first pilot study in 2001,[134] showing that GLP-2 administered to patients with SBS could increase intestinal absorption and promote accretion of lean body mass. The commercial development of peptidase-resistant GLP-2 analog teduglutide motivated further clinical study, culminating in high-quality clinical trials[135,136] that have confirmed its effectiveness in promoting intestinal adaptation.

Jeppesen et al. performed a multicenter, prospective, and double-blind 24-week trial comparing daily injected teduglutide (0.05 mg/kg/d; $N = 43$) to placebo ($N = 43$) in adults with SBS and PN dependence. At the end of the study period (Figure 61-3), significantly ($P = .002$) more subjects

given teduglutide (63%) met the primary end point (>20% reduction in PN volume) than did subjects in the control group (30%). Further, the proportion of subjects who were able to wean one or more days of parenteral support was significantly greater in the treatment than control group (54% vs. 23%; *P* = .005). Adverse events requiring study termination were no more common in the treatment group (two patients in the treatment group and three in the control group). Prolonged therapy (to 52 weeks) has been described.[135]

The Food and Drug Administration (FDA) approved teduglutide in 2012 for use in adults with SBS and PN dependence. It has not yet been evaluated in children. Concern does remain regarding cost, loss of effect once the drug is stopped, and long-term safety if the drug is continued. Adverse effects of the drug have included the development of intestinal polyps (screening colonoscopy is recommended before the drug is started), and positive fluid balance. Best practice approaches have already been described guidelines are available.[137]

Insulin has been shown to influence intestinal structure and absorptive function. The effects of parenteral insulin (INS) on structural intestinal adaptation, cell proliferation, and apoptosis were assessed in rats divided into three experimental groups: sham operated rats underwent bowel transection and reanastomosis, SBS rats underwent a 75% small bowel resection, and SBS-INS rats underwent a 75% small bowel resection and were treated with insulin (1 U/kg, twice daily subcutaneously) from day 3 through day 14.[138] SBS-INS animals demonstrated higher jejunal and ileal bowel and mucosal weights, jejunal and ileal mucosal DNA and protein, and jejunal and ileal crypt depth compared with SBS animals. SBS-INS rats also had a greater cell proliferation index in both jejunum and ileum and a trend toward a decrease in enterocyte apoptotic index in jejunum and ileum, compared with the SBS untreated group. Oral insulin may also promote adaptive changes in rats with SBS.[139]

Other hormones. A variety of other circulating factors have been considered for trophic effect in intestine. See Table 61-3 for a comprehensive list.

Intracellular observations. Differential gene expression certainly underlies the structural and functional changes characterizing intestinal adaptation. Investigations using cDNA microarray technology have recently begun to elucidate these pathways. Erwin et al.[60] resected 50% of proximal intestine in male mice and extracted RNA from residual ileum three days later. Compared to ileum from mice receiving sham operations, resected ileum had upregulation of genes that regulate apoptosis, cell cycle control, stress responses, ion flux, and transcription. The same group extended these findings by giving EGF, with demonstration that a novel gene product, small proline-rich protein 2, was significantly induced above baseline, with further enhancement after EGF administration.[49] Other

molecules have been considered, such as peroxisome proliferation-activated receptor α (PPAR α).[105] Molecular techniques will be instrumental in understanding the molecular correlates of adaptation, adaptation failure, and identifying logical pathways amenable to manipulation.

Summary

Animal and clinical data indicate that enteral nutrition, directly or indirectly, enhances intestinal adaptation. Complex macronutrients may enhance adaptation to a larger extent than single amino acid or monosaccharide-containing nutrition. Specific fatty acids or triglycerides may offer advantages over others, but discrepant findings disallow formulation of an ideal fat composition. Nonnutrient factors such as peptide hormones may exert important paracrine or endocrine affects; indeed, both GH and a GLP-2 analog are FDA approved for the promotion of intestinal adaptation in adults with SBS and PN dependence.

Pathophysiology

Parenteral Nutrition Cholestasis

Intestinal failure associated liver disease or (IFALD) is a leading cause of mortality in both adults and children with chronic IF and has been a primary indication for liver-intestinal transplantation in pediatrics. The prevalence, natural history, and liver histology differ between adults and children. The etiology is still unclear and likely multifactorial (see Table 61-4).

Cholestasis has generally been a problem for pediatric patients with IF. Most series have reported that 40%–60% of infants on chronic PN develop cholestasis, whereas 40%–55% of adults develop steatosis or steatohepatitis.[140] Yet, Cavicchi et al.[141] conducted a prospective investigation on PN cholestasis in their adult population of 90 home PN patients receiving PN between 1985 and 1996. The group reported that fully 65% of home PN patients developed chronic cholestasis after an average of 6 months on PN (range 3–132 months), with complications associated with portal hypertension developing in 41% of patients. A much lower burden of liver disease is suggested in more recent adult reports.[96]

TABLE 61-3 Peptides and Hormones with Demonstrated Effects (Animal or Human Studies) on Intestinal Adaptation

Following Resection			
Hormone	**Source**	**Receptor/Location**	**Action/Effects**
Gastrin	G cells (predominantly antrum and stomach)	CCK-B receptor on ECL cells	Increased gastric acid secretion gastric hyperplasia
Leptin	Fat cells, gastric mucosa	Surface receptors, many kids/concentrated in hypothalamus but also diffuse distribution	Enhances carbohydrate absorption in small intestine
GH	Anterior pituitary	GHR expressed in stomach, small intestine, colon	Increased cellular proliferation, increased absorption of water, sodium, and amino acids
IGF-1	Liver	IGF-IR (ubiquitous)	Increased cellular proliferation, increased weight
Peptide YY	L cell in ileum, colon	Y receptor family/diffusely distributed in intestine and CNS	Decreased gastric emptying, prolonged intestinal transit
GLP-2	L cells in ileum and colon	GLP-2 receptor	Increased cellular proliferation, increased weight
Hepatocyte growth factor	Intestinal fibroblasts	c-Met receptors/intestinal epithelial cells	Increased cellular proliferation, differentiation
Epidermal growth factor	Brunner's glands of duodenum, salivary glands, pancreatic secretions	TGF-α/EGFR receptor found throughout the intestinal epithelium	Increased cellular proliferation
Transforming growth factor-α	Epithelial cell throughout the GI tract	TGF-α/EGFR receptor found throughout the intestinal epithelium	Increased cellular proliferation
Keratinocyte growth factor	Stromal cells	KGFR/intestinal epithelial cells	Increased cellular proliferation
Interleukin-11	Stromal cells	IL-11R/intestinal epithelial cells	Increased intestinal mass, enhanced absorption
Bombesin	Brain and intestinal tissue	Several cell surface receptors/diffuse in GI tract including enteric nerves	Increased enterocyte proliferation, mucosal weight

Retinoic acid	Diet, stored in liver	Nuclear receptors	Stimulate crypt cell proliferation and enterocyte migration
Insulin	Released from enteral feeding		greater cell proliferation index decrease in enterocyte apoptotic

Abbreviations: CCK-B, cholecystokinin B; ECL, enterochromaffin-like cell; GHR, growth hormone receptor; GI, gastrointestinal; KGFR, keratinocyte growth factor receptor.

The burden of IFALD among children with IF is likely changing. Even a decade ago, approximately 60%–70% of patients with IF acquired in infancy had IFALD.[18,92] while up to one-third of infant cohorts went on to develop life-threatening liver disease.[92,142] Patients referred to transplant centers continue to have a high burden of IFALD.[143] We expect that modern cohorts will demonstrate lower burdens of IFALD; indirect evidence comes from the Intestinal Transplant Registry, which notes a recent drop in liver-inclusive grafts in children.[144]

IFALD has not been clearly defined. Clinical studies have typically used a direct bilirubin of greater than 2 mg/dL for more than two months in the context of PN.[18] A consensus conference in 2007[145] recommended that IFALD should be categorized according to severity, early, established, and late (Table 61-5).

IFALD is a serious complication, leading to increased mortality. Nasr et al.[146] reviewed all infants in their SBS registry (n = 70) born between 1997 and 2003 and found that infants (n = 23) whose direct bilirubin rose above 100 μmol/L (5.8 mg/dL) had a 70% chance of developing end-stage liver disease, on average 60 days (range 10–365 days) subsequent to reaching this threshold. With the rising tide of multidisciplinary centers of excellence and the use of more appropriate PN constituents, it is likely that IFALD and, more importantly, late IFALD will become much less frequent.

TABLE 61-4 Intestinal Failure-Associated Liver Disease: Etiology and Management

Predisposing Factor	Management Response
Prematurity	
Duration of PN	Cycling PN, vigilance in transition to drip enteral nutrition and

	oral nutrition
Length of bowel remnant	
Reduced bile flow	Ursodeoxycholic acid 20–30 mg/kg/d
Lack of enteral feeding	Early introduction of drip feeds
Recurrent sepsis	Daily line care, rigorous education, and reinforcement
Deficiencies	
Essential fatty acid	Balanced fatty acid supply (ω-6/ω-3)
Choline, taurine, cysteine	Pediatric amino acid formulations
Antioxidants	Supplementing α-tocopherol (vitamin E) in lipid emulsions
Toxicity	
Dextrose	Limit excessive administration; cycling
Phytosterols	Substitute other lipid sources for pure soy bean; if using pure soy oil-based lipid emulsion, administer 1 g/kg/d or less in face of worsening cholestasis and thrombocytopenia
Manganese	Monitor levels
Bacterial overgrowth	Targeted antibiotic therapy, surgical tapering, probiotics

TABLE 61-5 Intestinal Failure-Associated Liver Disease Severity

Severity Grade	Clinical	Laboratory	Imaging	Histology
Early	NN	Alkaline phosphatase and/or GGT >1.5 × ULN, total bilirubin abnormal and <3mg/dl for >6 weeks in children	Ultrasound shows an echogenic appearance	Up to 25% steatosis and up to 50% of portal tracts show fibrosis
Established	NN	Total bilirubin 3-6mg/dl, Alkaline phosphatase, GGT and/or transaminases > 1.5x ULN	Ultrasound shows highly echogenic liver with sludge, +/- stones, splenomegaly	Significant steatosis (>25) and fibrosis affecting >50% of portal tracks
Late	Splenomegaly,	Total Bilirubin	NN	Considerable

	spider angiomata, varices, ascites	>6mg/dl, transaminases and alkaline phosphtase >3x ULN, platelets <100, INR >1.5	fatty change, areas of intense fibrosis with architectural distortion

Abbrevations: NN none noted; GGT gamma glutamyl transferase

Source: Adapted with permission from Beath et al.[145]

Cholestasis and/or portal hypertension may hamper intestinal adaptation. Weber and Keller[147] stratified a group of 42 infants with SBS/IF by the severity of liver disease, assessed both clinically and with biopsy or measurement of portal venous pressure. Compared to infants with minimal clinical or objective evidence of liver disease, time on PN was markedly longer in those with marked clinical liver disease (80 vs. 100 days) or abnormal portal pressures (72 vs. 184 days). These data formed the basis for the recommendation that select patients with SBS and late IFALD should be considered for liver transplantation.[148]

Risk factors: Experimental studies suggest that lack of enteral feeding may indirectly lead to liver toxicity. Intestinal stasis and biliary stasis develop during fasting, likely influenced by a gastrointestinal hormonal milieu dramatically different from the fed state. Intestinal stasis may lead to overgrowth, translocation, and sepsis, whereas biliary stasis may cause accumulation of hepatotoxic bile acids. Biliary sludge may form in the context of biliary stasis from the lack of cholecystokinin (CCK) stimulation. However, CCK administration to pediatric patients with IF did not influence frequency or severity of cholestasis.[149] Retrospective analysis of clinical data suggests that early introduction of enteral feeding may be protective in this context.[88]

Early and repeated blood stream infections likely influence the severity or progression of IFALD. Hermans et al.[150] reviewed their experience with IFALD in children on prolonged PN (n = 30; mean PN duration, 65 months) who had received liver biopsies. Those children with severe fibrosis were more likely to have had more frequent (average 3.2 vs. 1.5 events/y) and earlier (average 1 vs. 4 months) sepsis events compared to those with mild to moderate fibrosis. Earlier retrospective reviews of infant IF have demonstrated strong relationships between cholestasis and early and/or frequency of sepsis events.[151,152]

Gestational age or diagnosis may influence risk for IFALD. Christensen et al.[153] reviewed a regional database and extracted data on all neonates receiving PN for more than 14 days (n = 1366). Groups at highest

risk for developing a persistently elevated direct bilirubin greater than 2 mg/dL (operational definition of IFALD) were those with birth weight less than 750 g and diagnoses of jejunal atresia or gastroschisis.

Clinical evidence suggests that hypertriglyceridemia (>150 mg/dL) may cause or be caused by hepatic dysfunction in neonates receiving more than two weeks of PN.[154] Colomb et al.[155] found that for 10 infants on chronic PN, more than half of 23 episodes of cholestasis were preceded by increases in IV lipid delivery. Improvements were noted with temporary discontinuation or decreasing lipid administration. Among adults, Cavicchi et al.[141] found that lipid administration in excess of 1 g/kg/d was an independent predictor of chronic cholestasis in 90 adults with IF followed between 1985 and 1996.

The nature of this lipid-related pathophysiology has been explored in vitro and in animals. Mechanisms include lack of enteral processing, direct hepatocyte toxicity from lipid peroxidation, and cytokine-induced injury. Compared to mice fed both PN solution and Intralipid® orally, mice given PN solution orally and Intralipid IV developed significantly greater fatty liver and hepatocellular damage after 19 days.[156] In vitro investigations found that Intralipid alters cholesterol metabolism when added directly to hepatocyte cell cultures.[157] Rabbits with PN-induced liver injury will show histologic and ultrastructural improvements when supplemented with IV glutathione, an intracellular antioxidant.[158] Vitamin E, particularly α-tocopherol, may also play a role in preventing hepatocyte lipid peroxidation.[159] Although the α-tocopherol content of different lipid emulsions is widely variable,[160] the implications of laboratory and clinical data are somewhat difficult to interpret.[161]

Phytosterols, which are natural components of the soy oil used to produce intravenous lipid emulsions, may alter cell membrane properties and decrease bile flow in neonatal pigs.[162] A mechanism was later suggested by Carter et al.,[163] who demonstrated that phytosterols are potent antagonists for the farnesoid X receptor, a critical regular of bile acid synthesis. Serum phytosterols have been noted to be significantly higher in neonates with IFALD compared to neonates with IF but without IFALD, and values were correlated with duration of PN, markers of liver injury, and histological damage.[164,165]

Lastly, rat models of inflammatory injury in the liver[166] show that endotoxemia via the portal vein may upregulate liver macrophages, which elaborate injurious cytokines. These findings were extended by El Kasmi et al.,[167] who noted that endotoxemia and intravenous lipid were both

necessary to activate liver macrophages and induce liver injury via a toll-like receptor 4-mediated pathway.

Management considerations: Knowledge of these risk factors and laboratory investigations give rise to the principles of IFALD management (Table 61-4). A critical strategy is the prevention of sepsis. Daily line care, intensive education and reinforcement, and multidisciplinary teams with dedicated staff to manage patients on home PN form the ideal system to prevent infection, monitor nutritional variables carefully, and address potential problems quickly. Introduction of small amounts of oral or enteral nutrition may help promote normal bile flow, although data suggest that CCK secretion may not be adequate in SBS/IF in response to enteral stimulus.[168]

Significantly decreasing the amount of soy-based lipid may be successful. Cober et al.[169] prospectively instituted a very low intravenous lipid (1gram/kg/day 2× per week) regimen in 31 infants with IF and IFALD (direct bilirubin >2.5mg/dl on >2 weeks of PN typically with soy-based lipid 3grams/kg/day). After 60 days, direct bilirubin had fallen significantly, compared to an age, diagnosis, and birth-weight matched historical control group. Mild essential fatty acid deficiency developed in 8 children, which corrected with increased intravenous lipid. Growth was similar between the treatment and control groups, and no adverse events were recorded.

Lower dose soy-based lipid has been studied prospectively.[170] Nineteen infants with intestinal failure were randomized in double blind fashion to initiate PN with either Intralipid 1gram/kg/day or Omegaven 1gram/kg/day. The trial was stopped early after 2 years because of very low incidence of cholestasis in either group. However, retrospective evaluation by these investigators found the same burden of cholestasis in patients who were receiving Intralipid 1gram/k/day as compared 2-3grams/kg/day.[171]

Increased attention to the kind of infused intravenous lipid has coincided with a dramatic change in the severity and burden of IFALD. Gura et al.[172] reported on two infants with severe IFALD whose biochemical cholestasis resolved after the substitution of an ω-3-rich, fish oil-derived IV lipid emulsion (Omegaven®) for soy-based lipid emulsion (Intralipid). Subsequently, this group[173] (see Figure 61-4) and other groups[174] have observed marked improvement in cholestasis and indicators of impending decompensated liver disease using this or related strategies. Recently, Omegaven was reported to improve cholestasis in an

adult.[175]

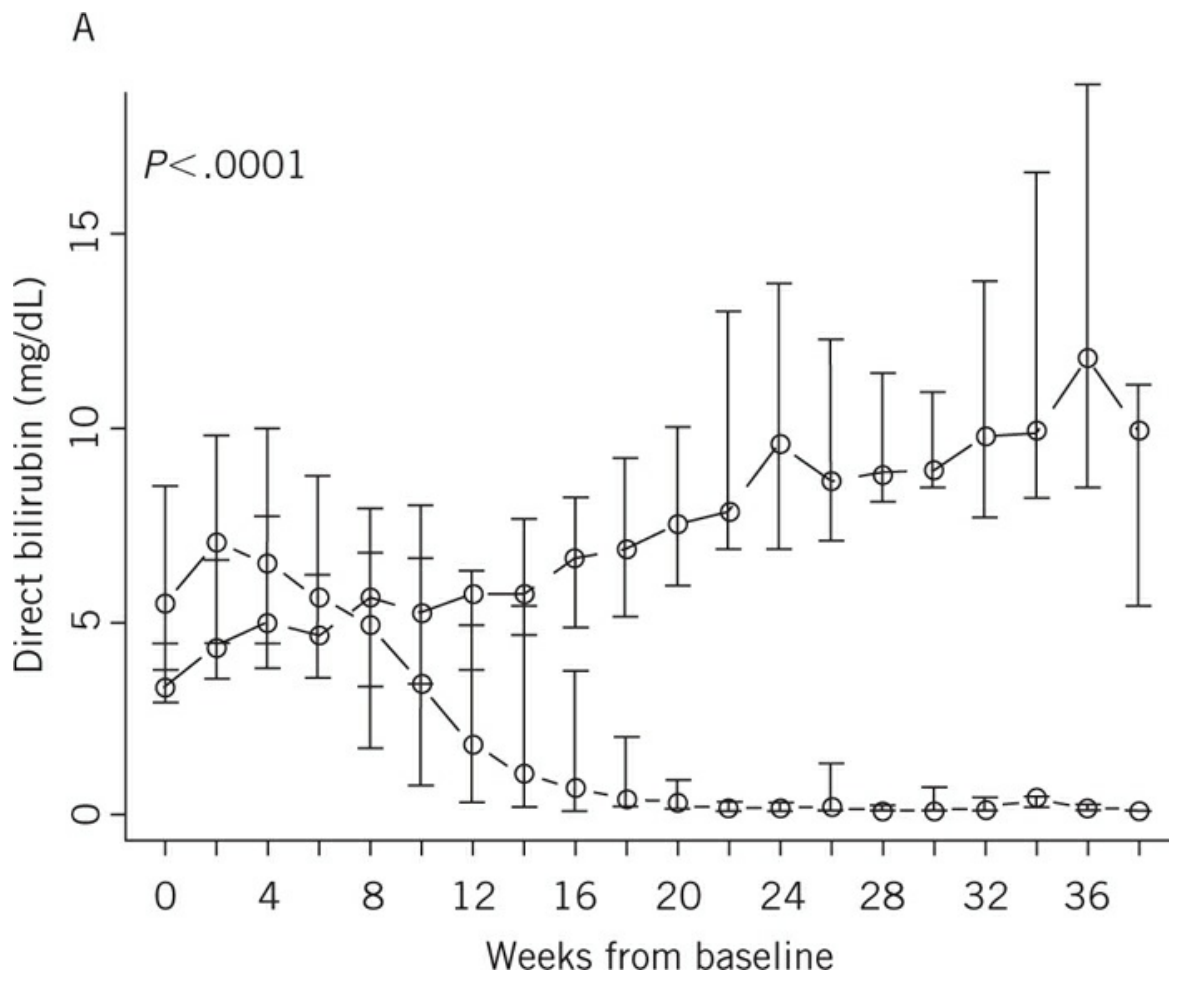

Figure 61-4 Trend in direct bilirubin for children given ω-3 fatty acid-based lipid mixture (Omegaven; *n* = 42; lower line) compared to a historical cohort of patients receiving soy oil-based lipid emulsion (Intralipid; *n* = 49; upper line). Points represent medians and vertical bars represent interquartile range. (Reproduced from Puder et al.[173])

Other lipid strategies may also successfully prevent or improve IFALD. Goulet et al.[176] prospectively demonstrated the efficacy and lack of hepatic toxicity of a lipid product containing a mixture containing soy, olive, medium-chain triglyceride (MCT), and fish-derived lipid (SMOFlipid®) compared to standard soy oil-derived lipid emulsion (Intralipid) among a cohort of children (*n* = 26) with IF over the course of one month. Finally, a retrospective evaluation of a single center's use of SMOFlipid (*n* = 8), compared to an historical cohort of children on

Intralipid (n = 9), suggested improvement in cholestasis after switching from Intralipid.[177] There has yet to be a prospective trial comparing the safety and efficacy of SMOFlipid and Omegaven. For this and other reasons, consensus guidelines[178] have not recommended a particular lipid emulsion strategy.

Biochemical and even clinical improvement does not equal resolution of disease. For instance, serial liver biopsies in six children with IFLAD on ω-3-predominant lipid mixtures demonstrated persistence of fibrosis even with resolution of biochemical liver abnormalities.[179] Fitzgibbons et al.[180] retrospectively evaluated liver biopsies in 66 patients with exposure to PN for greater than 30 days and found that liver fibrosis and cirrhosis did not correlate with biochemical markers of liver disease. Ongoing prospective evaluation of patients with a history of IFALD will be critical in determining the true natural history of this condition, setting the stage for recommendations regarding optimal strategies to prevent complications of chronic liver injury. Prospective randomized trials are needed.

Line Infections and Thrombosis

Any child with a central venous catheter (CVC) is at risk for developing catheter-related bacteremia or fungemia. Patients with IF/SBS may be at particularly high risk[181] because of the abnormal intestinal milieu. Intestinal stasis, bacterial overgrowth, and intestinal inflammation may increase the risk for bacterial translocation from the intestine to blood stream. The organisms can “seed” the venous catheter and not only lead to bacteremia or sepsis but also the need for removal of the line.

Although this scenario has been demonstrated in animal models,[182] definitive evidence in humans does not exist.[183] Suggestive evidence includes isolation of enteric organisms at a much higher frequency from the blood of patients with IF than from patients with CVCs but without IF.[184] Significant concordance has also been found between species isolated from stool or ostomy output and blood culture isolates.[185] Lastly, Weber[186] found that there was a statistically significant increase in enteric organism bacteremia during feeding advancement in 21 infants with IF/SBS compared to baseline as well as a reference population of infants with CVCs but without IF.

Thrombosis occurs when intravascular clotting occurs about the catheter. Scant literature indicates that IF/SBS is a hypercoagulatory state.[187] Whether IF patients compared to other patients with long-term central access have increased incidence of thrombosis has not directly been

studied. Moukarzel et al.[188] found that for long-term PN-dependent pediatric patients the mean life span for a CVC was 22.4 ± 14.7 months (range, 1.5–178 months); 25% of CVC removals were caused by catheter occlusion, which may or may not be due to thrombosis alone. Recurrent vascular occlusion/thrombosis limiting central venous access is particularly worrisome for patients who require central venous nutrition for survival, and this is one of the indications for intestinal transplantation. Nevertheless, true loss of all catheter insertion sites is rare.[189]

Bone Disease

Osteopenia and osteomalacia frequently develop in patients with IF. Ubesie et al.[190] retrospectively reviewed a cohort of 123 children with IF (defined as the need for PN for >30 days) and found that vitamin D deficiency and low bone mineral density occurred in 40% and 12% percent of subjects, respectively. Causative factors include inadequate vitamin D, inability to provide enough calcium and phosphorus parenterally without causing precipitation, magnesium malabsorption, aluminum toxicity, recurrent acidosis, and physical inactivity.[191] In the past, aluminum accumulation may have occurred because of the relatively large amounts found in the parenteral protein source.[192]

Management considerations include monitoring of serum alkaline phosphatase and circulating vitamin D, early consideration of supplemental enteral calcium while monitoring urine for hypercalciuria (see later), and reasonable weight-bearing physical activity. For more extreme cases, pamidronate might be considered.[193] Bone mineral ought to be monitored even after PN has been discontinued, as deficits have been noted in children with a history of PN use.[194] Long-term outcomes have not yet been well characterized.

Bacterial Overgrowth

Small intestinal bacterial overgrowth (SIBO) occurs frequently in patients with IF. The prevalence of SIBO in SBS/IF is widely variable and primarily depends on the methods chosen to make the diagnosis.[182]

Risk factors for SIBO include abnormal intestinal anatomy, decreased secretion of acid in the stomach and enzymes from the pancreas, and possibly an underlying immune defect. Motility in SBS is abnormal[195]; lack of effective migrating motor complexes during fasting because of dilated segments of intestine may promote retention of bacteria in the small intestine. The distal ileum, and not the ICV per se, may be

responsible for the propulsive function in the distal small intestine [196]; as such, resection of the ICV may be more a marker for SIBO risk than its cause.

SIBO may cause disease as a result of malabsorption and compromised intestinal epithelial barrier. Bacteria in the upper small intestine may deconjugate bile salts, leading to impaired micelle formation and increased risk for fat malabsorption. Vitamin B12 deficiency is thought to occur in SIBO because of sequestration by anaerobic bacteria.

The sequence of SIBO, mucosal inflammation, compromised intestinal epithelial barrier, bacterial translocation, and bacteremia/sepsis has been carefully studied in animals.[182,197] Human experiments have not found clear relationships. A small study of 10 infants with SBS noted a relationship between SIBO, markers of mucosal inflammation, and risk of bacteremia.[198] More recently, Gutierrez[199] reviewed 57 patients with IF who had duodenal cultures obtained to evaluate for bacterial overgrowth. Of them, 40 patients (70%) had bacterial overgrowth, and no association was found with bacteremia. In adults, O'Boyle[200] failed to demonstrate any relationship between humoral measures of permeability, mucosal inflammation or atrophy, and bacterial counts in mesenteric lymph nodes.

Nevertheless, SIBO may influence other organs or organ systems. IFALD[201] and sepsis[202] may be influenced not by bacterial translocation directly but instead via cell and humoral immunologic phenomena originating in the intestinal mucosa affected by SIBO.

The diagnosis of SIBO can be challenging as both invasive and noninvasive determinations have important limitations. Traditionally, SIBO has been defined as greater than 100,000 CFU/mL of fluid isolated from the proximal small intestine.[182] Bacteria cultured usually include flora typical of the oropharynx or colon, such as streptococci, members of *Enterobacteriaceae*, and staphylococci. Endoscopic jejunal cultures, although being the gold standard, are both difficult to obtain and poorly reproducible. Hydrogen breath testing has become the noninvasive test of choice for diagnosing SIBO. Hydrogen is a by-product of carbohydrate fermentation by intestinal bacteria, which can be quantified in the breath. Elevated background levels or early peaks after administration of a simple carbohydrate such as lactulose can be considered consistent with SIBO. Multiple reasons for falsely positive and negative tests exist. Moreover, testing will oftentimes be impractical or cumbersome in pediatrics. Thus, empiric antibiotic trials are the norm in the clinical setting.[182]

Management includes selective and periodic use of enteral antibiotics,

prokinetic agents, and surgical therapy to relieve partial obstructions or dilated loops of bowel (see later). Antibiotic therapy remains primarily empiric. Single 7- to 10-day courses may be prescribed, but more typical for patients with SBS/IF would be repeated regimens (e.g., first week of every month) or a continuous, rotating antibiotic regimen. Pro- and prebiotics likely have a role, but safety and efficacy have not been demonstrated clearly enough in clinical studies to recommend routine use. Further discussion and information regarding antibiotic and probiotic use in SIBO can be found elsewhere in the literature.[182]

Renal Calculi

Calcium oxalate nephrolithiasis may occur in patients with SBS because of the hyperabsorption of oxalate.[191] Oxalate is usually complexed with residual calcium, forming nonabsorbable salts. However, in the setting of fatty acid malabsorption with colon in continuity calcium is instead complexed with fatty acids, leaving the oxalate free to diffuse through the colonic mucosa. Nonabsorbed bile salts may also increase colonic permeability to oxalate.[203] Obligate renal excretion will lead to hyperoxaluria and increased risk for stone formation. Management may include low-oxalate diet, calcium supplementation, adequate hydration, resins such as cholestyramine, and medications to alkalinize the urine.

D-Lactic Acidosis

D-Lactic acidosis was first described in 1983,[204] and it is an uncommon but distinctive complication of SBS. The clinical presentation is highly variable but usually features altered mental status and anion gap metabolic acidosis. The mental status changes may be subtle, such as apathy or irritability, or dramatic, such as lethargy or even coma. Suspicion for this diagnosis should be raised in any patient with SBS and altered mental status, especially in a patient with known bowel dilation. Confirmation of the diagnosis requires the ability to measure *d*-lactate level in blood or urine. The pathophysiology is presumed to entail the overgrowth of *d*-lactate-producing bacterial organisms in the small bowel. In the setting of carbohydrate-rich feeding, large amounts of *d*-lactate are generated and promptly absorbed. D-Lactate is poorly metabolized in humans, such that toxic amounts may accumulate easily.[205]

Treatment primarily involves discontinuing enteral feeding, selective bowel decontamination, and sometimes bicarbonate infusions. Prevention may include surgical tapering of dilated bowel loops aimed at reducing

stasis and overgrowth.[206] Medical maneuvers using a mixture of antibiotics and long-term probiotics may also be successful.[207] However, antibiotics may occasionally promote the growth of *d*-lactic acid–producing organisms.[208]

MANAGEMENT AND OUTCOMES

Understanding the driving forces behind intestinal adaptation motivates a principled approach to what is primarily nutritional therapy for children needing intestinal rehabilitation. To be sure, the outcomes are slow to evolve. The results, however, are nothing short of momentous. Success demands patience, persistence, and attention to detail. This can best be achieved through a multidisciplinary approach, providing broad-based medical, nutritional, and surgical support for the patient and longitudinal social support for patients and caregivers.[142] More in-depth and comprehensive review of SBS management is provided in recently published texts.[209]

Medical Support

What to Feed

Although the general role of enteral nutrition in intestinal function and structure is well supported, the specific composition, especially in IF syndromes, has been less well delineated.

Breast milk: Breast milk's special immunologic and anti- infective properties ought to be especially advantageous to infants with IF. Breast milk contains growth factors, nucleotides, long-chain fatty acids, glutamine, and other amino acids that may promote intestinal adaptation. In addition, breast-feeding has been associated with improved immune function, as well as the genesis of a fecal microbiota rich in lactobacilli and bifidobacteria,[210] both of which might improve IF prognosis. On the other hand, breast milk contains lactose, which is sometimes not well tolerated in patients with reduced intestinal surface area. In a population of 30 infants with SBS (defined as >90 days of dependency on PN), the percentage of days that infants received breast milk was strongly correlated with fewer days of PN use ($r = -0.821$, $P < .03$).[88] Breast milk may be associated with the prevention of IFALD.[211] As a result of these theoretical and practical data, best practice may be to use breast milk, if available, for most infants with IF receiving enteral support.

Enteral formulas: For infants with SBS for whom breast milk is not

available, the choice of enteral formulas is controversial. On the one hand, the functional workload presented by complex nutrients may promote mucosal cell proliferation[212] via direct contact with disaccharides[63] or indirectly, whereby distal small intestinal or colonic exposure to luminal nutrients promotes release of trophic factors that stimulate small bowel adaptation.[54,78] On the other hand, the presence of a limited mucosal surface area can lead to lactose, protein, and long-chain fatty acid malabsorption. If this malabsorption is severe, fluid, electrolyte, and metabolic balance can be difficult to achieve.

Carbohydrates may be poorly tolerated by patients with IF, as they are broken down by gastrointestinal bacteria into small, osmotically active organic acids that can present a major osmotic load to the distal small intestine and colon.[213] For this reason, carbohydrate content should generally not exceed 40% of calories, and formulas given to IF patients are usually lactose free. While lactase activity is significantly lower in the jejunum compared with sucrase-isomaltase and maltase-glucoamylase activity,[214] unless there is an extensive jejunal resection most infants and children with SBS will tolerate small to moderate amounts of lactose.[189]

Fiber supplementation may be helpful in the older child with SBS with intact colon. Colonic bacterial fermentation of the unabsorbed fiber produces SCFAs, such as butyrate, which appear to induce trophic changes in animal small intestinal mucosa[77,215] and serve as a calorie source for colonocytes.[216] Moreover, pectin, a fermentable but nondigestable oligosaccharide, increased nitrogen absorption and decreased transit time in a child with SBS,[217] whereas supplementation improved electrolyte absorption and mucosal permeability for infants with protracted diarrheal illnesses.[218]

Although fat tends to be poorly absorbed in SBS, it is a dense energy source relative to carbohydrate or protein. Considering the relatively greater adverse effect of carbohydrate on osmotic diarrhea, it is usually advantageous for patients with SBS to include at least moderate amounts of fat in their diets.

MCTs may be more reliably absorbed than LCTs. MCTs are efficiently hydrolyzed by gastric and pancreatic lipases, giving rise to relatively water-soluble component fatty acids and monoglycerides, which readily diffuse into enterocytes and enter the portal blood directly.[219] This is relevant because infants with dysmotility or SBS often have dilated, poorly motile segments of intestine, conditions that encourage SIBO.[182] Bacteria metabolize and inactivate bile acids, preventing the solubilization

necessary for LCT digestion and absorption. On the other hand, excessive provision of MCT oil can cause diarrhea and ketosis, while MCTs do not provide essential fatty acids. Thus, MCT content should not be the sole source of dietary lipid.

Moreover, as previously noted, free fatty acids derived from hydrolyzed LCTs may have strong trophic effects on small intestinal mucosa. Specific fatty acids may influence intestinal adaptation, as animal data suggest that ω-3-, ω-6-,[56,57] and PUFA-supplemented[220] diets promote mucosal growth and/or function.

An ideal protein source for infants with IF has not yet been determined. Protein itself may have trophic properties. Colostrum protein concentrate improved weight gain and morphometric measures of intestinal adaptation in a piglet model of SBS using polymeric diet plus colostrum versus polymeric diet alone.[221]

Nevertheless, it is not yet clear if the type of protein in infant formulas influences outcomes. Bines et al.[222] reported a series of four SBS patients with persistent feeding intolerance. After receiving an elemental amino acid–based formula, all four patients discontinued PN within 15 months. In addition, histologic and physiologic measures of small bowel function improved concurrently. One retrospective review also found better outcomes (shorter duration of PN dependency) with the use of an amino acid–based formula.[88]

Hydrolyzed protein formulas have also been evaluated clinically. Intact protein infant formula was compared to hydrolyzed protein formula in a crossover study of 60 days' duration in 10 infants with SBS.[223] No effect of formula type was observed on growth, nitrogen absorption, or mucosal permeability. An earlier study in adult jejunostomy patients produced similar findings.[224]

Concern for the development of IgE-mediated[225] and non-IgE-mediated sensitization and allergic enteritis has favored the use of protein hydrolysate or amino acid–based formulas for children with IF. Allergic enteritis may occur in children with IF because of sensitization associated with abnormal mucosal permeability.[222,226] Retrospective small series have found eosinophilic gastrointestinal disease in patients with SBS who were not on hypoallergenic diets,[227] while small retrospective reports note[222,228] improved bowel function in patients who switched to amino acid–based formulas.

In summary, animal and some human data support an important role of enteral nutrition in children with SBS/IF. Modest data support the use of

protein hydrolysate or amino acid–based formulas. Most formulas are lactose free and many include a portion of their fat source as MCTs. Infants with diarrhea and protein-losing enteropathies may require formulas with enhanced protein content. Appendix 3 provides important details on enteral products used in infants and children with IF.

Supplementary fluids, electrolytes, and micronutrients: Excess fluid and electrolyte losses may complicate the management of IF patients, particularly in patients with high-output jejunostomies, in pseudo-obstruction patients who incur large gastric/duodenal fluid losses, or in those with persistent secretory diarrhea. Glucose-containing electrolyte solutions (also called oral rehydration solutions) with sodium concentrations of 75–90 mEq/L are typically used to replace jejunostomy and diarrheal losses. Replacement fluids, be they enteral or intravenous, may be adjusted based on electrolyte concentration of the lost fluids. The intravenous route should be used when there is still net loss of fluid following enteral replacement. Monitoring urine sodium concentration for excessive retention (<10 mEq/L) may indicate the need to provide more sodium-containing fluids, even if serum values are near normal. Excessive magnesium losses can occur with large ostomy volumes, and appropriate magnesium replacement may also improve calcium nutriture.[229]

Zinc[230] and selenium[231] losses increase with watery diarrhea and high ostomy output. Zinc supplements are often used empirically, given that serum values do not reliably reflect body stores. Fat-soluble vitamin supplements should be considered, as fat malabsorption is common when absorptive surface area or micellar function is limited. Serum vitamin B12 methylmalonic acid monitoring and/or parenteral supplementation are necessary for infants with ileal resection or diversion. Serum methylmalonic acid is considered a more sensitive and specific marker for B12 nutriture than serum B12 levels, owing to variable B12 assay performance.[232] Persistent methylmalonic acid elevation despite appropriate supplementation may indicate bacterial production of the metabolite.[233]

How to Feed

Continuous enteral feeding via a nasogastric or gastrostomy tube is advantageous in the patient with SBS or diarrhea,[86,234] as this permits constant saturation of carrier transport proteins, thus taking full advantage of the available absorptive surface area. A controlled study of intragastric feeds in infants with chronic diarrhea and/or SBS found that continuous feeding was associated with improved nutrient balance and weight gain

compared to intermittent feeding.[235]

Devices: Most centers recommend percutaneous enteral access for children who will require enteral nutrition for greater than 3 months. Nevertheless, most infants start with nasogastric or nasoenteric (transpyloric) feedings. Table 61-6 displays the methods, contraindications, and important features of enteral feeding strategies.

TABLE 61-6 Devices Used for Enteral Feeding

Devices	Indications	Contraindications	Advantages	Disadva
Gastric Feeding				
Nasogastric	Nutritional support <3 months	Severe GE reflux, aspiration, slow gastric emptying	Easy to place at home	Frequent dislodgem nasal sym
PEG	Nutritional support >3 months	History of abdominal surgery, abnormal abdominal anatomy, portal hypertension with dilated abdominal vessels	Fewer occlusions with larger bore, one-step low-profile devices available	
Surgical gastrostomy	Nutritional support >3 months and higher risk for injury to abdominal organs	Coagulopathy, poor candidate for surgery (cardiac or respiratory insufficiency)	Immediate placement of low-profile device, direct visualization of stomach	Open surg
Transpyloric Feeding				
GJ	Longer-term enteral nutrition for patients with severe GERD, gastric dysmotility, or need for gastric decompression	Recent proximal surgical anastomoses	Radiologic placement, transpyloric tube can be passed through existing gastrostomy tube	Requires h of gastrost tract prior replaceme GJ, intussusce around tub frequent occlusions jejunal por
Nasojejunal	Short-term nutritional support for patients with severe GERD, gastric	Recent proximal surgical anastomoses	Radiologic or bedside placement techniques, noninvasive	Frequent dislodgem intussusce nasal sym

	dysmotility, pancreatitis			
Jejunal	Long-term enteral nutrition for patients with severe GERD, upper intestinal dysmotility	Generalized dysmotility, poor wound healing	Direct access to small intestine	Open surg procedure mechanica problems

Abbreviations: GE, gastroesophageal; GERD, gastroesophageal reflux disease; GJ, gastrojejunal; PEG percutaneous endoscopic gastrostomy.

Methods for advancement: A protocol for enteral advancement in SBS, or in IF in general, is outlined in Table 61-7. Strict adherence to an ostomy/stool output maximum is unwise, and enteral advancement can occur so long as fluid and electrolyte balance is maintained. Small quantities of oral feedings should be introduced in infants two or three times a day to stimulate sucking and swallowing and to minimize the chances of feeding aversion in the future. Frequent setbacks are not unusual. Enteral feedings may eventually be transitioned to oral/bolus feedings, or oral/bolus and nocturnal feedings, to allow more freedom from the feeding pump.

TABLE 61-7 Enteral Advancement Methodology

A. Feeding Initiation

Audible bowel signs?

Functioning ostomy (if applicable)?

No contraindications?*

No, then continue IVF/PN/NPO [intravenous fluid/parenteral nutrition/nil per os]

Yes, then start feeds (NG/NJ/G-tube/J-tube) [nasogastric/nasojejunal]

Day 1: Breast milk (full strength) or formula (20 cal/oz.) @ 10–20 mL/kg/d continuously** × 24 h

*Contraindications to enteral feeding:

1) Paralytic or drug-induced ileus;
2) Grossly bloody stools or ostomy output and/or radiological changes of intestinal ischemia;
3) Shock/poor perfusion due to cardiac or respiratory insufficiency;
4) Bilious and/or persistent vomiting (defined as more than 3 episodes of emesis in 12 h);

5) Clinical suspicion of obstruction or ileus (severe abdominal distension, decreased ostomy or stool output, and/or radiologic changes of obstruction or ileus).
6) Electrolyte instability
7) Ostomy or stool volumes > 3 mL/kg/h

**Oral feeds may only be offered as follows:

1) Infant is developmentally able to feed by mouth (po).
2) One hour's worth of continuous feeds may be offered PO QD-TID after 5 days of continuous feeds. During this time, tube feeds should be held.
3) More than one hour's worth of continuous feeds may be offered PO once the infant has reached full volume of feeds by continuous route OR at least seven days have passed on the feeding advancement protocol.

B. Feeding Advancement

Principle 1: Quantify feeding intolerance primarily by stool or ostomy output and secondarily by reducing substances. Reducing substances should be measured twice daily. Persistent vomiting may also be indication of intolerance.
Principle 2: Tolerance assessed no more than twice per 24 h. No more than one advance per 24 h period.
Principle 3: Ultimate goals: 150–200 mL/kg/d, 100–140 kcal/kg/d
Principle 4: If ostomy/stool output precludes advancement at 20 cal/oz. for 7 days, then increasing caloric density of the formula can be performed.
Principle 5: Isocaloric reductions in PN support should be undertaken simultaneous with feeding advancement.

1. Stool output

If <10 g/kg/d or <10 stools/d----------> advance rate by 10–20 mL/kg/d
If 10–20 g/kg/d or 10–12 stools/d-----> no change
If >20 g/kg/d or >12 stools/d--------> reduce rate or hold feeds*

2. Ileostomy output

If <2 g/kg/h ----------> advance rate by 10-20 mL/kg/d
If 2–3 g/kg/h ----------> no change
If >3 g/kg/h ----------> reduce rate or hold feeds*

3. Stool-reducing substances

If <1% ----------> advance feeds per stool or ostomy output
If =1% ----------> no change
If >1% ----------> reduce rate or hold feeds*

*Feeds should generally be held for 8 h, then restarted at 3/4 the previous rate.

Surgical Support

Surgery plays a crucial role in the lives of children with IF/SBS.[18] The underlying gastrointestinal disease may demand urgent or emergent operative repair. Subsequent surgical management of IF/SBS alters the bowel physically to effect improvement in bowel function or to address complications. Reestablishment of intestinal continuity, relief of strictures (stricturoplasty), resections employing serosal patches, and bowel tapering for reestablishment of normal intestinal caliber (tapering enteroplasty) are essential surgical tools designed to repair common intestinal complications while preserving intestinal length.

Surgery may also assuage intestinal pathophysiology by altering normal intestine. Patients with SBS may have malabsorption of nutrients and electrolytes because of insufficient contact time with intestinal mucosa. Intestinal valves using sutures or synthetic material, denervation of intestinal segments, and intussusception of intestinal loops have been attempted in animals, but there are minimal published clinical data to support their use in increasing transit time in humans.[13] Segments of intestine may be reversed, which create antiperistaltic "valves" that slow transit enough to improve absorption. Colon segments have been transposed into small intestine for similar reasons, in either iso- or antiperistaltic fashion. A recently published retrospective series of 38 adult patients with SBS and prolonged IF describes a postsurgical PN weaning rate of 45%, using reversed small bowel segments 10–12 cm in length.[236] Nevertheless, this and other techniques have not gained wide acceptance because short and dilated intestine would not be well suited for this approach, reversal segment length choice is unclear, and disrupting normal bowel continuity is counterintuitive.

Longitudinal intestinal lengthening and tailoring (LILT) (Figure 61-5) and serial transverse enteroplasty (STEP) (Figure 61-6) represent advanced techniques that at once taper dilated segments of bowel and increase intestinal length. Digestive function may improve not only because aboral flow is facilitated by the normal caliber lumen but also because subsequent adaptation may lead to increased intestinal surface area.

LILT was first described in 1980 by Bianchi[237] and has since been used at many centers.[13] The technique involves separating the leaflets of mesentery, preserving the segmental blood supply to each side of the intestine. The intestine is then split longitudinally, maintaining the blood

supply to each half. Two lumens are formed by closing the halves along the longitudinal axis, finally forming an end-to-end anastomosis in the isoperistaltic fashion. The resultant bowel is half in diameter and up to twice as long.

Data regarding efficacy come from retrospective and prospective observational case series. A review of 19 pediatric IF patients undergoing LILT between 1984 and 2004 found that 79% were living, 60% were sent for intestinal transplantation, and 44% were able to completely wean from TPN after LILT. Nearly half of patients completely weaned from TPN require supplemental intravenous fluids, and bowel dilation in the LILT segment was common.[238] Satisfactory[239,240] and modest[241,242] success rates with LILT have been the norm. Standardized indications, contraindications, and surgical guidelines have not been developed, which may explain the inconsistent results reported in the literature.[243] Complications such as anastomotic leaking, obstruction, and dilatation are not rare and lead to significant ongoing morbidity or mortality.[244] Criteria for LILT vary but generally require greater than 20 cm of symmetrically dilated intestine in the context of residual intestine greater than 40 cm.[13]

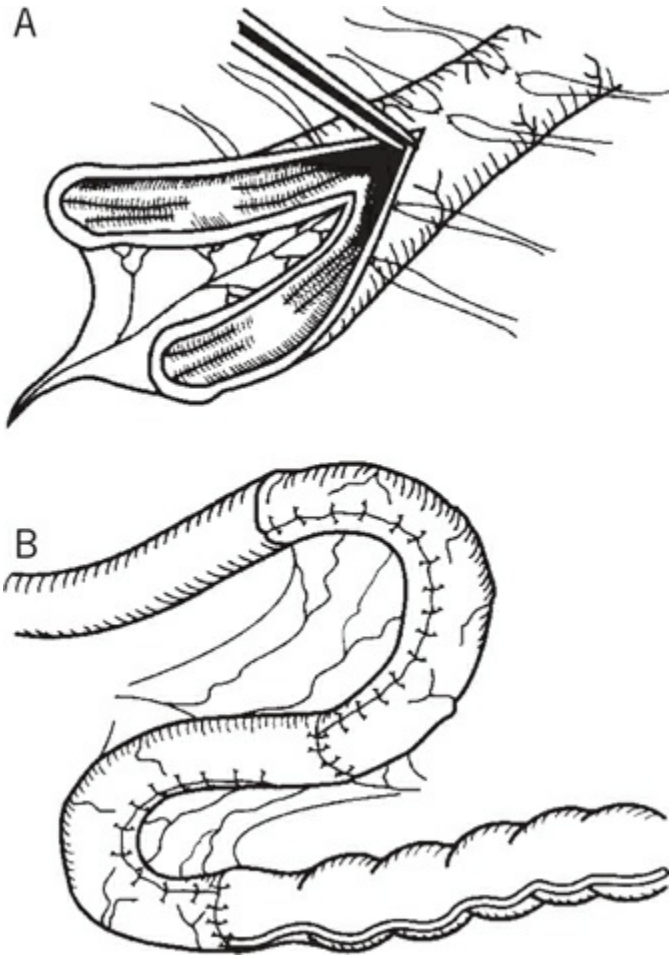

Figure 61-5 Longitudinal intestinal lengthening and tailoring (LILT). (A) Depiction of the separation of the two leaflets of mesentery each attached to longitudinally split piece of small intestine. (B) Final results after each piece of intestine has been sewed together longitudinally, and then end-to-end anastomosis made in series. (Reproduced with permission from Bianchi A.[243])

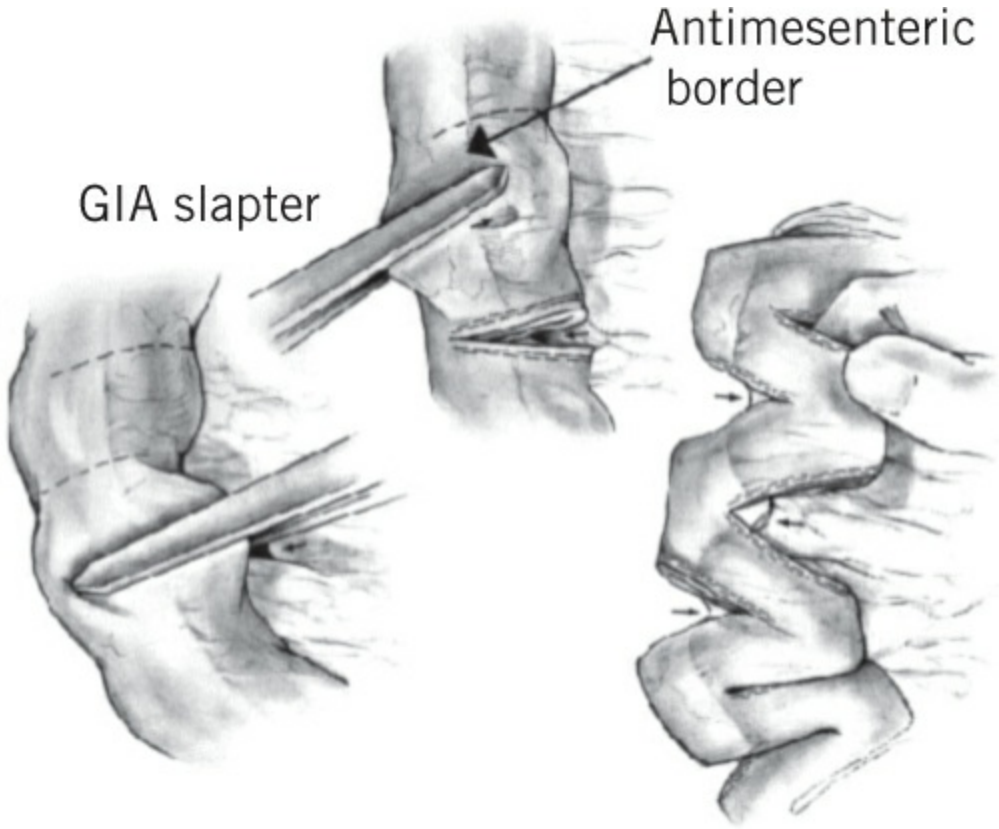

Figure 61-6 Depiction of surgical technique used to perform serial tranverse enteroplasty (STEP). (Reproduced with permission from Javid PJ et al.[309])

STEP involves the application of a staple gun incompletely across the intestine, on opposite sides in serial fashion, creating a zigzag pattern that results in a lumen both narrower and longer. Since its description by Kim et al.[245] in 2003, it has become an accepted technique at many IF centers. Potential advantages over LILT include no enterotomies, the ability to modulate lumen diameter based on the density of staple firings, and the feasibility even if intestinal dilation is in unusual locations or dilation is not of uniform caliber.[33]

A STEP registry has prospectively characterized the pooled experience with the procedure from 50 centers in 13 countries between September 2004 and January 2010.[246,247] Ninety-seven patients (mean age 6.6 years) underwent STEP and had adequate demographic and follow-up data for analysis. Survival was 89%. Of the 78 patients who underwent STEP for PN dependence, 47% achieved enteral autonomy after a median of 21

months. Longer preoperative bowel length predicted achievement of enteral autonomy, whereas higher preoperative serum bilirubin and shorter pre-STEP bowel length predicted death or transplant after first STEP. Fourteen patients in the registry had a "re-STEP" or a third STEP, with enteral autonomy achieved in six of these patients. Longer-term follow-up is emerging and generally encouraging[248]; vigilance is warranted with respect to acute anastomotic leaking and chronic anastomotic bleeding and bowel redilation.[249,250]

The nature of and mechanisms for specific physiologic adaptations have not been well characterized in SBS. Intestine subjected to lengthening procedures has only rarely been studied in this manner.[251] Chang et al. investigated mechanisms in young pigs (n = 10) who received 90% intestinal resections, half of whom had STEP to remaining bowel.[33] After six weeks on oral diet, STEP animals showed improved D-xylose absorption, higher serum citrulline levels (a biomarker for intestinal mass), and no gram-negative bacterial overgrowth. In pigs with surgically created SBS, Modi et al.[252] found that phase III contractions in the small bowel were increased after STEP, providing an additional mechanism for improved bowel function using this surgical technique. The impact of nontransplant surgery on mucosal immune/barrier function and gastroendocrine function is not known.

Long-Term Outcomes

Quality of life (QOL), mortality, and morbidity have been characterized in patients with IF; but, generally speaking, the retrospective nature of ascertainment and single-center experiences have limited the ability to apply findings confidently to individual patients.

QOL has been assessed mostly in adults. Not surprisingly, scoring on QOL tests is usually lowest during the first year on chronic PN, especially if before acquisition of IF the patient had been healthy, for example, mesenteric infarction. QOL slowly improves over the next year, leveling off at 60–70 (100 is "best quality of life") after five years of PN.[253] Factors associated with more favorable QOL include strong self-esteem in the patient and good family support.[254] Moreover, participation in strong peer support networks is associated with reduced incidence of sepsis and depression.[255] Personal stories demonstrating the possibility for meaningful life on chronic PN[256] imbue these statistics with meaning.

Pironi et al.[257] compared health-related QOL (using the SF-36 questionnaire) between adult patients on stable chronic PN (n = 18) and

those with intestinal transplants (n = 12). The results were nearly equivalent, with the exception of subjective physical health, which was significantly higher in the transplant group because of less body pain.

Gottrand et al.[258] conducted a cross-sectional, national multicenter QOL survey of children and adolescents on home PN because of digestive disease. Of the 104 eligible patients, 72 (70%) agreed to participate. QOL was high at all ages, and comparable to scores from a healthy pediatric reference population. QOL was significantly impaired in parents, especially mothers, and in adolescents with ileostomies. This study suggests that children with IF on home PN cope reasonably well, while parents perceive their own lives as significantly limited because of their children's illnesses. A more recent qualitative study of seven school agers and adolescents with lifelong IF found that affected children were resilient, family function was high, and the burdens of chronic illness were manageable.[259]

The growth pattern in children on chronic PN for gastrointestinal disorders can be favorable but may be difficult to consistently achieve. Colomb et al.[260] examined school-age girls and boys (n = 16) on home PN for an average of 10 years. Only four subjects had consistently normal weight and height velocities, whereas the others had fluctuating periods of regular (velocity > 50%) and slow (velocity < 25%) growth, not necessarily associated with illness. Analysis did suggest that inadequate nitrogen provision was closely associated with periods of slower growth. Consistent with earlier reports,[261] normal growth can be achieved on PN, but careful and repeated evaluation and biochemical monitoring are essential.

It is critical to confirm that normal growth can be maintained once PN and/or artificial nutrition are gradually discontinued. Goulet et al.[91] reviewed all cases (n = 87; average follow up time 15 years) of neonatal SBS at their institution in infants born between 1975 and 1991. The subgroup that had weaned from artificial nutrition (parenteral and enteral) grew up with normal puberty and achievement of expected height based on the parents. Gonzalez et al.[262] evaluated 10 children in cross-sectional fashion with history of SBS (mean age, 7.4 years; range, 3–12 years) who had been off PN for at least 2 years. Eight children had normal weight for height, although height for age was low in five children who had SBS in early life. The values were not adjusted for parental height. Body fat mass calculated from anthropometric measures was low in five subjects. These data are motivation enough for all patients with a history of IF to be

followed prospectively; publications based on prospectively obtained data will be instrumental for assessing nutritional outcomes in this population.

Cognitive development and outcomes have been sporadically studied in infants and children on long-term PN. It is difficult to separate the effect of the artificial nutrition from that of the underlying illness. Ralston et al.[263] examined a group of nine infants who were receiving home PN through to age 3 years. Although somatic growth was normal by 2 years of age, neurocognitive development in two patients worsened inexplicably to "mildly retarded" at 3 years of age, whereas for the others development appeared normal. More recently, Beers et al.[264] performed detailed neuropsychiatric testing in eight school-age patients with SBS, comparing results to eight patients with cystic fibrosis. Specific deficits were noted in visual-spatial performance, including left- but not right-sided upper extremity deficits in dexterity and psychomotor speed. The authors suggest that right-hemispheric central nervous system impairments may be present in patients with SBS. Earlier work also suggested the same pattern of deficits.[265] Studies confirming and/or extending these findings have not been published.

In the recent past, outcomes for children with long-standing IF were somewhat guarded, especially those with established or late IFALD. In the last five years, with the decreasing development of IFALD and improvement in intravenous catheter safety, this outlook has changed substantially.

Mortality for patients with IF on home PN is of particular interest, because decisions with respect to referring for intestinal transplant depend heavily on comparative mortality. Studies have typically been retrospective, spanning experiences over many years.[92,266–268]

Recently, Pironi[269] prospectively collected information on 854 patients (children n = 166 and adults n = 688) with IF from European centers between 2004 and 2008. Overall pediatric survival was approximately 90%. The only predictors of death on PN were presence of IFALD or intra-abdominal desmoid tumor, whereas those with ultra-short-segment SBS, intractable diarrhea, or less than 2 years of age statistically faired no differently from the overall group. This survey included only 22 patients who received intestinal transplants, with posttransplant survival notably poor at approximately 65% after up to five years of follow-up. Larger series from the United States report higher survival rates (see more later).

This compares reasonably well to the largest published experience in children. Colomb et al.[268] reviewed their experience in Paris with 302

children on home PN between 1980 and 1999. Survival rates were 97%, 89%, 81%, and 72% after 2, 5, 10, and 15 years of home PN, respectively. For children on home PN because of gastrointestinal disorders, half of deaths were attributable to PN complications such as liver disease or line sepsis, although only 9% (21 patients) of children with gastrointestinal diagnoses died during the study period.

Patients with IF continue to adapt over time. Amiot et al. noted in their cohort of 268 adults that some individuals achieved enteral autonomy up to 5 years after establishing full intestinal continuity.[96] In the latest retrospective review of young children with IF (*n* = 272 infants),[18] a few children achieved enteral autonomy up to 5 years after developing IF. As established IFALD and late IFALD become less common, the window of opportunity for developing full intestinal adaptation has widened.

In summary, long-term survival and QOL on PN are excellent. Care obtained in centers of excellence with multidisciplinary teams can make a marked difference in ensuring excellent and improving outcomes. Life-threatening complications related to the provision of PN have become much less frequent, while the hope of achieving enteral autonomy may be possible even years after developing IF.

TRANSPLANTATION

Intestinal transplantation was introduced into clinical practice in 1989 with the advent of modern immunosuppressive agents. The purpose was to save the lives of children and adults with IF dying from complications related to PN. Experience, surgical technique, immunosuppression, and medical/nutritional management have evolved significantly since then, as have organ and patient survival. Between 1985 and May 2011, the international Intestinal Transplant Registry has recorded approximately 2500 intestinal transplants, spanning 79 worldwide transplant centers, with approximately 200 operations performed per year. About half of organ recipients have been children, although in recent years the proportion of child recipients has fallen to about 30%.[144] Medicare began covering intestinal transplantation in 2001.

Indications

Because intestinal transplantation still has formidable immediate and long-term risks, strict criteria have been proposed[189,270] or are even required by insurance companies.[271] Current consensus regards intestinal transplant as

appropriate therapy for permanent IF when one or more of the following complications related to PN have occurred: (1) serious liver disease, with evidence of portal hypertension and/or coagulopathy; (2) thrombosis of major venous access points (>2 thromboses in jugular, subclavian, or femoral veins), (3) recurrent catheter-related sepsis events; (4) frequent hospitalizations caused by severe water and electrolyte abnormalities or surgical emergencies, (5) high risk of death attributable to underlying disease; and (6) IF with high morbidity or low acceptance of PN.[189,272] Common underlying conditions for patients receiving transplants are displayed in Table 61-8.

The definition of "permanent" is sometimes obvious. For instance, conditions such as severe congenital diarrhea from MVID, SBS with duodenocolic anastomosis, and extensive Hirschsprung's disease with minimal functional small intestine have been unequivocally associated with permanent IF. On the other hand, CIPOS and SBS that is less extensive may have rehabilitation potential that is more or less obvious depending on local experience and over time, as surgical and supports improve.

It would be best to evolve toward an objective score that uses clinical and biological data to predict survival on chronic PN.[273,274] Akin to model for end-stage liver disease, patients could be referred early before irreversible liver disease ensues and/or illness ensues that jeopardizes survival post transplantation. Alternatively, a valid scoring system would prevent premature or inappropriate referrals. Achieving this degree of sophistication is problematic, because intestinal transplantation is rare and the patient population is so heterogeneous.

The current criteria for intestinal transplantation have been questioned. Pironi et al.[272] prospectively followed approximately 300 adults and 90 children with IF on PN for five years and compared survival among transplant "candidates" and "noncandidates" (candidacy defined as meeting criteria for intestinal transplantation according to consensus guidelines[270]). For patients remaining on PN, five-year survival rates for candidates because of PN failure (impending or over liver failure, CVC-related thrombosis in two or more central veins, frequent or severe CVC-related sepsis, or frequent episodes of severe dehydration) and noncandidates were 73% (confidence interval, 62%–84%) and 87% (confidence interval, 83%–91%; difference, $P < .003$), respectively. However, as already noted, in comparison to noncandidates, the only patient-related factors (including indication for transplant, age, and diagnosis) among candidates that predicted death were liver failure and

intra-abdominal desmoid tumor.

TABLE 61-8 Indications for Intestinal Transplantation in Children and Adults, 1985–2011

Source: Adapted from Intestinal Transplant Registry.[144]

These data motivated the conclusion that intestinal transplantation ought to be offered expeditiously as lifesaving treatment for patients in IFALD-related liver failure or with desmoid tumors, whereas preemptive or rehabilitative intestinal transplantation might be considered for patients who meet other traditional criteria, with careful attention to the comparative costs of continued PN versus transplantation.[272] With improvement in the ability to prevent development of late IFALD, it is instructive to note that throughout Europe between 2004 and 2008 the study recorded 22 transplant procedures, only 6 of which included liver. Similar data do not exist in North America, but it is likely that in Europe the threshold for referral for transplant has been higher.[275]

Graft Considerations

The intestine may be transplanted alone or in combination with other abdominal organs. Isolated intestinal transplantation (ITx) is performed when significant liver disease is not present. These grafts (usually entire jejunum and ileum) may include ICV and some amount of colon, but the majority of transplants include only the small intestine. Living donor ITx can be performed,[276] in which a segment (approximately 200 cm) would be used.

The proportion of liver-containing grafts has fallen in the past five years.[144] Modern techniques have evolved so that en bloc methods are used to implant the graft without having to do complex biliary and vascular anastomoses. Thus, when there is serious liver disease but normal function of stomach and duodenum, an en bloc organ unit composed of graft duodenum, pancreas, small intestine, and liver can be implanted after removal of native small intestine and liver (LITx). The graft duodenum exists in addition to the native duodenum but serves only as a conduit for biliary secretions.

Multivisceral transplantation (MVTx) consists of removal and replacement of the entire foregut and midgut. The graft consists of stomach, duodenum, pancreas, jejunoileum, sometimes spleen, and most often the liver. This graft type would be reserved for patients with abdominal catastrophes so extensive that other graft types would be impossible or too difficult to implant. However, this graft type has been used in younger patients who might only have needed LITx.[277] Advantages include more available space for placement of organs, and improved hemostasis. Coagulopathy and portal hypertension can cause major hemorrhage during native organ explantation. Bleeding can be effectively controlled by ligating the celiac and superior mesenteric arteries during surgery when hemorrhage is severe.[278] This necessitates full foregut removal as the blood supply has been severed.

Children with SBS and significant liver disease have received isolated liver transplants.[279] As mentioned earlier, significant liver disease may hamper intestinal adaptation so that isolated liver transplant may allow more complete adaptation and avoid the need for intestinal transplantation. However, with modern methods to treat and prevent IFALD this approach may become obsolete.

Posttransplantation Management and Care

Care for pediatric intestinal transplant recipients comprises

immunosuppression and allograft rejection monitoring, prevention or early detection and treatment of immune and nonimmune complications related to immunosuppression, infection prevention, prophylaxsis and treatment, and nutrition support. Aside from nutrition support, the other aspects of care are in principle identical to care for children with other solid organ transplants, and they have been reviewed elsewhere.[280] There are no studies demonstrating superiority of any method of nutritional management post intestinal transplantation. What follows is an amalgam of personal experience and expert opinion deduced from informal communication at conferences and review of consensus statements.

PN is resumed usually in the first one to two days post transplantation. Most transplant programs will introduce enteral fluids within seven days of transplant and usually sooner if recovery from surgery is demonstrable with good ileostomy output and bowel sounds.[280] Many centers will secure access into the upper graft with a gastrojejunal tube, such that the tip of the feeding catheter lies well beyond the anastomosis and sits in the graft jejunum. Gastroparesis is expected after intestinal or multivisceral transplantation, and recovery may take weeks. The jejunal access enables increasing enteral nutrition in this context, so that full volume and calorie provision may be achieved enterally while the stomach and upper native intestine recover function. If gastric secretions are significantly bile tinged and pH is 5 or greater, some or all of the lost fluids can be “re-fed” into the jejunal port along with the enteral nutrition. Without surgical or medical complications, PN can typically be discontinued between three and four weeks after transplantation.

Hypoallergenic, MCT oil-supplemented formulas are considered standard for intestinal transplant recipients. These recommendations flow from suppositions that anticipated abnormal barrier function[281] and lack of physiologic lymphatic drainage may increase the chance of allergic sensitization and fat malabsorption, respectively. Maternal breast milk is rarely available by the time young children receive transplants, but administration of banked breast milk has not been well documented. Full-strength feeds are usually commenced after one to two days of clear fluid administration. Advancement is homologous to standards set forth for children with SBS.

Transition to gastric or oral feeds is based on individual patient tolerance and clinical context. The nature and timing of the recommended foods vary considerably between transplant centers. For infants or young children, it may be prudent to avoid highly allergenic foods,[282] as symptoms of gastrointestinal allergy may be confused with allograft

rejection. Nevertheless, food avoidance may have no influence on whether patients ultimately develop allergy or not. Food allergies have developed after intestinal transplantation.[283,284] However, in addition to risk from abnormal mucosal barrier function, immunosuppression may also increase the potential for allergic responses to environmental stimuli.[285]

Some centers prefer that patients consume low-fat diets, as fat absorption is expected to be abnormal with disruption of lymphatic drainage and loss of neural input to exocrine pancreas. Mean coefficient of fat absorption was 86% ± 12% among 22 pediatric intestinal transplant recipients receiving full enteral nutrition between 43 and 1000 days post transplantation.[286] Adequate vitamin E absorption could not be demonstrated until four months post transplantation. Individual case reports indicate that fat excretion normalizes by six months.[44,287] Finally, pancreatic insufficiency has not commonly developed in patients after MVTx.[288] Fat absorption may equally be a function of frequency and severity of infectious and immune complications. Thus, motivation for strict adherence to low-fat diet is likely less important than careful liberalization and monitoring for individual intolerance.

Similar to patients with SBS, sugar malabsorption can lead to osmotic diarrhea; most centers recommend that patients avoid excessive intake of fruit juices for instance. Sugar absorption has indirectly been evaluated by Kaufman et al.[286] Disaccharidase activities were all within normal ranges from small intestinal mucosal biopsies obtained 15-412 days post transplantation in 22 transplant recipients. Breath testing as a means of obtaining a functional index of carbohydrate tolerance will usually not be helpful, because of lack of colon in continuity and bacterial overgrowth.

As with all immunocompromised patients, good food safety practices should be reviewed carefully and periodically with parents and patients to reduce the risk of food-borne illnesses. Excellent resources are available[289] for seeking expert advice on this important subject.

Most intestinal transplant patients receive micronutrient supplements. Patients should receive supplemental fat-soluble vitamins, with attention also to zinc, calcium, magnesium, and iron status. Venick et al.[290] found in their cohort of 19 pediatric intestinal transplant recipients who survived greater than six months post transplantation that 4 had laboratory evidence of essential fatty acid deficiency and 17 had zinc deficiency. Iron deficiency was also common. Laboratory monitoring for fat-soluble vitamin, zinc, and iron deficiency should occur two times per year unless clinical context warrants more frequent testing.

Bone density will likely be abnormal in intestinal transplant patients for multiple reasons. One published case report[291] noted low bone density in the femur and femur neck of a pediatric patient who received a living donor graft from an identical twin. Annual bone density scans with appropriate bone-age, size, and sex standards may be prudent, although vigilance with respect to adequate calcium and vitamin D nutriture is appropriate in all cases.

"Functional foods," or nutrients that are beneficial to a bodily structure or function beyond mere caloric value, have not been evaluated clinically. Rodent work suggests that glutamine supplementation enterally[292,293] or parenterally[294] enhances restoration of normal mucosal architecture following intestinal transplantation, which may decrease bacterial translocation as determined by bacterial counts in mesenteric lymph node samples. Preservation injury may also be prevented by administering glutamine to the donor prior to removal of the organ.[295] ω-3 Fatty acids may exert an immunomodulatory effect at the mucosa[296,297] and small vessel[298] level to promote allograft function and prevent allograft vasculopathy. Concern exists with respect to giving probiotics to transplant patients, because immunocompromised patients or premature neonates make up the majority of cases of bacteremia with probiotics in the literature. A mouse study looking at acute graft versus host disease of the bowel found that administration of *Lactobacillus rhamnosus* GG was associated with reduced severity and frequency of graft versus host disease, as well as reduced bacterial translocation assessed in mesenteric lymph nodes.[299]

Because intestinal rejection causes significant organ dysfunction and increases the likelihood for bacterial translocation and sepsis, resumption of PN is not uncommon especially during moderate or severe episodes of rejection. Severe acute cellular rejection may result in loss of the intestinal graft, which would necessitate resuming lifelong PN unless another transplant is attempted. Chronic intestinal rejection results in the slow but progressive and irreversible loss of graft function and ultimately leads to requirement for long-term PN as well. Venous access may be challenging,[300] and invasive measures may be required to maintain access because of stenosis and collateralization of the usual large venous structures.

Outcomes

In the 1990s, graft and patient survival after intestinal transplantation were

poor, with patient survival rates less than 50% and 40% at one and three years post transplantation, respectively.[301] However, beginning in 2002–2003, overlapping with the usage of lymphocyte-depleting agents for induction, survival rates improved markedly. Experienced centers have reported one- and five-year patient survival rates of 92% and 70%, respectively.[302] The worldwide experience since the year 2000 is not as favorable, with 1-, 5-, and 10-year posttransplant patient and graft survival rates of 76%/71%, 58%/50%, and 44%/40%, respectively. Multiple regression analysis identified home location at time of organ offer, first transplant, and liver-inclusive graft as positive predictors of graft survival, whereas nonpredictive factors included age, diagnosis, and center volume. Graft function is also a concern, with approximately 25% of recipients needing intravenous fluids or PN six months and greater after transplantation.[144]

QOL after intestinal transplantation in children appears favorable. Sudan et al.[303] administered the validated Child Health Questionnaire to 29 pediatric intestinal transplant recipients (at least one year post transplantation) and their parents. Comparison was made to published norms for healthy children. Intestinal recipients (average, 5 years post transplantation; mean, 11 years of age) rated QOL the same as healthy children in all domains. More recently, the UCLA group[304] reported their experience with 24 recipients (median time since transplant, 2.8 years; median age, 6 years) assessing QOL using two validated instruments of determining pediatric health-related QOL. Particular deficits were identified in the self-reported school functioning and psychosocial health domains, while parents reported broad deficits in QOL. These results indicated that self-reported QOL was generally good, while particular domains and parental perception are important components that clinical teams can proactively address.

Nutritional outcomes following intestinal transplantation and predictors thereof have not yet been well characterized. Until the past decade, survival limited interest and ability to identify relationships and trends. Five centers have published growth outcomes after intestinal transplantation, as displayed in Table 61-9. It is expected that at transplant many patients would be stunted and underweight. Post transplantation, improvements in z scores can be appreciated, but it is not yet clear whether and how much length/height catch-up growth can be achieved. Rigorous prospective assessment controlling for bone age and parental height will be essential. In the UCLA cohort, Venick[305] identified low steroid dosage,

infrequent hospitalizations, and peptide-based formulas as positive predictors of linear growth.

CONCLUDING REMARKS

IF is a debilitating, life-threatening condition that predisposes children to significant medical, nutritional, and social disorders. Repair and rehabilitation require intimate knowledge of the process of intestinal adaptation, the nutritional principles guiding management of intravenous support for children of all ages (Chapter 70), and vigilance for medical and nutritional complications associated with IF. Medical and surgical innovations have changed the therapeutic landscape for children with IF. Attention to the composition of parenteral lipid, among other factors, has dramatically decreased the number of children who develop life-threatening IFALD, while early and persistent enteral nutrition remains a cornerstone of intestinal rehabilitation and IFALD prevention. Intestinal

transplantation has become a viable lifesaving treatment option when PN fails, and in select circumstances preemptive or rehabilitative transplantation is appropriate for patients with permanent IF and morbid diagnoses. Patients with intestinal transplants have different but nevertheless significant nutritional needs post transplantation, demanding ongoing monitoring and repair of abnormal growth and micronutrient deficiencies. In the future, "immunonutrition" will combine the goals of graft tolerance and nutrition support, with the prospect of withdrawal of traditional medications that negatively impact growth, glucose homeostasis, and cardiovascular health.

The Critically Ill Child

62

Eric A. Sparks, MD, Jeremy G. Fisher, MD, Faraz A. Khan, MD, Nilesh M. Mehta, MD, DCH, MRCPCH, and Tom Jaksic, MD, PhD

INTRODUCTION

Malnutrition among critically ill infants and children has remained prevalent with estimates ranging from 19% to 70%.[1–3,5] Mortality and outcomes including length of stay are influenced by nutritional status.[3,4] Unfortunately, the metabolic needs of critically ill children are frequently not met. Accurate individual assessment of the requirement of protein, energy, vitamin, and micronutrient and selection of the appropriate route of nutrient administration are important goal of pediatric critical care.

Sir David Cuthbertson first described the fundamental aspects of the metabolic response to injury in the adult.[6] Following insult, an acute catabolic phase precedes the metabolic process of recovery and repair. This metabolic response to trauma can be conceptually divided into two phases. The initial *ebb phase* is characterized by decreased enzymatic activity and oxygen consumption, low cardiac output with core temperature that may be subnormal. This is followed by the hypermetabolic *flow phase* characterized by increased cardiac output, oxygen consumption, and glucose production. During this phase, protein and lipid mobilization is associated with increased urinary nitrogen excretion and weight loss.[7]

The catabolic response is mediated by a surge in cytokines and the characteristic endocrine response associated with trauma or surgery. This results in the availability of substrates essential for wound healing and inflammatory response. Research regarding the pediatric stress response

has shown that although neonates and children demonstrate similar qualitative metabolic sequelae of illness as adults, significant quantitative differences exist.[8] An understanding of the metabolic events that accompany critical illness and surgery of the child is the first step in implementing adequate nutritional support. The goal of nutritional supportive therapy in this setting is to augment the short-term benefits of the pediatric stress response while minimizing the long-term harmful consequences. Ultimately, an individualized determination of nutrient requirements must be made to provide appropriate amounts of both macro- and micronutrients.

The metabolic response to critical illness differs from the response during prolonged nutrient deprivation or starvation. In starvation, ketone bodies are available as an energy source that spares protein catabolism. However, during illness, high insulin levels inhibit ketone formation. Furthermore, the exogenous administration of glucose does not quell protein catabolism in critical illness as it does during starvation.[9]

METABOLIC RESPONSE TO CRITICAL ILLNESS: AN OVERVIEW OF THE HYPERMETABOLIC OR STRESS RESPONSE

Children, similar to adults, rely on the breakdown and transfer of protein, carbohydrates, and lipid to meet the catabolic demands of the metabolic stress response. Figure 62-1 illustrates the basic pathways involved in the pediatric metabolic response. In general, this metabolic stress response is characterized by an increase in net muscle protein degradation that results in enhanced movement of free amino acid products through the circulation. These amino acids serve as the building blocks for rapid synthesis of proteins that act as the building blocks for tissue repair and the inflammatory response. Remaining amino acids not used in this way are channeled to the liver, where their carbon skeletons are used in gluconeogenesis. In injury, glucose is a necessary substrate for the brain, adrenal, and erythrocytes. Although the catabolism of muscle protein is an effective short-term adaptation for the child, it is of limited duration and potentially damaging owing to relative reduction in lean body mass.

Carbohydrate and lipid turnover is also increased several fold during the pediatric metabolic response. Although these metabolic alterations would be expected to increase overall energy requirements, evidence suggests that any increase is variable if present at all.[10–12] Overall, the

energy needs of the critically ill child are governed by the severity and persistence of the underlying illness. Accurate assessment of energy requirement in individual patients will allow optimal caloric supplementation and avoid the deleterious effects of both under- and overfeeding.

Finally, a unique hormonal and cytokine profile is found in the child with critical illness. These patients demonstrate an elevation in serum levels of insulin, catabolic hormones (glucagons, cortisol, catecholamines), and cytokines that are known to interact with the inflammatory process.[14,15] Current research in this field is focused on ways to manipulate these hormonal and cytokine alterations to minimize the deleterious consequences induced by the metabolic stress response.

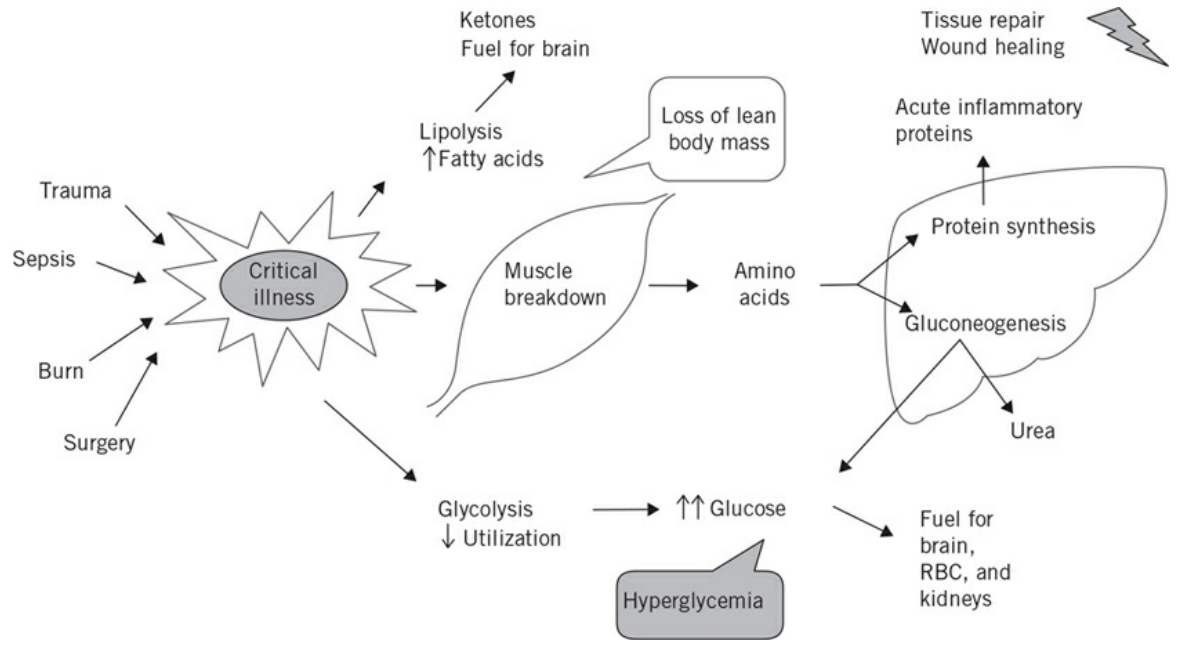

Figure 62-1 Basic pathways of the metabolic stress response.

MECHANISMS OF THE METABOLIC RESPONSE

Many of the deleterious consequences associated with the metabolic stress response can potentially be circumvented. Two integrated and complex systems are involved: neuroendocrine pathways and inflammatory cytokines. The neuroendocrine response to critical illness is relatively well defined, and its features are common to both children and adults. Beginning soon after the initial insult, a unique hormonal profile takes

hold. Catecholamines are released from the adrenal medulla on stimulation by the sympathetic nervous system. The secretion of adrenocorticotropic hormone mediated by the anterior pituitary results in an increase in serum cortisol and aldosterone levels. There are also increased concentrations of growth hormone and antidiuretic hormone, which are secreted by the anterior and posterior pituitary glands, respectively. In addition, glucagon levels rise with the surge in catecholamines. After a brief, initial decline, a rapid increase in serum insulin concentration is found.[16–18]

Overall, the hormonal changes in neonates and infants have been shown to be of greater magnitude but shorter duration than those found in older children and adults. The alterations in intermediary metabolism inherent in the metabolic response can be attributed, at least in part, to hormonal changes. The mobilization of amino acids from muscle, the increased rate of gluconeogenesis in the liver, and the increased lipolysis from adipocyte stores can be explained by the elevations in glucagon, cortisol, and the catecholamines. The increase in net protein degradation, however, is not consistent with the persistent elevation of insulin, a known anabolic hormone. It has been postulated that injury-induced protein degradation is the result of a postreceptor defect in insulin action.[19] This hypothesis is further supported by the finding that burn patients do not demonstrate the same degree of inhibition of protein breakdown compared with normal controls when subjected to hyperinsulinemic euglycemic conditions.[20]

The presence of inflammatory cytokines can be found in the circulation within hours of elective surgery or trauma. These peptides are secreted by leukocytes in a variety of settings and help to mediate the inflammatory response. In general, the prototypical cytokine response in neonates does not markedly differ from that of older children or adults. Interleukin (IL)-6 has been found in increased concentrations in the serum of children within hours after surgery, and this increase persists up to 24–48 hours postoperatively.[21] IL-6 levels have also been shown to be significantly elevated in critically ill children requiring extracorporeal membrane oxygenation (ECMO).[22] IL-6 levels have been directly correlated with increased protein turnover and catabolism as well as a higher incidence of postoperative complications and mortality.[18,19] Tumor necrosis factor (TNF) has also been shown to increase in neonatal critical illness such as necrotizing enterocolitis and sepsis. It is hypothesized that TNF is involved in the release of prostaglandins, thereby mediating the hypotension associated with the septic state. In addition, the release of IL-

1, IL-2, IL-8 interferon-γ, and other growth factors is known to augment the immunologic and hormonal response to injury.

PROTEIN METABOLISM

Amino acids are the key components of growth and tissue repair. The vast majority (98%) is found in existing proteins, with the remainder residing in the free amino acid pool. Proteins themselves are not static as they are continually degraded and synthesized in the process of protein turnover. The reuse of amino acids released by protein breakdown is extensive; protein turnover contributes more than two times the amino acids derived from protein intake. As a reference, healthy newborns have a protein turnover of approximately 6.7 g/kg/d, and adults have a protein turnover of approximately 3.5 g/kg/d.[23] An advantage of high protein turnover is that a continuous flow of amino acids is available for synthesis of new proteins. In this way, maximal physiologic adaptability is present in times of injury or illness.

In the metabolically stressed patient, such as adults with severe burn injury or children with significant cardiorespiratory failure requiring ECMO, protein turnover is double that of normal subjects.[24,25] Specifically, this process involves a redistribution of amino acids from skeletal muscle to the liver, wound, and other tissues taking part in the inflammatory response.[26] The mediators of the inflammatory response—enzymes, serum proteins, and glucose (via gluconeogenesis)—are thus synthesized. Evidence for this process can be seen in the serum by the marked increase in hepatically derived acute-phase reactants (C-reactive protein, fibrinogen, α1-antitrypsin, α-1-acid glycoprotein) and the reciprocal reduction in transport proteins such as albumin and retinol-binding protein (RBP).

Importantly, although children with critical illness have increases in both whole-body protein degradation and whole-body protein synthesis, it is the former that predominates during the stress response. Thus, these patients manifest net negative protein and nitrogen balance, skeletal muscle wasting, weight loss, and immune dysfunction.

Apart from the need for acute-phase protein production in the inflammatory response, another driving force for increased protein catabolism is the obligate production of glucose from amino acids through gluconeogenesis. This process is essential as glucose is the preferred substrate for the brain, erythrocyte, and adrenal medulla and is a versatile energy source for tissues involved in the inflammatory response. In this

process, free alanine and glutamine are produced by muscle protein degradation.[27] Glutamine is first converted to alanine in the intestinal mucosa and then transported through the portal vein to the liver, to be used in glucose production.[28] Alanine is deaminated to pyruvate and contributes a three-carbon unit toward gluconeogenesis, in the glucose-alanine cycle.[27]

Although in fasting subjects, alanine and glutamine account for over 60% of total amino acids released from muscle, this ratio is further accentuated in critical illness. From neonates to adults, increased gluconeogenesis is known to occur during illness and injury. On a per kilogram basis, this process is particularly prominent in smaller neonates, presumably because of an elevated brain-to-body weight ratio and hence an increased requirement for glucose as an energy source.[29]

Because hepatic gluconeogenesis incorporates deamination of these amino acids to cleave the carbon skeleton, the ammonia moiety by-product is detoxified through the urea cycle. Urea is a soluble metabolite that can be safely excreted in the urine. In addition, glycolysis is often activated for energy production given the anaerobic environment of injured tissue. Although this process is exceedingly inefficient compared to the aerobic oxidation of glucose, its end product, lactate, can eventually be reduced to pyruvate and shunted into gluconeogenesis via the Cori cycle.

Although the catabolism of muscle protein to generate glucose and inflammatory response proteins is an excellent short-term adaptation, it is ultimately limited because of the reduced protein stores available in children and neonates. Interestingly, unlike during starvation, the provision of dietary glucose alone is ineffective in reducing the endogenous glucose production via gluconeogenesis in the metabolically stressed state.[30] Therefore, without elimination of the inciting stress for catabolism (i.e., the critical illness or injury) the progressive breakdown of muscle leads to untoward consequences. Loss of diaphragmatic and intercostal muscle mass results in respiratory compromise, and the subsequent loss of cardiac muscle predisposes to fatal arrhythmia. Fortunately, the provision of amino acid nutritional supplementation has been shown to improve overall protein balance in the premature neonate.[31,32] The mechanism for this change appears to be an increase in protein synthesis, whereas the rate of protein degradation remains relatively constant.[33]

As expected, the amount of protein required to optimally enhance protein accretion is higher in critically ill than in healthy children. Infants demonstrate 25% higher protein degradation after surgery, a 100% increase in urinary nitrogen excretion with bacterial sepsis and a 100%

increase in net protein breakdown while on ECMO.[24,33] Children under treatment for cancer have also been shown to have increased net protein breakdown.[34] The provision of dietary protein sufficient to optimize protein synthesis, facilitate wound healing and the inflammatory response, and preserve skeletal muscle protein mass is the single most important nutritional intervention in critically ill children. The quantities of protein recommended for critically ill neonates and children are outlined in Table 62-1.[24] Certain severely stressed states, such as significant burn injury or patients requiring ECMO, may require additional protein supplementation to meet metabolic demands. Hence, growth rates and other indices for protein accretion (i.e., prealbumin levels) must be monitored closely in chronically ill patients. Excessive protein administration should be avoided as toxicity has been documented, particularly in children with marginal renal and hepatic function. Studies using high protein allotments of 4–6 g/kg/d have been associated with adverse effects such as azotemia, metabolic acidosis, and neurodevelopmental abnormalities.[35,36] Further research is needed to evaluate the safety of very high protein regimens in infants.

Although the precise amino acid composition to best increase whole-body protein balance has yet to be fully determined, stable isotope techniques have been described to study this issue.[37–39] Neonates, in particular, have immature biosynthetic pathways that may alter their ability to synthesize specific amino acids. For example, histidine is a conditionally essential amino acid until 6 months of age, and data suggest that biosynthetic pathways for cysteine, taurine, and proline may be of limited capacity in the premature neonate.[37–41] These immature amino acid pathways may have clinical relevance. Given that cysteine is essential for the production of the antioxidant glutathione in very low birth weight neonates, glutathione concentrations in erythrocytes are only 30%–40% of that in normal infants, suggesting that they may be more susceptible to oxidant stress.[41] In addition, proline demand has been shown to increase significantly in patients with severe burns.[25] Other studies of critically ill adults have linked citrulline deficiency to outcomes of morbidity and mortality. These authors propose correction of acquired citrulline and/or arginine deficiency as potential therapeutic aims. However, further research is needed to delineate these biochemical pathways as well as the safety and efficacy of replacement.[42–44]

TABLE 62-1 Estimated Protein Requirements for

Injured Children of Various Age Groups	
Age (yr)	**Estimated Protein Requirements (g/kg/d)**
0–2	2.0–3.0
2–13	1.5–2.0
13–18	1.5

In summary, during critical illness and recovery from trauma or surgery, there is increased protein catabolism. The short-term adaptive benefit of this response may, in time, be outweighed by the loss of protein in critical organs and the consequent morbidity associated with exhaustion of limited protein reserves. This sustained protein breakdown cannot be ameliorated by optimal caloric provision alone (as in starvation), but protein balance may be aided by optimal protein provision.

ENERGY METABOLISM (ASSESSMENT OF ENERGY EXPENDITURE)

During critical illness, increases in the metabolic turnover of protein, carbohydrate, and lipid result in an increased basal energy requirement for the pediatric patient. This question is important as both insufficient and excessive caloric provision has significant consequences for the critically ill child. Inadequate nonprotein caloric provision can accentuate negative nitrogen balance.[45] Conversely, the dietary provision of excess calories from glucose results in an increased production of carbon dioxide (CO_2), with no change in loss of lean body mass.[45,46] Recent data in neonates on ECMO therapy have also shown a possible paradoxical increase in net protein degradation from excess carbohydrate intake.[47] Administration of high glucose loads in critical illness may exacerbate hyperglycemia, increase carbon dioxide generation, and promote hyperlipidemia.

On the other hand, hypocaloric diet appears to have demonstrable benefits in critically ill obese adults. Obesity may be a risk factor for higher mortality in critically ill children.[48] In critically ill obese adults, permissive underfeeding consisting of a high-protein enteric diet providing 60%–70% of daily energy requirements is recommended. This strategy has been shown to aid weight loss while maintaining nitrogen balance, increasing insulin sensitivity, and reducing comorbidities.[49,50] Some critically ill obese children may benefit from a hypocaloric diet, although there is no data supporting this practice.

A careful appraisal of energy requirements in the critically ill pediatric patient is mandatory. The components of total energy expenditure (TEE) for a sedentary individual are (1) resting energy expenditure (REE)—70%, (2) diet-induced thermogenesis (DIT)—10%, and (3) energy expended during physical activity—20%. The sum of these components determines the energy requirement for an individual. Previous recommendations for energy requirements were based on estimates of basal metabolic rate (BMR) or REE derived either by indirect calorimetry or by standard equations.[51] REE can be measured using direct or indirect methods. The direct calorimetric method measures the heat released by a subject at rest and is based on the principle that all energy is eventually converted to heat. In practice, the patient is placed in a thermally isolated chamber, and the heat dissipated is measured for a given period.[52] This method is the true gold standard for measured energy expenditure. Although accurate, direct calorimetry is not practical for hospitalized critically ill patients. On the other hand, REE stimates using standardized World Health Organization (WHO) predictive equations are unreliable, particularly in the underweight subjects.[53–55] Newer equations have attempted to improve the prediction of REE in children by accounting for weight-based groups or including pubertal staging, with variable success.

The challenges of accurate REE estimation are further compounded in critically ill children. Their energy requirements show individual variation and are dependent on severity of injury. For instance, an infant with respiratory distress on pressure support is likely to have a high energy requirement due to increased work of breathing. The same patient when placed on mechanical ventilatory support, with muscle relaxants, is unlikely to have as high an energy requirement. Infants with congenital diaphragmatic hernia on ECMO support have been shown to have energy expenditures approximately 90 kcal/kg/d. Following extubation, the same patients may have energy requirements as high as 140 kcal/kg/d. Although stress factors ranging from 1.0 to 2.7 have been suggested to correct for these variations,[56,57] calculated standardized energy expenditure equations have not been satisfactorily validated in critically ill children.[57–60]

Indirect methods quantify energy production based on O_2 consumption and CO_2 production by the whole body during a specific time interval. Specifically, *indirect calorimetry*, measures VO_2 (the volume of oxygen consumed) and VCO_2 (the volume of CO_2 produced) and uses a correlation factor based on urinary nitrogen excretion to calculate the overall rate of energy production.[61] Historically, indirect calorimetry has

been utilized for energy expenditure estimation. This method employs a *metabolic cart*, a leak-free system with a computer-controlled gas exchange measurement device as well as 24-hour urine collection. Indirect calorimetry provides a measurement of the overall respiratory quotient (RQ), defined as the ratio of CO_2 produced to O_2 consumed, for a given patient. However, this method is not accurate in the setting of air leaks around the endotracheal tube, in some ventilatory circuits, in the setting of a chest tube for pneumothorax, or in subjects on ECMO support. High inspired oxygen fraction (FiO_2 0.6) will also adversely affect indirect calorimetry.

Another method of determining energy expenditure is based on the use of doubly labeled water (DLW), which has been used in humans since the early 1980s.[62] In this technique, orally administered stable isotopes of water ($2H_2O$ and H_2 18O) mix with the body water and the 18O is lost from the body as both water and CO2, whereas the 2H is lost from the body as water. The difference in the rates of loss of the isotopes 18O and 2H from the body reflects the rate of CO_2 production, which can be used to calculate the TEE. This method is noninvasive and isotope dilution is measured over two half-lives of the isotope, giving an average estimate of TEE over a period of few days. Isotope studies using DLW have since been validated and have been followed with intense and skeptical scrutiny.[63–65] However, the DLW method has its limitations and is not widely used.[63] The critically ill child with active capillary leak, decreased urine output, fluid overload, and diuretic use would pose major challenges to the assumptions made in the use of this technique. Moreover, this technique is not widely available, and due to the technical challenges, it is not often used outside dedicated laboratories.

Despite the limitations of available methods, experimental studies have tried to address the issue of estimating energy expenditure in the heterogeneous pediatric intensive care unit (PICU) population. Using ^{13}C-labeled bicarbonate and DLW ($2H_2$ 18O), studies in pediatric surgical patients have successfully measured TEE.[24,65] These techniques have been shown to correlate well with indirect calorimetry and have been used to measure energy expenditure of critically ill neonates in a variety of settings.[66] A common theme in these studies is the observation that the severity and duration of the critical illness govern the energy needs of the ill child. In general, any increase in energy expenditure during illness or after surgery is variable, and recent studies suggest that the increase is far

less than originally hypothesized.

In children with severe burns, the initial REE during the flow phase of injury is increased by 50% but then returns to normal during convalescence.[67] In neonates with bronchopulmonary dysplasia, in which the illness increases the patient's work of breathing, a 25% elevation in energy requirement is evident.[68] Newborns undergoing major surgery have only a transient 20% increase in energy expenditure that returns to baseline values within 12 hours postoperatively provided that no major complications develop.[69,70] Stable, extubated neonates, five days following surgery, have been shown to have REEs comparable to normal infants.[71] Effective anesthetic and analgesic management may play a significant role in muting the stress response of the neonate. Studies have demonstrated no discernible increase in REE in neonates undergoing patent ductus arteriosus ligation who receive intraoperative fentanyl anesthesia and postoperative intravenous analgesic regimens.[70] Finally, by using stable isotopic methods, it has been shown that the mean energy expenditures of critically ill neonates on ECMO are nearly identical to age- and diet-matched nonstressed controls.[22]

In critically ill mechanically ventilated children, use of sedation and muscle paralysis decreases the component of energy requirement related to physical activity,[72] and caloric needs in the critically ill child may be lower than previously considered. Thus, energy requirement estimates in some select groups of patients remain variable and possibly overestimated, leading to risk of overfeeding. Many studies reporting the energetic needs of critically ill children have been conducted on heterogeneous populations under various conditions. For practical purposes, the recommended dietary caloric intake for healthy children represents a reasonable starting point for the upper limit of caloric allotment in the critically ill child.[73]

Since predictive equations, used with stress factors to account for the degrees of illness, have proven inaccurate in determining individual energy expenditures, the preferred method to measure energy expenditure remains indirect calorimetry, when available.[54] This is particularly germane in children with identifiable risk factors for malnutrition. However, due to practical limitations of indirect calorimetry, current recommendation focus on using indirect calorimetry for children with identifiable risk factors for metabolic derangement.[74,75] Once protein needs have been met, safe caloric provisions using carbohydrate and lipid energy sources have similar beneficial effects on net protein synthesis and overall protein balance in critically ill patients. The rational partitioning of these

substrates requires knowledge of carbohydrate and lipid handling in critical illness.

CARBOHYDRATE METABOLISM

Glucose availability is crucial during critical illness. Glycogen stores are limited and quickly depleted resulting in the need for gluconeogenesis. In injured and septic adults, a threefold increase in glucose turnover and oxidation has been demonstrated as well as an elevation in gluconeogenesis.[30,76]

As mentioned earlier, a significant feature of the metabolic stress response is that the provision of dietary glucose does not halt gluconeogenesis. Consequently, the catabolism of muscle protein to produce glucose continues unabated.[30] However, it is clear that a combination of dietary glucose and amino acids effectively improves net protein balance in critical illness. This occurs primarily through the augmentation of protein synthesis and has little, if any, effect on protein breakdown.[33,77]

In early nutritional support regimens for critically ill patients, high glucose allotments were used in an effort to quell gluconeogenesis. The excess glucose was converted to fat, resulting in the net generation of CO_2. The synthesis of fat from glucose has an RQ of approximately 8.7. Clinically, this high RQ is not attained, as glucose is never purely used for fatty acid synthesis. Nonetheless, the provision of excess glucose results in an elevated RQ and thus increases the ventilatory burden on the child. The mean RQ in postsurgical neonates fed a high-glucose diet is approximately 1.0, whereas comparable neonates fed with reduced quantities of glucose in combination with a standard concentration of lipid have an RQ of 0.83.[78] Adult patients fed excess parenteral nutrition calories have a 30% increase in O_2 consumption, a 57% increase in CO_2 production, and a 71% elevation in minute ventilation.[46]

Thus, avoidance of excess calories from glucose provisions and the use of a mixed-fuel system employing both carbohydrates and lipid are theoretically and practically useful in critically ill children, many of whom already have respiratory challenges from the nature of their illness. This approach also helps to alleviate difficulties with hyperglycemia in the relatively insulin-resistant stressed child.

HYPERGLYCEMIA IN CRITICAL ILLNESS: ROLE OF TIGHT GLYCEMIC CONTROL

Hyperglycemia is prevalent in critically ill children including those in the posttraumatic and postsurgical state.[6,79–81] Multiple studies have demonstrated an association of the severity and duration of this hyperglycemia with morbidity and mortality.[79,82,83] Stess hyperglycemia develops in critical illness as a result of increased gluconeogenesis, glycogenolysis, and insulin resistance with subsequent impairment of cellular glucose uptake. These shifts are produced as a result of known changes in circulating counter-regulatory hormones and proinflammatory cytokines. The net increase in serum glucose concentration is an adaptive response to provide fuel to organs and injured tissues during illness. Upregulation of glucose-independent GLUC transport proteins in peripheral tissues leads to cellular glucose excess, which does not occur during normal homeostasis. This, in turn, leads to increased cellular glucose metabolism; increased production of reactive oxygen species; and results in increased apoptosis, systemic inflammation, and phagocyte dysfunction.[84]

Multiple investigators have attempted to curtail the dangerous effects of stress hyperglycemia using strategies of tight glycemic control (TGC). Some prospective studies of critically ill adults have demonstrated reductions in mortality using TGC. However, these studies have also reported increases in hypoglycemic episodes when lower blood glucose levels are targeted.[85,86] Two published prospective studies have evaluated the use of TGC in the pediatric critically ill population. A Belgian study randomized 700 infants and children to either a TGC strategy or a conventional glucose control. They found reductions in hyperglycemia, inflammatory response, secondary infections, PICU length of stay, and mortality in the TGC cohort, but at the cost of a significant increase in hypoglycemia.[87] Another trial from Boston evaluated 980 children after cardiac surgery randomized to standard care or TGC with the aid of continuous glucose monitoring. This study demonstrated a reduction of hyperglycemia and a significant but relatively low risk of hypoglycemia in the TGC group. However, the primary outcome variable of infection was unaffected and mortality, length of stay, and incidence of organ failure were not reduced.[88]

Thus, there appears to be a narrow therapeutic window of glycemic control in which negative sequelae of stress hyperglycemia may be avoided without causing complications of hypoglycemia. Although it is

prudent to avoid prolonged hyperglycemia in the PICU patient, in the presence of conflicting data, aggressive glycemic control cannot be recommended as yet.

LIPID METABOLISM

Analogous to protein and carbohydrate metabolism, lipid turnover is generally accelerated by critical illness, surgery, and trauma.[77] Although lipid use is compromised in the initial, brief ebb phase following acute trauma or sepsis, overall lipid turnover increases dramatically during the predominant flow phase. Adult patients demonstrate two- to fourfold increases in lipid turnover compared with healthy controls, and this increase is proportional to the degree of illness.[89] This process involves the recycling of free fatty acids and glycerol into and from triglycerides. In critically ill children, this increase in lipid turnover has been shown by several studies. Stressed infants and children demonstrate a reduction in RQ, an increased rate of fat oxidation, and a decline in plasma triglyceride levels.[60,90]

This evidence suggests that fats are the prime source of energy in metabolically stressed children. Glycerol, released along with free fatty acids from the breakdown of triglycerides, may be converted to pyruvate and thereby shunted into the gluconeogenesis pathway. Again similar to protein catabolism, the provision of dietary glucose does not decrease glycerol clearance or overall lipid turnover.

Because of the increased demand for lipid use in critical illness coupled with the limited lipid stores in the pediatric patient, critically ill children are susceptible to the evolution of biochemically detected essential fatty acid deficiency if administered a fat-free diet.[91,92] In infants, linoleic and linolenic acid are considered essential, whereas arachidonic acid and docosahexaenoic acid are thought to be conditionally essential. If the body lacks dietary linoleic acid, the formation of arachidonic acid (a tetraene) by desaturation and chain elongation cannot take place. The same pathway then converts available oleic acid to 5,8,11-eicosatrienoic acid (a triene), resulting in an elevated triene to tetraene ratio, which is empirically characteristic of essential fatty acid deficiency.[93] Clinically, this syndrome presents as dermatitis, alopecia, thrombocytopenia, and increased susceptibility to bacterial infection. To avoid essential fatty acid deficiency in critically ill or injured infants, the allotment of linoleic and linolenic acid is recommended at concentrations of 4.5% and 0.5% of total

calories, respectively.[94,95] The provision of commercially available lipid solutions to parenterally fed critically ill children reduces the risk of essential fatty acid deficiency, results in improved protein use, and does not significantly increase CO_2 production or metabolic rate.[96]

There are disadvantages, however, with lipid administration, including hypertriglyceridemia, increased rates of infection, and decreased alveolar oxygen diffusion capacity.[97–99] Most centers start lipid supplementation in ill children at 1.0 g/kg/d and advance over a period of days to 2–3 g/kg/d, with monitoring of triglyceride levels and screening for essential fatty acid deficiency where appropriate. Lipid administration is generally restricted to a maximum of 30%–40% of total calories, although this practice has not been validated by clinical trials.

ELECTROLYTE METABOLISM

Requirements for the basic electrolytes—sodium, potassium, chloride, bicarbonate, and calcium—must be evaluated frequently in the critically ill patient. In addition to routine electrolyte monitoring, careful attention to phosphate and magnesium levels is recommended. Hypophosphatemia may lead to hemolytic anemia and respiratory muscle dysfunction and may also be seen with refeeding syndrome in the ill child. Renal failure can result in the retention of phosphate, and nutritional allotments must be reduced accordingly. Deficiency of magnesium can cause fatal cardiac arrhythmia. Abnormalities of acid–base physiology in the critically ill child can also influence the nutritional regimen. For example, head-injured patients may develop an iatrogenically induced respiratory alkalosis. If a metabolic alkalosis secondary to active diuresis or gastric suction is also present, chloride administration should be used to correct the alkalosis. Untreated alkalemia tends to inhibit the respiratory drive, shift potassium intracellularly, and decrease ionized calcium concentrations by increasing the affinity of albumin for calcium. Metabolic acidosis can also be seen in critically ill children, often from associated hypotension or ischemic etiologies. In this case, the provision of acetate instead of Cl in the PN regimen should be used so as not to worsen the existing acidemia. The provision of excess acetate at 1 mEq/kg/d is usually a safe adjunct to limit metabolic acidosis.

VITAMIN AND TRACE MINERAL METABOLISM

Vitamin and trace mineral metabolism in critically ill and postoperative patients has not been extensively studied. For the neonate and the child, required vitamins include fat-soluble vitamins (A, D, E, and K) and water-soluble vitamins (ascorbic acid, thiamin, riboflavin, pyridoxine, niacin, pantothenate, biotin, folate, and vitamin B_{12}), and these are routinely administered. Because vitamins are not stoichiometrically consumed in biochemical reactions but rather act as catalysts, the administration of large supplements of vitamins in stressed states is not logical from a nutritional standpoint. The trace minerals required for normal development are zinc, iron, copper, selenium, manganese, iodide, molybdenum, and chromium. Trace minerals are used in the synthesis of active sites of a ubiquitous and physiologically essential class of enzymes termed metalloenzymes. As with vitamins, the role of metalloenzymes is to act as catalysts. Hence, unless there are excessive losses, such as increased zinc loss with severe diarrhea, large nutritional requirements in critical illness should not be anticipated. The Dietary Reference Intake of vitamin and trace mineral needs of healthy children and neonates are reviewed periodically and are well defined in the literature.[100] These recommended levels have been used in critically ill patients, and little evidence exists that they are nutritionally inadequate. In children with severe hepatic failure, copper and manganese accumulation can occur; thus, parenteral trace mineral supplementation is often reduced.

BODY COMPOSITION AND METABOLIC RESERVES

Table 62-2 outlines the body composition of the neonate, child, and adult patient.[101–103] The most striking difference in body composition between the adult and the child is the quantity of protein in reserve and available at times of illness. Table 62-3 outlines the relative protein stores in humans at various stages of development.[104] As a percentage of body weight, the protein stores of adults are nearly twice those of the neonate. In contrast, carbohydrate stores remain constant and do not afford significant reserve at any age. Lipid concentrations are low at birth and increase gradually during development; premature infants have even lower proportions of stored lipid at birth. In addition to the reduced macronutrient reserves in the child, both neonates and children have much higher baseline requirements. The REE for neonates is up to three times that for adults when standardized for weight.[105,106]

TABLE 62-2 Body Composition of Neonates, Children, and Non-obese Adults as a Percentage of Total Body Weight

Age	Protein (%)	Fat (%)	Carbohydrate (%)
Neonates	11	14	0.4
Children (Age 10 yr)	15	17	0.4
Adults	18	19	0.4

TABLE 62-3 Proportion of Skeletal Muscle in the Body of Humans at Various Stages of Development

Stage	Proportion of Skeletal Muscle (%)
Birth	21
Weaning	18
Adolescent	36
Adult	45
Elderly	27

This inverse relationship between energy expenditure and body weight is constant throughout mammalian species and is partially related to body surface area. The recommended intakes of macronutrients and water for healthy children and adults can be found in Table 62-4. The protein requirements of the full-term neonate (per kg body weight) are nearly three times that of the adult. Moreover, premature neonates require a minimum of 2.9–3.3 g/kg/d of protein to maintain growth rates similar to *those* in utero, and this is 3.5 times the requirement for protein balance in the adult.[107,108] Thus, the critically ill child has the potential to be much more susceptible to the harmful effects of protracted catabolic stress, and the prompt implementation of adequate nutritional support must be a priority in the patient's care.

Accurate assessment of body composition is necessary for planning ongoing nutritional intake, monitoring dynamic changes in the body compartments (such as ongoing loss of lean body mass), and assessing the adequacy of nutritional supportive regimens during critical illness. Ongoing loss of lean body mass is an indicator of inadequate dietary supplementation and may have clinical implications in the critically ill child.

However, standard measurements such as weight and anthropometrics

are frequently invalid surrogates for lean body mass in the critical care setting. This is largely due to the presence of capillary leak, manifesting as edema and large fluid shifts. Other techniques for assessing body composition (such as dual-energy X-ray absorptiometry (DEXA), biochemical parameters, ultrasound assessment, stable isotope studies, and air displacement plethysmography) are either impractical for clinical use, inaccurate in the setting of critical care, or have not yet been validated in the setting of critical care.[109] Ongoing studies attempt to identify the most appropriate body composition measures in the ICU.

TABLE 62-4 Dietary Reference Intakes (DRIs); Recommended Intakes of Macronutrients and Total Water

Age	Total Water (L/day)	Carbohydrate (g/day)	Fat (g/day)	Linoleic Acid (g/day)	α-Linoleic Acid (g/day)	Protein (g/day)
0–6 mo	0.7	60	3	4.4	0.5	9.1
7–12 mo	0.8	95	30	4.6	0.5	11
1–3 yr	1.3	130	30–40	7	0.7	13
4–8 yr	1.7	130	25–35	10	0.9	19
Males						
9–13 yr	2.4	130	25–35	12	1.2	34
14–18 yr	3.3	130	25–35	16	1.6	52
19–30 yr	3.7	130	25–35	17	1.6	56
31–50 yr	3.7	130	25–35	17	1.6	56

LABORATORY TESTS TO ASSESS NUTRITIONAL STATUS

Serum albumin is frequently used as a tool for nutritional assessment in the ICU. Levels 2.2 g/dL reflect malnutrition. However, the long half-life of albumin (14–20 days) makes it less responsive to acute changes in nutritional status. Serum albumin concentrations may be affected by albumin infusion, dehydration, sepsis, trauma, and liver disease, independent of nutritional status. Thus, its reliability as a marker of visceral protein status is questionable.

Prealbumin (also known as transthyretin or thyroxine- binding prealbumin) is a stable circulating glycoprotein synthesized in the liver. It binds with RBP and is involved in the transport of thyroxine as well as retinol. Prealbumin, so named by its proximity to albumin on an electrophoretic strip, has a half-life of 24–48 hours and reflects more acute nutritional changes. Prealbumin concentration is diminished in renal and liver disease and may be an unreliable marker for nutritional status in these settings. Chemical profile should be monitored on admission and repeated periodically.

Other laboratory tests that help in overall nutritional assessment include serum electrolytes, blood urea nitrogen, glucose, coagulation profile, iron, magnesium, calcium, and phosphate. The adequacy of cellular immunity can be estimated through the measurement of total lymphocyte count (TLC) and by delayed-type hypersensitivity testing with a series of common antigens (e.g., *Candida, Trichophyton*, and tuberculin). However, critically ill children in the postsurgical state may be anergic for many days, regardless of nutritional status.

ROUTES OF NUTRITIONAL PROVISION

Enteral Nutrition

Following the estimation of energy expenditure and requirement in the critically ill child, the next challenge is to facilitate the provision of this

nutritional support. In the critically ill child with a functioning gastrointestinal tract, the enteral route of nutrient administration is preferable to PN. Enteral nutrition is physiologic and has been shown to be more cost–effective without the added risk of nosocomial infection inherent in PN.[110,111] Gastric and postpyloric enteral feeding routes are used. No large studies have demonstrated a benefit of postpyloric feeding tubes over nasogastric tubes. Continuous feedings using standard formulas can adequately nourish the majority of injured patients. Diarrhea can often be avoided by carefully controlling the infusion rate until tolerance is established.

The enteral route has been successfully used for nutritional support of the critically ill child.[112–114] Enterally administered feeds meet nutritional requirements in critically ill children with functional gastrointestinal system and have the advantages of cost, manageability, safety, and preservation of gastrointestinal function. Early introduction of enteral feeds in critically ill patients has been shown to decrease infectious episodes and decrease length of hospital stay in critically ill patients.[115,116] This practice also helps to achieve positive protein and energy balance and restores nitrogen balance during the acute state of illness. It maintains gut integrity and elicits release of growth factors and hormones that maintain gut integrity and function.[117]

Despite its perceived benefits, current studies in ICUs show that a significant proportion of eligible patients do not receive enteral feeds.[118–120] Prolonged fluid resuscitation, interruption of feeds for procedures, and enteral feed intolerance are major factors hindering the achievement of estimated energy requirements despite maximizing the energy content of feeds. Consistently underachieved enteral nutrition goals are thought to be perhaps responsible for the absence of beneficial effect in multiple studies and meta-analysis of the efficacy of immunonutrition in preventing infection.[121]

Enteral feedings are indicated early on the course of critical illness if peristalsis has been established. Feeds can be administered into the stomach or jejunum with the aid of feeding tubes inserted nasally or orally. Intragastric or intrajejunal tip placement is often confirmed by radiograph. Postpyloric feeding is increasingly adopted to feed children with reflux or delayed gastric emptying who are at risk of aspiration.

Surgical placement of gastrostomy or jejunostomy tube allows long-term enteral feeding and administration of drugs in selected patients during intensive care and after discharge from the ICU. Stoma site infection,

obstruction, and tube dislodgement are common complications and must be identified and managed early. Tube tip malposition is frequently encountered with any of these devices either at placement or during the course of its use. Bedside screening methods for correct tip position range from auscultation during air insufflation to ultrasound-guided tip localization. However, feeds should be held when malposition of tip is suspected and when in doubt, radiographic confirmation of correct tip position should be obtained before recommencing feeds.

At the time of extubation, tube feeds are held for six hours to lower the corresponding risk of aspiration. It is also recommended not to use enteral feeds with patients who are hypotensive or who have evidence of bowel ischemia so as to limit the risk of small-bowel necrosis associated with rapid enteral feeding.[122] Intolerance to enteral feeds may be a limiting factor and supplementation with PN in this group of patients allows optimal nutritional intake. In a subgroup of critically ill patients, PN may be required for a period before initiation of enteral feeds. However, many studies have shown inability to achieve the set nutritional goal.

Parenteral Nutrition

PN allows intravenous administration of macro- and micronutrients to meet the nutritional requirements of the body. PN is indicated in children who are unable to tolerate enteral feeds for a prolonged period. Intravenous feeding may supplement enteral feeding or replace it entirely as in PN. Although widespread in its application, PN is associated with mechanical, infectious, and metabolic complications and hence should only be used in carefully selected patients. In the setting of an intact intestinal function, PN is not indicated if enteral feeds alone can maintain nutrition.

Fluid and electrolyte status will guide the initial PN prescription. The patient's hydration, size, age, and underlying disease will dictate the amount of the fluid to be administered. PN should not be used for replacing ongoing losses. PN should be prescribed daily and after reviewing electrolytes and blood sugar to allow adjustments in the macro- and micronutrient composition.

Careful biochemical monitoring is mandatory to prevent acute and long-term complications from PN therapy. A PN profile is recommended at initiation of therapy and then weekly. It includes serum levels of sodium, potassium, chloride, glucose, carbon dioxide, blood urea nitrogen, creatinine, albumin, magnesium, phosphate, total and direct bilirubin, and transaminases. For children requiring PN longer than 30 days, selenium,

iron, zinc, copper, and carnitine levels may be checked. It is essential to monitor daily vital statistics and routine anthropometry to ensure adequate growth and development. Critical care units benefit from the expertise of a dedicated nutritionist, who should be consulted on a regular basis to guide optimal nutritional intake of patients.

Central venous access is required to facilitate the delivery of hyperosmolar PN solutions into a large-bore vein with high- volume blood flow, to prevent thrombosis and phlebitis. The incidences of infective and life-threatening complications related to indwelling central lines have necessitated extreme caution when using central PN.[123–125] Central line tips are located in the superior vena cava, right atrium, or inferior vena cava. Central line tips must be placed by experienced operators and line tip confirmed on radiographs before using them for PN delivery. At our institution, only central lines are recommended for the delivery of infusates with osmolarity higher than 900 mosm/L (10% dextrose, 2% amino acids with standard additives). (Please see Chapters 67, "Enteral Nutrition," and 68, "Parenteral Nutrition," for further reading on enteral and parenteral nutrition.)

IMMUNITY-ENHANCING DIETS FOR THE CRITICALLY ILL CHILD

Immune-enhancing diets (IEDs) have been available for many years and their role in the care of critically ill patients remains controversial. Studies examining their role in critically ill patients suffer from heterogeneous clinical populations, methodological flaws, and the heterogeneous nature of the IED formulations used. Thus meta-analyses of these studies have resulted in conflicting conclusions that do not allow for dispelling current doubts regarding the safety and efficacy of these diets. The commercially available diets contain varied compounds in different doses and the role of individual compounds is impossible to interpret. Furthermore, there is little research evaluating the role of immunonutrition in critically ill children.

A recent meta-analysis of randomized clinical trials examining the efficacy of enteral immunonutrients (fish oil, glutamine, and arginine) in adult ICU, trauma, and burn patients included 3013 subjects from 24 studies.[126] The authors concluded that IEDs have no benefit in the critically ill adult ICU, burn, or trauma patients. In this analysis, only the subgroup of medical ICU patients receiving formulas high in fish oil saw a reduction in mortality, infections, and length of stay.

Arginine is a conditionally essential amino acid. It becomes essential in the setting of sepsis. Its effects, safety, and efficacy in the setting of critical care are ill-defined in the literature, with significant controversy. Some authors have suggested, with experimental support, that arginine supplementation results in nitric oxide–mediated protection against microvascular injury, which is typical of sepsis.[126] Some studies, however, have shown an increase in mortality as a result of arginine supplementation.[127–129] Thus, further research is needed before a definitive recommendation for or against arginine supplementation in critical illness can be made.

Recent studies have also investigated the role of glutamine supplementation in PN. Glutamine, cysteine, and glycine are precursors for glutathione, a major antioxidant. Glutamine is also a precursor for nucleotide synthesis and although a nonessential amino acid, it can become conditionally essential in catabolic states such as sepsis and trauma. Its applicability may be widespread and it has been introduced in PN solutions for its presumed benefits, such as restoration of protein and nitrogen balance, attenuation of gastrointestinal mucosal atrophy, reduced bacterial translocation, and reduction in bacteremia after chemotherapy. Pediatric burn patients have been shown to have deficient peripheral glutamine production. Glutamine supplementation was associated with reduced gram-negative bacteremia in severely burned patients in a double-blinded randomized control trial.[130] Glutamine has also been supplemented in enteral formulations, although only 50% is absorbed into splanchnic circulation when given enterally. The National Institute of Child Health and Development (NICHD) neonatal research network did not find any significant difference in outcomes in a multicenter randomized study of 1430 extremely low birth weight neonates who were randomized to PN containing 20% glutamine or isonitrogenous control.[131] Another large randomized trial of glutamine and antioxidant supplementation in 1223 critically ill adults did not demonstrate any improvement in mortality or secondary outcomes.[132]

OMEGA-3 FATTY ACIDS

Substitution of the intralipid component of PN (rich in proinflammatory omega-6 fatty acids) with fish oil has been demonstrated to alleviate some of the toxic effects of long-term PN on the liver. The beneficial effects of omega-3 fatty acids have been shown in animal and human models and this is an area of great interest. Omega-3 fatty acids have an anti-

inflammatory effect, with decreased cytokine production shown in some models. Several studies have demonstrated that initiation of parenteral fish oil in PN-dependent children with intestinal failure-associated cholestatic liver damage is associated with resolution of hyperbilirubinemia while avoiding essential fatty acid deficiency.[133–136] Other research has shown similar reversal of intestinal failure-associated cholestasis by employing a vegetable-based lipid emulsion at a restricted dose (≤1g/kg/d).[137,138] Prospective randomized clinical trials regarding these lipid management strategies are needed.

CONCLUSIONS

The pediatric metabolic response to critical illness is associated with a significant increase in the whole-body turnover of protein, carbohydrate, and lipid substrates. This process allows for the production of proteins necessary for the inflammatory response and wound healing. Protein loss is commensurate with the severity of illness and injury and is the hallmark of this metabolic process. Interestingly, energy expenditure is not markedly increased during this metabolic response.

Implementing an appropriate nutritional regimen to minimize the protein loss while facilitating recovery is of paramount importance in the long-term management of children suffering from critical illness or major injury. Maintaining positive protein balance in the face of protein loss requires substantially increased protein allotments, especially in neonates. Excessive carbohydrate provisions do not blunt the metabolic response and, indeed, have been shown to have deleterious consequences. In addition, because the energy expenditure of these patients does not appear to increase significantly, the recommended caloric intake for healthy children in a similar age group represents a reasonable starting point for the upper limit of caloric allotment in critically ill children. Nutritional therapy in the critically ill child should be provided via the enteral route where possible. PN may be employed to supplement or replace enteral nutrition in cases where the GI tract is unavailable. Careful monitoring, judicious application, and prompt recourse to enteral feeds, as feasible, will allow safe use of PN in the critically ill child. An interdisciplinary team approach is needed for the ideal nutritional management of the critically ill child.

Hyperlipidemia and Cardiovascular Disease

63

Sarah D. de Ferranti, MD, MPH

Cardiovascular disease (CVD) is a major cause of adult morbidity and mortality in the United States. Although rates of CVD mortality are decreasing, coronary heart disease (CHD) was the cause of death for more than 380,000 people in 2009, explaining 1 in 6 deaths.[1,2] Other atherosclerotic complications, including stroke and peripheral vascular disease, affect millions more.[2] Atherosclerotic CVD is multifactorial; dyslipidemia—high triglyceride (TG), high low-density lipoprotein cholesterol (LDL-C), and low high-density lipoprotein cholesterol (HDL-C)—is an important contributor. Elevated total cholesterol (TC) greater than 240 mg/dL was found in half of the Framingham Heart Study adult cohort who sustained a myocardial infarction;[3] interventions that reduced cholesterol by 8% reduced the risk of CHD by 19%.[4] Nutrition is an important determinant of dyslipidemia and has important effects on other CVD risk factors including hypertension and obesity. Given the ongoing childhood obesity epidemic,[5] pediatric and adolescent health-care providers can be assured that an important fraction of their clinical practice is at risk for diabetes and atherosclerotic vascular disease and that promoting improvements in nutrition and exercise is the first-line approach to treat—and ideally prevent—the cardiovascular risk factors in youth.

In this chapter, we describe how atherosclerotic vascular changes can begin in childhood based on evidence of preclinical disease by noninvasive testing, suggesting that early intervention is warranted on a population

basis and for individuals with identified risk factors. We briefly review lipid biochemistry and describe different pediatric hyperlipidemias, both primary and secondary. We discuss screening for lipid disorders, as recommended by the most recent guidelines related to pediatric lipid disorders, the National Heart, Lung, and Blood Institute (NHLBI) Expert Panel Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents (http://www.nhlbi.nih.gov/guidelines/cvd_ped/peds_guidelines_sum.pdf).[6] We review nutritional and pharmacologic treatments and lay out some practical approaches to treating children with hyperlipidemia including distinct dietary recommendations for elevated LDL-C and elevated TG in childhood.

ATHEROSCLEROSIS DURING CHILDHOOD

Atherosclerosis usually takes decades to develop. Symptoms and sequelae from atherosclerotic vascular disease are extremely rare in young persons and are limited to patients with profound genetic dyslipidemias. However, the disease pathophysiology itself and the nutritional habits that propagate the disease begin early. Autopsy studies of cohorts as early as the Korean War have shown atherosclerotic coronary artery disease in the second decade of life on gross examination[7] and by microscopy.[8,9] These pathology findings correlate with hyperlipidemia, as demonstrated in the Bogalusa cohort[10] and the Pathological Determinants of Atherosclerosis in Youth (PDAY) study,[11] among others.[12] In the PDAY study, fatty streak precursor lesions were present by age 15 years in the coronary arteries of children who died of noncardiac causes. Both the prevalence and the extent of fatty streaks and the fibrous plaques in the right coronary artery and in the thoracic aorta were directly related to non-HDL-C and decreased HDL-C, as measured at the time of death. A more recent autopsy study of US war veterans killed in combat suggests that the prevalence of atherosclerotic lesions has declined over the past several decades, although there is still an important atherosclerotic burden in young adults.[13,14]

PEDIATRIC DYSLPIDEMIA AND CARDIOVASCULAR DISEASE

Epidemiologic studies have shown that countries with higher rates of CHD

have higher pediatric population mean TC levels.[15] Cholesterol levels in the pediatric age group are important in part because they predict adult cholesterol levels. The Muscatine and Bogalusa cohorts showed cholesterol "tracks" reasonably well[16]; nearly half of Muscatine subjects with high cholesterol levels as children had high cholesterol levels as adults.[17] Childhood cholesterol levels may also be conceived as an indicator of lifetime cholesterol exposure.

There are data connecting cholesterol levels in young adults with future CHD. Johns Hopkins University medical students with high TC had a greater risk of CHD, mortality from CHD, and overall mortality over an average of 30 years of follow-up.[18] Similarly, the Princeton Lipid Research Clinic showed that childhood factors including abnormal cholesterol are a risk for early CVD.[19] These studies provide the most compelling link between measured cholesterol levels in young persons and subsequent risk of heart disease 30 or 40 years later. The Special Torku Coronary Risk Factor Intervention Project (STRIP) study showed infant boys whose parents were randomly assigned to receive counseling on low-saturated-fat diets had lower LDL-C and TC as adolescents, compared to a control group, by approximately 5%.[20] To date, there are no long-term studies demonstrating treatment for dyslipidemia during childhood results in a reduction in adult CVD events, due to the length of follow-up and the number of study participants needed to successfully answer these questions. Therefore, many of the recommendations we discuss here are based on inference, adult studies, and short-term interventions in the young.

HIGH-RISK PATIENTS

In adults, guidelines for primary and secondary prevention of CVD depend on accompanying cardiovascular risk factors. This concept has been applied to evaluating and treating lipid disorders in children,[6,21] although there are less data on which to base specific recommendations. Guidelines suggest when to initiate treatment and what target to use when treating lipid disorders; abnormal lipids should be modified in these high-risk groups. These include heart transplant recipients[22,23] and renal transplantation patients,[24,25] in whom the problem is related only in part to chronic transplant rejection. Children with previous Kawasaki disease who had or continue to have coronary aneurysms are another high-risk group.[26] Some types of congenital heart diseases are associated with an increased

risk of atherosclerosis even if repaired, such as coarctation.[27] Coronary manipulation as part of arterial switch operations for transposition of the great arteries may also make the coronaries more vulnerable.[28–30] Children with diabetes mellitus type 1 and type 2, both increasingly common in adolescence, are also at particular risk for CVD as young adults.[31] Children who have been treated for cancer during childhood are more vulnerable than the general population to future CVD and its precursors, including lipid disorders, hypertension, and central adiposity.[32,33] In assessing risk for individual children, solid organ transplantation and diabetes mellitus types 1 and 2 can reasonably be considered very high risk conditions in determining whether a child is a candidate for pharmacologic therapy and should lower the therapeutic cutpoint for treatment. For example, it is our practice to place all children on pravastatin after heart transplantation, regardless of cholesterol levels, due to the risk of coronary artery pathology and arteriopathy in this population.[34]

OBESITY, METABOLIC SYNDROME, AND TYPE 2 DIABETES MELLITUS

Obesity is associated with dyslipidemia, specifically hypertriglyceridemia and low HDL as well as a mild to moderate increase in LDL-C; other or additional diagnoses should be considered if the LDL is significantly elevated. In patients who are genetically prone to hypertriglyceridemia or have a family history of type 2 diabetes, trends toward “super-sized” fast-food meals, juice, and sedentary lifestyle are highly detrimental; overweight or obesity simply adds to this.

Metabolic syndrome is a term used to describe a collection of cardiovascular risk factors associated with a high rate of atherosclerotic disease and diabetes mellitus type 2. Childhood metabolic syndrome has been associated with adult metabolic syndrome.[19] There is controversy about pediatric metabolic syndrome as a concept, and many definitions have been proposed but none are generally agreed on.[35] Most proposed definitions, similar to the adult definitions,[36] include hypertension, disordered glucose metabolism, central obesity, low HDL, and high TG levels. Estimates of the prevalence of a pediatric metabolic syndrome in adolescents range between 4% and 12.7% of the population aged 13-19 years, depending on the population and the definition used.[37–38] Childhood obesity is associated with a greater burden of childhood metabolic risk factors and also associated with adult metabolic syndrome.[39] The main

clinical use of the concept of metabolic syndrome in childhood is to alert the clinician to the clustering of risk factors so that he or she can screen for other cardiovascular risk factors.

EMERGING CONCEPTS IN ATHEROSCLEROSIS: APPLICATIONS IN CHILDREN AND ADOLESCENTS

Abnormal cholesterol is an important CVD risk factor; however, half of the adults in the Framingham Heart Study who had myocardial infarctions had relatively normal cholesterol levels,[3] a finding supported by other studies.[40,41] This has prompted researchers to search for other contributions to atherosclerosis that might affect atherosclerosis accumulation, and eventually events.

Inflammation is an important physiologic process in atherosclerosis. It has been clinically assessed by measuring C-reactive protein (CRP). In adults categorized as moderate risk by the Framingham Risk Score, a CRP adds to CVD event risk prediction.[42,43] The relative risk of future CVD events is low in those with hsCRP levels less than 1 mg/L, average in those with hsCRP levels of 1.0–3.0 mg/L, and high in those with hsCRP greater than 3.0 mg/L.[44] No specific cardiovascular CRP cut point has been identified in youth because of the lack of long-term follow-up outcomes data, but it is likely that chronic inflammation in youth contributes to atherosclerosis. Offspring of first-degree relatives who had myocardial infarctions were found to have abnormally elevated CRP levels, even when controlling for body mass index.[45] Another study found that CRP was elevated in children with multiple cardiovascular risk factors.[46] At present, CRP is not recommended for clinical use in the assessment of the child for risk of future CVD,[47] although the test might arguably have some utility in individuals with high-risk family history and borderline lipid levels. It is worth bearing in mind that in clinical practice children with increased hsCRP levels may have an intercurrent illness (particularly if CRP > 10 mg/L) and/or excess adiposity. Other inflammatory biomarkers and cytokines are involved in the atherosclerotic process; however, none are presently used in clinical care.[47]

Perinatal exposures are another important feature related to cardiovascular risk in adulthood, often referred to as the fetal origins of adult disease hypothesis. For example, offspring of Dutch women who experienced famine during World War II had higher rates of obesity and

hyperlipidemia as adults.[48,49] A low birth weight has been associated with higher rates of type 2 diabetes, as described in a meta-analysis.[50] The relationship between birth weight and cholesterol levels is less clear. A twin study demonstrated that lower birth weight was associated with higher TC, and LDL levels.[51] The data on breast feeding and cholesterol levels later in life are mixed. A meta-analysis of 1532 British children and adults showed that breast-feeding was associated with higher TC and LDL in childhood but lower TC and LDL in adulthood.[52] However, being breast fed does seem to be protective against adult obesity.[53]

Lipoprotein (a), or Lp(a), is a variant LDL particle with a covalently bound protein portion, termed apolipoprotein (a). This particle is not measured on standard lipid profiles. High levels are thought to be atherogenic because the particle not only participates in atheromatous plaques (as does LDL) but also impairs fibrinolysis by preventing normal plasminogen activation,[54] and this particle, therefore, is likely involved in the thrombosis of CVD. Lp(a) is genetically determined, and high levels are associated with increased risk of coronary artery disease and stroke in a continuous fashion.[55] Normal levels are considered to be less than 30 mg/dL (or ~70 nmol/L), but higher levels are common in pediatric referral lipid clinic settings and the cutoff for increased cardiovascular risk may indeed be closer to 65 mg/dL.[51] Attention must be paid to the units among different assays, which measure either mass or molarity (mg/dL vs. nmol/L). Certainly, very high Lp(a) levels (more than 100 mg/dL) deserve attention and follow-up, particularly in the setting of a family history of early CVD events. Diet and exercise have no effect on Lp(a) levels. Pharmacologic doses of niacin lower Lp(a)[56]; however, there are very little clinical trial data in childhood,[57] and most adolescents find it difficult to tolerate this medication, even in the slow or extended release forms (adherence must be as near as possible to 100% to avoid tachyphylaxis). For this reason, and because niacin has not been shown to provide additional benefit in reducing CVD events in adults above and beyond standard medical therapy, including statins,[58] we generally do not recommend niacin to lower Lp(a) in pediatrics. However, high Lp(a) levels might be a reason to use lower statin treatment cut points in patients whose LDL values fall into the “gray zone” for pharmacotherapy, particularly if family history is a cause for concern.

LIPID BIOCHEMISTRY

Lipids, including cholesterol and other sterols, TGs, and free fatty acids, are essential for life. In the developed world, diet is typically a major contributor to total body lipid stores, although most fatty acids and TGs (three fatty acids esterified to glycerol) can also be endogenously synthesized from excess carbohydrates and proteins. The essential fatty acids including the basic precursors of polyunsaturated fatty acids (e.g., linoleic acid or linolenic acid) must come from the diet.

Fatty acids can be "saturated," with hydrogen at each carbon; "monounsaturated," with one double carbon bond; or "polyunsaturated," with two to six double bonds. Naturally occurring dietary fatty acids are in the "*cis*" configuration at each double bond. Polyunsaturated fats are prone to spoilage by oxygen, light, and heat; therefore, food processing, especially catalytic hydrogenation processing, which is used to avoid rancidity, produces nonnatural fatty acid chemistry, including a "*trans*" bond configuration. Readers will be familiar with "partially hydrogenated" oils from the list of ingredients in many processed foods, especially snack foods. In general, the larger the proportion of partially hydrogenated fats, the larger the proportion of undesirable *trans* conformation fatty acids. *Trans*-fatty acids not only act like saturated fats to increase LDL but also decrease HDL[59] and should be eliminated from, or at least minimized in, the diet.[60]

Cholesterol is partially absorbed from the diet and partially synthesized by the liver; 30%–50% of cholesterol consumed in the diet is actually absorbed (usually not much more than 300 mg/d). The only dietary source of absorbed cholesterol is animal products. Strict vegans synthesize 100% of their cholesterol needs, as vegetables contain no cholesterol. Dietary cholesterol is reesterified to fatty acids in plasma. Dietary TGs (typically dozens of grams daily) are degraded by lipoprotein lipase in the gut, absorbed, and reesterified to re-form circulating serum TGs. Dietary fat is distributed to body tissues, primarily the liver, in the form of chylomicrons. After absorption, cholesterol is esterified and carried in the serum on lipoprotein particles, as described here.

Cholesterol esters and neutral fats such as TGs are negligibly soluble in water and are therefore carried in the bloodstream by lipoproteins. Free fatty acids in plasma are carried mainly on albumin and are rapidly taken up by tissues for reesterification or for combustion as fuel. Lipoproteins are made up of hydrophobic lipids (TGs and cholesterol ester) on the inside and apolipoproteins, phospholipids, and unesterified cholesterol on the outside.

There are several types of lipoproteins, classified by density as

determined using plasma ultracentrifugation: chylomicrons, which float as a creamy supernatant; HDL; LDL; and very-low-density lipoprotein (VLDL):

- **Chylomicrons** are synthesized in the intestine from dietary TGs, cholesterol, and apolipoproteins synthesized in the liver. Chylomicrons have the lipoproteins apo A, apo C, and apo C-II. The chylomicron delivers the TG to muscle and adipose tissue, where it is modified by lipoprotein lipase, losing TGs, apo A, and apo C and gaining apo E. The chylomicron remnants are taken up by the liver via the apo E receptor and degraded.
- **HDL** is the densest and smallest lipoprotein. The major proteins (apoproteins) in HDL are apo A-I, apo A-II, apo C, and apo E. HDL is the primary lipoprotein responsible for reverse cholesterol transport, returning cholesterol from other tissues back to the liver. HDL also transports cholesterol from other lipoproteins, such as LDL, and cell membranes to VLDL and chylomicrons.
- **LDL** is the main reservoir of circulating cholesterol esters, supplying cell membranes and tissues. Each LDL particle carries an apolipoprotein B molecule, the protein responsible for LDL clearance by its cognate receptor. Cholesterol synthetic mechanisms are present in nearly all mammalian cell types, but exogenous sources are used prior to endogenous synthesis. Delivery to tissues is regulated by the number of LDL receptors, and a tight negative feedback system prevents cholestßerol synthesis and downregulates LDL receptors in normal humans when extracellular LDL is abundant. There is a small but measurable increased risk of atherosclerotic events in adults with small, dense LDL particles, above and beyond the effect of the LDL concentration,[61] which contain a relatively higher concentration of apo B. The effect of this is not known in pediatrics, and studies have shown some effect in young adults, although this may be less important in CVD events in young people.[62]
- **VLDL** is manufactured in the liver, particularly during fasting, as the main source of TGs when chylomicrons are absent. VLDL is secreted into the bloodstream and TGs are removed in the periphery by lipoprotein lipase. VLDL remnants are metabolized by the liver and serve as the precursor for LDL production.

MAJOR DYSLIPIDEMIAS

Normal lipid levels are age dependent; children have lower levels than adults. Normative pediatric values have been reported from National Health and Nutrition Examination Survey data.[63] Cut points for abnormal values are based on population distributions and are not determined by their relationship to health outcomes such as myocardial infarction, because events are vanishingly rare in childhood.[3] The NHLBI Guideline cutoffs for borderline and abnormal lipid values are shown in Table 63-1. Over two decades, there has been a small but important improvement in serum lipid levels in US youth, including a 5-mg/dL decrease in TC and 5-mg/dL decrease in LDL,[63] perhaps related to lower rates of smoking, less uses of *trans* fats, and a lower fat diet/higher glycemic diet.[64]

Dyslipidemia can be primary—monogenic or polygenic, and familial or sporadic—or secondary—related to medical conditions, medications, or lifestyle. The proportion of primary hyperlipidemia is higher in the pediatric population than in adults; however, secondary causes of hyperlipidemia should be considered because they may be modifiable or even treatable. The medical history and examination can help identify secondary causes of hyperlipidemia (Table 63-2) often with the help of simple laboratory testing.

TABLE 63-1 Low, Normal, Borderline, and High Lipid Values in Childhood

Lipid Parameter (mg/dL)	Low	Normal	Borderline	High
TC	—	<170	170–199	≥200
TGs (fasting)				
0–9 Years	—	<75	75–99	≥100
10–19 Years	—	<90	90–129	≥130
LDL (fasting)	—	<110	110–129	≥130
HDL	<40	>45	40–45	—
Non-HDL	—	<120	120–144	≥144

Acceptable, borderline, and abnormal cholesterol values according to the NHLBI pediatric guidelines are shown for TC, TG, HDL, and LDL.

Values are reported as serum; to convert to plasma values, divide by 1.03.

LDL and HDL values presented are for Caucasian subjects.

PRIMARY DYSLIPIDEMIAS

Primary hypercholesterolemias are usually dominantly inherited, with a

gene dosage effect. Heterozygous individuals have elevated lipids but are generally asymptomatic until the condition manifests as early stroke, angina, myocardial infarction, or sudden death in the fourth or fifth decade of life. However, homozygotes can manifest xanthomas, arcus cornea, and thickened tendons even before puberty and can have heart attacks or strokes in childhood or early adulthood. Although multiple genes affect lipid levels, several monogenic conditions have been distinguished and can be readily recognized if family history and laboratory data are available. A simplified guide for diagnosis based on lipid profile and family history is presented in Table 63-3. Among those with primary hyperlipidemias, dietary transgressions, lack of exercise, glucose intolerance, and obesity can worsen familial lipid disorders.

Familial hypercholesterolemia, though rare, is the genetic lipid disorder best understood at a biochemical level. The cause is a genetic defect in the LDL receptor gene. Heterozygotes show a decrease in the number of active receptors, and homozygotes have absence or near absence of functional receptors. Heterozygous deficiency has a prevalence of approximately 1 in 200–500 individuals (0.2%), but heterozygotes account for 5% of early myocardial infarction survivors.[65] These individuals usually have TC levels in the range of 200–500 mg/dL (5.2–13 mmol/L). They have a family history of high cholesterol and early coronary disease and require pharmacologic treatment. Premature atherosclerosis is seen in 30% of adults with heterozygous deficiency for familial hypercholesterolemia.[66]

Some populations have higher prevalence rates for familial hypercholesterolemia because of founder effects, such as French Canadians, Dutch Afrikaners in South Africa, and Lebanese Christians. Individuals with homozygous LDL receptor defects are rare, about one in a million individuals, and have very high TC levels of 500–1000 mg/dL (13–25.9 mmol/L). These are children who could have myocardial infarctions in the first or second decade of life and require not only pharmacologic treatment, which is usually ineffective even though it is sometimes used as an adjunct, but plasmapheresis or, if there is intractable coronary disease, consideration for liver transplantation. In the complete absence of LDL receptors (familial hypercholesterolemia patients homozygous for null mutations), statins are utterly ineffective at standard doses. LDL apheresis with devices such as Liposorber® columns is very effective in lowering LDL-C, although it carries a heavy burden for the child and family with respect to frequency and length of sessions (four to six hours per session every one to three weeks). Liver transplantation has

been used in some cases of progressive coronary disease,[67] or when apheresis is not available. Gene therapy approaches have been attempted,[68,69] but long-term benefit remains to be demonstrated.

Familial defective apolipoprotein B is clinically similar to familial hypercholesterolemia. Familial defective apolipoprotein B is attributable to decreased binding of LDL to its receptor because of a mutation in the apolipoprotein B protein itself rather than a receptor mutation. The condition is rare. The biochemical findings in untreated patients are indistinguishable from heterozygous familial hypercholesterolemia. However, response to pharmacologic therapy, including statins and other agents, tends to be poor, because the upregulation of hepatic LDL receptors, a key step in the mechanism of action for statins and bile-binding resins, will not increase clearance of the mutant particles from the blood.

TABLE 63-2 Medical, Physiologic, and Pharmacologic Causes of Secondary Hyperlipidemia

Endocrine and metabolic states
- Diabetes mellitus
  - Type I related to a large degree to poor glycemic control
  - Type II: particularly high TGs, low HDL
  - Insulin resistance states without overt diabetes (check for acanthosis nigricans)
- Pregnancy
- Hypothyroidism
- Hypopituitarism[a]
- Anorexia nervosa

Hepatic disease
- Hepatitis of any etiology
- Biliary atresia[b]
- Acute intermittent porphyria
- Glycogen storage diseaseb
- Genetic and acquired cholestatic disorders

Renal disease
- Nephrotic syndromeb
- Any renal inflammatory state
- Hemolytic uremic syndrome
- Idiopathic hypercalcemia

Lysosomal storage disease
- Cholesterol ester storage disease

- Niemann-Pick disease
- Other conditions, such as Tay-Sachs disease and Gaucher's disease

Recognizable genetic syndromes

- Klinefelter's syndrome
- Progeria (Hutchinson-Gilford disease)

Systemic inflammatory states

- Trivial inflammation (e.g., viral illnesses, simple urinary tract infection, and sinusitis); "healthy day" testing recommended
- Systemic lupus erythematosus: severe vascular risk if combined with primary hyperlipidemia
- Burns

Drugs and other agents

- Corticosteroids (systemic): primarily hypertriglyceridemia
- Thiazides
- β-Blockers
- Asparaginase
- Immunosuppressives: tacrolimus, cyclosporine, etc.
- Oral contraceptives: use with caution in those with severe hyperlipidemia
- Antiepileptic medications
- Ethanol: low-dose, regular consumption increases salutary HDL; in excess, hypertriglyceridemia

[a] If hypopituitarism is suspected, thyroid-stimulating hormone alone, as advocated for primary screening, is not sufficient to rule out central hypothyroidism.

[b] Elevations can be severe with xanthomas.

TABLE 63-3 Phenotype and Family History Commonly Found among Pediatric Lipid Clinic Patients

Common Phenotypes	Family History	Likely Diagnosis
Elevated LDL[a] and TC +/– low HDL (xanthoma)	Xanthomas/early heart disease[b]	Familial hypercholesterolemia (TC 500–1000 mg/dL found in homozygotes)
Elevated TGs + low HDL, often with obesity	Type 2 diabetes or similar lipid patterns	High risk for metabolic syndrome
Extremely elevated TGs and chylomicrons, pancreatitis	Elevated TGs, pancreatitis	Lipoprotein lipase deficiency, apoC2
Moderately elevated TGs and LDL	Elevated TGs, LDL, or both	Familial combined Hyperlipidemia

Low HDL only	Low HDL, early CHD	Familial hypoalphalipoproteinemia
High HDL (> 60 mg/dL), normal LDL	Often negative for early heart disease	Normal variant; 20% of children with elevated TC; no intervention

Cholesterol, HDL, and TG values were measured in a fasting state. Combination of phenotype with typical family history suggests diagnosis.

[a] LDL is calculated from fasting values using the Friedewald formula, in which LDL = TC – (HDL + TG/5), which is valid if the TG level is <400 mg/dL. When TG levels exceed 400 mg/dL, direct LDL is advised.

[b] Early heart disease is defined as myocardial infarction before age 55 in men and before age 60 in women.

There are several more recently described defects that phenotypically present in a manner similar to familial hypercholesterolemia. Proprotein convertase subtilisin-kexin type 9 (PCSK9) is a protein that promotes the degradation of the LDL receptor; gain of function mutations lead to elevated circulating LDL at levels similar to familial hypercholesterolemia, due to a lack of LDL uptake by the liver. PCSK9 promotes the degradation of LDL receptors; gain of function mutations lead to fewer LDL receptor and more circulating LDL. Autosomal recessive hypercholesterolemia is caused by the lack of a cofactor responsible for LDL binding to the LDL receptor, leading to less binding and more circulating LDL.

Familial hypertriglyceridemia is characterized by high TG levels, sometimes accompanied by low HDL. This is a very common profile, of polygenic origin, exacerbated by type 2 diabetes mellitus and obesity. Rare monogenic disorders cause chylomicronemia and profound hypertriglyceridemia. Homozygous deficiency of lipoprotein lipase or its cofactor, apolipoprotein C-II, causes isolated increase in chylomicrons, may present as recurrent pancreatitis, and is autosomal recessive. Affected individuals may have lipemia retinalis and a papular rash, but increased risk of early myocardial infarction has not been described.

Familial hypoalphalipoproteinemia exists; but in the general population, low HDL is a common trait, and low HDL is especially prevalent among young survivors of myocardial infarction. With rare exceptions, the exact genetic basis of low HDL is obscure.

Familial combined hyperlipidemia is the most common type of inherited hyperlipidemia. It is autosomal dominant and is found in 1 in 100 individuals. Of patients with early CHD, 10%–15% carry this diagnosis. The lipid abnormalities are moderate. About one-third of patients with familial combined hyperlipidemia have increased LDL, one-third have

increased TGs without altered LDL, and another third have increased TGs and increased LDL. The three types frequently coexist within a family. There are likely multiple genetic abnormalities that lead to this phenotype.

To date, genetic testing has not been used in clinical practice and treatment is based on phenotype; however, as the genetics of lipid metabolism are better understood it is likely that testing will be used in clinical practice, either related to therapeutic choices or screening of family members.

CHOLESTEROL SCREENING

Who to Screen: The Report of the NHLBI Expert Panel on Cardiovascular Risk Reduction in Children and Adolescents,[6] endorsed by the American Academy of Pediatrics, recommends selective screening of children with risk factors for atherosclerosis, including family history of hypercholesterolemia or early coronary artery disease (Figure 63-1 and Table 63-4), after age 2 years. Cholesterol screening is also recommended for children who have personal risk factors, such as obesity, hypertension, or smoking, and for those with high-risk medical histories, as described earlier. Additionally, and importantly, the NHLBI Guidelines recommended for the first time universal screening of all children once between the ages of 9 and 11 years and once again between the ages of 17 and 21 years in addition to selective screening. These recommendations have been very controversial,[70–72] and there are no published data on the extent to which these guidelines have been followed in general pediatric practices, although preliminary research results suggest that adoption is low.

Arguments for universal screening are as follows:

- Atherosclerosis begins during childhood and is associated with childhood cholesterol values.
- Cholesterol values track from childhood to adulthood, implying some degree of lifelong exposure.
- Hypercholesterolemia responds to lifestyle modification and pharmacotherapy, for example, there are available therapies.
- Family history–based screening identifies only approximately half of those with high cholesterol values. Often, the full family history is not available,[73] and very young children might have grandparents too young to have had early heart disease. Family history may be variably useful in screening in nonwhite

populations.[13,73,74]

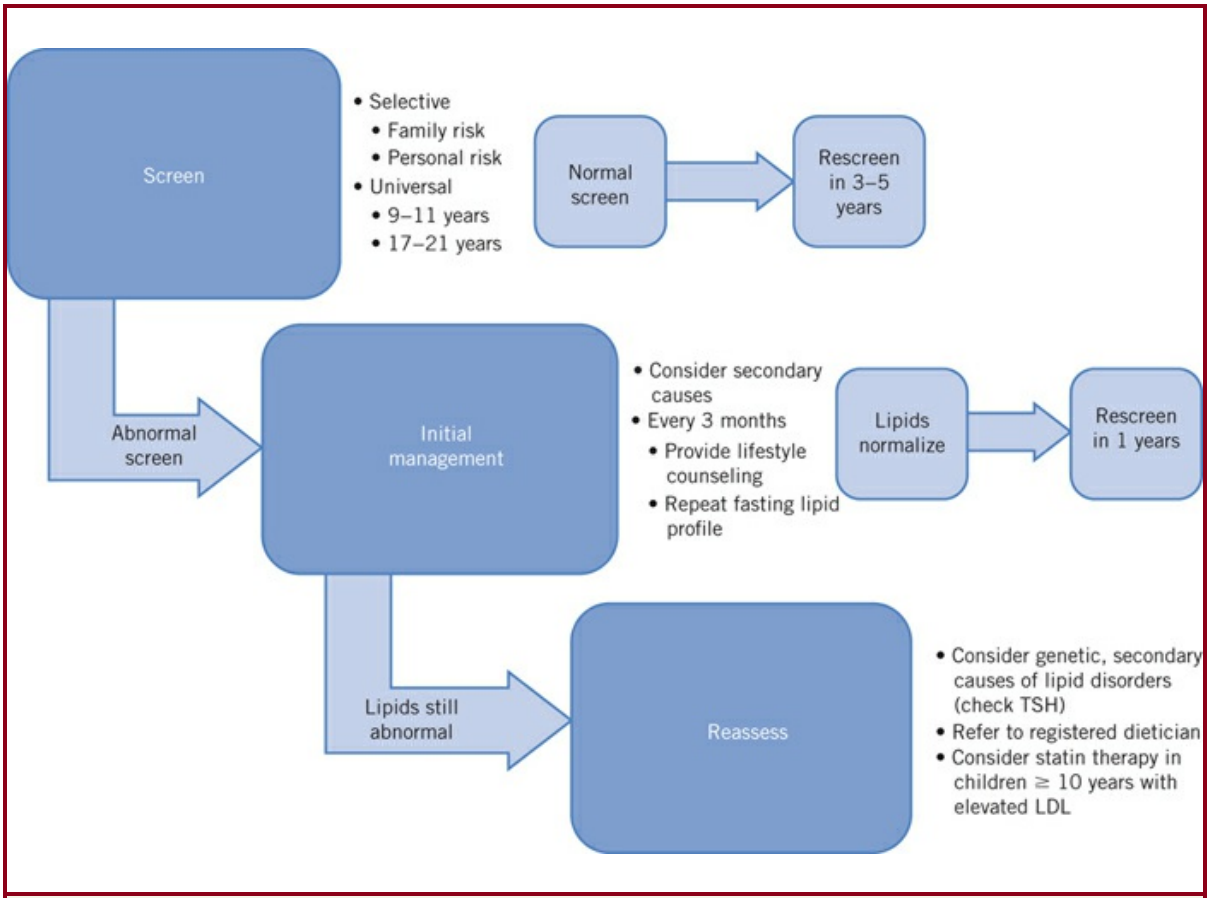

Figure 63-1 Selective screening approach based on our clinical practice and recommendations by the National Heart, Lung, and Blood Institute Expert Panel on Cardiovascular Risk Reduction in Children and Adolescents. (From Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents; National Heart, Lung, and Blood Institute. *Pediatrics*. 2011;128(Suppl 5):S213-S256.)[6]

Arguments against universal screening are as follows:

- The cost of screening some 60 million young persons is not known, nor is it clear how many additional patients would be identified by screening above and beyond a family history-based approach.
- Exact numbers are not known, but some argue that it would be rare to discover children by universal screening who would require medication before adulthood.
- All children should follow a heart-healthy diet and exercise

regularly, regardless of their cholesterol level.

- Labeling children as hypercholesterolemic unnecessarily could cause harm.

How to Screen: The 2011 NHLBI Guidelines recommend that selective screening should be done using a fasting lipid profile. The NHLBI-recommended method for universal screening is either a fasting lipid profile or nonfasting TC and HDL to calculate a non-HDL cholesterol, as is recommended for adult lipid screening.[75] Screening using only TC is not recommended due to high false-negative and false-positive results, based in part on differences in HDL.

NUTRITION AND CHOLESTEROL IN CHILDREN

Dietary habits among American children promote excess calories and CVD risk. Children and adolescents, like all Americans, eat out often, and this is associated with a higher calorie intake. According to national survey data, 34% of calories are now consumed outside the home.[76] Food eaten outside the home is higher in total and saturated fats and lower in calcium, iron, and fiber than food eaten at home.[77] Adolescents who eat fast food are more likely to have a poor-quality diet, one higher in saturated fat and sugar and lower in fruits and vegetables.[78] Fruit juice has been recognized as a major source of calories. High intake has been associated with both poor growth and also obesity in some[79] but not all studies[80]; reduced intake is one strategy for weight loss and TG reduction.

TABLE 63-4 Recommendations for Lipid Screening in Childhood According to the NHLBI Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents

	0–1.9 Years[a]	2–8 Years	9–11 Years	12–16 Years	17–21 Years
Screening recommendation	Do not screen	Screen if there is a family history of early CVD or high cholesterol, or if there is	Screen all children, once during this age range	Screen if there is a family history of early CVD or high cholesterol,	Screen all adolescents, once during this age range

		a high-risk condition		or if there is a high-risk condition	
Test	None	Fasting lipid profile	Fasting lipid profile or non-HDL[c]		Fasting lipid profile or non-HDL[c]
Treatment	None	Lifestyle modification[b]	Lifestyle modification for 6 months, statins for children ages 10 years and older	Lifestyle modification for 6 months, statins for children aged 10 years and older	Lifestyle modification for 6 months, statins for children ages 10 years and older

[a] Children younger than age 2 may be screened in rare situations of extreme family history or in the presence of xanthoma suggestive of homozygous familial hyperlipidemia. Treatment of any significant abnormalities at this young age should be supervised by an expert in pediatric lipid disorders. Metabolic disorders should be considered in the differential diagnosis.

[b] Children aged 8 and 9 years with severe lipid abnormalities that do not respond to lifestyle modification may be candidates for statin therapy under supervision of an expert in pediatric lipid disorders.

[c] Non-HDL is derived from subtracting HDL from TC. Results are valid in the fasting or nonfasting states, making it a convenient cholesterol screening test.

TREATMENT FOR DYSLIPIDEMIAS

Dietary treatment is the first line of intervention in childhood dyslipidemias. Diet modification is emphasized in the pediatric age range because pharmacologic agents have been tested primarily in adults and pediatric long-term safety data are limited. The NHLBI Guidelines recommend different nutritional approaches based on an individual's lipid abnormalities. It is recommended that all children keep fat intake to less than 30% of total calories, with a goal of saturated fat representing less than 10% of total calories and cholesterol intakes of less than 300 mg/day (CHILD 1).[6] The next step for children with elevated LDL is to restrict saturated fat intake to less than 7% of daily calories; added fiber and stanol esters can be used as adjunct nutritional therapy (CHILD 2 LDL). For children and adolescents with high TGs, the NHLBI Guidelines recommend the same restrictions on saturated, total fat, and cholesterol, and in addition decreased sugars in the form of simple carbohydrates and sugary beverages and increased fish to provide dietary ω-3 fatty acids. Calorie restriction and increased physical activity are recommended for obese and overweight children regardless of the lipid phenotype.[6]

In practice, low cholesterol and low saturated fat can be achieved by many children and adolescents. Relatively few US children now eat too much cholesterol, which is primarily found in shrimp, squid, and organ meats such as liver. Saturated fat is more prevalent in the diet; some suggestions that we provide to our patients for reducing dietary saturated fat are shown in Table 63-5. Professional nutritional counseling is very helpful for patients aiming for more significant changes in lipid values, such as might be achieved with the CHILD2 LDL diet. Dietary intervention trials in adults with stringent fat reductions show a TC reduction between 10% and 15%.[81] Several short- and medium-term studies demonstrate that diets low in saturated and total fat decrease TC and LDL cholesterol by approximately 10%.[82–84] Two key dietary counseling studies, the STRIP study[85–87] and the Dietary Intervention Study in Children (DISC) trial,[88] showed the safety of low-fat diets and the relatively small LDL-lowering effect in these large studies over time, 3–5 mg/dL, compared to control.

Some pediatric practitioners have raised concerns that diets designed to improve cholesterol will hamper pediatric growth and development; however, the DISC trial demonstrated that children counseled on a low-cholesterol, low-saturated-fat diet had the same growth and development than children on a diet close to the usual American intake.[88] The STRIP study also showed that dietary consumption of fat, saturated fat, and TC did not affect neurodevelopment, although higher protein intake was associated with better neurodevelopmental outcome in boys.[89] These studies demonstrate that some degree of saturated fat restriction is safe even in young children.

Several decades of dietary counseling focused on low-fat and low-saturated-fat approaches. However, dietary counseling in the current era is fairly individualized, focusing now not on eliminating fat from the diet so much as exchanging saturated fat for monounsaturated fat. This is in part because fat elimination can lead to substitution with refined sugars and carbohydrates that increase TG levels, whereas increased intake of monounsaturated fats can raise HDL levels and improve the cardiovascular risk profile. The Mediterranean diet, which focuses on mono- and polyunsaturated fats, has been associated with a reduced risk of cardiac mortality and morbidity in adults after their first myocardial infarction[90] and, more recently, has been associated with lower rates of CVD events in primary prevention populations.[91] There are limited trial data on the effect of the Mediterranean diet on lipids in children with hypercholesterolemia,

although one study did demonstrate a decline in TC, LDL, and carotid intimal-medial thickness, a measure of subclinical atherosclerosis,[92] and some practitioners recommend it to their patients and families.

TABLE 63-5 Simple Substitutions for a Healthy Diet

A. High LDL	
For	Substitute
Fatty meats	Fish, skinless chicken, lean beef, Vegetable proteins, pork tenderloin
Saturated fat (e.g., butter)	Monounsaturated fat
Partially hydrogenated oils (*trans*-fatty acids) in regular Margarines	Canola or olive oil, monounsaturated margarines
Regular peanut butter (partially hydrogenated)	"Natural" peanut butter
Ice cream	Frozen yogurt
Whole milk	Skim or 1% milk
Regular cheese	Low-fat cheese
Lunch meats	Low-fat equivalents
Chocolate (saturated oils)	Dark chocolate
Less healthful school lunch purchased	Lunch packed at home
B. High TGs	
For	Substitute
White rice	Brown Rice
Regular pasta	Whole grain pasta
White bread	Whole wheat bread
Instant oatmeal	Rolled oats or steel cut oats
White potatoes	Sweet potatoes
Low fiber cereals	High fiber cereals
Sugary beverages	Water or low calorie beverages

To modify TG and HDL levels, most recommend reducing carbohydrate intake as a percentage of total calories. A reduction in total calories leads to weight loss and an improvement in cardiovascular risk factors associated with the metabolic syndrome. Studies of low-carbohydrate diets in adults show greater initial weight loss in the short term (~6 months) compared to low-saturated-fat diets; as with all dietary interventions, results at one year are less impressive.[93,94] Low-glycemic-load diets are associated with lower rates of CVD in adults in

observational studies, and reduced CVD risk factors including lipid levels in short-term interventional trials.[95–97] Glycemic index is a property of carbohydrate-containing food that describes the rise of blood glucose occurring after a standardized amount of food is consumed. In general, most refined starchy foods eaten in the United States, such as white bread, prepared breakfast cereals, rice, and potato products, have a high glycemic index, whereas unprocessed grains, nonstarchy vegetables, fruit, and legumes tend to have a low glycemic index. Several studies in children have demonstrated greater weight loss in children on low-glycemic-index diets.[78,79] Weight loss in children has been shown to effectively decrease TC and TG and increase HDL[81] and is a goal of many nutritional interventions if the child is overweight. Furthermore, data are beginning to emerge about the effect of the low-glycemic-load approach to managing lipid disorders in children, and not all of them are favorable[98,99]; however, some trials do support the importance of the low-glycemic-load approach in weight and lipid management.[100–102]

Other types of interventions to improve lipid levels on a population basis have been explored, including community-based programs. Several studies of nutritional teaching in school resulted in a lower average TC in children at the intervention schools than in the comparison schools.[103,104] The DISC is the largest published experience with school-based interventions and also showed improved cholesterol.[88]

SPECIAL NUTRITIONAL INTERVENTIONS: FIBER, STANOLS, AND *ω* -3 FATTY ACIDS

Several specific nutritional tools have been used to modify lipid profiles in dyslipidemic children. Studies of children with familial hypercholesterolemia who received fiber supplementation on top of a low-cholesterol and low-saturated-fat diet had decreases in TC with preserved HDL.[105–107] Certain sterols, similar in structure to cholesterol but not absorbed by the small intestines, lower cholesterol by inhibiting the absorption of cholesterol, both dietary and in the form of bile acids. As part of a low-fat diet in adults, stanols decrease TC by 8%–10%, above and beyond the 7% reduction from the low-fat diet alone.[86] Studies in children confirm these findings.[108–110] In adult observational data, higher intakes of n-3 polyunsaturated fatty acids (*ω*-3 fatty acids) in the form of fish have been associated with lower risks of CVD mortality after a myocardial infarction[111]; however, an interventional trial of 1 g of *ω*-3

fatty acid supplement daily did not demonstrate lower event rates compared to olive oil placebo.[112] Of course, no such data are available for children. Fish are a rich source of ω-3 fatty acids and should be recommended. Flax oil and ground flaxseed are reasonable substitutes for children who will not eat fish. For children with high TGs, particularly those who do not consume many ω-3 fatty acids, supplements can be used, although data supporting their efficacy are not currently published; care should be taken with respect to docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) content as this varies substantially in over-the-counter preparations and is not standardized. In younger children with high TG levels unresponsive to lifestyle therapy, we have used a dose of 2000 mg/d of preparations containing approximately 700–800 mg of DHA+EPA per pill, over the counter or prescription, and 4000 mg/d of the high-dose ω-3 pills in older adolescents with high TG levels.

PHARMACOLOGIC INTERVENTION

Studies of adults with hypercholesterolemia demonstrate significant reduction in cardiovascular morbidity and mortality with cholesterol-lowering medications. The benefit is seen not only in severely affected patients or those who have existing heart disease[113] but also as primary prevention in patients with only moderate hypercholesterolemia and no previous CVD.[114,115] As in adults, lipid-lowering drugs effectively lower LDL in children.[6] There are no long-term trials evaluating the effect of lipid-lowering medication during childhood on CVD event rates. Studies are needed that consider long-term benefits, risks, and costs of statin therapy in children with FH, and other patient populations.

The NHLBI Guidelines make the following recommendations about lipid lowering in childhood: after approximately six months of nutritional and lifestyle changes, children aged 10 years or older with severe hyperlipidemia, defined as having LDL cholesterol greater than 190 mg/dL or greater than 160 mg/dL with two additional risk factors for CVD, are eligible for consideration for pharmacologic treatment. Children as young as 8 years of age who are severely affected may be treated with medications if supervised by a pediatric lipid specialist. Factors that are also considered in clinical practice include high beneficial HDL levels, high-risk medical conditions such as diabetes mellitus, a history of Kawasaki disease aneurysms, chronic inflammatory disorders such as lupus, severe family history, and so forth.

A number of pediatric trials have shown that lipid-lowering

medications act similarly in childhood to adulthood. Usual dosages are shown in Table 63-6. The oldest class of medications are bile acid–binding resins, including cholestyramine and colestipol, which bind to bile acids in the gut and prevent their reabsorption; this prompts the body to convert more cholesterol to bile acids, thereby lowering cholesterol by 10%–15%.[116,117] These medications may also decrease dietary cholesterol absorption from the gut and have been demonstrated to increase LDL receptor expression and HMGCoA reductase activity.[118] The bile acid-binding medications are not absorbed into the bloodstream, minimizing systemic effects; however, the powder forms have a gritty texture and the pills are large and can be difficult to swallow.[117] Both forms can cause constipation. For these reasons, compliance can be an issue. These medications also bind to lipophilic and acidic drugs, making them somewhat challenging to use in patients on multiple medications.

3-Hydroxy-3-methylglutaryl CoA reductase inhibitors, or statins, are the clear first-line agents for adults with elevated LDL cholesterol levels and have been used in selected, high-risk pediatric and adolescent patients for many years; statins are the recommended first-line therapy for children and adolescents with high LDL requiring pharmacotherapy.[6] Randomized controlled clinical trials of statins have shown good efficacy and safety in the short and medium terms, with an LDL lowering of 20%–50%.[119] These trials are too small and too short to definitively eliminate the possibility of long-term sequelae, the major but very rare adverse effect of rhabdomyolysis, or the theoretical modification of sex-steroid production. It should be noted that while these adverse effects cannot be excluded, there are no data to support them either; in fact, adults seem to experience benefits from statins over decades.

Gemfibrozil and fenofibrate are indicated for hypertriglyceridemia in adults but are used only for teenagers at risk for pancreatitis (TGs > 500–1000 mg/dL). Niacin can be an effective adjunct to lipid therapy in some adult settings, but flushing, abdominal discomfort, and risk of hepatotoxicity limit its use in children.[57]

Ezetimibe is a selective inhibitor of cholesterol absorption that was approved for use in adults by the US Food and Drug Administration in late 2002. It reduces LDL by approximately 20% with minimal side effects.[120] It is frequently used in adults as an adjunct to statins but has not been shown to decrease CVD events. Two pediatric trials of ezetimibe in children show 15%–30% decrease in LDL, with no significant adverse effects.[121] It is the primary medication recommended for sitosterolemia, a

rare genetic cause of early atherosclerotic disease associated with xanthomata and paradoxically only moderately elevated LDL levels.

OTHER THERAPIES FOR SEVERE HYPERCHOLESTEROLEMIA

For patients with severe hypercholesterolemia unresponsive to diet or pharmacologic intervention, plasmapheresis or LDL apheresis with a Liposorber column has been successfully used to lower TC, LDL, TGs, and lipoprotein (a). Case series of patients with homozygous familial hypercholesterolemia suggest a slowing down or even regression of atherosclerosis with the use of apheresis.[122] The technique has been used in children,[123] although the issue of vascular access is a difficult one. New pharmacotherapies for LDL lowering are now emerging for use in adults with resistant and/or severe hypercholesterolemia such as monoclonal antibodies PCSK9[124]; mipomerson is an antisense oligonucleotide complementary to the coding region for human apolipoprotein B (apo B) mRNA. These newer medications all have injection sight, and there are concerns about hepatic congestion.[125] There is little experience with these agents in childhood; however, their use might ultimately be considered when apheresis is not available. Liver transplantation has also been used in homozygous or compound heterozygous familial hypercholesterolemia, with good short-term success, albeit trading hypercholesterolemia for lifelong immunosuppression.

MULTIDISCIPLINARY CLINICAL APPROACH

Because atherosclerosis has a complex and multifactorial pathophysiology, pediatric lipid treatment programs that employ a multidisciplinary approach are a priori more likely to be successful. In our center, the approach is combined nutritional and physical activity counseling, along with risk assessment and lipid monitoring. We find that lifestyle habits can be more easily modified during childhood and that changes put into place in younger children may have an impact for years to come. This is the prime rationale for seeing children at young ages. Contrary to adult lipid treatment, pediatric lipid specialists begin with lifestyle modification and use pharmacotherapy in only the most severely affected patients. Figure 63-2 describes one such approach to patient management.

TABLE 63-6 Dosages of Medications Commonly Used in Hyperlipidemia

Lipid Lowering Bile Acid Binding	Dosage Forms	Typical Dosage Range	Comments
Cholestyramine powder	Generic powder is unflavored; Questran Light and LoCholest are flavored	Weight < 40 kg: start with 2 g bid, increase to 4 g bid if well tolerated Weight > 40 kg: start as above, to 6 g bid; max. adult dose, 24 g/d	Not systemically absorbed; side effects of bloating, constipation fairly common. Absorbs other medication including antibiotics; adherence is poor
Colesevelam	625 mg Tablets, 3750 mg/packet	1.875 gm bid or 3.75 g/d; take with liquids	Tablets are large; can be difficult for children to swallow
Colestipol	Powder or tablet (2 g)	5–30 g of powder div bid (supplied as 5 g packets or scoops) 2–16 g Tablet form, div bid	As above
Absorption Inhibitor[a]			
Ezetimibe (Zetia)	10 mg Tablets	10 mg po qd	Inadequate LDL control on statins, Statin intolerance, sitosterolemia
Statins[b]			
Lovastatin	10, 20, 40 mg Tablets	In children begin at lowest dose Increase gradually based on effect	
Pravastatin	10, 20, 40, 80 mg Tablets		
Simvastatin	5, 10, 20, 40, 80 mg Tablets	Doses above 40 mg/d are associated with increased risk for muscle toxicity	
Atorvastatin	10, 20, 40, 80 mg Tablets		
Rosuvastatin (Crestor)	5, 10, 20, 40 mg Tablets		No generic available for rosuvastatin

Fibrates			
Gemfibrozil	600 mg	600 mg twice per day	Use caution when combining with fibrates with a statin Significantly increased risk of muscle toxicity
Fenofibrate	(Depends on brand)	(Depends on brand)	May have less risk of muscle toxicity compared to gemfibrozil
ω-3 Fatty acids			
OTC	(Depends on brand)	~700 mg DHA + EPA/1000mg	For TG levels > 500 mg/dL (adult data)
	~700 mg DHA + EPA/1000 mg	900 mg of ethyl esters/1000 mg	Start with 2 g/d, measure effect
Lovaza		2–4 g/d	In ~4 weeks

Dosages are provided as a guide only and should be reviewed independently prior to prescribing.

[a] Side effects are minimal in adults and include gastrointestinal upset. No long-term studies in children.

[b] Statin therapy is contraindicated in pregnancy. Liver function tests should be monitored at baseline, after 6 weeks of therapy, and then intermittently if normal. Caution patients about rare rhabdomyolysis; creatine phosphokinase should be checked if patient has myalgias. Sleep disturbances and abdominal discomfort are infrequent side effects.

Clinic sessions may include group and individual nutritional education, review of all available laboratory results, and a session with a clinician. A three-day food recall provides a basis for individual nutritional counseling at the initial visit and in follow-up. Patient and family group education can include the basics of “good” and “bad” cholesterol, saturated and *trans*–fatty acids, protein, sugars, and fiber. The concept of glycemic index/load can be helpful in most cases of hypertriglyceridemia and obesity. Parents can be taught to read labels and to read between the lines on labels, and children can learn the concept of budgeting their fat and sugar intake so that, for example, birthday cake is not completely off limits but requires a lean period in compensation. It is useful to show children the actual amount of sugar in a can of soda or a serving of juice, or the appearance of fat clogging a tube that represents an artery. Methods of dieting for children can include using the “plate method” (Figure 63-3). We stress that diet does not mean weight loss for slender patients with genetic hyperlipidemia but that weight loss is paramount in patients with moderate to severe obesity, even when genetic hyperlipidemia is present. In general, emphasizing substitution of foods, as opposed to restricting or eliminating

food, is more positive and seems more effective. Table 63-5 presents some simple suggestions for dietary modifications in hyperlipidemia.

The physician or nurse practitioner portion of the visit should involve a review of family history, a review of general medical history, an assessment of physical activity and inactivity (screen time), and an evaluation of lipid values. Twelve-hour fasting lipid values are the most valuable for children referred to a specialist clinic, as it is important to have accurate TG and LDL levels, at least on two occasions. Because severely affected children in a pediatric lipid setting usually have severely affected parents, we have found that often the most pressing medical issue for the child is having his or her parents tested and if necessary treated for hyperlipidemia. It is important to ask about cigarette smoke exposure, encourage children not to smoke, and encourage parents not to smoke around their children because children exposed to cigarette smoking have lower HDL levels.[126,127] We stress the need to find physical activities that the child will enjoy.

We try to emphasize that for most children these issues are not an emergency but rather are long-term modifications that are important not for present health but for cardiovascular and metabolic risk 20–40 years in the future (a nearly unimaginable length of time for most children). This helps parents and children to view this as a long-term project and removes the pressures of enforcing an immediate turnaround. Having only appropriate food in the home is helpful in making choices easier. Lifestyle changes seem to be more effectively made if the entire family joins in the effort.[128] Often, the changes we suggest benefit multiple family members even if only one child in the family is referred. Follow-up is crucial for monitoring progress, medication compliance, and somatic growth, and for encouraging further efforts in lifestyle modification.

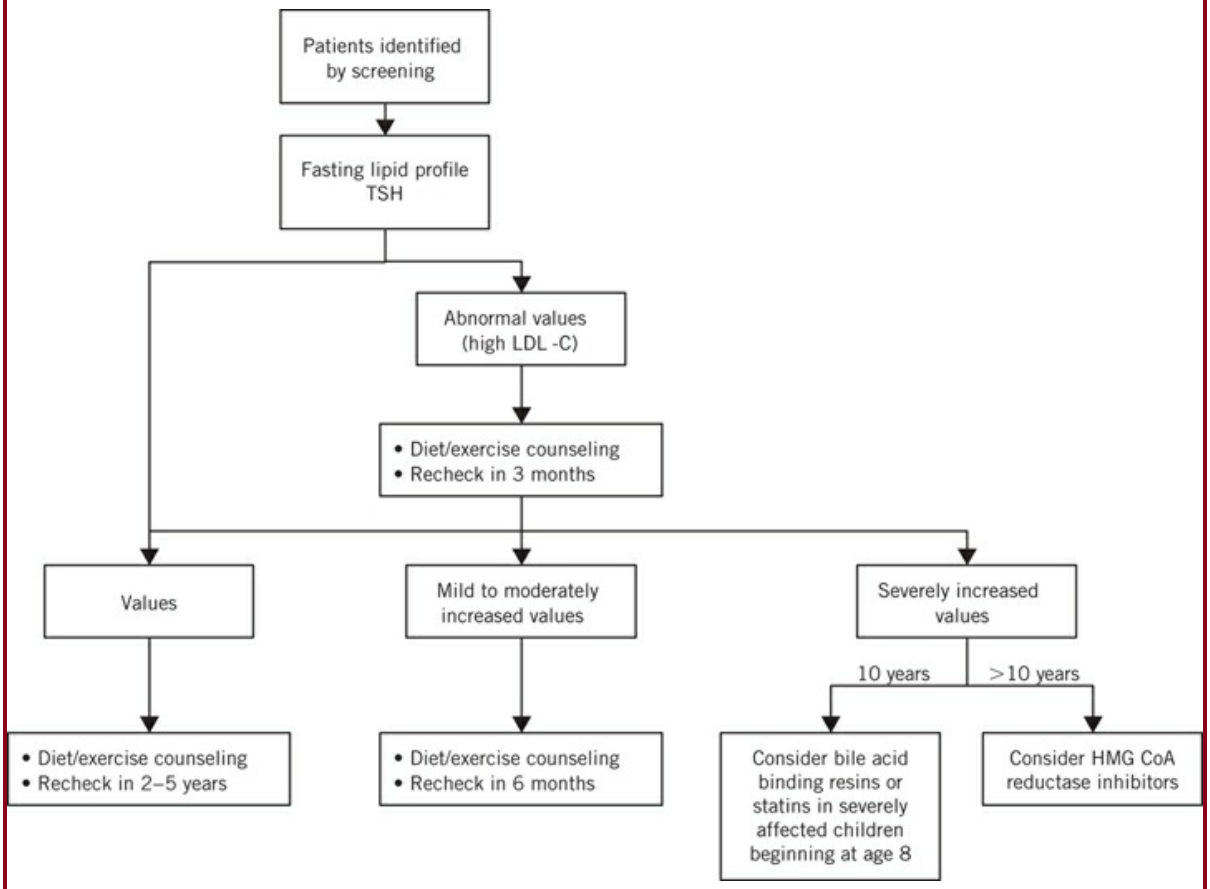

Figure 63-2 Proposed approach to cholesterol screening and initial treatment in pediatric patients. Thyroid-stimulating hormone (TSH) serves as an inexpensive screen for primary hypothyroidism.

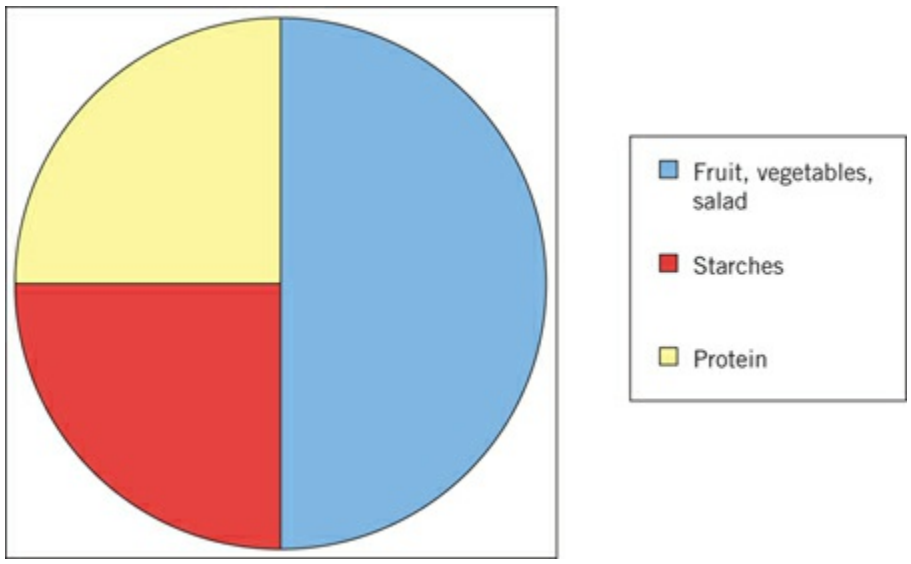

Figure 63-3 The plate method is a simple means for balancing the diet and reducing carbohydrate consumption without counting calories or grams of fat. One-half to one-third of the plate should contain fruits and vegetables, whereas one-quarter should contain starch and the final quarter should contain protein. The method is effective in patients with lifestyle-related hypertriglyceridemia and for obesity, if given with a few suggestions: (1) the entire family, not just the patient, should try the method for 4-6 weeks and then recheck lipids and weight; (2) if the patient wants second helpings, he or she must finish the entire plate (e.g., eat all the fruits and vegetables); and (3) "seconds" cannot be just starches, but it must again be balanced.

SUMMARY

Pediatric lipid disorders contribute to future cardiovascular risk, and as such it is important to address them directly. At the same time, the majority of pediatric hyperlipidemias are most safely, and perhaps most effectively, treated with a multidisciplinary lifestyle approach that includes plenty of physical activity, minimizing inactivity, nutritional counseling for an optimal diet, and adequate sleep in the setting of an individualized intervention for the child and the family. Care should be exercised to prevent the establishment of negative behavioral patterns because the health implications of dyslipidemias occur, for the most part, far in the future. Future research should focus on how lifestyle modification changes —including diet—can be best implemented; longer term evaluation of antihyperlipidemic medications in young patients; the utility of markers of preclinical disease either blood or vascular testing for evaluating the efficacy of interventions for atherosclerosis prevention; and better understanding provider, patient, and parent preferences around lipid screening and treatment that will impact implementation for lipid screening and treatment.

Diet and Dental Disease

64

Rosalyn Sulyanto, DMD, MS and James H. Shaw, DMD, PhD

The position of the oral cavity at the entrance to the gastrointestinal tract requires that it perform functions that need diverse tissues and specialized structures. The foods and other items that children eat and drink vary widely in their particle size and texture, degree of hardness, pH, and other chemical stimuli, as well as wide ranges of temperature. These different characteristics produce stresses on the oral components that must be moderated before swallowing. In the mouth, food items must be subdivided by chewing and simultaneously diluted and buffered with saliva until the bolus is suitable to swallow and pass on to the esophagus and lower areas of the gastrointestinal tract. The amount and composition of saliva secreted on each occasion are in response to the whole experience of eating—from the initial seeing, smelling, and anticipating to the tasting, chewing, and swallowing.[1,2] Especially in young children, many undesirable materials are taken into the mouth, which contribute various kinds of microorganisms and/or other dangerous entities.

The temperature and humidity of the oral cavity, as well as the frequent presence of all required nutrients for cellular growth and multiplication in food and drink, result in the mouth being an ideal incubator for many types of microorganisms (oral biofilm) from birth onward. It has been demonstrated through evidence-based dentistry that dental caries is an infectious disease and that mutans streptococci are the primary etiologic bacterial agents in the biofilm in humans. The pathogenicity of these microorganisms is related to their adherence characteristics; acidic nature; and resistance to low pH levels. Early colonization by mutans streptococci is closely related to a high dental caries experience, although the mere presence of mutans streptococci is

not sufficient to develop dental caries. At present, there are three events for the development of carious lesions during early childhood: (1) primary infection and initial colonization by mutans streptococci; (2) increase of the mutans streptococcus population in the mouth associated with the frequent and long exposure to a cariogenic diet rich in carbohydrates; and (3) demineralization and development of caries.[76] An important source of the infant's oral microbiome is the primary caregiver.[3] There is evidence of matrilineal transmission of mutans streptococci in very early childhood. Strong correlations between salivary mutans streptococci counts in mothers and their children have been reported. Recent studies indicate that mutans streptococci can colonize the mouth of predentate infants and that horizontal transmission (e.g., between family members or children in a day care setting) as well as vertical transmission (between caregiver and child with the major reservoir from mother to infant) occurs.[4] Maternal salivary levels of mutans streptococci infection may influence infection rates of mutans streptococci in their children at ages 6–18 months and at 4–5 years. Salivary concentrations of 10^5 colony-forming units mutans streptococci per milliliter of maternal saliva were associated with a 52% infection rate in their children compared with only a 6% infection rate when the maternal saliva concentration was 10^3 or below.[5,6] The presence of caries in the mother and siblings increases risks for the child, but the most consistent predictor of risk of caries (dental decay) in children is past caries experience.[7] Nutrients and the foods that provide them have numerous relationships to the oral tissues and structures, and these relationships vary depending on the nature of the tissue or structure itself. Some relationships differ from those elsewhere in the body. For example, sugars, when metabolized throughout the body, are wholesome sources of energy for the cells' many and varied functions. However, in contrast to this vital systemic relationship, the sugars have an undesirable local effect in the mouth. On the surfaces of dental enamel, sugars support the metabolism of microorganisms in dental plaque with the production of acid.

In the life history of the soft tissues, a transition occurs at birth as a result of the new, stressful exposure of their outer surfaces to microorganisms and food, meanwhile still being nourished systemically. A much more striking transition occurs for the teeth, especially the enamel surfaces, at the time of their eruption into the oral cavity. Prior to eruption, the external surfaces of enamel are surrounded by the enamel cap, including the enamel-forming cells of ectodermal origin, the ameloblasts, and the inner surface of the dentin is covered by the layer of odontoblasts,

the dentin-forming cells, which are embryonically of mesodermal origin. Both enamel and dentin throughout their formation and mineralization are related fully to the systemic environment. At eruption, the enamel cap is ruptured and the outer surfaces of enamel become exposed to the oral milieu of saliva, microorganisms, and food. The odontoblastic layer remains intact in contact with the capillaries of the pulp and continues to metabolize slowly with the centripetal formation of secondary dentin at the expense of the connective tissue in the pulp. The latter process accelerates when toxic metabolites from a deep carious lesion in the dentin trigger a protective response with more rapid production of secondary dentin.

STRUCTURE OF ENAMEL

Enamel and dentin are characteristically different from other tissues in the body. When fully mature, enamel contains only about 1% organic material and 2% water. Its tiny organic component consists of proteins chemically similar to the keratins of skin and is dispersed throughout the inorganic crystals as a network of extremely delicate and intricate fibrils.[8] The rest of enamel is the complex calcium–phosphorus salt hydroxyapatite, which varies somewhat in its composition, depending on the concentrations of anions and cations in the extracellular fluids at the time it crystallizes in the embryonic organic matrix. The hydroxyapatite in enamel has more perfectly formed crystals than those in dentin and bone. After its eruption, enamel contains no cells and is cut off from systemic influences other than through saliva, which bathes it continuously throughout life. Elements in saliva exchange with those on the outer surface of the enamel, especially in the period shortly after eruption.[9] Owing to its acellular nature, enamel has no ability to heal or remodel, with the exception that remineralization of early (precaries) surface lesions with the incorporation of calcium and phosphorus from saliva can occur under suitable conditions.[10,11]

STRUCTURE OF DENTIN

Dentin contains about 20% protein of the collagen family comparable to bone. About 70% of dentin is hydroxyapatite. Although dentin continues to form centripetally at a slow rate, like enamel, it is unable to remodel or repair itself as it does not contain anything comparable to the haversian system of bone. Any developmental errors in the formation of enamel and dentin remain throughout life as chemical or histologic artifacts in the kymographic record.

NUTRITIONAL STUDIES ON THE ORAL TISSUES AND STRUCTURES

Soft Tissues

The soft tissues, mucosa, gingiva, tongue, and taste buds, are especially susceptible to local stresses. Their metabolic activity is high. Oral mucosal cells in rats, for example, are replaced in 3–5 days by rapid cell division in the basal layer and sloughing of the surface cells; in contrast, the turnover rate in cheek skin is about 10 days.[12] This high metabolic activity accounts for the rapid healing of injuries to soft tissues within the mouth. However, the high metabolic activity of oral tissues results in a high susceptibility to nutritional deficiencies as adequate nutrients must be available to support the rapid cell multiplication and replacement.

In the early decades of nutrition as a discipline, deficiencies were often recognized first as clinical entities because of manifestations in the oral cavity; scurvy (vitamin C) and pellagra (niacin) are the prime examples.[13] The ease of oral examination for abnormalities with minimal violation of the subject's privacy also contributed to early recognition of nutritional deficiencies that affected oral components.

The increased understanding of nutrition and the attention to preventive nutrition, including legally required fortification of foods, such as niacin for the prevention of pellagra, have led to almost total elimination of such nutritional deficiencies in children of the industrialized nations. However, in the developing nations of the third world, especially in times of famine, such deficiencies still occur.

Mineralized Tissues

In early experimental studies with rats, severe deficiencies of vitamin A caused abnormalities in the ameloblasts, which led to hypoplastic enamel.[14] Severe vitamin C deficiency in guinea pigs, which, unlike rats, require preformed vitamin C in their diets, produced a syndrome in which the odontoblasts produced much less dentin.[15] As a result, the erupting teeth were thin and fragile. Acute deficiencies in rats and dogs of vitamin D or calcium or grossly abnormal calcium-to-phosphorus ratios resulted in inadequate mineralization and hypoplasia of the teeth.[16,17]

Little evidence exists to suggest that moderate deficiencies of these nutrients are of clinical significance in children in industrialized countries, although we still see cases of vitamin D–resistant rickets and scurvy. In severely malnourished children in developing countries, a linear enamel

hypoplasia (natal line) has been described in the anterior teeth of the primary dentition (Figure 64-1), which is much less frequent or absent in better nourished children in the same communities.[18,19] The poorly mineralized ring around the teeth in this syndrome was being formed about the time the children were born and was highly susceptible to dental caries. All children at birth had low serum vitamin A levels.

Low protein intake during the reproductive cycle of white rat dams resulted in delayed eruption of the molars of their offspring. Their teeth were smaller and more susceptible to tooth decay than those of the offspring of loosely related females provided with adequate protein.[20] The increased caries susceptibility in the deprived rats may be attributable to structural abnormalities in the salivary glands produced by the protein deficiency.[21]

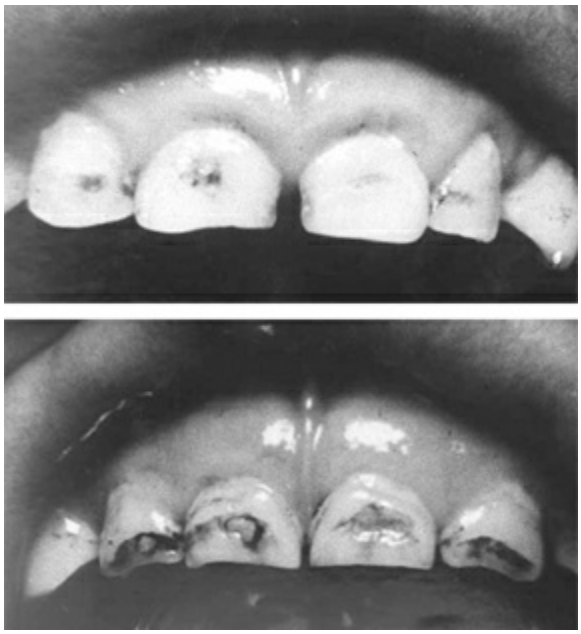

Figure 64-1 Photographs of linear hypoplasia of the anterior teeth of Guatemalan children. These hypoplastic areas are prone to develop dental caries. (Reproduced with permission from Sweeney and Guzman[18] and Sweeney et al.[19])

Alvarez[22] conducted two cross-sectional and one longitudinal study among Peruvian children in whom malnutrition in early life was prevalent. He studied the influence of malnutrition on the time of tooth eruption and of deciduous tooth exfoliation and the susceptibility of both deciduous and

permanent teeth to dental caries. As in the earlier studies with rodents, tooth eruption was delayed significantly among malnourished children. Because rodents have only a single dentition, exfoliation could not be studied in the laboratory. Among the malnourished Peruvian children, their deciduous teeth exfoliated appreciably later than those in better-nourished children in the same communities. When the length of time that the deciduous teeth were exposed to the oral environment was considered, instead of the traditional method of considering only the chronologic age of the children, the deciduous teeth of malnourished children were observed to have a higher incidence of caries than those of the better-nourished children. Even a single episode of moderate malnutrition before 1 year of age also resulted in a higher incidence of dental caries of the permanent incisors and first molars, which were being formed and were starting to mineralize during that interval. The increased incidence of dental caries among these children again paralleled the rodent studies conducted three decades earlier. Alvarez suggested that this observation may result from imperfect formation of dental enamel early in life.

Several studies, in animals and humans, have evaluated the effect of nutrition and nutrients on the growth and development of oral structures. The conclusion of many studies is that adequate nutrition is essential from the earliest periods of development. Further, a firm diet enhances proper growth and development compared with a soft diet. Specifically, the effect of diet consistency has been shown to affect growth of the mandible and maxilla and proper tooth eruption. Ongoing research on the harmful effects of nutrition on oral growth indicates that excess vitamin A can be a potent teratogen that may contribute to oral defects such as cleft palate. Protective effects of folic acid have been shown in animal studies but not in humans as yet, probably owing to the complexity of other factors also involved.[23]

Adequate amounts of all nutrients should be provided throughout the long periods of tooth formation in children to ensure their normal development, that is, from the last trimester of pregnancy through 16 years of age.

DISEASES OF THE ORAL CAVITY

The two principal diseases of the oral cavity are dental caries and periodontal disease (destruction of the tissues that support the teeth in the jaws). Although the latter is the chief cause of tooth loss in adults, juvenile periodontitis occurs infrequently in children, is much more localized than in adults, and may be associated with an immunologic defect in some

children. Both diseases are of multifactorial origin, are chronic in nature, and progress slowly and intermittently. Nutrition is not known to have a relationship to juvenile periodontitis except possibly through dietary influences on the dental plaque.

Etiology of Dental Caries

A carious lesion results from an interaction between the carbohydrates in food, especially the sugars, with cariogenic microorganisms in the dental plaque on tooth surfaces (dental biofilm) and the tooth surface in the presence of saliva; the gross anatomy of the tooth, the composition of the enamel and dentin, and the quantity and quality of saliva all vary in ways that influence the rate of progression of tooth decay. The most serious adverse influence on the ability of the teeth to be maintained in the oral cavity is any reduction in the flow of saliva owing to salivary disease, radiation, or drug use that modifies the ability of the salivary glands to function.[24,25]

Under certain circumstances, the acidic metabolic products of the dental biofilm's microorganisms on the tooth surfaces from sugars reduce the pH of plaque sufficiently to demineralize enamel and, later, the dentin progressively until a carious lesion is produced. The epidemiologist commonly speaks of this type of disease production as the relationship of the agent (microorganism[s]), host (the tooth and the person in which it functions), and environment (the components in the milieu around the tooth and the home and community in which the individual lives) (Figure 64-2).[26]

All three parameters must simultaneously be in a caries-producing mode for carious lesions to be initiated and progress to become visually detectable. Periodontal disease also results from the interaction of food, the microorganisms in the crevices between the teeth and the gingiva, and the tissues in the area.

Agent. The microorganisms producing carious lesions are able to colonize the smooth surfaces of the teeth and/or the pits and fissures of the biting surfaces.[27] These microbiota (known as dental biofilm) are able to produce sufficiently acidic environments (pH around 5) on the tooth surfaces when metabolizing actively to demineralize enamel and later dentin. They must be able to continue to metabolize actively at these low pH values as the lesion progresses deeper into the tooth. The primary sources of energy required by these organisms are the sugars. *Streptococcus mutans* is of special interest because it produces mutans, a

polysaccharide of glucose, which enables it to adhere to smooth surfaces and to build up colonies in dental plaque. The nature of plaque is such that the microbial metabolites are produced in close proximity to enamel with restricted access to buffering saliva. In the human mouth, plaque contains numerous species of microorganisms with acid-producing capabilities. The complex nature of the oral milieu makes it virtually impossible to fully apply Koch's principles for identification of a specific causative organism. Probably more than one species is involved in most situations, but especially as lesions progress more deeply into the tooth with the need to metabolize in a strongly acidic environment. The recent recognition that dental plaque is a bacterial biofilm and that it behaves quite differently from its individual constituents has led to research to control plaque formation by preventing bacterial adhesion to the tooth surface. Physical approaches include coating the enamel surface with a polymer, whereas biological approaches to prevent initial colonization include inhibition of plaque matrix formation and inhibition of the bacterial signaling mechanisms.[28]

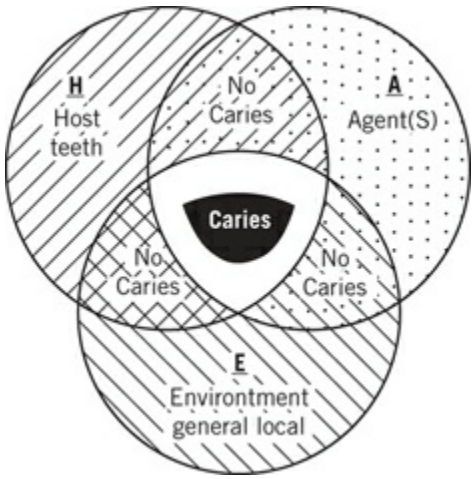

Figure 64-2 Diagrammatic illustration of the three major parameters simultaneously required for the initiation and progression of carious lesions. (Reproduced with permission from Keyes and Jordan.[26])

Host. Evidence of genetic determinants of caries resistance is limited in humans, yet a variety of subtle indications of genetic influences has been reported. Early suggestions that large differences in caries experience between national groups were genetically determined have been largely

discredited. The caries prevalence in industrialized nations tended to be routinely higher than in developing countries; however, as the dietary customs of the high-caries industrialized nations were adopted in developing countries with increased sugar consumption and more frequent eating, their low-caries experience has been increasing. Meanwhile, in the last 20 years, dental caries prevalence in the industrialized nations has been decreasing significantly.[29]

Comparison of the dental caries experience of twins indicated that identical twins had more similar caries experiences than fraternal twins.[30] This may not be a truly genetic influence as such environmental experiences as food preferences, frequency of eating, and tooth brushing techniques may be more similar for identical than for fraternal twins. Similarities in dental caries for twins reared separately were considered to be about 50% attributable to genetic influences.[31] Numerous trials have been conducted to develop animal strains of divergent caries resistance. Superficially, differences attributable to heredity seemed to be produced. However, when so-called resistant strains were heavily challenged early in life with cariogenic microorganisms, carious lesions developed readily, although not always as extensively as in the seemingly more susceptible strains.

Mandel[32] suggested three avenues through which genetic influences may be mediated: (1) salivary components that buffer plaque acids—elevating the pH and influencing the bacterial ecology of plaque, (2) immunologic and nonimmunologic constituents of oral fluids that have the capacity to alter the ability of cariogenic bacteria to attach to enamel, and (3) protein-bound lipids on the surfaces of teeth that may alter the permeability to acids produced in plaque.

Environment. The single most important variable in the oral environment is the frequency of consuming foods containing sugars that adhere to tooth surfaces. The absolute amount of sugars consumed is less important than the frequency of eating. In the 1930s and 1940s, numerous studies were conducted on the relation of frequency of eating to caries experience (Figure 64-3).[33] Almost invariably, the conclusion was that caries experience increased as frequency of food consumption, especially of between-meal snacks, increased. More recently, this type of trial has been less frequent and the above relationship has not been as readily demonstrable. Since the earlier studies, food habits have changed dramatically. At that time, most food was prepared and eaten at home, and the amount of sugar used was controlled by the homemaker. Between-meal snacks were usually candy and cookies. Today, relatively little food

is prepared at home; many items are commercially prepared, with the amount of sugar controlled industrially on the basis of the amount needed for "best" taste. In addition, a much higher percentage of meals are consumed away from the home. Snack consumption is much more frequent, and less dependence is placed on three main meals a day.

The amount of sugar available per capita in a country is a reasonable index of the prevalence of dental caries among its children (Figure 64-4).[34] The information supporting the pivotal role of sugars in the etiology of dental caries was considered by 1977 to be sufficiently conclusive that Horowitz stated that in human dental experimentation:

> *the control group should not be asked to engage in any practice that may have a harmful effect on the dentition or its surrounding tissues. For example, subjects in a control group should not be given or asked to use chewing gum sweetened with sucrose, nor should they be asked to use sucrose rinses or other agents to produce decalcification of tooth enamel or initiate carious lesions, unless the investigators are certain that they can completely "reverse" the defects.*[35]

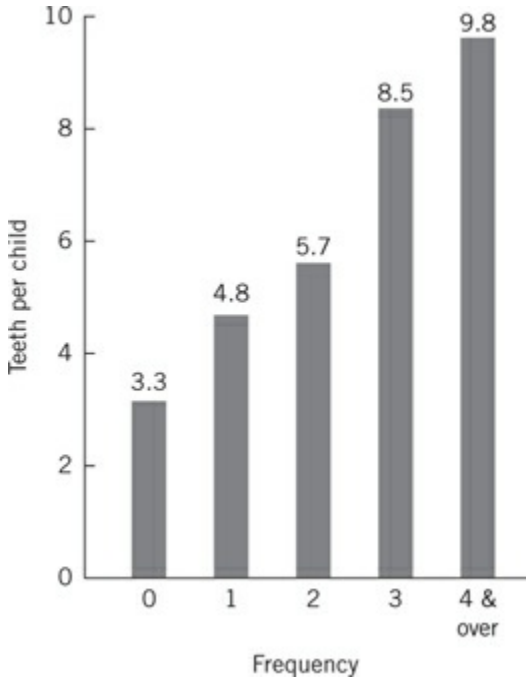

Figure 64-3 This bar graph compares the number of decayed, missing, and filled deciduous teeth with the frequency of between-meal eating in preschool children in Tennessee.

*Includes extracted primary molars. (Reproduced with permission from Weis and Trithart.[33])

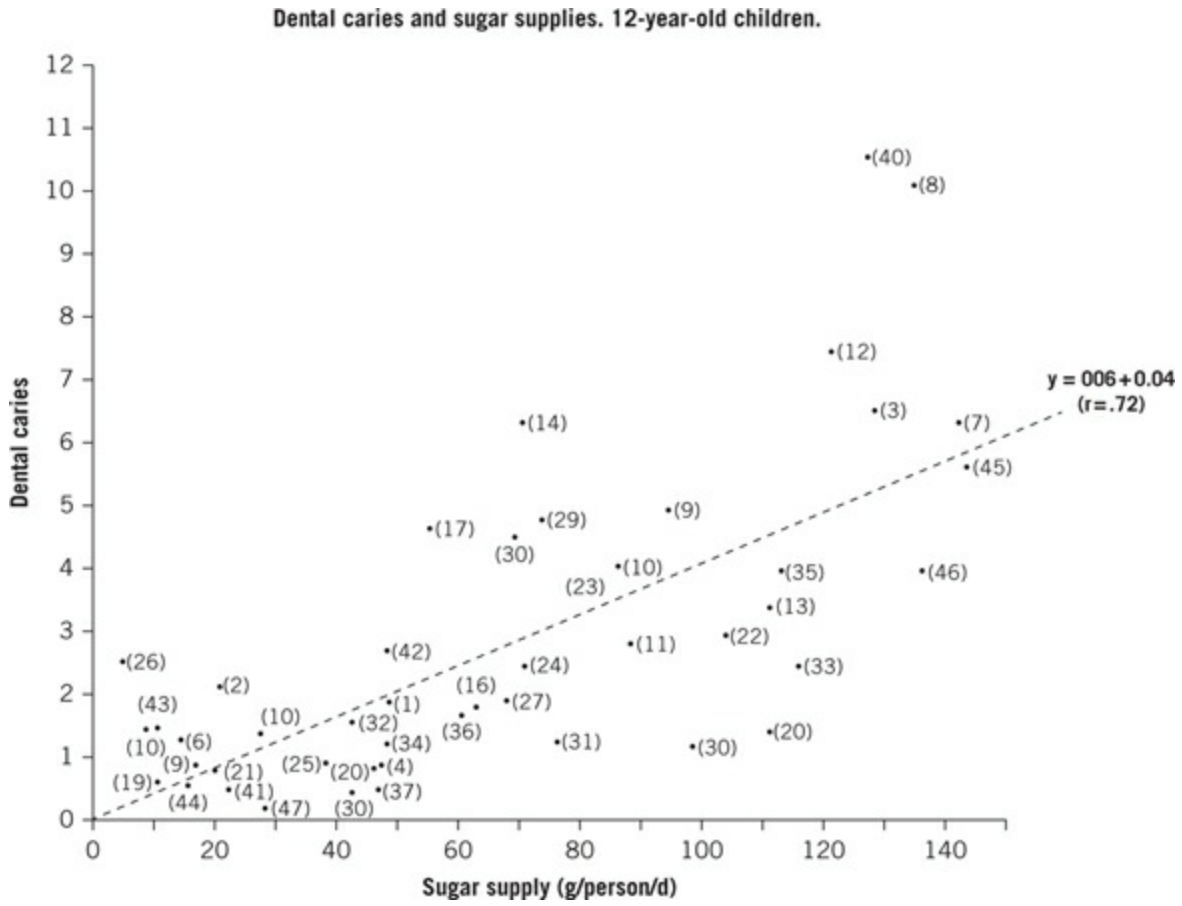

Figure 64-4 This graph represents a comparison of the number of decayed, missing, and filled permanent teeth with the sugar supply in grams per person per day for 47 countries. (Reproduced with permission from Sreebny.[34])

Mandel[32] stated that little disagreement exists that differences in amount, form, and frequency of readily fermentable carbohydrates can affect the rate of caries attack, but considerable variation between children exists when intake appears to be generally comparable.

Foods are complex mixtures of many chemicals. As yet, it has not been possible to devise a series of animal trials and evaluations in the human oral cavity that dependably estimate the caries-producing value of a specific food.[36] Some food items that contain relatively little sugar but substantial amounts of starch are more capable of producing caries lesions

than expected; others containing high amounts of sugar are less capable of supporting the caries process than expected.

A special case of rampant dental caries limited to the maxillary anterior deciduous teeth and posterior molars has become known as early childhood caries. This problem occurs in young children who are put to bed at night or for rests during the day with a bottle of formula or sweetened juice. When they go to sleep, salivary secretion decreases drastically, and the fermentable carbohydrates in the milk or juice are not diluted or washed away but are readily available to the microorganisms on tooth surfaces.[37] It is believed that the tongue affords protection to the mandibular anterior teeth so that they are pathognomonically not affected. Excessive on-demand breastfeeding is also capable of causing the same problem. The sugar, lactose, in human milk is clearly able to support the caries process.

Pediatricians and pediatric dentists on a preventive basis need to urge mothers of young infants to follow feeding practices in which excessive exposure to sweetened fluids and breast milk does not occur. When early childhood caries is already present, appropriate dietary corrections need to be made by less frequent feeding and the use of fewer sweet snacks of all kinds. Appropriate professional dental care is needed, probably including topical fluoride applications, such as a fluoride varnish, coupled with strong oral hygiene procedures at home.[38] The latter will include the parent's brushing of the infant's teeth with fluoridated toothpaste. Care is needed so that excess fluoride is not swallowed.

The importance of maintaining the deciduous teeth is not to be underestimated. They are needed as "space maintainers" as the jaws grow in order that there will be adequate room for eruption of the permanent teeth. Increased likelihood of orthodontic problems accompanies the early loss of deciduous teeth. High levels of untreated caries in the deciduous teeth provide reservoirs of cariogenic microorganisms from which the permanent teeth become quickly infected when they erupt into the oral cavity.

Reduced Ability of Polyols to Support Caries. Measurement of the pH of dental plaque in vivo with tiny, sensitive electrodes has become a convenient means of evaluating how various solutions and foods in the oral cavity affect the metabolism in the dental plaque in proximity to the tooth surface. In 1944, Stephan reported on a sharp depression in the pH of dental plaque after a glucose rinse was swished around the mouth.[37]

This depression from the resting value with a pH around 6.6–7.0 (the range observed in saliva) to 5.0 or less within minutes after the start of the

glucose rinse lasted for a few minutes and then slowly returned to the resting value. Plots of results from this kind of evaluation have become known as Stephen curves (Figure 64-5).[39,40] The consensus from the Stephen curve concerning the relation of plaque pH to caries production is shown in Table 64-1.

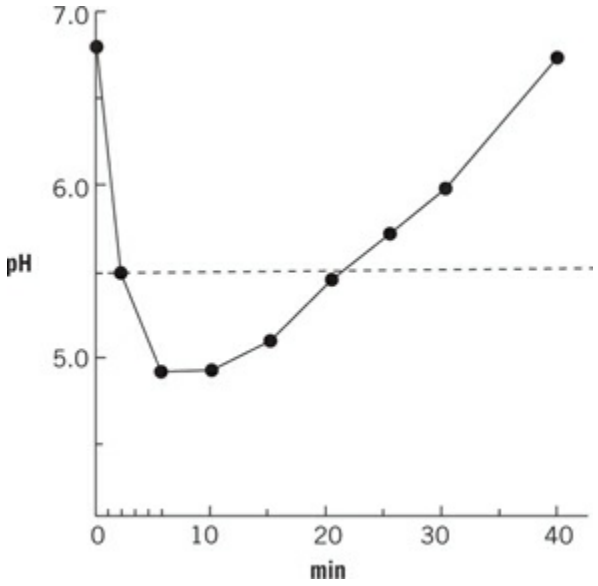

Figure 64-5 The typical Stephen curve showing the precipitous decrease in pH measured in vivo in dental plaque after a glucose rinse and the slower return to the resting pH. (Adapted from Stephan[39] and Edgar.[40])

Both the equipment and the procedures for intraoral tests have been refined and are used widely today. For example, certain varieties of cheese eaten shortly after a sugar rinse or a sweet food prevent the rapid pH drop in dental plaque (Figure 64-6).[40] Likewise, chewing a gum sweetened with a polyol, sorbitol, or xylitol does not result in a pH decrease, whereas chewing a gum sweetened with sucrose causes the typical caries-producing decrease (Figure 64-7).

Oral microorganisms have greatly limited abilities to metabolize the polyols, xylitol (5 carbon), sorbitol, and mannitol.[41,42] The effect of sugar substitutes on changes in caries rates has been evaluated in several observational studies as well as clinical trials, with results consistently demonstrating a protective effect of xylitol on caries incidence. Sorbitol was also shown to decrease caries rates compared with controls; however, the reductions in caries rates were greatest when xylitol was the sugar

substitute. Some limitations of these studies include a lack of radiographs in caries diagnosis, high loss to follow-up, potential confounding, and bias owing to the nature of long-term community intervention studies. The criteria for causality—consistency, strength association, biologic plausibility, temporal sequence, and dose–response relationship—should be considered. First, these studies are remarkably consistent both in terms of the magnitude of the effect observed as well as the consistent demonstration that xylitol was superior to sorbitol in decreasing the risk of dental caries. Second, the relative risks observed are considered strong (0.19–0.4). It is biologically plausible that xylitol can reduce dental caries because the pH of plaque is lowered with xylitol compared with sucrose. Fourth, a dose–response trend was observed in the two studies that evaluated different concentrations of xylitol, with the greatest effect observed in the subjects using the strongest xylitol preparations. The evidence to date suggests a strong caries-protective effect of xylitol.[43]

TABLE 64-1 Relation of Plaque pH to Caries Production

	Potential for Caries
Plaque p^H	**Initiation and development**
Above 6.0	Safe area; low solubility of enamel; calcium and phosphorous adequate to saturate environment
6.0–5.5	Doubtful or very slow progression
Below 5.5	Danger area; high solubility of enamel; calcium and phosphorous inadequate to saturate environment

Sources: Adapted from Stephan[39] and Edgar.[40]

In vivo pH testing has been used extensively in Switzerland, not only in basic research but also in the estimation of the potential of a specific product to cause dental caries when used excessively. When a product has been evaluated by approved methods for in vivo testing and is found not to cause an excessive decrease in pH, the Swiss Health Authority grants permission to identify the product as “zahnfreundlich” (friendly or safe for the teeth) and imprint a distinctive logo on the label (Figure 64-8).[44] This procedure has not been adopted elsewhere because of the inability to find a consensus that this procedure is adequate for the intended purpose.

FLUORIDES AND HUMAN HEALTH

Because fluoride has relationships to dental caries through both the host and the environment, a separate section for fluoride discussion is appropriate. Fluoride ion from any salt of the highly reactive halogen fluorine occurs ubiquitously in water supplies, soils, and foods. Fluoride is also present in all body fluids and tissues, even when the amount of fluoride ingested is low. Probably no nutrient demonstrates more clearly the physiologic spectrum from the influence of an insufficient intake, through normal to toxic levels of ingestion.

TOXICITY OF EXCESS FLUORIDE: MOTTLED ENAMEL

Toxic manifestations of excess fluoride ingestion were observed before recognition of its benefits, unlike other nutrients, for which the effects of deficiencies were described first. In 1901, Eager,[45] a physician in the U.S. Public Health Service stationed in Naples, Italy, described an esthetically disfiguring problem of dental enamel in otherwise healthy adults. Their enamel was variously mottled with brown stains; he attributed the problem to local geologic conditions. In striking contrast, he recognized that the enamel of teeth in young children in the area was normal, which he postulated might be attributable to a recent change known to have occurred in the water supply.

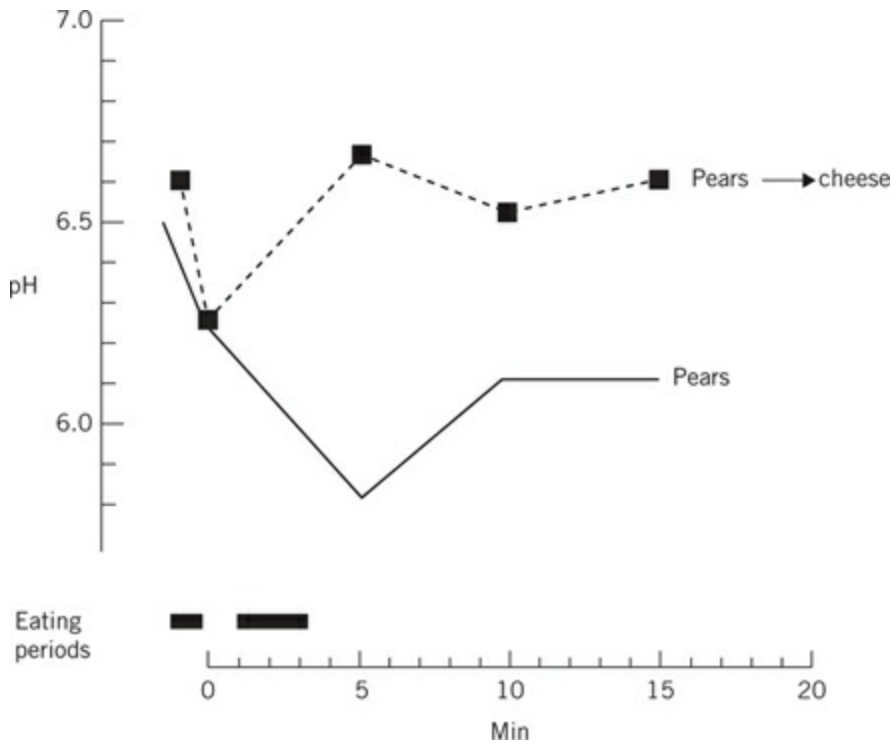

Figure 64-6 An example of the sharp pH decrease after eating a portion of sweetened pears and the moderating influence of eating cheese immediately after the same portion of pears. (Reproduced with permission from Edgar.[40])

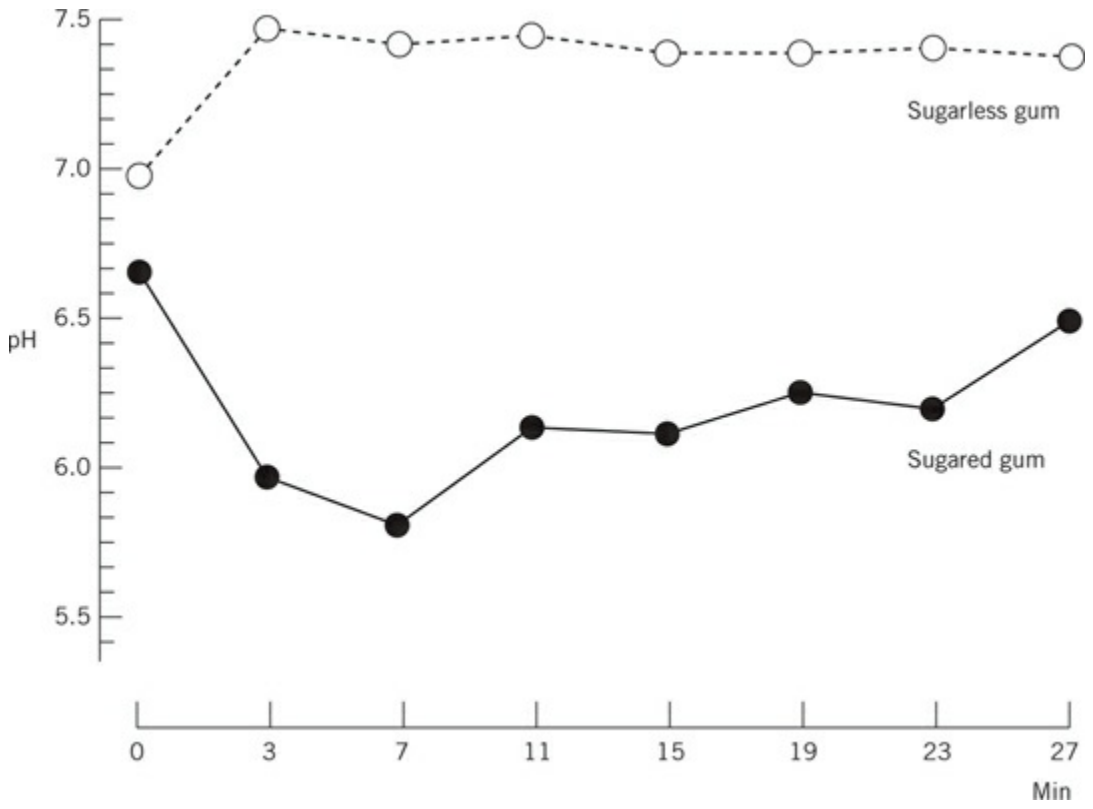

Figure 64-7 A comparison of the Stephen curve after chewing sucrose-sweetened gum with the pH curve after chewing gum sweetened with a noncariogenic polyol. (Reproduced with permission from Edgar.[40])

Subsequently, descriptions of mottled enamel were reported from numerous parts of the world in humans as well as in domestic animals.[44] Evidence became increasingly clear in humans that this esthetically disfiguring problem was caused by some agent in community or home water supplies. In animals, the problem sometimes was caused by their water supplies and in other situations was related to rock phosphate supplements added to their feeds as a source of calcium and phosphorus.

By 1931, reports from several widely separated laboratories established that the mottled enamel in humans and experimental animals was attributable to excess ingestion of fluoride from drinking water that contained more than 1.5 ppm fluoride, that is, 1.5 mg/L of water.[46–48] At this point, the popular name, mottled enamel, was superseded by the scientific descriptor, chronic endemic dental fluorosis.

This abnormality was determined to result from some as yet undefined altered relationship(s) in the deposition of crystals of hydroxyapatite in the

organic matrix formed by ameloblasts, the enamel-forming cell of ectodermal origin. This developmental interrelationship is apparently the most sensitive process to excess fluoride in the extracellular fluids of any in the body. Higher intake (20 mg) of fluoride per day in industrial exposure causes abnormal calcification in the spine and, after 20 years, serious crippling fluorosis.[49]

CLASSIFICATION SYSTEM FOR MOTTLED ENAMEL

Dean developed a classification system to describe the various visual levels of enamel pathology and a weighting system to provide a community fluorosis index.[50] He used the terms: (1) questionable—slight aberrations from the normal glossy translucency of enamel, which the examiner could not be certain was pathologic (weight = 0.5); (2) very mild—small, dull, paper-white areas scattered irregularly over the tooth surface but covering less than 25% of its area (1.0); (3) mild—more extensive white opacities but less than 50% of the area involved (2.0); (4) moderate—all surfaces affected with marked wear on the chewing surface accompanied by brown stains (3.0); and (5) severe—all surfaces affected with marked hypoplasia, discrete or confluent pitting, and widespread brown stains.

Figure 64-8 The “safe for teeth” logo approved for use on the label of an approved product in Switzerland. (Reproduced with permission from Guggenheim.[44])

The community fluorosis index was calculated by combining the weight for each child with the frequency of occurrence of each grade in the child population. A community fluorosis index over 0.5 was considered undesirable, indicating the need to reduce the water fluoride level.

As shown in Figure 64-9, mottled enamel does not become a problem until in excess of 1.5 ppm fluoride in drinking water was ingested during

tooth development.[49] However, water concentrations beyond this amount caused increasingly severe fluorosis and increasing frequency. As a public health measure, excessively high fluoride amounts must be reduced or a new lower fluoride water supply found. It must be emphasized that mottled enamel cannot result from consuming excessively high amounts of fluoride after the teeth are formed because this abnormality is completely of developmental origin.

DENTAL BENEFITS OF NATURALLY AVAILABLE FLUORIDES

One of the earliest observers of enamel fluorosis in this country, McKay,[52] in Colorado Springs, where the water supply was later shown to contain 2.0 ppm fluoride, reported that teeth with mottled enamel did not seem to have an increased susceptibility to dental caries despite the surface irregularities. In the late 1920s and 1930s, several small studies suggested that fluorosis appeared to be associated with reduced dental caries experience.

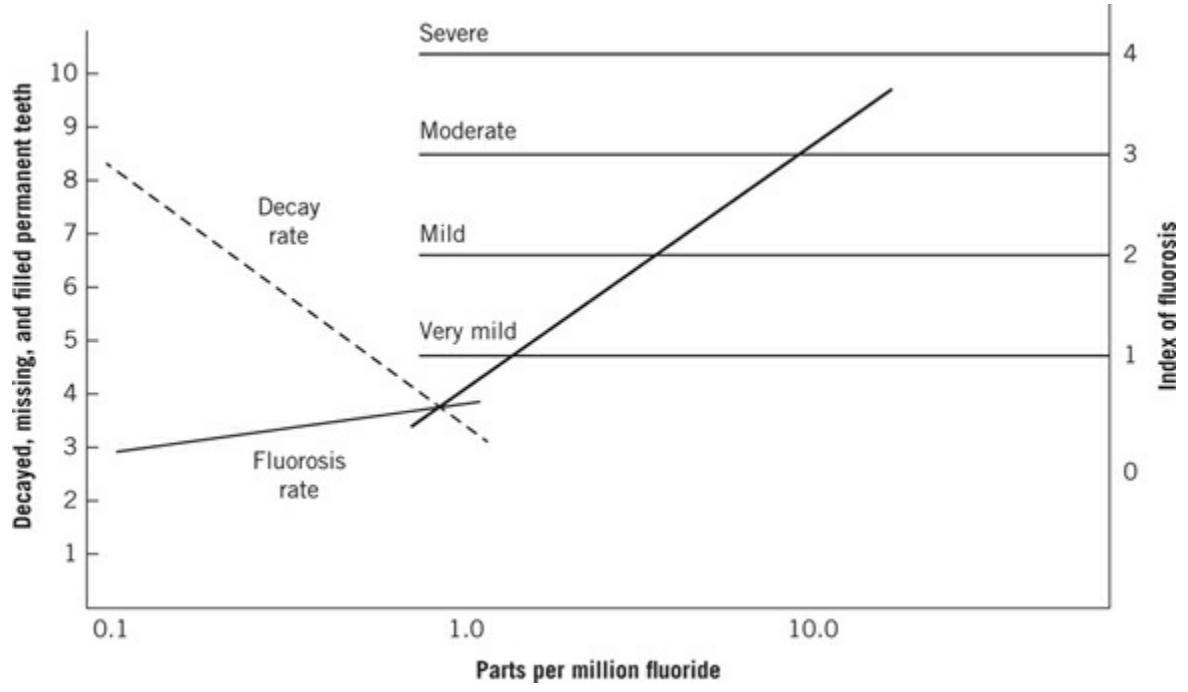

Figure 64-9 Relation between decayed, missing, and filled permanent teeth (broken line), severity of dental fluorosis (solid line), and fluoride concentration in the public water supply, with

the latter on a logarithmic scale. (Reproduced with permission from Hodge and Smith.[51])

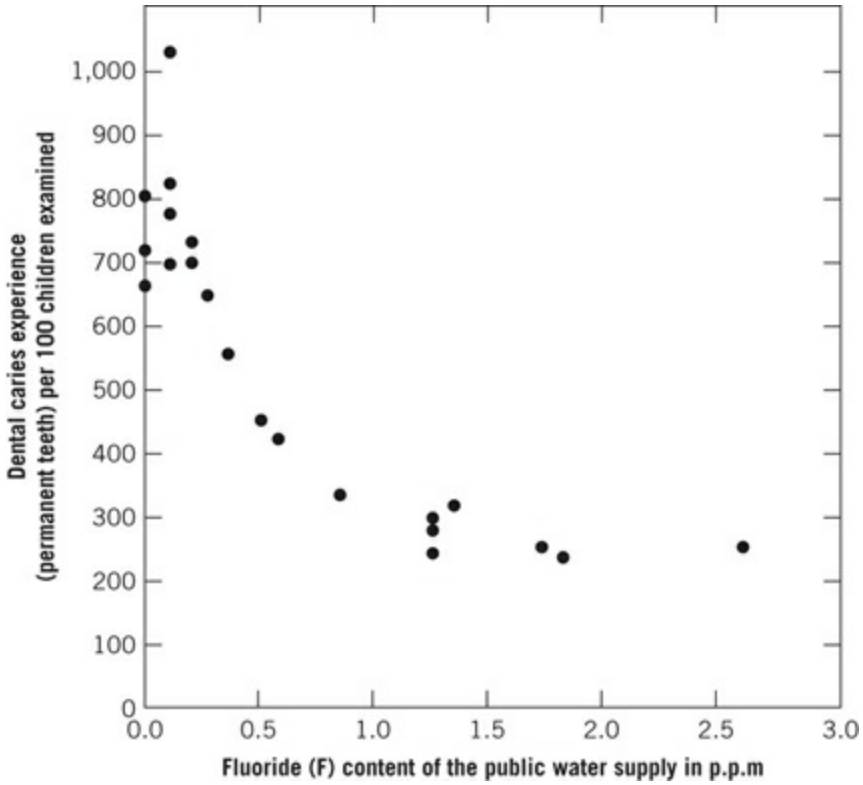

Figure 64-10 Relationship between the fluoride content naturally available in public water supplies and the number of decayed, missing, and filled permanent teeth per 100 children 12–14 years old. (Reproduced with permission from Dean et al.[53,54])

A combination of the need to know the permissible upper limit of fluoride in drinking water plus the increasing concern about the generally high incidence of dental caries among American children led to many extensive epidemiologic surveys among children. Numerous increasingly large surveys in the 1930s and 1940s indicated the strong correlation between fluoride ingestion during tooth development and tooth decay. For example, Dean et al.[53,54] reported on data for 7257 12- to 14-year-old children in 21 cities in 4 states. Figure 64-10 indicates the convincing relationship between fluorides during development and dental caries experience. They also considered other factors that might be related—composition of diet, hours of sunshine, and hardness of the water—and

concluded that none could explain the naturally available fluoride–dental caries relationship.

DENTAL BENEFITS OF WATER FLUORIDATION

By 1945, the dental benefits of fluoride in communal water supplies had been demonstrated to the satisfaction of almost all investigators and many health-related professional organizations. The possibility of pathology elsewhere in the human body or of increased susceptibility to other diseases had been thoroughly studied, with negative results with one exception, the crippling fluorosis described above, which has never been observed at the optimal level for caries reduction. Hence, in 1945, three clinical trials were initiated to adjust the fluoride concentration of community water supplies to an optimal level, with the expectation that 10 years would be needed for demonstration of the benefits. Grand Rapids, Michigan, was selected as one trial community, with Muskegon, Michigan, to serve as the unfluoridated control city and Aurora, Illinois, as a natural fluoride city. A second study was initiated in Newburgh, New York, with nearby Kingston as the unfluoridated control. The third community was Brantford, Ontario, with Sarnia, Ontario, as the unfluoridated control and Stratford, a nearby community with an optimal fluoride level naturally present. The data soon demonstrated that the results from water fluoridated in the distribution system duplicated those observed where fluoride was naturally present, with caries reductions from 50% to 60% in permanent teeth (Figure 64-11).[54–58]

The benefits in teeth developed during the study began to show up sufficiently rapidly that Muskegon dropped out as the control community for Grand Rapids before the 10-year test period ended and initiated its own water fluoridation program. In addition, some unexpected reductions in caries initiation were observed among the teenage population in teeth formed before fluoridation was begun; this observation suggested that an oral environmental influence was occurring in addition to the expected systemic influence on developing teeth. As in communities with naturally available fluoride, the greatest benefit was for the smooth surfaces of the anterior teeth and the least for the carious lesions that develop in the developmental pits and fissures on the grinding surfaces of the posterior teeth. No evidence of esthetically disfiguring mottling was observed in these trials.

Fluoridation of water supplies has been widely adopted in the United States as a valuable and inexpensive public health measure. The

Fluoridation Census in 1992 reported that 134.7 million individuals on communal water supplies in 8572 communities received water fluoridated in the water processing system; in addition, 10.0 million individuals lived in 1924 communities where the water contained at least 0.7 ppm fluoride naturally.[59] The total percentage of the population benefiting from fluoride in the water in the United States was 62.1.

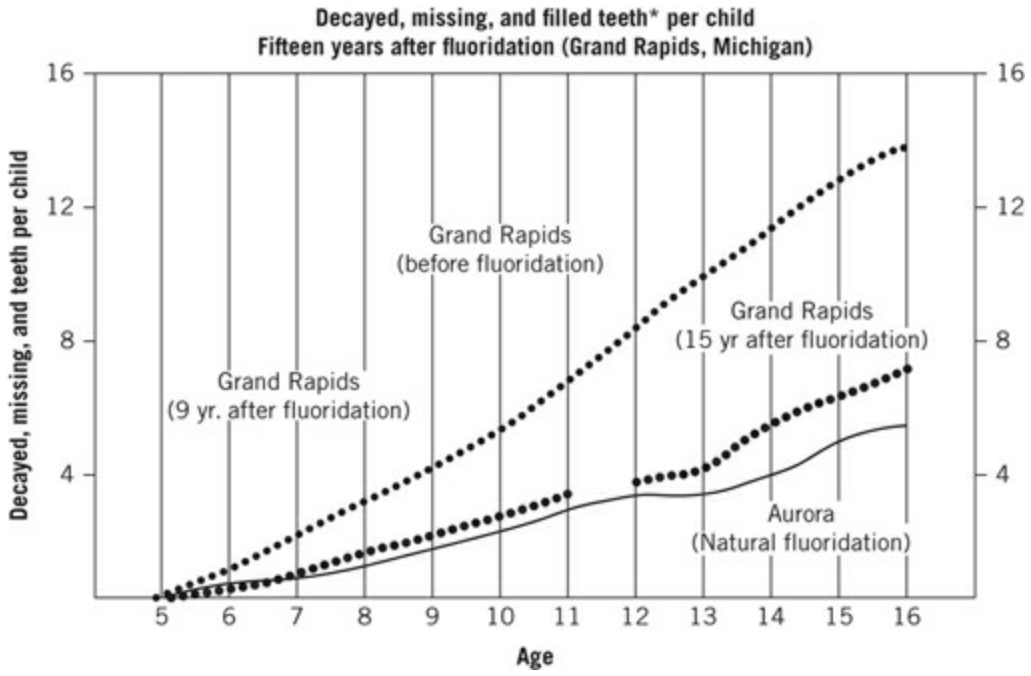

Figure 64-11 The benefits of fluoridation of the communal water supply in Grand Rapids, Michigan, are shown for the deciduous teeth after 9 years and for the permanent teeth after 15 years. The inclusion of the data for Aurora, Illinois, where the water naturally contains an adequate comparison of how similar the benefits are between natural fluoride and fluoride introduced at the water treatment facility. (Reproduced with permission from Arnold et al.,[55,56] Ast et al.,[57] and Hutton et al.[58])

METABOLISM OF FLUORIDES

The varying evidence of mottled enamel within the child population of any community in both natural fluoride areas and areas where fluoridation is practiced has been the subject of much interest since the first evidence of the fluoride relationships. Some variation undoubtedly occurs in the amount of water consumed by individual children; the amounts of canned

fish with bones and the use of tea, the only foods with substantial amounts of fluoride, constitute additional variables.

Fluorides from soluble salts are readily absorbed from the gastrointestinal tract.[60] In the presence of high concentrations of cations that produce much less soluble salts of fluoride, its absorption is reduced. When much less soluble sources of fluoride are ingested, absorption of fluoride is also reduced.

The kidneys are the major route for fluoride removal from the body, which is characterized by variable degrees of tubular resorption. A range in resorption has been reported in humans; in four studies, the average resorption of fluoride after filtration into the tubules varied from 23% to 38%.[61] In general, fluoride clearance tended to increase with increased urinary flow rate. Urinary pH also influenced fluoride excretion. In rats with a urinary pH less than 5.6 induced by administration of ammonium chloride, urinary excretion was less than 5% of the amount filtered; alkaline pH as high as 8.0, induced by administration of sodium bicarbonate, resulted in fluoride excretion approaching 70%. Various factors can chronically alter the acid–base status and affect fluoride relationships. The composition of the diet is normally the major determinant of acid–base balance and urinary pH. In addition, various metabolic and respiratory disorders, level of physical activity, and altitude of residence contribute to acid–base status.

The combination of slightly different levels of fluoride ingestion by children with the above factors, which modify excretion in the urine, is probably adequate to explain the different degrees of mottled enamel in children within the same community.

DENTAL BENEFITS OF FLUORIDE TABLETS, TOOTHPASTES, AND ORAL RINSES

Efforts to extend the systemic benefits of fluoride to populations for whom waterborne fluoride was not available led to the development of fluoride dietary supplements. Three major factors have combined to change the way in which fluoride supplements are used in contemporary practice: (1) a shift in our understanding of fluoride’s mode of action from systemic to topical; (2) an increased exposure among children to other sources of fluoride; and (3) concern for the risk of fluorosis in permanent teeth. With those factors in mind it is recommended that prior to prescribing fluoride supplements, assay the child’s primary drinking water supply for fluoride

content. In addition, practitioners should consider other sources of fluoride exposure for their patients and do a caries risk assessment.[62] The levels recommended by the American Academy of Pediatric Dentistry for different ages and levels of fluoride in the water supply are shown in Table 64-2.[63]

Because young children are prone to swallow toothpaste, use of fluoridated toothpaste (usually containing 1000 ppm fluoride, i.e., 1 mg F per gram) contributes to the level of fluoride ingested. Therefore, it must be used sparingly; the size of a pea on the brush is adequate and must be applied by the child's caregiver. As a safety factor, a maximum of 120 mg of fluoride should be prescribed at one time. This amount would be a certainly lethal dose only for those children weighing less than 8 kg and would be a probably toxic dose for children weighing 24 kg or less.[64]

The overall effectiveness of fluoride supplements has been estimated to provide 20%–30% reduction in dental disease. The level of evidence for the effectiveness of fluoridated dentifrices in the permanent dentition is high and sufficient to warrant a strong recommendation for their use to reduce the incidence of caries. Unfortunately, there is no evidence regarding their effectiveness in the primary dentition, but logically it should follow that they would be as effective in younger patients.

TABLE 64-2 Dietary Fluoride Concentration in the Water Supply

	Fluoride Concentration in the Water Supply		
Age of Child	**Less Than 0.3 ppm F**	**0.3–0.6 ppm F**	**More Than 0.6 ppm F**
Birth–6 months	0	0	0
6 months–3 years	0.25 mg	0	0
3–6 years	0.50 mg	0.25 mg	0
6 years up to atleast 16 years	1.0 mg	0.50 mg	0

Source: Adapted from Whitford.[61]

Fluoridated mouthrinses (0.05 sodium fluoride) and self-applied gels (stannous fluoride) should be reserved for use with children judged to be at moderate or high risk for dental caries, including children with orthodontic appliances or prosthetic appliances, children with special health care needs, and those with reduced salivary flow. Fluoride mouthrinses should

be recommended only for children who have demonstrated mastery of their swallowing reflex.[62]

In children with special health care needs who are especially at risk for dental caries (children with gastroesophageal reflux disease) who cannot control their swallow reflex, it is recommended that the caregiver dip the brush in the mouthrinse before bedtime or use a supplemental gel.

Fluoride varnish recently received Food and Drug Administration approval in 1994 for use as a desensitizing agent and as a cavity liner. It has been used off-label as a caries preventive agent. Fluoride varnish is easily applied to the teeth, and it sets relatively quickly in contact with moisture. A typical application requires 0.2–0.5 mL, resulting in a total fluoride ion application of approximately 5–11 mg. The Cochrane Database for Systematic Reviews found a 46% pooled prevented fraction for permanent teeth and 33% for primary teeth. The authors concluded that fluoride varnish provides a substantial caries-inhibiting effect in both dentitions.[65]

The extent to which the various uses of fluorides contribute to the dental health of the United States is demonstrated by a statement by Harold Varmus, Nobel laureate and director of the National Institutes of Health, at a Senate Appropriations Subcommittee Hearing on March 17, 1994.[66] In response to Senator Harkin's question, "Does medical research contribute to long-term cost savings?" Varmus stated that his favorite example of the benefits of research concerned the use of fluorides to prevent dental caries, which alone saves the taxpayer several billion dollars per year.

MECHANISMS OF ACTION OF FLUORIDES

When the dental benefits of fluoride were first observed, systemic mechanisms of action were sought. The degree of crystallinity of hydroxyapatite in enamel increased as its fluoride concentration increased. Acid solubility of hydroxyapatite decreased as its fluoride concentration increased. Enamel surfaces had particularly high fluoride concentrations.[67]

Saliva contains about 0.019 ppm fluoride (1 μmol/L), about one-fiftieth of the concentration in communal water fluoridated at 1 ppm.[68] Even this low concentration appears to be important in the maintenance of the integrity of the tooth surface and in the remineralization of precarious lesions in the enamel. The mechanisms of action of fluoride in caries inhibition include the following: (1) the enhancement of remineralization during the repeated cycles of demineralization/remineralization in the early

stages of the caries process, (2) the inhibition of glycolysis by which sugar is metabolized by bacteria to produce acid, and (3) while a preeruptive systemic effect cannot be ruled out, no direct evidence of such an effect has been demonstrated.[69]

TREATMENT OF CARIOUS LESIONS

Because a visually detectable carious lesion is rarely self-limiting (as in most bacterial infections), it continues to progress until the pulp is infected, with the probable loss of the tooth, unless specific action is taken to interrupt the progress of the lesion. Decayed enamel and dentin must be removed and replaced with an inert material that is able to resist the forces of mastication and the influences of the oral milieu.

Significant bactericidal benefits can be achieved by the use of fluoride-containing products preparations, such as stannous fluoride gels in young children. Bacteristatic benefits can be seen in high fluoride (5000 ppm) containing toothpastes for children over 6 years of age.

Xylitol is a low-calorie, naturally occurring, and diabetic safe sugar that is not metabolized by cariogenic bacteria. Incorporating xylitol into the diet inhibits pH changes and reduces bacterial attachment to teeth. Xylitol currently is available in many forms (gums, mints, chewable tablets).

Use of xylitol gums by primary caregivers has been shown to decrease oral bacterial load and interrupt vertical transmission. Xylitol products also stimulate salivary flow and aid in the symptomatic treatment of xerostomia sometimes associated with chronic childhood disease.

Although there are no definitive clinical studies to support the dosage in tooth wipes containing xylitol, they may be used to compliment, but not completely replace, regular mechanical removal of plaque through brushing. It is important to note that many sugarless gums containing xylitol also contain phenylalanine and are contraindicated for phenylketonurics.[75]

Pit and fissure sealants have been demonstrated to be effective in the primary prevention of caries, and their effectiveness remains strong as long as the sealants are maintained.[6] Sealants are intended to protect caries-susceptible tooth surfaces, which are benefited least by fluoride. They should be placed as soon as possible after the tooth erupts and isolation to prevent moisture contamination during placement can be achieved.

Identification of early carious lesions and treatment with preventive

resin restorations allow for decreased dental bioload while preserving tooth structure. This very conservative treatment allows for the removal of just the small pit and fissure lesion and subsequent restoration with esthetic composite resin to which a sealant can be applied. By removing only the carious enamel and dentin, the preventive resin technique provides a restoration with a minimum of tooth reduction while ensuring the prevention of future caries in other pits and fissures through sealant placement.[70]

Amalgam is the least expensive restorative material to purchase and insert. The new high copper amalgams are expected to last over 30 years. Questions have been raised in a few publications about the safety of amalgams because of their gradual release of mercury vapor. The media picked up this concern and exaggerated the problem with regard to both its severity and its frequency. Berglund[71] estimated that 1.7 μg of mercury vapor was inhaled from 12 amalgam fillings in a 24-hour period. He noted that the World Health Organization threshold limit value for mercury vapor in the workplace is 100 times greater than this amount.

Osborne[72] stated that allergies to amalgam has been reported in the literature infrequently but that it is speculative as to which component(s) of amalgam (mercury, silver, tin, or copper) is causative. Owing to their frequent handling of amalgam, dentists and their staffs are exposed to more mercury than any patient. Even though the profession urges great care in amalgam handling and ventilation of dental offices, guidelines that are followed by most dentists, dentists still accumulate a greater body burden of mercury than do nondentists. However, dentists have 21/2 years longer life expectancies than the population in general, including physicians. Dentists and their staffs do not have elevated levels of spontaneous abortions, and their children do not have a higher incidence of birth defects.[73]

SUMMARY AND RECOMMENDATIONS

Typical of all areas of the body, the mouth and each of its components require a nutritionally well-balanced diet containing adequate amounts of all essential nutrients throughout development and maintenance.

Attention must be drawn to one special requirement for the adequate development and maintenance of the teeth throughout their entire life histories, namely, a source of fluoride. The easiest and least expensive way to provide fluoride is through a communal water supply containing 1.0 ppm fluoride that is present naturally or is added in the local water

treatment plant. If, for any reason, water fluoridation is not possible, a proprietary source of fluoride in tablets or drops should be used. However, it is imperative that the diet should not be supplemented if the water already contains 0.6 ppm or more fluoride; an undesirable level of mottling is likely to occur with fluoride from two sources.

Söderling demonstrated that habitual use of xylitol chewing gum by mothers was associated with a statistically significant reduction in the probability of vertical transmission of mutans streptococci at age 2 years. Saliva sharing activities, such as tasting food before feeding and shared toothbrushes also contributes to the horizontal and vertical transmission. Clearly, efforts made to reduce the risk for early vertical and horizontal transmission of mutans streptococci translate into a decreased risk for dental caries in the child.[74]

Consumption of sticky snacks containing sugars should be kept to a minimum and be replaced whenever possible by such noncariogenic snacks as fresh fruits and vegetables, cheese, or nuts. Candy and gum sweetened with a xylitol are good substitutes for products sweetened with sugar.

Good oral hygiene habits need to be followed at least once a day using a small amount of fluoridated toothpaste. Use of a fluoride oral rinse or varnish is appropriate, especially when the child has a high degree of susceptibility and when there is a problem of reduced manual dexterity.

Visits to a dentist regularly are essential to detect and treat early lesions. Usually, every 6 months is sufficient, but when the child is especially susceptible, more frequent visits are important, as suggested by the dentist. Preventive procedures, such as topical fluoride applications to the tooth surfaces and the use of sealants to flow into and fill the susceptible pits and fissures on the occlusal surfaces of the posterior teeth, are to be encouraged.

Children who have special health care needs or have had radiation of the head or neck or chemotherapy may have a reduced salivary flow, which is probably the most serious deleterious influence on caries initiation and progression. Special attention to frequent and careful oral hygiene and frequent use of oral fluoride rinses are imperative.

Adolescent Eating Disorders

65

Kendrin R. Sonneville, RD, ScD and Alison E. Field, ScD

DEFINITIONS

There is confusion about the prevalence of eating disorders (EDs), with the general public believing they are common and many clinicians believing they are relatively rare. One reason for this discrepancy in perception is that the Diagnostic and Statistical Manual for Mental Disorder (DSM) versions IIIR and IV only recognized two EDs, anorexia nervosa and bulimia nervosa, which combined affect <5% of women, but many more people meet some, but not all, criteria of those disorders. In both treatment-seeking and general population samples, the majority of eating-disordered individuals do not meet the DSM cut-offs and are therefore categorized as having an eating disorder not otherwise specified (EDNOS). This is a large heterogeneous group in terms of their symptoms and treatment needs.[1–4] In the DSM-5, this group will be slightly smaller and less heterogeneous and will be renamed to other specified feeding and eating disorders (OSFEDs).

Anorexia nervosa (AN) is considered the most serious ED. It is characterized by having a very low weight, a distorted body perception, an intense fear of gaining weight despite being underweight, amenorrhea (females only), and usually a refusal to recognize the seriousness of their low weight. In adults, the low weight is the result of a large weight loss, but in children and adolescents who are expected to be growing, the low weight may present as failure to make adequate gains in weight. In the DSM-IIIR (1987–1993) and DSM IV (1994–2013), it was suggested that a

weight ≤85% of expected weight for age and gender would meet the weight criterion. Although 85% of expected weight was given as an example in the DSM-IV, it is widely used as an accepted cut-off. There have been many criticisms of the diagnostic criteria for anorexia nervosa. First, the weight cut-off is arbitrary. A nontrivial number of treatment-seeking cases do not meet the stringent weight criterion and therefore considered to have partial or atypical AN, a subtype of EDNOS. Moreover, since people lose weight, or for children fail to make adequate gains in weight, because of the eating-disordered cognitions and behaviors, individuals with shorter duration of illness may not (yet) have achieved the requisite weight criteria to meet the diagnostic criteria. To remedy this problem, the DSM-5 will have a less stringent weight criterion. It will require that an individual, relative to age-, gender-, and activity-level-specific needs, has limited his or her calorie intake sufficiently to result in a significantly low body weight. This change in diagnostic criteria will have several consequences. First, it will reduce the number of OSFED cases because some will now be classified as having AN. Second, it will capture a wider spectrum of anorexia cases for whom treatment may differ by severity of illness and duration of insufficient intake.

Another limitation of the diagnostic criteria for AN and other EDs is that they are not developmentally appropriate for children. Children and some adolescents have limited verbal skills and reasoning ability. Until children transition from concrete to abstract reasoning, concepts, such as denial of the seriousness of low body weight, are beyond their cognitive level. Therefore, some ED cases may fail to meet full diagnostic criteria because they do not appear to have the adult cognitive features of the disorder or they have difficulties understanding the criteria and reporting their feelings.[5] In addition, since the prefrontal cortex, the region of the brain involved in complex decision making, such as future consequences of a behavior and planning for achieving goals, does not finish maturing until young adulthood, it has been suggested that the cognitive criterion related to evaluation being heavily influenced by weight and shape and those related to denying the consequences of their behaviors and weight should not be require for a diagnosis in a child.[6]

Bulimia nervosa (BN) is the other recognized ED in DSM-IV. It is characterized by frequently engaging in overeating episodes during which the person feels out of control and they cannot stop eating. In addition, the person engages frequently in inappropriate compensatory behaviors to counteract the large caloric intake during the binges. The compensatory behaviors include self-induced vomiting, use of laxatives, diuretics,

enemas, and fasting. DSM-IV required that individuals engaged in both binge eating and the compensatory behaviors at least two times per week. In DSM-5, the frequency criteria will be reduced to at least once per week. Although AN and BN are the recognized disorders, more adolescents and young adults engage in only binge eating or purging. Those who only binge eat, but do not engage in compensatory behaviors, are considered to have binge eating disorder (BED). In DSM-IV, this has been a subgroup of EDNOS; in DSM-5, BED will be a third recognized ED. In contrast, individuals with purging disorder (PD) who purge but do not binge eat, will remain part of OSFED.

In recognition that AN and BN do not capture some of food avoidant behavior in children Avoidant Restrictive Food Intake Disorder (ARFID) will be another officially recognized condition in DSM-5. ARFID is more common among children, but DSM-5 will not restrict the diagnosis to children. People with ARFID will refuse to eat many foods due to characteristics of the food.

INCIDENCE AND PREVALENCE

The peak age of onset of AN and BN is during adolescence.[7,8] Some have reported a bimodal age of onset during adolescence,[7] others have reported only one mean or median age of onset. However, the exact distribution of age of onset has been difficult to study since it is a rare disorder and this requires a very large sample size to ascertain. In the National Survey Replication Survey sample of 9282 adults, median age of recalled onset of AN was 18 years, with an interquartile range of 16–22 years[9]; whereas, among the 21,425 adults in the European Study of the Epidemiology of Mental Disorders (ESEMeD) project, all cases of anorexia developed before 20 years of age.[7]

Among adolescent and young adult women in the United States, approximately 0.1%–1% have AN and 1%–3% have BN.[9,10] The prevalence of BED is higher; in population-based samples, the prevalence has ranged from 2.5% to 4.1% among females[11–14] and slightly lower among males.[9,15] Purging disorder has been much less studied, but among the 9000 girls in the Growing Up Today Study, 4.1% of the girls developed PD.[11] A slightly lower rate (3.4%) was observed in a smaller sample followed for 8 years.[13] The rates of EDs are thought to be much lower in males. Swanson et al. observed, among 10,123 adolescents, that BN and BED were three times more common among females than males,

but the prevalence of partial criteria BED was similar among females and males.[15] Among the 5527 adolescent and young adult males in the Growing Up Today Study, only 0.8% had partial or full criteria BN or PD, many more (2.9%) had partial or full criteria BED. Since the adolescence and young adulthood are the periods of highest incidence for BED, rates are lower in younger samples. Among adults, BED is the most common ED, and the lifetime prevalence of partial or full BED is similar for males (3.9%) and females (4.1%).[9]

CLINICAL ASSESSMENT

Although many ED screening questionnaires are available, the SCOFF questionnaire (Table 65-1) is a popular, brief screening tool among health professionals, which demonstrates good validity compared to clinical interview.[16] Once an D has been diagnosed, a careful history and physical examination can reveal much information about the chronicity of an adolescent's illness, abnormal eating behaviors, and potential strategies for management. A clinician can start the history-taking session by asking the parent and the adolescent individually why he or she is being seen. This information can be most helpful in revealing hidden agendas or different perceptions of parents and their teenagers. Confidentiality should be established immediately, with the explicitly stated caveat that the provider will break confidentiality if the situation is life-threatening or extremely dangerous. In addition to the physical exam conducted by a medical provider, a teen should be assessed by a mental health provider and should meet with a registered dietitian for a thorough nutrition assessment. The nutrition assessment will have different components depending on the stage of illness and the treatment setting.[17] A full nutrition assessment reveals current dietary intake, present eating patterns, history related to foods, nutrient deficiencies, supplement use, risk of refeeding syndrome, beliefs about food, binge purge patterns, and physical activity patterns.[17]

TABLE 65-1 The "SCOFF" Questions[16]

S	Do you make yourself SICK (vomit) because you feel uncomfortably full?
C	Do you worry that you have lost CONTROL over how much you eat?
O	Have you recently lost more than ONE stone (15 pounds) in a three-month period?
F	Do you believe yourself to be FAT when others say you are thin?
F	Would you say that FOOD dominates your life?

Letting patients tell their story provides an in-depth and personal picture of the ED. Ideally, the parent and the adolescent each should be given time alone with the provider to promote a sense of individualized caring and listening to each one's needs. In general, the younger a child, the more the registered dietitian (RD) will rely on parental report.[17] Parents will provide information about their child such as eating history, typical food intake, weight history, temperament, and behavior changes.[17] In children and adolescents, it is important to find out about family meals, who buys and prepares food and who will be providing care to the young person with an ED.[17] Weight history and lifetime growth charts can provide information for estimation of goal weight, while inquiring about the frequency of weight monitoring, desired weight, and body checking can help assess fear of weight gain and body image concerns.[17] Information about typical meal patterns and food rules and rituals such as counting calories, focusing on numbers, rigid food patterns, dietary extremes, or missing food groups should be collected during the nutrition assessment.[17] A review of purging behaviors should be conducted and should involve asking about amount, frequency, and type, including self-induced vomiting, laxative use, use of enemas, suppositories, diuretics, and diet pills.[17] Physical activity routines including type of activity, sessions per week, intensity, and duration of exercise should be assessed in addition to information about compulsive exercise.[17] Macro and micronutrient deficiencies are evaluated by dietary intake, diet history, physical signs and symptoms, and laboratory values.[17] Initial laboratory assessment typically includes complete blood count, comprehensive serum metabolic profile, electrolytes, liver function, and thyroid function texts.[17] Reduced sodium levels may result from water loading, water intoxication, and excessive fluid loss due to vomiting, diarrhea, sweating, while hypernatremia may be seen with dehydration and insufficient water intake.[17] The most common cause of low potassium is gastrointestinal loss due to purging behaviors, while dehydration from water withholding may elevate potassium.[17] Low bicarbonate levels are seen with laxative use, while elevated bicarbonate level is seen with vomiting.[17] Although most laboratory results will be normal in patients with EDs, normal laboratory results do not exclude serious illness or medial instability.

MEDICAL FINDINGS AND COMPLICATIONS

No organ system is spared the effects of EDs, weight-control behavior, and

malnutrition.[18] As such, the medical complications (Table 65-2) can be serious or even life-threatening, thereby warranting a comprehensive history and a comprehensive physical examination.[18] Physical exam findings in some adolescents with EDs are shown in Table 65-3. Physiological signs of EDs include marked weight changes, absence of expected weight gain, or growth delay in children or adolescents, low bone mineral density, and weakness, fatigue, or lethargy.[17] Cardiovascular signs and symptoms include low pulse; low blood pressure; orthostasis with blood pressure and/or pulse changes; and poor peripheral perfusion characterized by cold extremities, delayed capillary refill, and acrocyanosis.[17,19] Gastrointestinal complaints include abdominal pain, postprandial fullness, and bloating related to delayed gastric emptying, constipation, and gastroesophageal reflux.[17,19] Endocrine dysfunction may include hypothyroidism, hypercortisolism, and disturbances of the hypothalamic–pituitary–adrenal axis, which may result in hypogonadism, loss of menstrual cycle, or delayed menarche.[17,19] Hair and nail changes are seen in EDs and include dry skin, brittle nails, hair loss, and lanugo (white downy hair).[17,19] Neuropsychiatric symptoms include poor concentration, memory loss, insomnia, depression, anxiety, and over concern with weigh/shape.[17]

Medical stabilization and nutritional rehabilitation are the most important determinants of short-term outcomes and are essential for correcting cognitive deficits to allow for effective mental health interventions.[19] Most of the medical complications of EDs resolve with refeeding and/or resolution of purging; however, there is increasing concern that some complications, particularly growth retardation, structural brain changes, and low bone density, may become irreversible over time.[17]

REFEEDING SYNDOME

Refeeding syndrome is a potentially life-threatening cluster of metabolic events that occur when feeding is initiated in the starved catabolic individual. Patients at risk for refeeding syndrome include those with AN, any child with prolonged under-nutrition over weeks and months, and individuals with a rapid and significant weight loss prior to hospital admission regardless of current weight. The starved catabolic individual has low body stores of phosphate, thiamin, and potassium, which are needed to synthesize metabolic intermediates, particularly of carbohydrate

metabolism. In uncomplicated starvation, however, laboratory values may be normal and then change once feeding begins.[17] The start of aggressive refeeding shifts serum electrolytes into the intracellular compartments, which drops serum levels. Biochemical findings in refeeding syndrome include hypophosphatemia, hypomagnesemia, hypokalemia, glucose intolerance, fluid overload, and thiamin deficiency. To avoid complications of refeeding syndrome, feed very conservatively at the beginning of refeeding.[17] Initiating replacement therapy for electrolytes and fluids prior to refeeding and monitoring electrolytes (K, P, Ca, Mg) frequently at the beginning of refeeding is also recommended.[17]

TABLE 65-2 Medical Complications and Consequences of EDs

General	Dehydration Hypokalemia Hypomagnesemia Hyponatremia Irreversible cardiomyopathy and myositis (ipecac toxicity) Amenorrhea and menstrual irregularities Low bone mineral density; osteoporosis Cognitive deficits Mood symptoms Obsessive/compulsive symptoms Suicide
Caloric restriction and weight loss-related	Inability to maintain body temperature Prolonged corrected QT interval or increased QT dispersion (uncommon but may predispose patient to sudden death) Dysrhythmias (including supraventricular beats and ventricular tachycardia, with or without exercise) Other electrocardiographic abnormalities Mitral valve prolapse Pericardial effusions Delayed gastric emptying and impaired gastrointestinal tract motility Constipation Bloating; postprandial fullness Hypoglycemia Hypercholesterolemia Abnormal liver function test results Sterile pyuria Anemia, leukopenia; thrombocytopenia Sick-euthyroid syndrome Growth retardation Cortical atrophy
Vomiting-related	Hypochloremic metabolic alkalosis (vomiting)

	Esophagitis Gastroesophageal reflux Dental erosions Mallory–Weiss tears Esophageal or gastric rupture (rare) Aspiration pneumonia (rare)
Laxative-related	Hyperchloremic metabolic acidosis (laxative abuse) Hyperuricemia Hypocalcemia Fluid retention (may gain up to 10 lb in 24 h) with laxative withdrawal
Binge eating-related	Weight-related hypertension Abnormal lipid profile Diabetes
Refeeding-related	Diaphoresis and night sweats Polyuria and nocturia Peripheral edema Refeeding syndrome

TABLE 65-3 Physical Exam Findings Seen in Some Patients with EDs

Sinus bradycardia; other cardiac arrhythmias
Orthostatic changes in pulse (>20 beats per min) or blood pressure (>10 mm Hg)
Hypothermia
Cachexia; facial wasting
Cardiac murmur (one-third with mitral valve prolapse)
Dull, thinning scalp hair
Sialoadenitis (parotitis most frequently reported)
Angular stomatitis; palatal scratches; oral ulcerations; dental enamel erosions
Dry, sallow skin; lanugo
Bruising/abrasions over the spine related to excessive exercise
Delayed or interrupted pubertal development
Atrophic breasts; atrophic vaginitis (postpubertal)
Russell sign (callous on knuckles from self-induced emesis)
Cold extremities; acrocyanosis; poor perfusion
Carotenemia (orange discoloration of the skin, particularly palms and soles)
Edema of the extremities
Flat or anxious affect
Parotid gland swelling

Treatment

The goals of ED treatment are numerous (Table 65-4). As such, ED treatment requires a collaborative approach by a multidisciplinary team of mental health, nutrition, and medical specialists.[17] Best treatment practices

in general for AN and BN include early detection, early and aggressive intervention, and early return to physical stability. Normalization of attitudes and eating behaviors usually follows physical restoration, but this aspect of recovery can take years and clinicians vary in terms of what they define as full recovery from EDs.[17]

Various levels of care for EDs are available including outpatient, intensive outpatient, partial hospitalization, inpatient hospitalization, and residential treatment, although most adolescents with EDs will be managed in an outpatient setting. Family-based treatment (FBT), often referred to as the "Maudsley method," is emerging as the outpatient treatment of choice for adolescent AN and BN. FBT for adolescent AN and BN is a short-term treatment designed to mobilize parents in assisting their ill child reverse his/her state of starvation (AN), eliminate eating-disordered behaviors such as eating and purging episodes (BN), reestablish healthy eating patterns, and ultimately achieve remission.[20] FBT consists of three phases, the first of which involves parents taking charge of their ill child's eating. Control over eating is returned to the adolescent in the second phase and the final phase addresses issues of family structure and normal adolescent development.[20] FBT is gaining scientific acceptance in light of its demonstrated efficacy to date.[20] A small number of studies have demonstrated that FBT for AN is effective for weight restoration thereby preventing hospitalization in the short term[21–23] and that gains are maintained four to five years after treatment ends.[24–26] FBT for BN has been shown to be superior to supportive psychotherapy for binge/purge abstinence in one study.[27] While outpatient treatment for BED among adolescent remains understudied, both cognitive behavioral therapy and interpersonal psychotherapy (IPT) appear to be promising psychological treatments for BED.[28]

Hospitalization of an adolescent with an ED is necessary in the presence of severe malnutrition, physiologic instability, severe mental health disturbance, or failure of outpatient treatment.[18] Medical decisions regarding stability in AN cases are based on pulse, blood pressure, body temperature, orthostatic changes, electrolyte imbalance, refusal to eat, lack of progress in the outpatient setting, percent of weight lost and percent body fat and cardiac arrhythmias.[17] With BN, different criteria for medical stability are taken into consideration and include syncope, serum electrolyte concentrations, esophageal tears, hematemesis, body temperature, suicide risk, cardiac arrhythmias, and also failure to progress in outpatient treatment.[17]

Long-term Consequences

Health effects of EDs are often immediate, but some may persist well beyond ED remission (Table 65-2). While little is known about the long-term consequences of BED and PD since they have been less studied, more is known about the myriad of health consequences of AN. The peak age of onset of AN corresponds to a time of intense physical, psychosocial, and cognitive development in adolescence and overlaps with the pubertal growth spurt during which adolescents acquire up to 50% of adult weight, more than 20% of adult height, and 50% of adult skeletal mass.[29] Adolescence is also a critical window for bone development, approximately 40%–60% of the maximum adult bone mineral density is acquired between 11 and 18 years of age.[30,31] The severe caloric restriction among people with AN causes increases in bone resorption and decreases in bone formation. Not only do adolescents with AN have low estrogen levels but also they have high cortisol, both of which adversely impact bone mineral density. As a result, adolescents with AN are at increased risk of osteopenia, which is defined as being two standard deviations below the mean for bone mineral density, and the loss in density may not be completely reversible. This loss makes them up to seven times more likely to sustain a fracture.[32] Adolescent females who recover by mid-adolescents may partially recover for the loss,[33] but adolescent-onset cases who recover after peak bone mineral density has been achieved, appear to have a permanent decrease in bone mineral density.[33,34] However, there are cases that onset in adulthood have less bone loss than those with onset during adolescence, a critical window for bone development.

Young female athletes who have amenorrhea, engage in eating-disordered behaviors or have an ED, and have osteopenia is a group at particularly high risk of fracture. This constellation of symptoms is known as the female athlete triad. Although physical activity can promote bone formation, when activity volume becomes very high, weight loss and oligomenorehea or amenorrhea may develop. Thus, at high levels, activity is associated with a hypoestrogenic state, hypothalamic dysfunction, and osteopenia and fractures, particularly stress fractures. Moreover, among children and young adolescents, high levels of activity and AN can both interrupt or delay puberty, and thus decrease bone density and cause stunting. Although some studies have found that girls with BN or subthreshold EDs are at increased risk of low bone mass density, the results have not been consistent.

TABLE 65-4 Goals of ED Treatment	
Treatment goal	Treatment components
1. Restore patients to a healthy body weight, if necessary 2. Eliminate disordered behaviors including restricting, bingeing, purging, and compulsive exercise 3. Improve self-esteem and body image 4. Correct dysfunctional thoughts and beliefs related to food and weight 5. Learn new coping skills 6. Develop healthy, flexible eating habits 7. Stabilize accompanying symptoms and medical conditions of the ED	Outpatient treatment (individualized meal planning and nutrition counseling + medical monitoring + psychotherapy) or family-based treatment or non-outpatient supervised refeeding (partial hospitalization, inpatient hospitalization, or residential program) Multidisciplinary outpatient treatment (psychotherapy + nutrition counseling + medical monitoring ± family therapy) Medical monitoring

Although estrogen may have an independent effect on bone mass in adolescents, hormonal replacement therapy alone is inadequate without weight gain to overcome the detrimental effect of low weight for height on bone density.[35] Weight gain and resumption of menses appears to be the best means of increasing peak bone mass in teens with EDs.[35]

CONCLUSION

EDs, including AN, BN, and BED, and related subthreshold conditions are complex illnesses that often begin in adolescence. EDs are accompanied by myriad complications and consequences that affect almost every organ system of the body. ED treatment should include a collaborative, multidisciplinary team and is most effective when initiated early in the course of illness. Because EDs are prevalent and difficult to treat, effort should be dedicated to prevention and early detection.

Adolescence: Advancing Bone Health

66

Keith J. Loud, MDCM, MSc and Catherine M. Gordon, MD, MSc

Adolescence is a critical period for lifetime bone health. Evidence has accumulated that an individual's peak bone mass (PBM), which is the strongest predictor of his or her future risk of osteoporosis, is reached by early adulthood. At least half of all adults' mineralized calcium is laid down during the adolescent years, with the most rapid bone accretion occurring in late childhood and early adolescence.[1,2] Any condition that impairs this process may create a deficit in bone mass that will have permanent ramifications for future risk of osteoporosis, which afflicts over 10 million Americans[3] and results in more than $22 billion in direct medical expenditures in 2008.[4]

Many disease states, each related to nutritional deficits, can inhibit bone accretion during adolescence, including rickets, eating disorders, the "female athlete triad," inflammatory bowel disease (IBD), celiac disease, cystic fibrosis, cancer, and other multisystem or inflammatory disorders. In this chapter, these conditions are discussed in detail. Adolescent behavior itself may also prevent maximal PBM attainment, as the dietary habits of many teenagers do not lead to optimization of calcium and vitamin D intake.

Normal Bone Physiology and Development

Bones are the fundamental units of the skeletal system, providing an adaptable framework that supports and protects the major organ systems of the body while allowing for locomotion. Because of its role in calcium and

phosphate homeostasis, bone can also be considered an organ system. The skeletal system is the reservoir for the calcium used in essential mechanisms ranging from the regulation of cardiac electrical activity, contraction of muscles, and varied inter- and intracellular messaging systems. Each bone, housing lymphoid and myeloid precursor cells within the marrow, is also an organ unto itself. Finally, these organs are composed of a unique tissue substance that is called "bone."[5]

Types of Bone

Bone as a tissue takes on two forms in normal health: cortical (dense) and trabecular (cancellous or spongy) bone.[5] Cortical bone, which makes up 80% skeletal bone mass, is found in the diaphysis (shaft) of long bones such as the femur, as well as the "walls" of almost all other bones, including the vertebrae. It provides strength against tensile, torsional, and shear forces. The remaining 20% bone mass consists of trabecular bone, found in the metaphyses (ends) of long bones and the entire bodies of the vertebrae. It is well suited to resist compressive forces. Because of its high surface area-to-volume ratio, trabecular bone occupies greater than 20% volume of the skeletal system and has approximately eight times the metabolic activity of cortical bone.[5] Because of its higher metabolic availability, trabecular bone is more significantly affected by disease states.

Histology: The Building Blocks of Bone

Regardless of its structure or ultrastructure, on a microscopic level bone consists of thin layers, or lamellae, of a mineralized protein matrix. This mature lamellar bone is 70% (by dry weight) mineral, predominantly calcium and phosphate in the form of hydroxyapatite crystals [$Ca_{10}(PO_4)_6(OH)_2$] and a less pure, carbonate-rich analogue called bone apatite, which is more soluble and thus more available for metabolic activity.[5] The remaining 30% mass is an organic substance called osteoid, primarily protein in the form of type I collagen. Cellular elements, which produce all of the metabolic activity of bone, make up only 2% of the osteoid.

Osteoblasts are bone-forming cells derived from fixed-tissue osteoprogenitor cells.[6] Osteoblasts synthesize osteoid on the surface of already mature lamellar bone, periosteum, or endosteum. They then regulate the process of mineralization of the collagen matrix through the actions of bone-specific alkaline phosphatase (BSAP), which is different

than the alkaline phosphatase produced in the liver and can be distinguished from it by specific assays.

Once the osteoid matrix has mineralized, it is considered bone. The osteoblasts, which are synchronized in such a way as to create the parallel lamellae, become trapped inside small caverns called lacunae and mature into osteocytes that communicate via long processes with each other to direct mineral homeostasis.

Osteoclasts are multinucleated cells from the marrow monocyte–macrophage cell line.[7] By producing lysosomal enzymes such as acid phosphatase, osteoclasts break down the mineralized bone matrix, mobilizing calcium and phosphorus for participation in homeostasis, in a process called bone resorption.

Growth and Remodeling: The Bone Cycle

Bone is a dynamic tissue. Growth in long bones occurs at the physes (growth plates) and apophyses (secondary centers of ossification) by a process known as enchondral ossification in which osteoblasts lay down bone on a cartilaginous framework that is ultimately resorbed by osteoclasts. Even after skeletal maturity, osteoblasts respond to structural stresses in bone by laying down new matrix. Osteoclasts concomitantly resorb areas of bone under less stress. Thus, bone is constantly remodeling. Newly identified factors, which comprise the Wnt/Lrp5 signaling and BMP pathways, among others, are responsible for the "cross-talk" that occurs between osteoblasts and osteoclasts.[8] During times of growth, bone formation by osteoblasts is greater than resorption by osteoclasts. With disuse, osteoclasts outpace osteoblasts and bone mass decreases. Otherwise, osteoblasts and osteoclasts are tightly "coupled" to keep formation and resorption equally balanced in what is known as "the bone cycle."[6,7]

Importance of Adolescence

Bones grow at different rates throughout the skeleton. The extremities (appendicular skeleton) have largely completed growth by the time of the pubertal growth spurt (peak height velocity [PHV]). Increases in estrogen and testosterone during puberty result in growth of the trunk and spine (axial skeleton). These increases in vertebral bone size are accompanied by dramatic increases in bone mineral density (BMD) in cross-sectional[9,10] and longitudinal studies.[11] This trabecular bone reaches its peak BMD by age 20–30 years, but steadily declines thereafter.[12] Alarmingly, one animal

model showed that calcium restriction in adolescence resulted in a decreased bone volume throughout life, even after restoration to recommended calcium intake in young adulthood.[13] Adolescence is an essential time for significant bone accretion. Over half of adult bone calcium is laid down during the teenage years.[1] Maximal rates of bone mineral accretion follow PHV by 6–12 months.[14] As a consequence, at the time of PHV (Tanner pubertal stage II–III in girls, Tanner III–IV in boys), teenagers have reached approximately 90% of their adult height but they have acquired only 60% of their adult total body mineral content, resulting in relatively less mineralized bone.[14] In North America, these pubertal stages are reached by age 11–14 in girls and 13–17 in boys. Classic studies by Thientz et al.[2] are consistent, showing that girls' BMD may plateau by age 16 (or 2 years post menarche) and boys' by age 20. This is a much earlier window of opportunity than was previously suspected. In fact, 95%–100% PBM may be attained by the end of adolescence.[11,15]

Maximizing Bone Health

Nonnutritional Factors

Intrinsic Factors: Genetics

Intrinsic factors dominate the determination of bone density. Males have a higher bone mass than females at nearly all ages (Figure 66-1).[11,16] African–American children demonstrate an approximately 10% higher BMD by dual-energy X-ray absorptiometry (DXA) than do children of other ethnicities,[11,16] even after correcting for bone size.[15] A large cohort study in the United States showed that these differences contribute to a doubling in fracture risk among children of Caucasian European descent when compared with their peers.[17] An interesting finding among African–American and Caucasian girls was that their spinal BMD was similar until puberty, at which point the African–American girls had an increase of 34% while the Caucasian girls improved only 11%.[18] Family history of osteoporosis in postmenopausal women predicts lower BMD for their daughters,[19] and both elderly men and women have an increased risk of osteoporosis when other family members have been affected.[20] In all, 60%–80% variance in PBM is attributed to heritable factors.[12] Polymorphisms in the genes encoding receptors for vitamin D, estrogen, type I collagen,[21] insulin-like growth factor I (IGF-I), transforming growth

factor beta (TGF-β), and interleukin 6 (IL-6) are under ongoing study,[22] but none have been able, singly or in combination, to account for more than a small percentage of this variance in PBM.

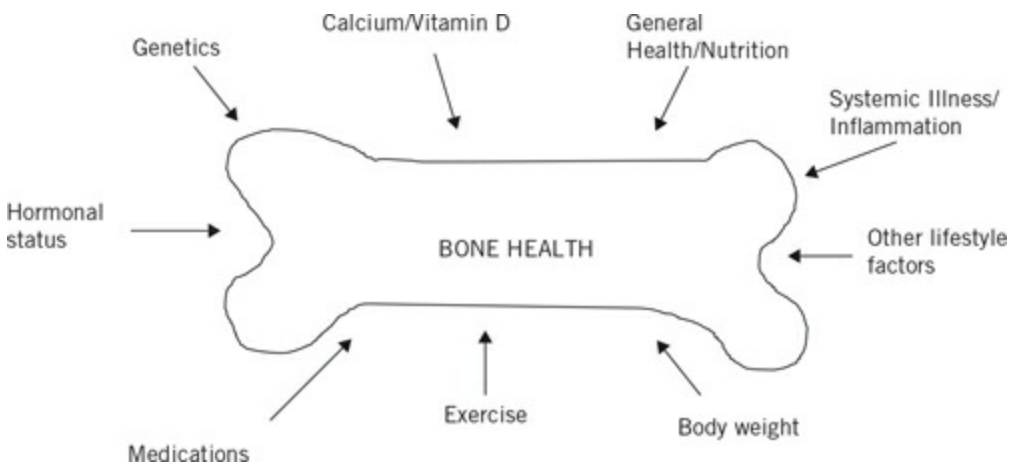

Figure 66-1 Factors affecting bone health. (Reproduced with permission from Loud KJ and Gordon CM.[194])

Hormonal Status

A balanced hormonal milieu is essential to attain and maintain normal bone formation. Early menarche and regular menses are strong predictors of increased bone mass in women,[23] demonstrating the importance of estrogen.[24] Among adolescent girls, an estimate of estrogen exposure was positively correlated with spine BMD.[12] Estrogen deficiency may also slow growth in axial bone size[25–27] when it occurs during adolescence, a time when truncal growth typically accelerates.

Androgens exert independent and positive effects on PBM.[28] Although men with a history of delayed puberty and documented low serum androgen levels have been shown to have decreased BMD, a meta-analysis of randomized, placebo-controlled clinical trials of testosterone use in men showed only a modest improvement in lumbar spine BMD and inconclusive results at the femoral neck.[29] Nonetheless, androgen replacement therapy to teenage boys may provide skeletal benefits during the formative adolescent years.[30] Patients with androgen insensitivity have a mutation in the androgen receptor, with consequent impaired androgen action, such that there is resistance to even elevated androgen levels. Previous reports have shown that affected individuals have decreased bone

mineralization.[31–33] Even after administration of estrogen replacement therapy in these individuals, BMD did not significantly increase, again highlighting the importance of androgens in bone physiology.[31] Women with androgen excess also have been shown to have a higher BMD.[34,35]

Children and adults with childhood-onset growth hormone (GH) deficiency have lower BMD than controls.[36,37] Although patients on adequate replacement doses of GH have increased BMD compared to GH-deficient patients,[38] those adolescents who discontinued the medication at the completion of linear growth demonstrated decreased spine and hip BMD in long-term follow-up, suggesting that bone mineral accretion continues beyond completion of linear growth.[39] The actions of GH are likely mediated by IGF-I, an anabolic factor that stimulates osteoblast function directly.

Exercise

Patients with impaired activity due to central nervous system or neuromuscular disease develop disuse osteoporosis.[40] It is well established that individuals engaged more intensely in weight-bearing activities have higher measured BMD than less active controls.[41] Even among women with amenorrhea and adolescents with anorexia nervosa (AN), those who are more athletic have higher bone density.[42,43] Unfortunately, swimmers do not consistently reap this benefit, as their activity is largely weightless, highlighting the importance of weight-bearing activities.[44] The increases in BMD are site specific; for example, runners and ballet dancers have higher proximal femur (hip) BMD than controls, whereas gymnasts have higher measured radial (arm) BMD.[45] Elite men and women rowers have also been shown to have a higher spinal bone density.[46] Although not all intervention studies have replicated these findings, and the specifics of optimal frequency, intensity, and duration remain elusive, most clinical trials of physical activity demonstrate a positive association between exercise and the bone health of children, adolescents, and adults.[47,48]

Chronic Illness and Systemic Inflammation

Many of the medical conditions associated with impaired bone density are listed in Table 66-1. Some of these diagnoses are associated with malnutrition, with concomitant decreases in BMI and absorption of important nutrients that are described in detail later in this chapter, in the sections on celiac disease, inflammatory bowel disease, and cystic fibrosis. Many are additionally marked by systemic inflammation, which is

increasingly known to result independently in decreased BMD. For example, the magnitude of glucocorticoid use is the single greatest predictor of low bone mass in patients with both ulcerative colitis (UC) and Crohn's disease (CD).[49] Glucocorticoids directly decrease bone formation by inhibiting osteoblast activity. Indirectly, these agents also decrease the secretion of estrogen and testosterone, which are necessary for bone accretion, as well as decrease the absorption of calcium in the gut and reabsorption of calcium in the kidneys.

These adverse effects of glucocorticoids are a concern for other patients with systemic steroid–dependent diseases such as idiopathic juvenile arthritis (IJA; formerly juvenile rheumatic arthritis), childhood leukemia, collagen vascular and connective tissue diseases, and solid organ transplant recipients. One study has shown a dose-related loss of BMD at the hip in premenopausal adult women using inhaled glucocorticoids for treatment of their asthma.[50] Although there is a similar concern for children and adolescents, it is largely speculative. Reassuring evidence comes from a study of steroid-responsive nephrotic syndrome in children and adolescents, which showed that decreased BMD is not correlated with steroid dosage but with underlying disease severity, for which steroid use is merely a marker. Body mass was also shown to be protective of BMD in that study.[51]

Other autoimmune-mediated diseases, allergic conditions, and even chronic infection have been associated with decreased regional and total body bone density, further implicating systemic inflammation as a cause of bone loss.[52] The proinflammatory cytokines IL-1α, IL-1β, IL-6, IL-11, IL-17, tumor necrosis factor (TNF)-α and TNF-β, TGF-α, EGF, and prostaglandin E_2 all activate osteoclastic resorption of bone.[52] TNF-α and IL-1β also decrease osteoblastic bone formation while stimulating the osteoblasts to secrete IL-6, further activating the osteoclasts.[52]

Basic experiments have continued to elucidate the final common pathways of the signaling cascade that modulates the coupling of the bone remodeling cycle. Of particular interest is the osteoblast surface ligand called the receptor activator of nuclear factor kappa B ligand, or RANKL. When binding to the osteoclast precursor, RANK is predominant and osteoclast differentiation and maturation is favored, leading to increased bone resorption. Osteoprotegerin (OPG) blocks the RANK–RANKL interaction, thus shifting the balance in favor of bone formation.[6] The observation that RANKL also regulates early lymphocyte development and some T-cell interactions[6] further links bone remodeling with the

activity of the immune system.

Nutritional Influences

General Fitness and Macronutrients

In addition to participating in weight-bearing exercise, individuals must maintain appropriate weight. At most weights, there is a direct relationship between body mass index (BMI) and BMD, with underweight individuals at increased risk for lower BMD.[53] Adolescent girls with low weight due to AN have decreased BMD, as is discussed below. Excessive BMI may also have a deleterious effect on BMD. Work by Goulding et al. has suggested that overweight boys and girls are fracture prone,[54] and have bone mass and bone area that are increased for their age, but not appropriately relative to their total body weight.[55] An anthropometric study of normal weight, overweight, and obese female adolescents demonstrated no difference in measures of bone mineral content and density when controlling for lean body mass, suggesting a deleterious effect of increased adiposity on the skeletal development of overweight children and adolescents.[55,56] Clinical investigations linking visceral, rather than subcutaneous, adipose tissue to low bone mass in obese adolescent girls have begun to implicate adipokines (adiponectin, leptin) and proinflammatory cytokines (as mentioned above) in the pathophysiology.[57] These adipokines also appear to be at play in the mediation of bone loss in amenorrheic women athletes and adolescent girls with AN.[58]

TABLE 66-1 Conditions Predisposing to Osteoporosis in Children and Adolescents

Chronic illnesses mechanisms = malnutrition, pro-inflammatory and antiresorptive cytokines, endocrinopathies, medication effects, decreased activity	Inflammatory bowel disease (IBD) (Crohn's disease, ulcerative colitis) Celiac disease Asthma Chronic renal failure Cystic fibrosis (CF) Connective tissue diseases Cancer Idiopathic juvenile arthritis (IJA) Other chronic illnesses
Organ transplantation mechanisms = malnutrition,	Bone marrow

cytokines, immunosuppression, endocrinopathies, medication effects, decreased activity	Heart Lung Kidney Pancreas Liver
Endocrine abnormalities	Genetic sex hormone deficiency Turner syndrome Acquired sex hormone deficiency Anorexia nervosa Exercise-induced amenorrhea Primary ovarian insufficiency Irradiation, chemotherapy Other endocrine abnormalities Cushing syndrome Hyperparathyroidism Hyperthyroidism Growth hormone deficiency Hyperprolactinemia Diabetes mellitus (type 1 and 2)
Medications	Glucocorticoids Anticonvulsants Cyclosporine A Lithium GnRH agonists Heparin Methotrexate
Family history	Osteoporosis Frequent fractures
Female athlete triad definition = interrelations of energy availability, menstrual function, and bone density	Any female athlete, but particularly those in activities that emphasize lean physique
Prolonged immobilization	Cerebral palsy and other neurologic conditions Postoperative immobilization

The macronutrients carbohydrate, fat, and protein are essential building blocks for growth and attainment of appropriate BMI to maximize BMD. These nutrients also provide energy for the muscle contractions that mechanically load bone, thereby stimulating bone formation. In addition, lipids are substrates for the synthesis of prostaglandins, which are cytokines that may play an essential role in regulating bone metabolism.[59]

Proteins are particularly important as the fundamental elements of muscle tissue, as well as the predominant components of osteoid, the unmineralized precursor of bone. In one study, protein intake and bone mass gains were positively correlated in children, possibly mediated by IGF-I production.[60] Although small, poorly controlled additional studies[61] cite the importance of increased macronutrient intake to bone health, most larger scale research focuses on the effects of calcium and vitamin D.

Other nutrients with putative, but less well studied, influences on bone density include magnesium, phosphorus, copper, manganese, zinc, and vitamins C and K (see Appendix II for Recommended Daily Allowances [RDA] of these nutrients). Approximately 60% body's magnesium and 85% phosphorus is in bone. Magnesium may decrease the brittleness of bone by modulating the size of hydroxyapatite crystals. The other minerals and vitamins are important cofactors in the synthesis, folding, and cross-linking of the proteins found in bone, including collagen, elastin, and osteocalcin.[59] A small study of British female endurance athletes showed a significant positive correlation between lumbar spine BMD and dietary magnesium and zinc intake.[62]

Calcium

As described above, bone is a calcified tissue that derives its compressive strength from its calcium phosphate crystal structure, and in turn serves as the body's vast reservoir of calcium. Enormous gains are made in total skeletal calcium over childhood and adolescent development, from approximately 25 g at birth to 900 g (women) to 1200 g (men) at skeletal maturity.[14] It follows that calcium is an essential nutrient for skeletal as well as general health. Dairy products are an important source of dietary calcium, providing approximately 75% calcium in a typical North American diet.[59,63] Epidemiologic data suggest that osteoporosis is more prevalent in regions where dairy intake is low[64] and that milk consumption in childhood and adolescence correlates with postmenopausal BMD.[65]

Although dietary calcium intake would therefore be a seemingly obvious factor promoting increased BMD, the literature is inconsistent. In growing children, the influence of calcium availability on gains in bone density has been demonstrated. Dietary calcium is one of the most significant predictors of bone mass in cross-sectional studies of children and adolescents.[66–68] Controlled supplementation trials in healthy children and adolescents,[69–73] including twin studies,[74,75] have generally shown increased gains in BMD in at least some subgroups of those supplemented

with calcium, milk extract, or dairy products.[76] However, the response to calcium varied among studies with respect to skeletal site, pretreatment calcium consumption, pubertal stage, and genetic factors.[77] There is also uncertainty in how well the gains are maintained after supplementation is discontinued, as only one of the studies demonstrated persistence of the increase more than one year.[78] Similarly, women consuming greater than 1000 mg calcium daily made no significant gains in their BMD if they did not concomitantly increase their activity patterns,[79] suggesting an interesting synergy between calcium intake and exercise that represents an area of active research. This is an area of much scrutiny,[77] but expert panels have recently reaffirmed the recommended daily intake of 1300 mg elemental calcium for adolescents (see Table 66-2).[63,80]

There has been recent controversy regarding potential adverse cardiovascular side effects of calcium supplementation in the elderly that has raised questions about its safety among youth. Specifically, reports have suggested that daily calcium supplementation of 500 mg or above is associated with increased risk of stroke and myocardial infarction, while others refute this claim.[81–83] Of note, no data currently exist to substantiate concerns about adverse side effects in children and adolescents, but the adult data have generated concern among patients and their families. Promoting adequate dietary calcium remains the primary recommendation with use of supplemental calcium reserved for known lactose intolerance or in the setting of documented vitamin D deficiency.

Vitamin D

The active form of vitamin D, 1,25-dihydroxyvitamin D [1,25(OH)2D], is necessary for normal mineralization of bone. In addition to being absorbed through the gut, Vitamin D is also synthesized endogenously in the skin under the influence of ultraviolet sunlight. It is converted to 25-hydroxyvitamin D [25(OH)D] in the liver and then to 1,25(OH)2D in the kidney. Activated 1,25(OH)2D facilitates absorption of calcium and phosphate from the duodenum and jejunum, as well as reabsorption of calcium from the renal tubules. At high levels in the serum, it can stimulate osteoclasts to resorb bone, but this action is mediated via receptors on osteoblasts.[84]

The effects of calcium and vitamin D are difficult to separate. When calcium intake is sufficient, non-vitamin D-dependent passive absorption predominates. However, in the face of low calcium intake, vitamin D-dependent active transport becomes the major route for calcium

absorption. Thus, the effect of vitamin D deficiency on calcium bioavailability is critical when it coexists in the setting of low dietary calcium intake.[85,86] Fortunately, such a deficit can be easily treated, and the incidence of fractures possibly decreased,[87] with combined vitamin D and calcium supplementation.[88]

Vitamin D deficiency has been clearly linked to fractures in postmenopausal and osteoporotic women, and is a common problem across the age spectrum.[84,89–93] Plasma 25(OH)D levels, the most sensitive clinical index of vitamin D status, are positively correlated with BMD in middle-aged and elderly women.[90] Seasonal variation of vitamin D metabolites, with high summer/fall and low winter values, has been established in adults and is generally more pronounced in northern latitudes, where there is reduced cutaneous production of vitamin D for up to six months of the year.[91–97] Some,[98–101] but not all,[102] studies have indicated a similar seasonal difference in BMD. In postmenopausal women with low intakes of vitamin D, BMD significantly decreases in winter, which can be prevented by vitamin D supplementation.[101]

In a study of hospitalized adults, Thomas et al. reported that 57% men and women screened were vitamin D-deficient on serum testing.[103] Research in Scandinavia has shown that the dietary intake of vitamin D in children, even when combined with vitamin stores from the summer months, is not sufficient to sustain healthy vitamin D levels during the winter.[104,105] The prevalence of vitamin D insufficiency among otherwise healthy American adolescents has been demonstrated to be as high as 42%, with prevalence highest among African–American teens and during the winter months.[89] Other studies have replicated the findings of a high prevalence of vitamin D deficiency among teenagers.[106,107] A concern is that the occurrence of vitamin D deficiency during this important developmental period results in an increased bone remodeling rate, which could impair bone density achievement during skeletal growth.[108]

TABLE 66-2 Dietary Reference Intakes/Recommended Daily Allowance of Calcium and Vitamin D

	Calcium			Vitamin D		
Life Stage Group	Estimated Average Requirement (mg/d)	Recommended Dietary Allowance (mg/d)	Upper Level Intake (mg/d)	Estimated Average Requirement (IU/d)	Recommended Dietary Allowance (IU/d)	Upper Level Intake (IU/d)

*For infants, adequate intake is 200 mg/d for 0–6 months of age and 260 mg/d for 6–12 months of age. **For infants, adequate intake is 400 IU/d for 0–6 months of age and 400 IU/d for 6–12 months of age.

Source: Adapted from Institute of Medicine.[80]

Dietary vitamin D intake of some of the patients identified as deficient in the Thomas study exceeded the RDA and many had no apparent risk factors for vitamin D deficiency.[103] To address this issue, investigations are ongoing into the mechanisms of vitamin D action. One such area is the role of the vitamin D receptor (VDR) gene in calcium absorption and bone mass accretion. One study noted a significantly lower spinal BMD in girls with a homozygous recessive (BB) genotype at one restriction site when compared to heterozygous (Bb) or dominant (bb) genotypes.[109] Thus, alleles for this receptor may influence an individual's response to calcium intake and other environmental factors.

Finally, there is an ongoing debate regarding both the appropriate vitamin D supplementation dose for children and adolescents as well as the optimal serum 25(OH)D concentration needed to promote bone health, among other health outcomes. Vitamin D dosing depends on whether the young person is found to have vitamin D deficiency (25(OH)D < 20 ng/mL) or insufficiency (25(OH)D < 21–29 ng/mL).[80,110] In 2010, the Institute of Medicine (IOM) of the US National Academy of Science published recommendations aimed at the healthy population that established a new RDA of 600 IU daily for the pediatric age group (see

Table 66-2).[80] In 2011, the Endocrine Society, an international organization of pediatric and adult endocrinologists, published similar guidelines that were targeted at individuals with chronic diseases associated with bone loss, and/or who are at high risk for vitamin D deficiency.[110] In these patients, vitamin D supplementation doses as high as 2000 IU daily are recommended. Either vitamin D_2 or vitamin D_3 is effective in raising blood levels to the desired range, although recent research suggests that vitamin D_3 is more potent and supports cortical bone mass and strength better than vitamin D_2.[110,111]

DISTURBANCES IN ADOLESCENT NUTRITION WITH IMPLICATIONS FOR BONE HEALTH

General Nutrition

It should be remembered that rates of gastrointestinal calcium absorption and urinary excretion significantly influence the bioavailability of calcium. Foods high in oxalic acid such as spinach, beans, sweet potatoes, and rhubarb, which are not typically major components of the average teenager's diet, may inhibit calcium absorption.[59] Otherwise, calcium absorption is relatively high and excretion relatively low in adolescents when compared with adults. The typical adolescent's high-salt diet may negate this advantage; each gram of urinary sodium excretion obligates a loss of 26 mg of urinary calcium.[112]

Dairy intake

A US survey in the late 1990s showed that although adolescents overwhelmingly (>90%) believed that calcium is healthy and important for bones, few (19%) were aware of the RDA for calcium and even fewer (10%) knew how to meet this goal with dairy products.[113] It is not surprising, therefore, that less than 16% adolescent girls in the United States met the RDA of calcium of 1300 mg/d.[114] In 2006 the mean calcium intake for girls aged 9–13 years was approximately 988 mg/d, or 76% of DRI; this value dropped to approximately 918 mg/d, or 71% of DRI in 14–18 year-old girls.[115] For vitamin D, girls aged 9–13 years consumed 7.7 μg/d (308 IU) but declined to 5.0 μg/d (200 IU) by age 14–18.[115] Boys in the United States fared slightly better, with mean daily intakes of 1093 mg calcium (84% DRI) and 7.5 μg (300 IU) vitamin D in

ages 9–13 and 1296 mg calcium (99.6% DRI) and 6.9 μg (276 IU) vitamin D in ages 14–18,[115] probably due to better dairy consumption.

Carbonated Beverages and Tobacco

Wyshak has shown that consumption of carbonated beverages, particularly cola (phosphoric acid containing) drinks,[116] in teenaged girls may be associated with increased risk of bone fractures.[117] The association was not found to hold for teenaged boys.[117] Similarly, a large observational study in Northern Ireland linked lower BMD with increased carbonated soda beverage consumption, but again only in 12-to-15-year-old girls.[118] The pathophysiology is not completely understood, and is a source of significant debate.[119] Cola drinks, in particular, are implicated because they create a high phosphoric acid load that both chelates calcium and may increase parathyroid hormone (PTH) secretion, but others argue that this is a less important factor than the simple replacement of milk by carbonated beverages.[119] Between 1970 and 1997 in the United States, per capita consumption of carbonated beverages increased by 118% while consumption of milk declined by 23%.[120]

Finally, tobacco, by decreasing osteoblast function,[121] and excessive alcohol use increase the risk of lower BMD in young women. A study of these factors in younger adolescents showed that the effects of alcohol use and smoking were synergistic, and magnified the negative associations between teen anxiety, depression, and BMD.[122]

BONE DISEASES

Osteomalacia

Rickets, or vitamin D-deficient osteomalacia, is a classic example of the detrimental effect of malnutrition on bone and continues to be a problematic condition for growing children in North America and worldwide. As previously mentioned, evidence has accumulated that vitamin D deficiency may be prevalent among American adolescents and young adults, particularly those who live in northern latitudes.[89,106,107]

Low levels of 1,25(OH)2D lead to low levels of serum calcium, which stimulates PTH secretion. Under the stimulus of PTH, osteoclasts increase the rate of bone resorption to maintain calcium homeostasis. Osteoblasts respond to the increased osteoclast activity by increasing osteoid formation. Because of the relative lack of calcium and phosphate, this

osteoid is poorly mineralized. As a consequence, vitamin D deficiency impacts negatively not only on trabecular bone, which is more hormonally responsive and more commonly affected by such deficiencies, but also on cortical bone.

In addition to poor dietary intake, vitamin D deficiency can be caused by inadequate exposure to sunlight. Anticonvulsants cause increased hepatic breakdown of vitamin D. Patients with renal disease may have decreased activation of 25(OH)D to 1,25(OH)2D, in addition to increased tubular losses of calcium and phosphate. Use of aluminum-containing antacids impairs phosphate absorption. Other gastrointestinal conditions also impair absorption of vitamin D, calcium, and phosphate, as described later.

Clinical manifestations of rickets in skeletally immature children include flaring of the metaphyses and growth retardation. In skeletally mature adolescents and adults, findings are more subtle, including bone pain, susceptibility to fracture, and pseudo-fracture. Serum levels of 25(OH)D are a reliable measure of total vitamin D stores. However, the desirable level for 25(OH)D, including what constitutes the threshold stimulus for rises in PTH, remains a subject of debate.[85,105] A recent study by Hill et al. showed that the 25OHD inflection point for maximal PTH suppression is more difficult to define in children and adolescents versus adults. Thus, this endpoint is difficult to use as an outcome for defining optimal vitamin D status in a young population.[123]

Prevention of vitamin D deficiency and rickets includes ensuring adequate dietary intake of vitamin D, with empiric supplementation now recommended by the IOM for healthy neonates (400 IU daily) and children age 1 year and above (600 IU daily).[80] For children with a documented low bone mass or previous history of vitamin D deficiency, oral supplementation doses of 1000–2000 IU daily or 50,000 IU once weekly may be appropriate.[110] There are data suggesting an increased efficacy of vitamin D_3 (animal-derived) over vitamin D_2[124,125]; this preparation is generally preferred, if readily available. Parenteral dosing of 50,000–300,000 IU provided as vitamin D_2 intramuscularly can also be used, but must be undertaken cautiously, with assurance of adequate calcium intake and appropriate monitoring of vitamin D and PTH levels. However, parenteral preparations are presently difficult to obtain due to limited production.

Osteoporosis

Definitions

In contrast to osteomalacia, which refers to a condition in which the bone matrix is poorly mineralized regardless of the actual mass of bone tissue produced, osteoporosis is defined as a systemic skeletal disease characterized by low bone mass and micro-architectural deterioration of bone tissue, with a consequent increase in bone fragility and susceptibility to fractures.[126] A related term, osteopenia, is used to describe a significant reduction in bone mass for age and sex, but only in postmenopausal women and older adult men.[127] The term osteopenia should be avoided in a child, as this terminology generates confusion.[128] In each of these conditions, the osteoid is mineralized normally to form calcified bone, but there is less of it and its structural arrangement is abnormal.

Diagnosis

Adult osteoporosis is defined by the World Health Organization (WHO) as a BMD below 2.5 standard deviations from the mean peak BMD attained for sex (i.e., T-score < –2.5) as measured by DXA. Osteopenia in adults is the term reserved for BMD with T-score between –1.0 and –2.5.[127] Using these definitions, DXA scanning has become the standard modality for diagnosing osteoporosis in postmenopausal women and older adult men. In adolescents and younger adults, these WHO definitions do not apply; the International Society for Clinical Densitometry (ISCD), in a 2007 position statement, specifies that osteoporosis in these age groups is a clinical diagnosis, requiring evidence of skeletal fragility in addition to decreased BMD.[127,128] Appropriate DXA use and terminology in the pediatric population is discussed below.

Nutritional Disease States Associated with Impaired Bone Health

Anorexia Nervosa

Patients with AN are at risk for profound deficits in BMD, which are often irreversible, even with a return to appropriate weight. Patients with chronic AN have a sevenfold increased incidence of fractures and are at increased risk for developing early osteoporosis.[129–132] Because the incidence of anorexia increases during the years of attainment of PBM, the lifelong impact on skeletal health in maturity is particularly concerning. The mechanisms of this bone loss are certainly related to decreased dietary intake of calcium, vitamin D, and other macronutrients. Recent investigations have focused on the role of paradoxically increased fat in

the bone marrow of these patients.[133,134] One of the first investigations of male adolescents with AN confirmed the decreases in BMD seen in women, and suggests some of the same mechanisms are at play.[135]

Women with AN also develop hypothalamic amenorrhea that results in low circulating levels of estrogen.[136] It is hypothesized that estrogen helps regulate bone mass by impairing osteoblast-mediated bone resorption. Oral contraceptive (OCP) use by young women with AN was shown in a retrospective cross-sectional study to be associated with a higher BMD.[137] In a small pilot study of women with AN and hypothalamic amenorrhea, ERT resulted in increases in BMD.[138] A recent trial of transdermal estrogen showed gains in bone density in the young adolescents studied, but below what was expected for age.[139] Unfortunately, ERT alone has not consistently been shown in other controlled studies to be able to reverse the bone loss in patients with AN, with the possible exception of those most profoundly affected (below 70% of ideal body weight).[140] Ultimately, nutritional rehabilitation and weight restoration are necessary to return menstrual function, circulating estrogen levels, bone formation, and BMD to normalcy.[141] It may be frustrating to the patients that it often requires a higher body weight to resume menses than the level at which they ceased.[136] Even prior to attainment of menstrual regularity, however, bone density increases with weight gain in adolescent girls with AN.[142]

It has been suggested that bone formation is more profoundly decreased than resorption is increased in patients with AN.[131] This "uncoupling" of the normal bone cycle has led investigators to address both sides of the formation–resorption dyad.[43,143–145] Serum levels of IGF-I have been found to be decreased in patients with AN.[145] Randomized controlled trials of IGF-I administration showed significant increases in bone formation in patients with AN, with greatest improvement in those who were also given OCPs,[146] arguing for a synergistic effect between ERT and IGF-I. Unfortunately, use of this agent in children and adolescents may be limited because of its availability only as an intravenous or subcutaneous preparation. Longitudinal data are also needed to determine long-term efficacy.

Nutritional Supplements: Dehydroepiandrosterone

Similar to IGF-I, levels of the adrenal steroid dehydroepiandrosterone (DHEA)[147] can be low in patients with AN. DHEA is positively correlated with BMD in adults[148] and parallels the pattern of bone accretion in that

secretion of DHEA peaks during the same adolescent years as bone mass acquisition accelerates.[149,150] DHEA is thought to increase levels of IGF-I, thereby increasing bone formation by stimulating osteoblasts, and also decrease mediators of osteoclast-mediated resorption.

Studies on the administration of oral DHEA, which is currently sold as a nutritional supplement, in adolescent girls with AN have shown that this agent is well tolerated.[151] The adolescents who were given DHEA showed significant decreases in concentration of NTx, a marker of bone resorption, and increases in osteocalcin and BSAP, markers of formation.[151] In a randomized, double-blind clinical trial, the effect of DHEA on BMD in these patients was the same as that of ERT; both agents resulted in maintenance of BMD, but no significant gains, after controlling for weight gain.[151] However, bone turnover markers again revealed increased bone formation after DHEA, and a more significant suppression of bone resorption after ERT.[151] A subsequent randomized placebo-controlled trial showed an arrest of bone loss in older adolescents who received the combined therapy.[152] Because DHEA is unregulated by the FDA, it is potentially unsafe, depending on the purity of the preparation and dosing. For all of these reasons, DHEA cannot yet be recommended as a therapy for patients with bone loss secondary to AN.

The Female Athlete

Athletic participation has become increasingly common among adolescent girls since the enactment of Title IX of the US Educational Amendments Act in 1972, which required women's intercollegiate athletic offerings to be proportional to their representation in the student body. As noted previously, an active lifestyle has the potential for improved skeletal health. Unfortunately, some female athletes may develop patterns of unhealthy eating, irregular menstrual cycles, and an ensuing state of low estrogen levels, which can undo the beneficial effects of exercise on bone density.[136] In 1992, 20 years after Title IX, the American College of Sports Medicine (ACSM) coined the term "female athlete triad" to define this negative inter-relatedness of disordered eating, amenorrhea, and osteoporosis in certain female athletes.[153] Since most athletic women with menstrual irregularities do not meet criteria for osteoporosis nor frank eating disorders, the prevalence of the entire female athlete triad has been difficult to establish, although commonly cited references estimated that 3.4%–66% female athletes have experienced amenorrhea,[154,155] compared with only 2%–5% in the general population, and 15%–62% female college

athletes demonstrated disordered eating, compared with a 5%–10% prevalence of eating disorders in the general population.[156] A more complete epidemiologic characterization of athletic female adolescents conducted in the United States showed that while approximately one in five demonstrated any one of the components, only 1.2% met criteria for the full triad.[157]

Moreover, many active women with irregular menses consume adequate calories, leading some clinicians to use the term “athletic amenorrhea,” believing it is caused by the stress of exercise. Loucks et al. have disputed this concept, showing that low energy availability, defined as a failure to match food intake directly to exercise energy expenditure, not stress of exercise, alters luteinizing hormone (LH) pulse frequency and amplitude.[158] These disturbances in LH pulsatility can cause amenorrhea or more subtle menstrual dysfunction, including irregular, anovulatory, and short luteal phase cycles, all of which can cause a relative estrogen deficiency and increased bone resorption. Work with elite gymnasts and runners has shown that even within day, hourly energy deficits cause changes in body composition, with greater amplitude and frequency variations in energy balance correlating with increased body fat percentage.[159] The authors suggest that these wide swings also predispose to menstrual dysfunction.[159]

An alternative but complementary hypothesis is that cognitive dietary restraint, defined as the intention to limit food intake to control body weight, regardless of actual food limitation, is associated with higher levels of cortisol, which in turn impairs bone mass accretion by directly decreasing osteoblast activity and indirectly increasing osteoclast activity. In studies by McLean et al., exercising women with high dietary restraint measures by questionnaire had similar BMI and menstrual cycle length compared to those with low restraint, but higher urinary cortisol excretion[160] and lower total body bone mineral content.[161] In a group of younger female endurance athletes, elevated dietary restraint was similarly associated with decreased BMC and lumbar spine BMD without affecting menstrual regularity.[162] In any event, it is important to counsel adolescent female athletes to maintain positive energy balance throughout the day with frequent appropriate pre-, post- and between-exercise meals. Loucks’ work, in particular, suggests that a daily energy availability of approximately 30 kcal/kg in lean body mass may be required to protect against a catabolic state.[158]

Recognizing the spectrum of behaviors exhibited by female athletes, in

2007 ACSM refined the definition of the triad to encompass all possible relationships among energy availability, menstrual function, and bone health. This shift has removed the pathologic stigma of the female athlete triad, allowing it to include those active girls and women who achieve optimum bone health by maintaining adequate dietary intake to preserve normal menstrual cycles.[163]

CELIAC DISEASE

Celiac disease is a disorder of nutrient absorption in the small intestine, which affects as many as 1 in 250 people of European descent. In susceptible individuals, an immunologic reaction to gluten (a protein found in wheat, barley, and rye) leads to a chronic enteropathy of the proximal intestine. See Chapter 54: Celiac Disease for details.

Low BMD is a common complication of celiac disease, caused by general malnutrition secondary to anorexia (reduced dietary intake) and impaired absorption of nutrients, especially calcium and vitamin D,[164] among other etiologies. Vitamin D deficiency can be challenging to treat due to malabsorption in the setting of active, untreated celiac disease.

A gluten-free diet (GFD) is the mainstay of treatment for celiac disease, decreasing intestinal manifestations and improving BMD in adults and, in short-term trials, children. A long-term longitudinal study in children and adolescents showed that spinal BMD in patients with celiac disease was significantly lower than in controls at the time of diagnosis. After long-term GFD treatment (four years), patients had regained BMC and BMD to levels similar to controls, with significant “catch up” gains made in the first year of GFD treatment.[164] Provision of adequate calcium to these patients is critically important for bone mass.[165]

INFLAMMATORY BOWEL DISEASE

Similar to patients with celiac disease, adolescents with IBD are at risk for low BMD.[166,167] Patients with CD have a higher incidence of low bone mass than those with ulcerative colitis (UC),[168] likely related to the more widespread distribution of intestinal inflammation in the former versus the latter diagnosis. In addition to malabsorption of calcium, phosphate, and vitamin D, these patients have generalized malnutrition. Recent studies highlight the high prevalence of vitamin D deficiency among these patients, and the challenges encountered in trying to replete levels.[169,170]

They may also have delayed puberty, leading to inadequate levels of estrogen and/or testosterone to promote adequate bone accretion. The negative role of inflammation and proinflammatory/resorptive cytokines IL-1β, IL-6, and TNF-α on bone turnover and ultimately, bone density can be seen in pediatric patients with CD.[171,172]

Patients with IBD have relatively reduced lean body mass as a percentage of body composition, leading some to describe this deleterious combination of cytokines and malnutrition as "inflammatory cachexia."[173] Finally, extensive mucosal disease or surgical resection of the small bowel, particularly the terminal ileum, seen in CD further impairs calcium and vitamin D absorption. See also Chapter 53: Inflammatory Bowel Disease for more detail.

CYSTIC FIBROSIS

Patients with cystic fibrosis (CF) are at increased risk for significant bone disease. A review of the literature from 1988 to 1998 showed relative BMD decreases for patients with CF, with measured Z-scores ranging from –0.31 to –2.14 in studies with varying age populations and densitometry methods. This decrease in BMD translates into measurable increases in fracture rates and kyphosis (compression of the thoracic vertebrae) in CF patients aged 6 years and older.[174]

As with other chronic diseases, the pathophysiology of bone loss in these patients is felt to be multifactorial, with malabsorption of calcium and vitamin D, general malnutrition, inflammatory cytokines, and systemic corticosteroid use all playing roles. Vitamin D is a fat-soluble vitamin that relies on pancreatic enzymes for optimal absorption and reabsorption via enterohepatic circulation. Patients with CF have been shown to have a high prevalence of vitamin D deficiency, even after exogenous supplementation.[174] In addition, CF patients have decreased levels of IGF-I[175] and growth impairment, with height deficits as great as one standard deviation when compared with controls,[174] which impairs maximal bone mineral accretion and may warrant GH replacement. Pubertal delay and hypogonadism ensue, even in adulthood, leading to deficits in the estrogen and testosterone necessary to optimize the bone cycle. Low concentrations of IGF-I have also been directly correlated with decreased bone density.[176] An additional consideration in CF can be a lack of exercise tolerance in patients because of their respiratory disease. Since bones require mechanical loading for remodeling, lack of weight-bearing activity further

hinders normal bone mineral acquisition. See also Chapter 56: Exocrine Pancreatic Disease Including Cystic Fibrosis.

EVALUATION AND MANAGEMENT

Diagnostic Tools

Dual energy x-ray absorptiometry

DXA utilizes X-rays of two differing photon energies passing through the body to a sensitive detector. The beams are attenuated differentially depending on the tissues through which they pass. A computer then calculates body composition, BMC, and BMD based on the attenuation. DXA scanners report BMC in grams of mineralized calcium and BMD in grams per area of bone region in centimeters squared (g/cm^2). Advantages of DXA scanning include relatively rapid scanning times (approximately five minutes for each scan), low levels of radiation exposure (1/10th the radiation of a chest X-ray), and precision in the range of 1%. For all of these reasons, DXA can be used in children, with reliable normative databases consistently available, with some including children as young as 5 years.[12,128]

Limitations of DXA for Adolescents

The major limitation of DXA is that it utilizes a 2-dimensional technique to quantify a 3-dimensional structure. Density is, by definition, a measure of mass per unit volume. The BMD reported by DXA scanners is areal, or per unit area in gram per square centimeter. The significance of this calculation is more than academic, as the mechanical properties of bone are dependent on its architecture and geometry, as well as on its composition. Good mathematical models have been developed to calculate the approximate volumetric BMD—known as bone mineral apparent density (BMAD) in gram per cubic centimeter—although their prognostic value is not well established.[177]

These limitations of DXA are more significant in adolescents.[128] First, not all DXA scanners are equipped with the proper software to evaluate pediatric body composition and, therefore, BMD. Even comparing a single adolescent with him or herself on a single machine with reliable pediatric software is subject to flaws. Presumably, one could measure serial DXA scans over time to assess the effect of a disease state or treatment on BMD. Unfortunately, the growth of the child complicates interpretation. To illustrate, consider quantifying the density of a tree trunk by measuring the

shadow cast by the tree in the sun. After one year of growth, the tree trunk casts a wider (and perhaps darker) shadow, but the trunk itself may be no denser than it was previously. Using DXA, the "shadow" or areal BMD (aBMD) of this tree would be reported as greater than it was the previous year. The same phenomenon occurs when measuring a growing child's bones. The opposite phenomenon, that of a growing child's measured aBMD remaining constant, should therefore appear ominous to the clinician. Unfortunately, limitations on the actual scores reported for BMD do not allow the clinician to quantify the degree of risk. Fortunately, bone grows stronger as it increases in diameter, even at the same BMD.[178]

As mentioned, interpreting even reliable values for BMD is challenging. One standard deviation score, the T-score, which compares an individual adult's BMD to the mean peak BMD (or PBM) attained by young adults of the same sex, provides a valid estimate of the risk of fracture for postmenopausal adult women. A second standard deviation score, the Z-score, compares an individual's BMD to the mean BMD (in standard deviation units) for his or her age and sex, which is useful to grade patients with respect to their peers. The Z-score has limited prognostic significance, although a large prospective population-based cohort has begun to quantify a significantly increased risk of fracture associated with decreased BMD Z-scores starting at age 10.[179] Reliable pediatric databases report both T- and Z- scores, but the T- scores are not generally informative since most children and adolescents have not reached their peak young adult BMD and therefore may prove confusing to the reader of the report. For this reason, the ISCD has recommended that T-scores not appear on printouts or reports from DXA scans of children and adolescents younger than age 20 years.[128] In the same position statement, ISCD recommends the terms "low bone density for chronologic age" or "below the expected range for age" for Z-scores lower than –2.0 and discourages use of the term osteopenia entirely in this age group.[128]

Furthermore, as bone mass accretion is strongly influenced by Tanner stage, which does not directly correlate with chronologic age, comparing BMDs based on age alone (as in Z-scores) may be problematic. Finally, most databases include predominantly or exclusively Caucasian populations, which make the interpretation of BMD data more difficult for patients of different ethnic groups.[128]

Other Imaging Techniques

Quantitative computed tomography (QCT) is a technique of bone

densitometry, which is rapidly becoming the gold standard in research protocols because it can generate direct measures of bone volume, and thus a more accurate volumetric BMD. Pediatric algorithms are available, but the increased time required and significantly increased radiation doses limit its clinical use in this age group. Peripheral QCT (pQCT) is becoming increasingly used as a research tool in pediatric patients as it affords a measure of volumetric BMD in assessment of the appendicular skeleton, and provides insight into bone geometry and strength.[12,180] A final appeal of this methodology is that it involves a minimal radiation dose. Another technology, quantitative ultrasound (QUS), showed promise as it has no associated radiation exposure and demonstrates reasonable precision, but has proven difficult to validate in comparison with DXA and QCT.[181,182]

Serum markers

Bone turnover markers are used infrequently in the assessment of metabolic bone disease, primarily for research purposes, to gauge the relative contributions of bone formation versus bone resorption in the bone remodeling cycle.[183] Some endocrinologists also use them to monitor response to medical treatment. Serum alkaline phosphatase levels, particularly BSAP, reflect osteoblast function, as does serum osteocalcin, an osteoblast-specific product. Serum tartrate-resistant acid phosphatase (TRAP) is an osteoclast equivalent for BSAP, whereas collagen type I cross-linked *N*-telopeptides (NTx), which, as breakdown products of collagen, reflects osteoclast activity and can be measured in the urine. Adult studies have shown these markers to be inferior to bone densitometry for diagnosing osteoporosis and monitoring skeletal health, and pediatric reference ranges are more limited (compared to adults), as growth, puberty, and diurnal cycling cause wide variation in these values.[183]

Diagnostic Considerations

The conditions described above are only a few of those which predispose children and adolescents to osteoporosis (Table 66-1). The wide variety of conditions that impair skeletal health necessitates a high index of suspicion and heightened level of concern for bone health on the part of the pediatric health care or nutrition practitioner. The limitations of DXA scanning in pediatric populations detailed above have delayed its widespread use. Therefore, there is little evidence on which to make general

recommendations as to when and how frequently specific groups of children should have bone density measurement by DXA. The Cystic Fibrosis Foundation (CFF) first convened an expert panel in 2002 to develop practice guidelines for the management of bone disease in CF, which has served as a model for providers of other patient groups.[184] These guidelines include a screening and treatment protocol calling for a baseline DXA scan at the time of diagnosis of patients age 8 years and older. It may be reasonable to apply this recommendation and others from the CFF consensus statement, to patients with celiac disease, IBD, intestinal failure, and IJA, among other diagnoses. Standard practice in the authors' clinics is to perform DXA scans on girls and young women with AN after six months of hypothalamic amenorrhea. Bone density measurement is also recommended for patients with multiple fractures, regardless of etiology, pathologic or atraumatic fractures, and repeated long-bone stress fractures. A higher level of suspicion should also be raised in any patient with a strong family history of osteoporosis or with long-term use of systemic corticosteroids. DXA scans should then be repeated over time, but not more frequently than annually in clinical practice, as the changes noted over a shorter period are unlikely to be significant.[128]

Patients found to have a subnormal BMD on DXA scanning should have a screening evaluation of calcium homeostasis in addition to any clinically indicated laboratory assessments of their underlying medical conditions. A panel including serum calcium, phosphorus, magnesium, 25(OH)D, PTH, thyroid-stimulating hormone (TSH), and urinary spot calcium-to-creatinine ratio (normal < 0.2) would be sufficient. At present, it is generally agreed that a teenager with a BMD Z-score less than −2.0 warrants referral to a provider (e.g., endocrinologist) experienced in calcium metabolism and skeletal health. Consideration should be given to early referrals for patients with a BMD Z-score less than −1.0 if the adolescent has sustained recurrent fractures or a strong family history of documented osteoporotic fracture.

Management of Bone Diseases

Management of bone disease in patients with chronic illnesses described otherwise consists primarily of optimizing nutritional status, particularly with respect to calcium and vitamin D, and ensuring a normal hormonal milieu, with exogenous replacement of estrogen, testosterone, and growth hormone, as warranted. GFDs have already been mentioned for patients with celiac disease. Systemic glucocorticoids should be used judiciously,

but should not be withheld if that would jeopardize management of the underlying disease process. As with many decisions in clinical medicine, potential risks and benefits must be balanced for each individual case.

Novel Therapies

The uses of DHEA, IGF-I, and transdermal estrogen as new treatment modalities in patients with AN have already been discussed. The positive effects on BMD may make them attractive candidates for use in other diseases, particularly IGF-I for CF. However, persistent long-term improvements as well as solutions to the limitations mentioned above (nonstandard preparations for DHEA, parenteral administration for IGF-I) will need to be demonstrated before widespread use can be recommended.

Another class of agents being explored in several clinical trials of patients with AN[185] and some of the other abovementioned subgroups are the bisphosphonates. These agents are irreversible inhibitors of bone resorption, which become incorporated permanently into the mineralized bone matrix. These investigations have been prompted by the successful use of the bisphosphonate pamidronate in children with osteogenesis imperfecta (OI),[186] which represents a life-changing therapy for these children, as well as widespread experience with the bisphosphonate alendronate in postmenopausal women with osteoporosis. The CFF consensus statement includes the bisphosphonate alendronate as a therapeutic option in OI screening and treatment protocol.[184] However, concerns still exist around use of bisphosphonates in pediatrics, especially with respect to possible inhibition of primary remodeling of growing bone, increased risk of osteomalacia, long half-life in bone (>10 years), and unknown effects on the growing fetus. In addition, despite increases in BMD, there is concern that bone matrix, intercalated with bisphosphonate, may not provide normal mechanical strength. A case report of osteopetrosis (excessively dense and brittle bone) induced in an adolescent treated with very high-dose bisphosphonates highlights the caution with which these agents should be used.[187] Therefore, although there is promise to translate the established benefits of bisphosphonates in the elderly and younger patients with specific diagnoses to a wider pediatric population, these agents should currently be used extremely cautiously and/or in the setting of a controlled research study.

Finally, early recognition of the conditions that predispose to low bone density and early identification of patients at risk are essential to the prevention of bone loss in adolescents with chronic illnesses, which may be the most effective way to manage bone disease in these patients.

Prevention

In addition to managing the skeletal complications of chronic illnesses, one of the most important goals of adolescent nutrition is the potential prevention of osteoporosis by maximizing skeletal health in otherwise healthy teenagers. It is essential to ascertain family history of osteoporosis, especially early-onset osteoporosis, or frequent fractures. Dietary sources of calcium and vitamin D should be assessed and inadequacies addressed. Recommended age-appropriate daily calcium and vitamin D intake guidelines developed in the United States by the IOM[80] and endorsed by the American Academy of Pediatrics (AAP) have been highlighted in this chapter (see Table 66-2). Metabolic studies of calcium retention in adolescent girls[188,189] showed such large variation, however, that it might be necessary to individualize calcium requirements based on post-menarcheal age. Others have argued that sex and physical activity should also modify recommendations for optimal calcium intake.[190]

The success shown by a single supplementation trial in maintaining increases in BMD several years after discontinuation of concentrated milk protein as the primary calcium source may suggest the superiority of milk over other sources,[78] but further study is necessary to confirm this finding. Adolescent girls may need to be reassured that consuming low-fat dairy products instead of calcium supplements will not increase their weight or percent body fat. Indeed, evidence from one large study often cited in the lay press suggests that regular consumption of milk may be protective against weight gain.[191]

The AAP once again reaffirmed the importance of dairy products for bone health in a position statement that recommends the increasingly widely available "partially digested" forms of milk, cheese, and yogurt as the primary source of calcium and vitamin D for patients with lactose intolerance due to relative lactase deficiency.[192] Pretreatment with lactase enzyme replacement tablets were also recommended. For those patients with the most severe forms of lactose intolerance or those who will not consume adequate dairy products, there are other dietary sources of calcium (see Table 66-3), along with calcium supplements as a suitable alternative. Despite concerns to the contrary, chronic consumption of high levels of calcium has not been shown to impair absorption of such essential nutrients as iron,[193] magnesium, and zinc, as long as the intake is held below 2500 mg daily.[59]

TABLE 66-3 Examples of Dietary Sources of Calcium

Food	Serving Size	Calcium Content (mg)	No. of Servings to Equal Calcium Content in 1 Cup of Low-Fat Milk
Dairy foods			
Low-fat (1%) milk	1 cup (244 g)	264	—
Yogurt, nonfat, fruit variety	6 oz (170 g)	258	1.0
Frozen yogurt, vanilla, soft serve	½ cup (72 g)	103	2.6
Cheese	1 1-oz slice (28 g)	202	1.3
Cheese, pasteurized, processed	1 ¾-oz slice (21 g)	144	1.8
Nondairy foods			
Salmon, sockeye canned, drained, with bones	3 oz (85 g)	203	1.3
Tofu, firm, prepared with calcium sulfate and magnesium chloride	½ cup (126 g)	204	1.3
Broccoli, cooked	1 cup, chopped (156 g)	62	4.3
Collards, cooked, boiled, drained	1 cup, chopped (190 g)	266	1.0
Baked beans, canned	1 cup (253 g)	127	2.1
Foods fortified with calcium			
Calcium-fortified orange juice	1 cup (240 mL)	300	0.9
Selected fortified breakfast cereals	¾–1 cup (30 g)	100	2.6
Calcium-fortified soy milk	1 cup (240 mL)	200–500	0.5–1.3

Conclusions

The growing body of literature highlighted in this chapter should alert

clinicians in all disciplines to the adverse effects of chronic illnesses and inadequate nutrition on the skeletal health of adolescents. Most clinicians should find the solutions less obscure, however, as the promotion of skeletal health is ultimately no more than the promotion of good general health, including recommending balanced general nutrition, moderate weight-bearing exercise, and avoidance of alcohol and tobacco for all adolescents. The challenge lies in helping teenagers modify their behaviors to meet these goals.

Enteral Nutrition and Formulas

67

Zoë McCallum, MBBS, FRACP and Julie E. Bines, MBBS, FRACP, MD

Enteral nutrition refers to both the delivery of nutrients via a feeding tube directly into the stomach or intestine and the provision of oral nutritional supplementation. The concept of enteral nutrition support is not new. In ancient Egypt, and later in Greece, feeds were introduced into the rectum, and in the nineteenth century, rudimentary tubes were used to infuse basic foods such as broths, eggs, milk, and even alcohol into the esophagus and stomach.[1] Since the 1980s enteral nutrition has been increasingly recognized as a safe, effective, and cost-efficient method of providing nutrition to patients with a functional gut. The last three decades have seen advances in the formulation of nutritionally complete and disease-specific formulas as well as improvements in feeding access devices.[2] Patients who had previously received parenteral nutrition can now be successfully managed with enteral nutrition alone or in combination with parenteral nutrition. Home enteral nutrition support is an important adjunct to the management of infants and children with chronic disease or feeding problems.

Nutrition support is required by patients who are unable to consume orally any, or adequate, fluid and nutrients for survival or for normal growth and development in children (Figure 67-1). Enteral nutrition support has a number of advantages over parenteral nutrition therapy. Enteral nutrition mimics the normal gastrointestinal (GI) response following the ingestion of a meal, with the exception of the oral phase. The presence of nutrients within the intestinal lumen provides stimulation of the gallbladder and normal GI function, helping to maintain balance within

the complex intraluminal environment. Luminal nutrients stimulate GI neuroendocrine function, effecting motility and digestion through the secretion of digestive enzymes and GI hormones. Intestinal functional and structural changes occur through local and systemic interaction of nutrients and neuroendocrine peptides, cytokines, and hormones.[3] The list of these mediators is extensive and includes gastrin, enteroglucagon, peptide YY, interleukin-3, 11, or 15, epidermal growth factor, growth hormone, insulin-like growth factors-I and -II, and glucagon-like peptide-1 and -2.[3] Monosaccharides and fatty acids influence the secretion of enteroglucagon and peptide YY and via these mediators effect mucosal growth and decrease intestinal transit time.[4] Carbohydrate, protein, zinc, magnesium, potassium, or manganese deficiency can modify the effect of growth hormone and insulin-like growth factor II.[5–7] Luminal nutrients assist in the maintenance of gut mucosal mass, including the gut-associated lymphoid tissue (GALT).[8] The GALT consists of the lamina propria, intraepithelial lymphocytes, immunoglobulin A (IgA), Peyer's patches, and mesenteric nodes and is responsible for processing antigens presented to the gut mucosa.[8] During periods of "bowel rest," such as occur with intravenous feeding and starvation, there is a reduction in gut mass and the function of the GALT is suppressed.[9] This has been associated with a reduction in IgA secretion and increased gut permeability resulting in increased bacterial adherence to the intestinal wall, cellular injury, and bacterial penetration, translocation with adverse systemic host responses.[10–12] Oral or enteral feeding may reduce the potential risk of bacterial translocation, except when disturbances in intestinal permeability are related to an underlying disease process (e.g., short bowel syndrome) or the chemical composition of the enterally provided substance (e.g., blue food dye).[11–15]

The GI tract is a delicate ecosystem with the balance determined and maintained through the interplay between nutrients, bacteria, and the intestinal defense system (luminal, mucosal, and submucosal immune system). Luminal nutrients play an important role in the development and function of the GI ecosystem through the modulation of the resident bacterial flora. The contribution of prebiotics to development of normal intestinal flora and the intestinal immune system is now recognized.[16,17] The interaction between specific bacteria and toll-like receptors located on intestinal enterocytes and lymphoid cell from as early as birth influences the development of physiologic intestinal immune response.[16,17]

Enteral nutrition therapy is easier and safer to administer than is

parenteral nutrition. Not only are the risks of intravenous access avoided but there is also a wider margin for error with most metabolic complications.[18,19] Due to advances in formulas, enteral feeding tubes and delivery systems, development of protocols for management, specialized Nutrition Support Teams, and better education of parents and caregivers, the administration of enteral nutrition has been associated with improved clinical outcome and safety profiles.[18,19] There are also a relative cost advantage of providing nutrition support via the enteral route compared to parenteral nutrition therapy. Enteral nutrition support is approximately two- to four-fold cheaper than parenteral nutrition on an inpatient or outpatient basis.[20–23] Based on U.S. Medicare charges, the annual cost of providing enteral nutrition per patient is approximately USD$9605 ± $9327 compared with USD$55,193 ± $30,596 for parenteral solutions.[20] In addition, the frequency and cost of hospitalizations are higher for patients supported on parenteral nutrition therapy compared with enteral nutrition therapy.[23] However, despite these relative advantages, the delivery of safe and effective enteral nutrition therapy may still present challenges for families and caregivers in terms of time, technical expertise, and cost.[21]

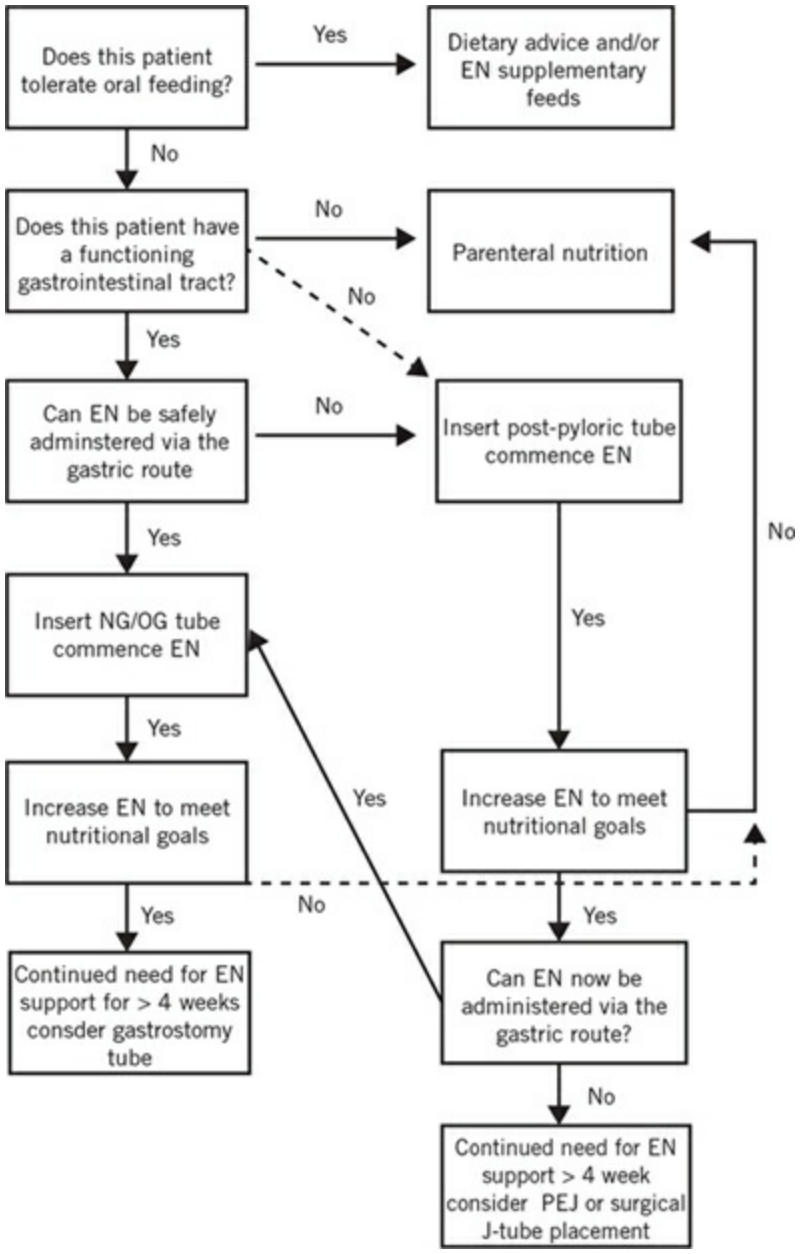

Figure 67-1 Decision flowchart for the provision of enteral nutrition support.

INDICATIONS FOR ENTERAL NUTRITION

Enteral nutrition should be considered for any patient with a functional GI tract who requires nutritional support (Figure 67-2). Enteral feeding may be required if adequate oral nutrient intake cannot be provided in children with growth failure, weight faltering, or weight deficit. See Chapter 47,

"Failure to Thrive." This may be defined as a child with a weight or weight for height less than third percentile below the mean for sex and age and/or crossing of two growth curves on the weight, height or weight/height percentile charts, no weight gain, or weight loss during the last 2–3 months and/or triceps skinfold measurements less than the fifth percentile. The requirement for enteral nutrition support may be temporary in the presence of acute illness or inadequate quantity or quality of nutrition provided. Enteral nutrition support may be an important adjunct in the long-term management of children with chronic diseases associated with increased energy needs that are difficult to achieve via the oral route such as may occur in cystic fibrosis[24,25] or in congenital heart disease (Figure 67-2).[26] Children with severe neurological dysfunction may have difficulty with the oral and esophageal phase of feeding and feeding may be slow and entail risks of aspiration. Tube feeding can provide welcome respite for families and caregivers who previously may have spent over 6 hours a day assisting with oral feeding.[27] Children with cognitive, psychiatric, and behavioral disorders that interfere with oral feeding may develop nutritional deficiency and enteral tube feeding may provide a safe and reliable route for the delivery of essential nutrients.

Disorders of the GI tract that are characterized by abnormal digestion and absorption of oral diet are an important indication for enteral nutrition support. Patients with short bowel syndrome, secretory diarrhea, or dysmotility syndromes resulting in excessive GI losses, frequently will have improved absorption and a reduction in losses with small volume continuous enteral feeds of a specialized formula.[28,29] See Chapter 61, "Intestinal Failure." Because of their composition, these formulas are often unpalatable and require tube administration to obtain adequate volumes of administration. Most patients receiving parenteral nutrition will also receive some enteral nutrition to sustain gut mucosa integrity.[28] Enteral nutrition usually provides an important transition stage as the patient progresses from parenteral nutrition to oral diet.[29]

Advances in understanding of the role of nutrients in the modification of inflammation and immunity has led to the development of disease-specific formulas as a primary treatment modality, such as in Crohn's disease[30,31] (see Chapter 52, "Inflammatory Bowel Disease"). Enteral nutrition has been advocated as a primary treatment for conditions associated with a metabolic disturbance, such as the use of gastrostomy tube feeding to infuse a ketogenic diet in children with epilepsy.[32] Although in most clinical scenarios enteral nutrition support has a

therapeutic intent, it is also used to prevent the development of malnutrition, such as can occur during stem cell transplantation.[33]

CONTRAINDICATIONS TO ENTERAL NUTRITION

With developments in options for GI access, delivery systems, and enteral formulas, the list of absolute contraindications for enteral nutrition therapy has been reduced significantly. Contraindications include GI ischemia, including the initial phase of necrotizing enterocolitis and toxic megacolon, severe intractable vomiting or diarrhea, diffuse peritonitis, and mechanical intestinal obstruction. Extreme care should be taken when administering enteral nutrition in patients in whom the GI blood flow could be compromised, such as during treatment with hypothermia, low cardiac output, multiorgan failure, compression syndromes, or infusions of specific drugs.[34] However, enteral nutrition has been shown to protect the splanchnic oxygen balance during intraoperative duodenal feedings in severely burned patients,[35] and in some forms of GI bleeding enteral nutrition may protect the gut mucosa and reduce further bleeding.[36] Controversy remains regarding the appropriate form and timing of nutritional support for the patient with circulatory shock.[37]

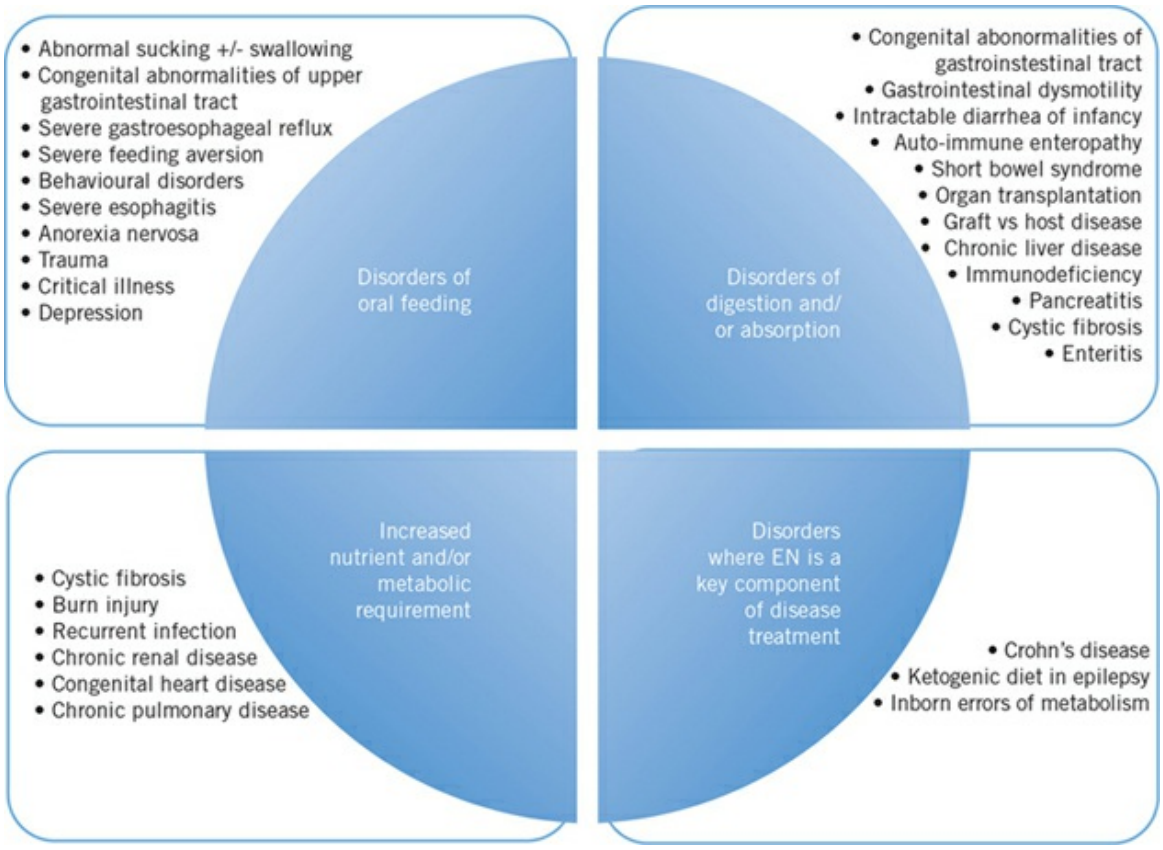

Figure 67-2 Indications for enteral nutrition in infants, children, and adolescents.

ENTERAL FORMULAS

In the early days of enteral nutrition, a mixture of blenderized diets and milk products was administered through a large-bore feeding tube. This approach was associated with nutritional imbalance, micronutrient deficiencies, feeding intolerance, and tube blockage. Today, there is a wide range of enteral nutrition products suitable for use in infants, children, and adolescents (see Chapter "Enteral Products" in Appendix III). Formulas have been designed for different age groups and for children with certain diseases.

Composition of Formulas

The majority of patients with a normal GI tract will tolerate the gastric administration of a polymeric formula. Polymeric formulas are based on intact protein or polypeptides usually derived from cow's milk or soybean.

The nitrogen to non-nitrogen calorie ratio approximates 1 to 150. Carbohydrates are sourced from different starches, including corn and tapioca. Maltodextrin and hydrolyzed cornstarch, glucose-derived saccharides, and corn syrup are commonly used. Formulas can have different lactose contents. Fats are usually present as polyunsaturated fatty acids from corn, safflower, sunflower, or soybean oil or from animal fat. The content of medium-chain triglycerides (MCTs) is increased in formulas developed for the treatment of patients with malabsorption. Some enteral nutrition formulas contain soluble fiber. The soluble fiber is added primarily to normalize GI transit, but after it is converted to short-chain fatty acids it provides an additional source of calories and can exert trophic effects on the colonic mucosa. In all complete enteral formulas, electrolytes, vitamins, and trace elements are added to provide the Dietary Reference Intakes of micronutrients and minerals at the target volume. At standard dilution, the caloric content of infant formula is usually 0.67 kcal/mL, and of standard enteral formula, 1 kcal/mL. Concentrated enteral nutrition formulas are also available (1.5 and 2 kcal/mL). The osmolality of enteral formulas can range widely depending on the nutrient composition and caloric density (~200–750 mOsm/L).

Age Considerations

Due to the difference in normal macro- and micronutrient requirements at different stages of development, enteral formulas have been developed to meet the recommended needs of specific age groups.

Infant Formulas

Human breast milk should be considered as the first option for enteral nutrition support for infants requiring a feeding tube. Human milk has a number of key nutritional, immunological and neuroendocrine advantages over commercial infant formulas (see Chapters 30 and 31), but if breast milk is not available, commercial infant formulas will be required. Standard infant cow's milk based protein formulas have been shown to support normal growth in full-term infants.[38] The serum amino acid profiles of infants fed casein predominant cow's milk formulas are different to that of breast-fed infants and have been linked to metabolic disturbances in some infants.[39] The amino acid profile of infants fed whey protein predominant cow's milk formulas more closely resembles human milk than cow's milk, but is associated with a higher percentage of branched chain amino acids and threonine compared with human milk.

Whether this has any clinical significance is not known.[40,41] Nucleotides are normally present in human breast milk and have been added to some cow's milk–based formulas. The rational for this addition is based on reports of decreased diarrheal disease in infants receiving formulas supplemented with nucleotides.[42] Most standard cow's milk based formulas are also supplemented with iron to prevent iron deficiency, particularly in preterm and small-for-gestational-age infants. The global standard for the iron present in infant formula ranges from 0.3 mg to 1.3 mg/100 kcal.[43] The renal solute load of standard cow's milk based formulas is higher than human milk and may pose a problem for preterm infants or infants with renal impairment. Plant oils are used in cow's milk based infant formulas to replace animal fats. Improved fat and calcium absorption has been observed in infants receiving formulas with a greater proportion of triglycerides with palmitic acid in the beta position of the glycerol backbone, similar to human milk.[44] Arachidonic acid (AA) and docosahexaenoic acid (DHA) are important structural elements of cell membranes in the retina and brain. Preterm infants fed formula supplemented with AA and DHA have been observed to have improved visual acuity and cognitive development.[45,46] However, this observation has not been consistently reported in term infants.[47,48] Lactose-containing cow's milk–based formulas are contraindicated for infants with galactosemia and lactose intolerance.

To meet the nutritional needs to support the rapid growth expected in preterm low-birth-weight and extremely low-birth infants who also have immature intestinal and renal systems, specialized preterm infant formulas are required. These formulas are energy rich, usually with a higher proportion of MCTs to enhance fat absorption. A benefit of these formulas is enhanced calcium absorption and nitrogen retention.[49,50] The calcium and phosphorus concentrations are also increased in preterm infant formulas to support rapid bone growth.

Soy protein formulas are used in the management of infants with cow's milk protein intolerance. Although soy protein is a high-quality protein, soy formulas are supplemented with L-methionine, taurine, and/or carnitine to meet the needs of human infants. The carbohydrate source is sucrose, corn syrup and/or maltodextrin and therefore soy formulas can also be used to treat infants with lactose intolerance. Zinc and iron are supplemented due to their decreased bioavailability in the presence of phytic acid and polysaccharides.[51] High plasma concentrations of isoflavones have been reported in infants receiving soy formulas although

the clinical significance of this finding is unclear.[52] Aluminum is present as a contaminant in soy formulas, therefore soy formulas should be avoided in infants with renal disease. Soy protein formulas are not recommended in infants with fructose intolerance or in preterm infants weighing less than 1800 g due to concerns regarding aluminum toxicity, and lower weight gain and bone mineralization observed in some infants.[53]

Formulas for Infants >6 Months of Age and Children

Follow-up formulas are aimed at supplementing the weaning diet for children greater than 6 months of age. These formulas have adjustments in the nutrient concentration compared to standard cow's milk based or soy protein infant formulas. It is not intended that these formulas interfere with the normal transition to solid food.

As it is expected that healthy children will have transitioned to solid food and complimentary liquids by 1 year of age, formulas for children over 1 year are aimed at providing complete or supplementary nutrition for children with acute or chronic illness. These formulas have a higher caloric density and protein concentration compared to standard infant formulas and micronutrient content reflects age-based recommendations. In patients with underlying GI disease or those requiring jejunal feeding, an oligomeric formula might be indicated. The protein in oligomeric formulas has been hydrolyzed to peptides or a combination of peptides and amino acids. The carbohydrate complexity varies among formulas, although most oligomeric formulas are lactose free. The potential advantages of oligomeric formulas over formulas containing chemically derived amino acids is the lower osmolality and faster intestinal uptake of amino acids derived from peptides.[54] Elemental or monomeric formulas contain digested macronutrients, including monosaccharides, MCT, and amino acids, with an essential to nonessential amino acid ratio reflecting high biologic protein values. Lactose and gluten are absent and residues are low. The unpalatability and high osmotic load of simple sugars and amino acids generally limit the use of elemental formulas to tube feeding when feeding intolerance occurs with other types of formula (e.g., severe malabsorption or short bowel syndrome). Modular feeds are built from individual nutrient components aimed at providing a specific nutritional requirement as a supplement to a diet or formula or to provide a complete formula to meet the specific needs of an individual. Indincations include conditions requiring a change in the calorie to protein ratio in a patient with burns or trauma or in increased caloric density in a patient who is severely fluid restricted.

Disease-Specific Formulas

Advances in the understanding of the role of specific nutrients and their effects on metabolism have led to modification of enteral nutrition formulas for the treatment of an expanding range of diseases. Immunonutrition is the enrichment of formulae with single components or a combination of key substrates that might play a crucial role in metabolism in sepsis, inflammation, tissue healing, and growth.[55] The aim of the disease-specific formulas is to provide therapeutic benefits in addition to the maintenance of general nutritional status. Glutamine-enriched formula has been advocated for the prevention and treatment of intestinal mucosa injury associated with chemotherapy and critical illness.[56,57] Glutamine is an essential amino acid in critical illness and is an important source of energy for the intestine. Glutamine supplemented formula was associated with a decrease in the frequency of sepsis and bacteremia in adult trauma patients and those supplemented with 0.4 gm of glutamine/kg/d had better enteral nutrition tolerance.[58] The American Society for Parenteral and Enteral Nutrition,[59] the European Society for Parenteral and Enteral Nutrition (ESPEN), and Canadian guidelines recommend the use of enteral glutamine in adult patients with burn injury and trauma.[60] Formulas supplemented with arginine, glutamine, ribonucleic acid nucleotides, MCTs, and/or omega-3 fatty acids have been also been advocated as enhancing the immune system of critically ill patients.[56,57] However, whether the benefit of glutamine or immune-enhancing formulas in malnourished and critically ill children outweighs the additional cost of these formulas remains unresolved.[61,62]

Formulas have been tailored for patients with inborn errors of metabolism. These formulas aim to prevent toxicity in patients unable to metabolize a specific amino acid, such as phenylalanine in phenylketouria, or as part of the management of acute metabolic instability during infection. Formulas have been modified for patients with severe pulmonary disease to provide 40%–50% of energy from fat in an effort to limit CO_2 production from the metabolism of carbohydrates. Formulas for patients with renal disease have a lower protein and sodium chloride content. Formulas for burns patient have a low fat and high carbohydrate content. Patients with chronic liver failure receiving formulas with a high concentration of branched amino acids had improved clinical outcome and quality of life.[63] However, evidence for improved clinical and economic outcomes of many of the disease-specific formulas, compared with standard formulas, is still required to justify recommendations of their

routine use.[56,58]

ROUTES OF ADMINISTRATION

During enteral nutrition therapy, nutrients are directly delivered via a tube into the stomach, duodenum, or jejunum. The tube is inserted either through the nose or mouth for short-term enteral nutrition (less than 4 weeks) or through a surgically or endoscopically created stoma for long-term enteral nutrition (more than 4 weeks). The choice of the location and the route of administration will depend on the patient's underlying medical or surgical condition, including GI anatomy and function, the indication and duration of enteral nutrition therapy, and psychosocial factors. Additional factors, such as local technical expertise, tube availability, and cost, will also influence the route and type of device selected. As a general principle, tubes that deliver nutrients into the stomach are the preferred choice. Gastric tubes are easier to insert and allow a physiological digestive process with bolus or continuous feeding regimens. However, in the presence of gastric outlet dysfunction, severe gastroesophageal reflux, or gastric paralysis, transpyloric access may be indicated.

Gastric Access Feeding Tubes

Nonsurgical or nonendoscopic placement of a feeding tube through the mouth or nose is the most common method of establishing GI access in infants and children due to the ease of placement and cost. The nasal access is usually preferred, except in preterm infants or in patients with nasopharyngeal abnormalities or obstruction as may occur following trauma or with congenital malformations. The tube is generally of small diameter (5–12 Fr) and is well suited to nutritional support of short or intermediate duration or intermittent nutritional therapy. However, the small luminal diameter renders these tubes susceptible to blockage particularly when medications or nutrient supplements are infused. To minimize the risk of blockage it is recommended that the tube is flushed with water after each feed and each infusion of medication. There is a wide range of enteric feeding tubes available for use in children. Current feeding tubes are made from flexible silicone, polyurethane, or elastomer and may require a stylet to assist placement. Despite the increased flexibility, they have a long lifespan and may incorporate specialized features. Weighted tips are designed to allow gravity to assist with small bowel placement and to prevent retrograde displacement. However, with the possible exception of patients requiring mechanical ventilation, the weighted tubes have not

been shown to have significant benefit over nonweighted tubes.[64] With training, nasogastric tubes can be safely inserted by allied health staff, caregivers, family members, and even the patients themselves.

Placement of a feeding tube using surgical, radiological, or endoscopic techniques is recommended for long-term enteral nutrition therapy or gastric decompression. There are a number of important advantages of these tubes over nasogastric or nasoenteric tubes in children. The gastrostomy tube can be maintained in position for a longer period because it is fixed against the anterior abdominal wall. The tube does not interfere with breathing and avoids potential complications of chronic nasal discharge, sinusitis, and developmental abnormalities of the nose. In addition, for some children, repeated insertion of a nasogastric tube is associated with psychological trauma and feeding aversion. Gastrostomy tubes are usually large-bore tubes (14–24 Fr) to deliver high feeding volumes and medications with minimal risk of occlusion. Most gastrostomy tubes are made of a biocompatible material such as silicone or polyurethane and are anchored in place with either parallel bumpers or a mushroom or balloon at the gastric site with a retention disk at the skin. This allows the tube to be secured to the stomach wall without sutures. A wide range of gastrostomy tubes is available for use in children. Most devices have an antireflux valve to prevent the release of gastric contents when the tube is accessed. Gastrostomy device can be easily disguised under clothing and the feeding tube is connected only at the time of infusion as a result it is particularly popular with older children and adolescents (Figure 67-3).

The percutaneous endoscopic gastrostomy (PEG) technique has revolutionized the placement of enteric feeding tubes in children.[65] This relatively simple and fast procedure can be performed during esophagogastroduodenoscopy in an endoscopy suite with the use of conscious sedation and local anesthesia or general anesthesia with a success rate of up to 96% even in small infants (<3.5 kg).[66] Although several techniques (Ponsky pull, Sachs-Vine push, Russel introducer) have been developed, all have in common the basic principle that the endoscope locates the site of tube placement from within the stomach while transillumination of the light from the endoscope through the abdominal wall identifies the site of skin incision. Radiological placement of gastrostomy tubes has also been shown to be safe and cost-effective in pediatric patients.[67]

The external bolster should be routinely checked for secure position to avoid tube migration and to prevent injury to the abdominal wall due to

compression between the internal and external bolsters. The stomal site requires regular cleaning to avoid chemical injuries from the gastric secretions and infection. Stomal granuloma and skin irritation or infection need prompt attention with referral to a stomal therapist if necessary, to prevent further complications. Eventually gastrostomy tubes will degrade over months to years due to physical or chemical trauma from yeast contamination or medications. Balloon-type skin level gastrostomy devices can also suffer from balloon rupture so it is general practice to replace these every 6 months as needed.[68]

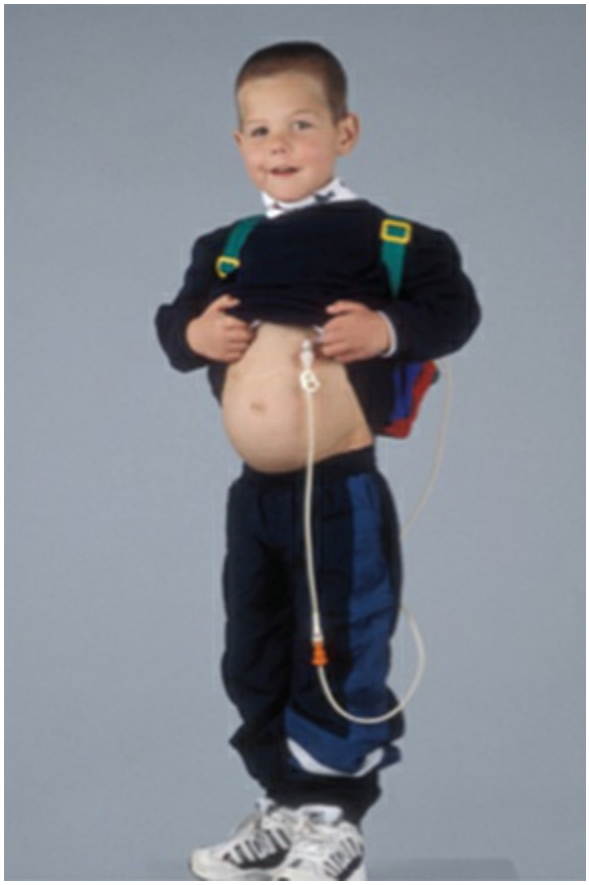

Figure 67-3 Child receiving continuous enteral nutrition via a gastrostomy using a portable enteral feeding pump in a backpack.

Postpyloric Feeding Devices

Advances in tube technology and the techniques for placement of nasoenteric tubes in children have provided an opportunity for postpyloric feeding in children in whom gastric feeding is difficult or contraindicated

(Figure 67-1). As a result, there has been renewed enthusiasm for the use of postpyloric feeding in the critically ill. Compared with intragastric feeding, postpyloric feeding in the critically ill is associated with a higher caloric intake and avoids complications associated with parenteral nutrition therapy. In a study of critically ill children requiring mechanical ventilation, the risk of aspiration was similar in patients receiving either postpyloric or intragastric feeding was less in the intragastric fed group compared to the post-pyloric fed group. The percentage of daily caloric goal achieved was less in the gastric group compared to the small bowel group.[69] Nasoenteric tubes can be placed blindly or under fluoroscopic or endoscopic guidance.[70,71] The percutaneous endoscopic technique can also be used to place an enteric tube using either a direct approach (direct percutaneous endoscopic jejunostomy) or by the creation of a PEG and placement of a specialized double-lumen tube (percutaneous endoscopic gastrostomy jejunostomy).[72] Among the range of surgical techniques described for jejunostomy tube placement, the needle–catheter jejunostomy is the most common. Using this technique, a large-bore needle is tunneled through the seromuscular layers of the jejunum distal to the ligament of Treitz. Enteric feeding tubes are generally smaller in diameter (9–12 Fr) than gastrostomy tubes and tend to have a shorter lifespan (3–6 months). Dislodgement of gastrojejunal tubes is not uncommon and may be a limiting factor for the use of this type of tube in patients requiring long-term home enteral nutrition.[19,73]

MODES OF DELIVERY

The mode of delivery of enteral nutrition will depend on the route of administration (gastric, duodenal, or jejunal), characteristics of the feeding tube (small- versus large-bore catheter), the desired feeding pattern (bolus, intermittent, cyclic, or continuous), and the cost and availability of equipment (by gravity or syringe, or by infusion pump). Bolus tube infusion usually mimics the normal meal pattern based on age. Intermittent or cyclic feedings are delivered at a specified rate over 1 or more hours, with 4–8 h/d of gut rest allowing freedom from tubes and pumps for a period of the day. Continuous feeding delivers a constant-rate infusion, usually by an infusion pump, over the entire day or a prolonged period. The infusion pump allows accurate nutrient delivery. Some pumps are specifically designed for outdoor activities and may be carried in a small backpack improving mobility for children on long-term enteral nutrition therapy (Figure 67-3).

Gastric feeding is preferred because it is considered more physiologic, allows bolus feeds through large-bore tubes, and is generally cheaper and easier to administer.[34] Many patients intolerant of bolus feeds can be successfully fed intragastrically using an intermittent or continuous feeding regimen. Energy intake goals are more successfully achieved in brain trauma patients receiving postpyloric feeds compared with those receiving intragastric feeds.[74] Postpyloric feeding is usually delivered as an intermittent or continuous infusion because rapid-rate infusion of nutrients is often limited by abdominal discomfort, diarrhea, or dumping syndrome. There are specific physiologic and metabolic considerations associated with continuous-rate feeding. During continuous intragastric feeding, gastric emptying increases parallel to the rate of infusion if the infusion rate is maintained at less than 3 kcal/min.[75] Increased caloric density, fat, and osmolarity of the formula can delay gastric emptying. The protein composition also influences gastric emptying. Whey-based enteral formulas enter the duodenum faster than casein-based enteral formulas.[76] In animals, the absorptive capacity of the proximal small intestine is unchanged during continuous enteral nutrition, but the enzymatic and functional capacity of the distal small intestine and colon is reduced.[75] The continuous delivery of nutrients into the small intestine affects glycemic control by modifying the typical fluctuating pattern of insulin and glucagon production.[77,78] The reduction in steatosis during continuous enteral nutrition compared with parenteral nutrition with the same carbohydrate intake is consistent with this observation. In addition, energy expenditure due to the thermic effect of feeding is lower in patients receiving continuous enteral nutrition than in patients receiving the same quantity of nutrients delivered by bolus.[74,77]

ENTERAL NUTRITION IN SPECIFIC DISEASE STATES

Critically Ill Children

Enteral feeding has now eclipsed parenteral nutrition in its role as primary nutrition support of the critically ill. Enteral nutrition not only reduces the risk of sepsis and metabolic complications associated with parenteral nutrition therapy but also prevents mucosal atrophy, reduced enzymatic activity, and dysmotility[79] associated with starvation.[80] The lack of bowel sounds on auscultation or lack of passage of flatus or stool is no longer

absolute contraindications for the initiation of enteral nutrition. In a recent multicenter cohort study of 31 pediatric intensive care units (ICUs) across eight countries, 30% of patients had severe malnutrition on admission.[80] Mortality was lower in those children who received enteral nutrition (rather than parenteral nutrition) and children receiving a higher percentage of their energy goal energy via the enteral route had lower 60-day mortality.[80] ICUs that implemented enteral nutrition protocols had a lower prevalence of acquired infections.[80] Despite potential complications such as diarrhea and aspiration, early enteral nutrition has been shown to decrease infectious complications and decrease mortality and infections when compared with parenteral nutrition.[81] Early enteral nutrition (<48 hours) in adult with severe traumatic brain injury has been shown to improve survival and the Glascow Coma Score on day 7 and was associated with an improved clinical outcome 1 month postinjury.[82] Gastric feeding is problematic in some patients and up to 50% of adult patients with traumatic brain injury exhibit intolerance to enteral nutrition due to impaired GI motility, reduced absorption, hypoalbuminemia, and chronic diarrhea. In a meta-analysis of critically ill adult patients, enteral nutrition reduced the risk of potentially life-threatening infections and noninfection-related events when compared with parenteral nutrition, as well as reducing length of stay, time in the ICU, and length of nutritional treatment.[83] Savings from reduced adverse event risks averaged nearly $1500 per patient and savings from reduced length of stay amounted to nearly $2500 per patient. The authors concluded that shifting 10% of parenterally treated adult patients in the United States to enteral nutrition would save $35 million annually due to reduced adverse events and another $57 million due to shorter hospital length of stay.[84] Adequate nutrition is crucial in children after surgery for congenital heart disease and can be challenging in the setting of greater demands and poor oral intake. Use of feeding protocols and a home surveillance system for hypoplastic left heart syndrome improves outcomes.[84] Children who have undergone cardiac surgery that is complicated by chylothorax require a fat-free diet or a formula that has a high proportion of medium-chain fatty acids.[85] Although myriad of barriers may exist to prevent achieving complete nutrition support in critically ill children, it is generally recommended to commence enteral nutrition within 48 hours of admission to the ICU.[86] See Chapter 64, “The Critically Ill Child.”

Gastrointestinal Diseases

Short bowel syndrome is an important cause of intestinal failure in childhood and usually as a consequence of surgical resection of the small intestine. Parenteral nutrition is essential for survival and to support growth while awaiting intestinal adaptation and improved enteral tolerance to occur. Although enteral feeding may be limited in the initial phase of recovery, if possible small amounts of enteral nutrition should be infused to support mucosal integrity and enhance the adaptive response. Enteral feeding will also promote normal motility and gall bladder emptying.[28] Human milk rich in nucleotides, IgA, glutamine, and growth factors is first choice but if unavailable oligomeric feeds with a high MCT content may be tolerated. The route of enteral feeding, either oral or via tube and continuous versus bolus, remains a matter of debate in terms of efficiency and feasibility.[28,29] A slow and constant infusion rate may promote absorption as a result of increased mucosal contact time however may also alter the normal intestinal motility pattern.[28,29,87] See Chapter 63, "Intestinal Failure."

Exclusive enteral nutrition has resulted in induction of remission of Crohn's disease, especially in children.[30] There is also emerging evidence regarding the role of ongoing supplementary enteral nutrition in the maintenance of remission from Crohn's disease in children and adolescents.[31] This is postulated to be the result of benefits of improved general nutrition as well as intestinal specific effects resulting in enhanced mucosal healing.[32] There is now a substantial body of evidence that enteral nutrition significantly reduces infectious complications, surgical interventions, and mortality in adults with severe acute pancreatitis compared to that observed in patients treated with parenteral nutrition.[88,89] This has yet to be studied rigorously in pediatric pancreatitis.[90] There is evidence, albeit relatively weak, to support the provision of minimal enteral nutrition (preferably with human milk) within the first 2 days of life, in the prevention of necrotizing enterocolitis in high-risk neonates.[91] After a diagnosis of necrotizing enterocolitis it has been recommended that feeds be withheld. Early introduction of enteral nutrition may have the potential for benefit by limiting the duration of parenteral nutrition therapy and the risk of catheter-related sepsis as well as reducing the risk of postnecrotizing enterocolitis intestinal stricture and length of hospitalization.[92]

MANAGEMENT OF ENTERAL ACCESS

Principles of Management

Monitoring patients receiving enteral nutrition will minimize the risk of developing complications and ensure optimal nutrition. The use of protocols for the management of enteral nutrition support has been associated with improved outcomes.[93] Enteral nutrition support monitoring includes nutritional, anthropometric, clinical, and laboratory measures. Frequency of laboratory monitoring of electrolytes, blood glucose, liver function, renal function, and serum lipids will depend on the clinical and nutritional status of the patient.[94] Nasally inserted tubes require daily check for nasal erosion, tube fixation, and tube integrity (Table 67-1). Gastrostomy and postpyloric tubes require daily stoma site and tube position check, weekly tube rotation, and balloon water volume check. Other anthropometric measures such as body mass index, mid-arm circumference, and triceps skinfold thickness may be performed as required to monitor growth and nutritional progress.

TABLE 67-1 Bedside Evaluation Tests for Tube Placement in Children

Aspirate	Color and Appearance	pH value	Pepsin (μg/mL)	Trypsin (μg/mL)	Bilirubin (mg/dL)
Gastric secretions	Yellow-gray or white-tan; cloudy	< 6	> 100 (> 20)[a]	< 30 (< 50)[a]	< 5
Intestinal secretions	Green	> 6	< 100 (< 20)[a]	> 30 (> 50)[a]	> 5
Respiratory secretions	Yellow-gray; mucoid	6–8	< 100 (< 20)[a]	< 30 (< 50)[a]	< 5

[a]Trypsin and pepsin ranges specific for children

Complications

Despite the potential benefits of enteral nutrition, complications can occur. Fortunately, life-threatening events are rare. However, problems related to the tube, the method of delivery, or the composition of the formula can seriously interfere with achieving nutritional goals. To minimize complications, prior consideration should be given to the patient's medical and physical condition, including any metabolic or electrolyte abnormalities and previous dietary tolerance.

Gastrointestinal Complications

Intestinal discomfort, bloating, cramping, diarrhea, nausea, and vomiting can occur during enteral feeding. Whenever symptoms occur, the position and integrity of the tube should be confirmed. In some cases, these symptoms relate to the high osmolality of the formula or the rate of infusion and alterations to the formula composition or infusion rate will be sufficient to improve feeding tolerance. The assessment of a sample of stool from a patient with diarrhea can assist in directing further investigations as required (bacterial culture, absorptive status by microscopy, analyzing pH, and reducing substances). The use of concomitant medications should be reviewed for possible drug–nutrient interactions or GI side effects. Bacterial contamination of the feed or the tubing can result in diarrhea or vomiting.[93] Therefore, the method of formula preparation and storage and the technique of hanging and administering should be reviewed. Samples of the feed, the tubing, and the feeding reservoirs are necessary to confirm this diagnosis.

Patients with a primary GI disorder could be at risk of bacterial overgrowth owing to disturbances in gut motility. Bacterial culture of an intestinal biopsy or a lactulose breath hydrogen test will assist in establishing the presence of bacterial overgrowth of the small intestine. Constipation associated with enteral nutrition is uncommon and when it occurs is usually associated with insufficient fluid or fiber intake, intestinal dysmotility or obstruction, or medications. Gastroesophageal reflux can be exacerbated by intragastric feeding. The nasogastric tube can stent open the lower esophageal sphincter, and irritation owing to tube trauma can contribute to lower sphincter incompetence. The placement of a gastrostomy tube will plicate the stomach against the anterior abdominal wall, distorting the normal gastric anatomy, with a potential impact on gastric function.

Pulmonary Complications

Aspiration of gastric contents due to incorrect tube placement or tube dislodgment into the airway can be fatal. Children at high risk include those with chronic neurologic disease, depressed conscious state, intestinal dysmotility, severe gastroesophageal reflux, and those requiring mechanical ventilation. In addition to checking tube position, tracheal aspirates can be measured for glucose content or fat-laden macrophages. The addition of blue dye to the formula to assess tube position and aspiration patients should be avoided because it has been associated with fatalities.[15]

Infectious Complications

Irritation due to the mechanical trauma or exposure to gastric or intestinal secretions render the skin and mucosa susceptible to infection. A well-fitting, well-maintained device specifically designed for enteral nutrition use will limit this complication. Contamination of the formula and the delivery set can occur as a result of preparation or administration of the feed.[94] Bacterial contamination occurred in 35%–50% of enteral feeding bags at the end of the infusions in a pediatric hospital.[95] Feeding devices also harbor biofilm growth of various bacteria and fungi in the outer and inner surface with potential risk of local and systemic infections.[96] Long-term nasogastric and nasoenteric tubes can be associated with chronic nasal discharge, otitis media, and sinusitis.

Mechanical Complications

Mechanical complications related to enteral tube feeding are common. However, these can generally be successfully treated and do not involve the same risks as a central venous catheter in critically ill children. Tube occlusion can occur as a result of problems related to the tube (length, caliber, characteristics), the infusion (formula, drugs), pumps and clamps, the method and rate of delivery, and the level of tube care (method, frequency). Infusions that contain a highly viscous formula or crushed or powdered drugs can be associated with tube occlusion. If flushing the tube with warm water is unsuccessful in clearing the blockage, a number of other options are available. The instillation of pancreatic enzyme supplements is sometimes successful in clearing a blockage. The use of meat tenderizer is not recommended because of its high sodium content and the risk of tube breakage during infusion. Cytology brushes, guide wires, neonatal tubes inserted into larger tubes, and specially designed catheters have been developed to treat tube occlusion. Key to the prevention of tube occlusion is careful monitoring and repeated flushing of the tube. Mixing of drugs and formula should be avoided. Irritation can occur anywhere along the interface between the tube and the skin or mucosa, resulting in inflammation, ulceration, or even perforation of any structure present along the tube lining (e.g., laceration or bleeding of nasal or oral cavity, perforation or laceration of the gut). Granulation tissue formation at the stoma site can occur as a result of chronic irritation. The migration of tubes with an internal balloon or retention device distally along the GI tract can cause bowel obstruction. Migration of a gastrostomy tube along the fistula tract can cause pain and inflammation around the site or the buried bumper syndrome. Complications such as dislodgment,

ampullary obstruction, and jaundice can occur with jejunal tubes.

Metabolic Complications

Metabolic complications associated with enteral nutrition are uncommon. Patients with chronic malnutrition or cardiac, hepatic, or renal impairment require careful monitoring of fluid and electrolyte status to prevent imbalance. Patients commencing enteral nutrition who have had a period of prolonged fasting, inadequate nutritional intake, or significant weight loss (>10% body weight) should be monitored for the metabolic features of the refeeding syndrome.[97] Regular monitoring of fluid status, serum sodium, potassium, phosphate, and magnesium levels is required until stability has been achieved with feeding advancement. Serum glucose levels, which are usually stable during continuous enteral nutrition therapy, can increase with overfeeding or as part of a stress response during critical illness. Hypoglycemia during intermittent feeding can be prevented with a progressive slowing of the rate of infusion in the period prior to disconnection. Dumping syndrome is reported in patients during enteral feeding in association with a rapid infusion of a formula with a high nutrient density and is treated with modifications in the rate of delivery or to the formula (such as adding uncooked cornstarch).

Drug–Nutrient Interactions

Administration of medications through an enteral feeding tube, either in combination with formula or alone, is problematic because only a few drugs have been tested and approved for tube delivery. Characteristics of the composition of the tube can influence the binding of drug to the tube wall.[98] Interactions between a drug and a nutrient can result in an undesired side effect of the drug or feeding intolerance. Drug–nutrient interactions can result in changes in medication bioavailability, distribution, metabolism, or excretion. Common drug–nutrient interactions are described with substances containing calcium, zinc, and iron or when acidic and neutral liquid medications are combined with casein or soy protein. Impaired absorption of phenytoin is well documented in the literature and occurs as a result of pharmacokinetic incompatibility.[98] Long-chain fatty acids can enhance the absorption of lipid-soluble drugs but hasten the degradation of other medications (e.g., carbamazepine). Liquid preparations of medications are preferred by children and for enteral administration. However, liquid drug preparations tend to have a high osmolality (1000 and 11,000 mOsm/kg) and may cause feeding intolerance when infused into the jejunum. The osmotic properties of these

liquids are usually attributable to the presence of sorbitol, propylene glycol, or polyethylene glycol. Although included among the inactive ingredients on drug labels, the amount is often not quantified. Osmotic diarrhea and delayed gastric emptying can occur if the cumulative dose is more than 20 g (range: 7.5–30 g).

HOME ENTERAL NUTRITION

Over the past three decades, advances in tube design, methods of delivery, and formulas have made enteral nutrition therapy safer, cheaper, and easier to administer for a wide range of disorders in childhood. With attention to appropriate patient selection, education, and providing adequate technical support, enteral nutrition therapy can be safely and effectively provided in the home.[99] It was estimated that in 1992, 152,000 patients of all ages received home enteral nutrition in the United States.[7] In Britain, home enteral nutrition therapy has been increasing rapidly—at a rate of up to 20% per year.[100] Of patients receiving home enteral nutrition therapy in Britain, 40% are children, compared with 5%–20% reported in three U.S. cohort studies.

Best-practice guidelines for the administration of safe and effective home enteral nutrition therapy have been developed by national nutrition support organizations. These guidelines take into consideration patient selection, assessment, monitoring, and the development of the enteral nutrition plan, including methods of implementation, documentation, and protocols for termination of therapy. Training patients, their families or caregivers in safe and effective home enteral nutrition therapy is ideally performed by a multidisciplinary team, including the gastroenterologist or surgeon, dietitian, stomal therapist, or nurse specialist.[98] An essential component of a successful home enteral nutrition service is availability of health professionals to provide support to the patient or caregivers at home to address concerns and direct appropriate intervention when necessary. A mechanism should be available to manage after-hours tube malfunction. To facilitate this process, all patients should carry a card with the type and size of tube and the date of last insertion clearly listed. Written documentation of routine tube care, as well as the recommended steps to take in the event of tube malfunction, is invaluable to the patient and caregiver at home. Regular review by the multidisciplinary home enteral nutrition team is cost-effective and improves quality of care.[101] At regular outpatient appointments, all aspects of the administration of enteral nutrition can be assessed. The tube is examined for size, function, and

integrity and can be changed if necessary. The stoma site is examined. The method of delivery is reviewed, along with protocols for formula preparation. The intake of formula is assessed with reference to the nutritional goals. The patient is examined for growth, weight gain, and nutritional status. Laboratory markers of nutritional status can be obtained as indicated.

CONCLUSION

Advances in enteral formulas, tube placement techniques, tube design, and delivery systems have enabled the safe and effective provision of enteral nutrition support for a broad range of disease indications in children. The successful provision of enteral nutrition support has limited the use of parenteral nutrition therapy, resulting in important benefits in terms of safety, manageability, and cost. The management of nutritional problems in patients with chronic diseases, such as neurologic disorders, Crohn's disease, cystic fibrosis, and short bowel syndrome can be enhanced by home enteral nutrition therapy. The development of disease-specific formulas provides new therapeutic options. Further improvements in technology enabling light, simple, feeding pumps and modifications to tube design continue to assist in the administration of enteral nutrition to children.

Parenteral Nutrition

68

Corina Hartman, MD, Arie Riskin, MD, and Raanan Shamir, MD

INTRODUCTION

Providing nutritional support to patients unable to eat has been a dream and a challenge for many centuries before the advent of modern parenteral nutrition (PN). The ability to provide intravenous alimentation has been made possible only through the advances in our understanding of anatomy and physiology, biochemistry and metabolism, microbiology and mostly, the tremendous technological advances that occurred in the 20th century.[1] To these should be added the landmark research in several areas including, but not limited to, the development of accurate methods for analysis of body fluids and body composition, useful for nutritional assessment; the identification of the essential amino acids and their requirements for humans; the use of intravenously infused hydrolyzed protein and emulsified fats for nutritional support. In the 1930s, another major milestone was reached by Cuthbertson's landmark demonstrations of "catabolic response to injury" that revolutionized the approaches to management of severely ill patients.[2,3]

The era of modern PN has been initiated by the pioneer work of several researchers. In 1924, Robert Matas, a New Orleans surgeon, was the first to use a continuous drip infusion of glucose in humans.[4] Progress in protein metabolism and essential amino acids requirements made by William Rose, enabled Robert Elman to provide parenteral replacement of protein by injection of an enzymatic hydrolysate of casein.[5] Using an admixture of glucose, amino acids, and electrolytes, Elman showed improvement in nitrogen balance, serum protein concentration, and clinical status of 35 malnourished patients.[6] Concomitantly, the first intravenous protein hydrolysate solution in Europe was developed by Arvid Wretlind

in 1944.[7] Wretlind and Oscar Schuberth were also the designers of the first readily available fat emulsion from soybean oil with egg yolk phospholipids as an emulsifying agent.[8] Although frequently used in Europe, their use in United States has been banned for several years due to serious adverse effects reported in the previous years with cottonseed oil infusions. In 1968, a new milestone in the history of PN was marked by Stanley Dudrick who used a catheter placed in the superior vena cava (SVC) to deliver a solution of concentrated glucose, along with all other essential nutrients (although, lacking lipid emulsions), in a child with small bowel and colonic atresia. During the 44 days of intravenous nutrition, until "running out" of venous access, the child achieved normal growth and development.[9]

Currently, provision of nutrients parenterally enables short- and long-term growth in infants and children suffering from intestinal failure (IF) or immaturity. Improved knowledge of nutrient requirements and methods of nutrient delivery, and better understanding of prevention and management of complications, have enabled safer and more efficient delivery of PN in hospitals and at home. In 2005, the European Society of Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) and the European Society for Parenteral and Enteral Nutrition (ESPEN) published exhaustive guidelines on PN in children. That document represents the consensus statement of a multidisciplinary working party of professionals, knowledgeable in the management of children treated with PN, and represents so far the most exhaustive collection of data and guiding principles on PN use in children.[10]

INDICATIONS

PN is generally indicated in infants and children who are unable to tolerate adequate oral or enteral feedings to sustain their nutritional requirements. This commonly includes (a) premature infants, due mainly to immaturity of their gastrointestinal tracts, (b) infants or children in whom a period of prolonged fasting is anticipated, that is, necrotizing enterocolitis (NEC), pancreatitis, gastrointestinal graft-versus-host disease, or postoperatively, and (c) pediatric patients with temporary or permanent IF from any reason, that is, congenital diarrheal syndromes, motility disorders, congenital malformations, short bowel syndrome, and so forth. Given the risks and the costs associated with its use, PN should be avoided whenever possible by the appropriate use of oral or enteral nutrition.

When should nutritional support be started? The maximum tolerable

period of fasting depends on the patient's age, nutritional status, and underlying medical conditions. Energy substrate utilization relies on substrate availability during periods of fasting, but depends on the "neurohormonal" milieu and inflammatory/injury mediators elicited during stress. During fasting, most organs derive their energy from the oxidation of fatty acids (FAs) or ketone bodies produced from FAs in the liver. The central nervous system, nevertheless, is an obligate glucose user under ordinary conditions. In the absence of carbohydrate (CHO) intake or significant stored CHO, the only source of glucose is gluconeogenesis from amino acids, most of which are supplied by the breakdown of body proteins. However, there are no reserves of visceral proteins and each body protein has a specific function. Therefore, utilization of proteins for energy purposes results in an obligatory functional insult. In adults, this demand for glucose results in the catabolism of about 75 g of protein (which is about 375 g muscle tissue) a day during fasting.[11]

As starvation progresses, several adaptations take place which aim to conserve lean body mass. The most important of these are (a) gradual decrease in metabolic rate, and (b) progressive rise in serum concentration of ketone bodies. At high concentrations, ketone bodies cross the blood–brain barrier and can be utilized as an energy source by the central nervous system.[12] The adaptation to starvation is limited in sick and fasting patients. Illness and injury increase metabolic energy expenditure and the hormonal milieu of stress favor glycogenolysis and gluconeogenesis.[13] The rise in serum insulin, which accompanies the elevated blood glucose inhibits the increase in serum ketone body concentration that would be used by the brain as primary fuel. Thus, production of glucose and concomitant loss of protein continue at a high rate in sick and starving hospitalized patients.[14]

How can these observations be applied to children? There are very few studies on the physiology of starvation in children, but some reasonable estimates can be made. Protein makes up about 10% (dry weight) of total body weight.[15] In infants, about half the total protein is in muscle and half is found in other tissues. Taking into consideration body composition, basal metabolic rate (BMR), and brain metabolic rate for patients of various ages, one can roughly estimate the number of days in which one-third of body protein will be catabolized in an individual who is totally fasted. This ranges from less than four days in small premature infant to 10–15 days in older children and adolescents, which clearly illustrates the different time frames for nutritional intervention in infants and young children. Furthermore, each day without nutrition support will have

significantly different consequences in premature infants compared to full-term infants, toddlers, children, and adolescents.

Hospitalized patients are rarely totally starved as most intravenous fluids contain glucose, although the same principles hold for "semistarvation." In 1947, Gamble was the first to demonstrate the protein-sparing effect of CHO when he found that nitrogen excretion was considerably reduced in fasted subjects who were given 100–150 g of glucose.[16] This amount of glucose supplies a major part of the energy requirements of the central nervous system, thereby reducing, although not eliminating, the need for gluconeogenesis. Provision of sufficient glucose (100–150 g/d in adults) to meet the metabolic requirements of the brain has been shown to reduce nitrogen losses by half.[17] The nitrogen-sparing effect of CHO may be even greater in children as the brain consumes a much higher proportion of total metabolic expenditure, but this has not been specifically studied. The addition of proteins, vitamins, and minerals to the intravenous infusion will further slow the rate of catabolism of endogenous body protein. However, it has been repeatedly shown, that patients are in negative nitrogen balance unless their complete protein and caloric requirements are met.[18] In practice, if the child is taking nothing by mouth for more than a few days, proteins, vitamins, and minerals should be added on the third to seventh day, depending on age, clinical status, and disease. The exceptions are the very low-birth-weight infants (VLBW) as discussed below. The number of days must be reduced considerably for children who have already lost weight prior to hospitalization or who have increased metabolic requirements.

As part of nutritional care, PN should be provided only after thorough consideration/trial of other means of nutritional support, that is, enteral nutrition. Planning for PN should include a clear statement of PN support goal and patient's further evaluation and follow-up including (a) nutritional requirements, (b) baseline metabolic parameters, (c) nutritional goal (maintain nutritional status, improving nutritional status), (d) anticipated PN duration, (e) venous access including route and type of catheter used for delivery, and (f) monitoring for efficacy and complications of therapy. Despite the obvious benefits of PN, numerous complications (metabolic, infectious, and mechanical) may arise as a result of PN use. Consequently, the multiple risks of PN should be weighed against the benefits of nutrition support prior to the initiation of therapy in each individual patient.

PARENTERAL NUTRITION IN PRETERM INFANTS—GENERAL CONSIDERATIONS

The survival of preterm infants has increased significantly over the last few decades, especially for VLBW infants weighing less than 1500 g. The goal of nutritional support for the VLBW infant is to achieve a postnatal growth rate that approximates that of a normal fetus at the same gestational age. Nutrition aims to mimic intrauterine growth and body composition, and equally important to obtain functional outcome comparable to infants born at term.[19–21]

Human growth is unique due to special emphasis on the protection of brain development. The period between 20 and 32 weeks after conception is one of rapid brain growth and development. Illness, infection, or undernutrition during this critical time period may compromise neurodevelopment and affect later outcome. The clinical consequences may include motor problems, principally cerebral palsy, visual and hearing impairments, learning difficulties, and psychological, behavioral, and social problems.[22] Thus, the importance of providing early nutrition to preterm infants is related not only to short-term outcomes, but has implications on long-term development as well.[23] Nutritional strategy in preterm infants should be directed to achieve the best possible outcomes in terms of body growth and composition and neurodevelopment.[24,25]

The current focus of nutritional science has shifted from meeting nutritional needs to the biological effects of nutrition on short term and lifetime health. The term “programming” was coined to emphasize the long-term effects of nutritional and environmental factors especially for preterm infants. Programming relates to a stimulus or insult during a critical or sensitive period of development that can have long-term effects. In that context, there is ample evidence that nutrition in early life has a major impact on long-term health and development, notably on growth, cognitive function, bone mineralization, and cardiovascular health.[26] Nutritional insults at a vulnerable period of brain development are associated with effects on brain size, cell number, and function. Although slow growth below the intrauterine rate might have some benefit for later cardiovascular outcome, it carries the risks of undernutrition and its adverse consequences, and has profound adverse effects on later cognition.[27] Thus, in contrast to hypothetical reservations regarding catch-up growth in full-term infants, the current accepted concept is to provide the best optimal nutrition possible and try to achieve fetal accretion rates in premature infants and disregard the potential long-term disadvantages of

catch-up growth. The immediate postnatal period is specifically important, as the old practice of providing intravenous fluids with very little nutritional value has been shown to have negative long-term outcomes on growth and neurodevelopment.[21]

To minimize the harmful effects of near starvation associated with the interruption of fetal nutrient supply at and after delivery, the approach to nutritional support of preterm infants has been switched to "early aggressive nutrition." According to this approach full nutrient supply should be delivered to the preterm infant as soon as possible to prevent the catabolic state associated with delivery and separation from intrauterine nutrient supply as well as the morbidities associated with premature delivery (e.g., respiratory distress syndrome).[20,28–30] Delivering adequate amounts of nutrients to premature infants is challenging at all times because the infant's immature gastrointestinal tract is initially unable to accept enteral feedings, necessitating the use of PN. This is especially true for VLBW sick preterm infants who are usually dependent on PN during their first weeks of life. Not surprisingly, neonates represent today one of the largest age group of patients receiving PN.[31]

Protein intake is the major driving force of weight gain and brain development in VLBW infants and deficits and growth deficits start already in the first week of life.[32,33] Early amino acids administration improves outcome by providing substrate for tissue growth (especially the brain), and for protective glycoproteins, such as glutathione.[34,35] Early PN, started as soon as possible after delivery, is mandatory for VLBW premature infants in order to provide the required high protein intake and to prevent negative nitrogen balance. These tiny preterm infants can tolerate up to 3.5–4.0 g/Kg/d within the first days of life with only relatively mild transient increase in serum urea nitrogen and no significant acidosis.[35,36] As the minimum protein intake needed to prevent tissue breakdown is 2.0–2.5 g/kg/d, probably the best practice is to start with at least 2.0–3.0 g/kg/d amino acids as soon as possible following birth, and advance to full protein intake of 3.5–4.0 g/kg/d of amino acids within 3–4 days.[37] Early high amino acids' intake requires higher energy intake.[37] This implies that CHO–amino acids PN admixture solutions are not sufficient, and addition of lipids is needed very early in life, probably from the first day, to provide the extra energy.[38] Lipids provide not only energy for growth, but also essential fatty acids (EFAs), that is, long chain polyunsaturated fatty acids (LC-PUFA), especially docosahexaenoic acid (DHA), which are particularly important for brain and retinal development

of premature infants.

Early PN in premature infants should provide (a) adequate protein intake and supply of essential amino acids to encourage nitrogen retention that is essential for growth and brain development; (b) adequate calories for energy expenditure, protein synthesis, and growth; (c) CHO to prevent hypoglycemia and provide energy supply; (d) lipids to meet the caloric needs and supply of essential FAs; (e) essential nutrients including electrolytes, minerals (especially calcium and phosphate), trace elements (TEs), and vitamins.[39] Nutrition support in VLBW infants should prevent growth failure and improve extrauterine growth,[40] decrease morbidity and mortality, and support better short as well as long-term outcomes,[23] especially neurodevelopmental outcomes.[41]

ENERGY REQUIREMENTS

The fundamental cornerstones of nutritional support are prevention of weight loss in the short term and promotion of growth in the long term. Providing the energy needs is fundamental both in health and disease. Positive energy balance is associated with energy storage and tissue deposition, weight gain, and adequate linear growth. Negative energy balance is associated with depletion of tissue and thus weight loss, and if prolonged, leads to poor linear growth. Although protein is a potential energy substrate, it should be utilized only for tissue synthesis (accretion or renewal) and not as an energy source. The recommendations for energy needs in children usually include the protein contribution to caloric intake as well as fat and CHO, and as such are referred to in this chapter. Ideally, the distribution of calories should be 45%–55% CHO, 10%–15% proteins, and 35%–40% fats.[42]

Total daily energy expenditure (TEE) is the sum of the BMR, diet-induced thermogenesis (DIT), the energy spent on physical activity, and losses in urine and stools (obligatory losses). BMR, the largest (60%–70%) component of TEE, represents the energy needed to maintain essential body functions and tissue and cellular integrity. BMR can be considered as the energy expended by a fasting individual at rest in a thermoneutral environment, and is similar to measured resting energy expenditure (REE). The energy expended for physical activity is the second largest component of TEE, and the most variable accounting for 15% to 40% of TEE. DIT accounts for a small proportion of daily energy expenditure, the remainder being the energy cost of growth and obligatory losses.

REE varies between individuals, largely because of differences in body

size and composition. A large child has a higher REE than a small child. The difference in REE between two individuals is principally determined by the amount of fat-free mass (FFM). The variation in fat mass (FM) and FFM may have a significant impact on a child's energy requirements: a child with a high FFM is likely to have a higher energy requirement compared with a child with a high FM.[43] Moreover, FFM contains both internal organs and skeletal muscle. In a healthy child, organ mass is more metabolically active than skeletal muscle, therefore, organ mass contributes more to total REE than skeletal muscle. Boys tend to have higher REE than girls even when corrections for differences in body composition have been made. Several studies have demonstrated differences in REE in children from different ethnic backgrounds.[44] REE significantly decreases with age independent of other factors, partially because of the decrease in energy cost needed for tissue replacement with advanced age.

DIT is the ''obligate'' energy cost of processing food (e.g., chewing, peristalsis, digestion, absorption, postabsorptive processing). DIT represents the increase in energy expenditure that occurs after consumption of a mixed meal. DIT is a small component of TEE and is particularly difficult to measure. Therefore, by convention it is assumed to be about 10% of TEE.[45] Abnormalities in DIT are unlikely to be important contributors to variations in energy balance. DIT varies, depending on the macronutrient composition of the diet but also on body size and FM (nutritional state) of the child. When malnourished children experience rapid weight gain, they have a larger increase in energy expenditure after a meal compared with that when there is no weight gain or there are slower rates of weight gain.[46] This is likely the result of a higher energy requirement to synthesize new tissue during more rapid (catch-up) growth. During PN administration, DIT and the respiratory quotient (RQ) are affected by the mode of PN administration (continuously vs. cyclic).[47,48]

The energy cost of growth is inherently difficult to determine as growth is variable and influenced by age, pubertal status, illness, medications, and obviously nutritional status. Energy needs for growth contain two components: (1) the energy used to synthesize growing tissues, which is part of the total energy expenditure; and (2) the energy deposited in those tissues, basically as fat and protein. Studies in infants and young children recovering from malnutrition have estimated that the energy cost of growth is between 4 and 6 kcal/g of tissue deposited, with most of this attributable to the energy deposited (stored) and approximately 1 kcal/g being the energy cost of synthesis. However, there

are no studies to estimate the energy requirements of catch-up growth in older children and adolescents.[46,49] In clinical practice, during recovery from acute illness or in chronic disease, the children are usually supplied with 120%–150% of energy requirements to ensure adequate catch-up growth.

The measurement of physical activity is inherently difficult because of daily variation, but estimates can be made over several days with the use of accelerometers, heart rate monitors, or diaries.[50] An acutely unwell child will have very little physical activity, but as soon as recovery starts, their activity level will quickly return to normal. Obese children are difficult to assess because despite the sedentary lifestyle, the mechanical work done by their muscles to produce movement can be quite large. In general, obese subjects tend to underestimate intake and overestimate physical activity, whereas children with anorexia nervosa typically underreport the amount of exercise they perform and overestimate their intake.

Energy requirement can be measured directly using different techniques for TEE, REE, or physical activity. TEE can also be estimated by adding together the three component parts: BMR, DIT, and the energy expenditure of activity (activity thermogenesis).

TEE can be measured by using doubly labeled water (DLW) method. The use of the DLW ($^{2}H_2{}^{18}O$) technique to calculate total production of carbon dioxide (CO_2) over several days and, from this, total energy expenditure was originally developed for use in small mammals,[51] and its application was later validated in humans.[52] The subject ingests water with labeled isotopes of hydrogen and oxygen. The hydrogen-labeled isotope can only be cleared from the body through water loss, whereas the oxygen isotope is excreted through water loss and CO_2 production. By measuring the relative amounts of each isotope and the amount of CO_2 production, energy expenditure can be calculated. Although this method is considered the gold standard in TEE assessment, it is still subject to imprecision particularly in disease states.

REE can be measured by indirect calorimetry (IC) or determined using predictive equations, which are easily accessible without the need to use specialized equipment and appliances. The measurement of energy expenditure is the most accurate method to assess energy needs, especially in acutely ill patients. IC uses the measurement of carbon dioxide production (VCO_2) and oxygen (VO_2) based on the assumption that all

inspired oxygen is used to oxidize substrates and that all the expired CO_2 is produced from these reactions. Total average daily energy expenditure in kcal is usually calculated using the modified Weir equation with substitution of the measured VO_2 and VCO_2 values.[53] The urinary nitrogen component (uN_2) is often excluded when calculating energy expenditure because it only accounts for about 4% of the true energy expenditure and contributes to a small error of 1%–2% in the calculation of final energy expenditure in both inpatients and outpatients.[54] Thus the abbreviated equation is commonly used[55]:

Energy expenditure (kcal/d) = $[(VO_2 \times 3.941) + (VCO_2 \times 1.11)] \times 1440$

The technique requires adherence to strict conditions including environmental temperature, fasting, and rest before measurement to obtain measurements close to BMR.[56]

In addition to measurement, REE can be estimated from many equations. Several such equations have been developed to calculate REE, BMR, and TEE. Of these, the WHO equations (1985), Schofield (1985), and Harris Benedict (1919) equations are the most commonly used.[57–60] New equations for BMR estimation, Oxford equations, have been published recently.[61] The Oxford equations are based on the data available from 10,552 subjects (5794 males and 4702 females) from 166 separate investigations and report calculated BMR for a range of body weights and ages (0–3, 3–10, 10–18,18–30, 30–60, >60 years) for both males and females. For all available equations, the main predictor for each component of energy expenditure is body weight whereas height also accounts for some of the variability in energy needs (Table 68-1). These predictions of REE are derived at a population level and do not necessarily correlate with measured REE of an individual patient.

The performance of these equation compared to the actual measured REE has been estimated in several studies in healthy children populations. WHO and Schofield-wt/Ht have both underestimated[62] and overestimated[63] REE in healthy infants. Harris Benedict equation overestimates REE in infants and adults too.[64] In older children, 5–16 years, both WHO and Schofield-wt equations have been shown to be reasonably accurate.[65] The Schofield equations also provided the best estimates in another study in 7.8–16.6 years healthy children.[66] Overall the equations are not reliable in children with abnormal growth or body composition, but in children with failure to thrive, the Schofield-wt/Ht was

found to be the best predicting equation.[67]

The referred equations were never intended to predict REE in patients with complex disease processes. In sick children, the differences in actual energy needs versus calculated needs based on general equations arise from the special status of the patient, that is, energy losses from malabsorption, diarrhea, ostomies, underlying disease, inflammation, infection, impaired body composition (decreased lean body mass due to increased catabolism), and different energy routes of supplementation (oral, enteral feeding, continuous vs. intermittent feeding, and PN). Caution is also needed in applying estimates to individuals in whom height, weight, and physical activity deviate significantly from the pattern of the reference population. In addition, a hospitalized child lying in bed has reduced physical activity and growth is usually altered, further reducing the TEE. Measurement of REE in 398 chronically ill children found a wide variability for % measured REE/predicted REE (SD ± 27.2) and poor agreement between measured REE and predicted REE, as more than 50% of the children in this cohort would have been underfed if their daily energy requirements were prescribed based on predicted REE.[68] As most of the children in need of PN suffer from one or more of the above, the estimated energy needs based on current equations may be incorrect. However, a study in stable children on home PN found no difference in daily EE compared to age and gender matched controls.[69]

TABLE 68-1 Equations Used for Calculating REE/BMR (kcal/day) in Children 0–18 Years Old

Source	Gender and Age	Equations
Harris–Benedict[58]	Females	REE = 655.0955 + 9.5634*wt + 184.96*ht − 4.6756*age
	Males	REE = 66.4730 + 13.7516*wt +500.33 *ht − 6.7550*age
FAO/WHO/UNU[57]	Females 0–3	REE = 61*wt − 51
	Males 0–3	REE = 60.9*wt − 54
	Females 3–10	REE = 22.5*wt + 499
	Males 3–10	REE = 22.7*wt + 495
	Females 10–18	REE = 17.5*wt + 651
	Males 10–18	REE = 12.2*wt + 746
Schofield[59]	Females 0–3	BMR = 16.25*wt + 1023.23*ht − 413.5

	Males 0–3	BMR = 0.167*wt + 1517.43*ht − 617.6
	Females 3–10	BMR = 16.97*wt + 161.8*ht + 371.2
	Males 3–10	BMR = 19.60*wt + 130.3*ht + 414.9
	Females 10–18	BMR = 8.365*wt + 465*ht + 200
	Males 10–18	BMR = 16.25*wt + 137.2*ht + 515.5
Oxford[61]	Females 0–3	BMR = 30.4*wt + 703*ht − 287
	Males 0–3	BMR = 28.2*wt + 859*ht − 371
	Females 3–10	BMR = 15.9*wt + 210*ht + 349
	Males 3–10	BMR = 15.1*wt + 74.2*ht + 306
	Females 10–18	BMR = 9.4*wt + 249*ht + 462
	Males 10–18	BMR = 15.6*wt + 266*ht + 299

All equations are for kcal/day; wt, weight in kilograms; ht, height in meters; age in years.

Both approaches (measuring REE and calculating REE) are used in clinical practice. Whatever method is used, the need to make corrections for physical activity, DIT, and energy losses increases the likelihood of inappropriate estimates. Thus, adjustments are needed, according to the clinical situation and by observed responses to treatment (weight gain/growth). Providing nutrient supply by PN should also take into consideration the recommended intake of the different macronutrients (lipids, CHO, and protein) as well as possible intolerance and complications (hyperglycemia, hypertriglyceridemia, liver enzyme abnormalities, cholestasis). Average daily parenteral energy intakes per kg body weight considered adequate for a major proportion of patients are shown in Table 68-2.

Nutritional Support in Pediatric Intensive Care Unit

Children admitted to the pediatric intensive care unit (PICU) exhibit unpredictable metabolic response to critical illness depending on its nature and severity. Adequate nutritional support is critical for these children, as both overfeeding and underfeeding are associated with complications.[70] Pollack et al. reported that 16% to 20% of critically ill hospitalized children developed significant acute protein-energy malnutrition, some within 48 hours of admission to PICU.[71] Malnutrition is associated with decreased immunocompetence, increased risk of infection, poor wound healing, increased morbidity, and increased mortality, whereas overfeeding increases the risk of hyperglycemia, high RQ, and fatty liver.[71]

TABLE 68-2 Estimated PN Requirements for Energy,

Amino Acids, Fat and Glucose Supply					
	Preterm	0–12 Months	1–7 Years	7–12 Years	12–18 Years
Energy, kcal/kg/d	110–120	90–100	75–90	60–75	30–60
Amino acids[a,b], g/kg/d	1.5–4.0	1.5–3.0 < 2 months 1.0–2.0 > 2 months	1.0–2.5[a] < 3 years 1.0–2.0 > 3 years	1.0–2.0	1.0–2.0
Lipids[c,d], g/kg/d	1–4	3–4	2–3	2–3	2–3
Glucose[e], g/kg/d	8–18	16–18	10–14	10–12	<10

[a]A minimum of 1.5 g/kg/d (preterm and term newborns) to 1 g/kg/d (older children) amino acids is necessary in to prevent negative nitrogen balance.

[b]For critically ill older children the protein intake may be as high as 3 g/kg/d.

[c]The lower limit necessary to prevent EFAD is estimated at 0.25 g/kg/d in premature infants and 0.1 g/kg/d in term infants and older children, of linoleic acid. The intravenous lipid emulsion (ILE) dose necessary to prevent EFAD should be calculated according to ILE composition used, and is different for the different ILE formulations. For example, if the ILE is Intralipid (100% soybean oil, 53% linoleic acid), the minimal lipid intake in a premature infant is 0.5 g/kg/d and 0.2 g/kg/d in infants and older children. If the ILE is Clinoleic (20% soybean oil, 18.5% linoleic acid), the needed lipid intake necessary to avoid EFAD in a premature infant is 1.8 g/kg/d and 0.5 g/kg/d for full term and older children. For Lipofundin (50% LCT/50% MCT, 27% linoleic acid) the lipid intake necessary to avoid EFAD in a premature infant is 0.9 g/kg/d and 0.4 g/kg/d for full term and older children. For SMOFlipid (21.4% linoleic acid), the needed lipid intake necessary to avoid EFAD in a premature infant is 1.16 g/kg/d and 0.5 g/kg/d for full term and older children.

[d]Parenteral lipid delivery should be limited below 0.13–0.17 g/kg/hour in infants and 0.08–0.13 g/kg/hour in older children.

[e]The table shows the maximal glucose supply by age, under standard conditions. The glucose supply should, however, be adapted to child' clinical and nutritional status, type of PN delivery (continuous or cycling) and the presence of additional medications.

In some critically ill adults, it was shown that a hypermetabolic state occurs during critical illness, characterized by significantly greater energy expenditure than REE in the non-stressed state.[72] Extrapolating from the adult studies, it has been suggested that the energy requirements in critically ill children should also be estimated by adding a stress-related correction, "stress factor," to the REE. Stress or activity "correction factors" traditionally have been added to energy requirement estimates to adjust for the nature of illness, its severity, and the activity level of hospitalized subjects. The hypermetabolic state reported in adults is less prevalent in critically ill children. In addition, children admitted to PICU may have significant reduction in true energy expenditure, attributable to multiple factors including decreased activity, sedation, mechanical ventilatory support, and transient absence of growth during the acute illness. These patients may be at a risk of overfeeding when estimates of

energy requirements are based on age-appropriate equations developed for healthy children, especially if stress factors are incorporated.[73] Thus, the application of predetermined values of correction factor based on broad diagnostic groups of patients in the PICU is likely to be inaccurate and may increase the risk of overfeeding or underfeeding.[74,75] Studies in critically ill children have shown that REEs using presently available equations either overestimate the true energy expenditure or underestimate the energy requirements.[76–79] Tilden et al. and Coss-Bu et al. reported that measured REE was much higher than the predicted BMR estimated by either the Harris-Benedict or the Talbot equations.[80,81] In general, the estimates from prediction equations compare poorly to measured values; calculated values have shown an error range[82] of 7% to 55%.

In conclusion, it is recommended that in critically ill children, REE be measured rather than calculated due to individual variability and over or underestimation of energy requirements by the predicting equations.[83] Unfortunately, multiple factors have limited the application of this testing in everyday clinical practice, and IC is only sporadically used in the PICU. In a review of PICU practice across 111 centers in Europe, only 17% of centers reported the regular use of IC to measure energy expenditure.[84] Resource and technical restraints seem to preclude regular IC testing in most units. Selecting candidates for IC according to American Society for Parenteral and Enteral Nutrition (ASPEN) recommendations, a recent study in 150 pediatric ICU patients, showed that three of four patients were candidates for IC. Children less than 2 years of age, malnourished (underweight/overweight) on admission, or with >5 days ICU were at particular risk for nutritional imbalances, therefore, should be above all candidates for IC. Further studies are needed to examine the effectiveness of a model of selective use of IC and its impact on patient outcomes. Application of IC at the bedside to provide nutrition intake that is tailored to individual patients and adjusted dynamically to their illness course is a desirable goal in the future.[85]

Energy Requirements in Preterm and VLBW Infants

In preterm low-birth-weight (LBW) infants, energy requirements should cover both energy expenditure and energy needed for growth. Estimates of energy requirements are dependent on protein intake,[21] because energy is required for both protein metabolism (i.e., avoiding catabolism) and deposition (i.e., linear growth).[20] To achieve optimal growth, the premature infant on PN needs 90–100 kcal/kg/d. This estimate is based on

the minimum energy requirements that allow unlimited growth of lean body mass. Above this intake, the energy is presumably stored in adipose tissue.[21] Out of this, 40–60 (average 50) kcal/kg/d account for REE.[86,87] This is the minimum energy required to avoid protein catabolism when 1.5 g/kg/d protein intake is supplied, that is, the minimum protein intake required to induce positive nitrogen balance from the first day of life.[37] Energy expenditure appears to be greater with lower birth weights, associated morbidities, advancing postnatal age, and as the infant grows and gains weight.[86–88] To support further growth, an additional 20–25 kcal/kg/d should be provided in addition to the daily energy expenditure.[89] This results in a total of 90–100 kcal/kg/d of energy required for preterm infants on PN in the first days of life, considered as transitional period. It must be remembered that VLBW preterm infants on PN have lower energy requirements compared to infants on enteral nutrition (90–100 kcal/kg/d vs. 120–130 kcal/kg/d, respectively) due to less fecal energy losses, less energy required for activity and lower energy requirements for thermoregulation, as these infants are usually kept in neutral thermal environment at this stage. Later on, energy intake of 110–120 kcal/kg/d is required for optimal weight gain and growth in VLBW infants on PN. This is supplied by combined administration of lipid and glucose and can usually be achieved only after several days from birth, because of limited glucose and lipid tolerance, and the need to avoid hyperglycemia and possibly aggravate respiratory status.[21,90] Current recommendations endorse provision of 40 kcal/kg/d on the first day of life, 60–80 kcal/kg/d in the following days, and a target goal of 90–100 kcal/kg/d from PN by the end of the first week of life.[10] Balanced distribution of calories from CHO and lipids is also important as it favors protein accretion[91] and avoids protein oxidation that may occur if high glucose is given parenterally with low or without lipids.[92] Although the gold standard for caloric distribution is human milk (40%–45% calories from CHO and lipids), the energy distribution usually achieved in preterm infants' PN covers 45%–55% of the calories from CHO, 35%–40% from lipids, and 10%–15% from protein (amino acids). Keeping average protein/energy ratio of 3.3 g protein/100 kcal (range 2.7–3.9 for PN, higher ratios for lower gestational ages and birth-weights) is essential to maximize protein accretion, improve lipid and protein tolerance, and avoid acidosis.[20,21]

PROTEIN REQUIREMENTS

Proteins serve as the main structural element of the body. In addition, as biochemical catalysts and regulators of gene expression, proteins are essential elements for most metabolic functions. Proteins are complex structures that consist of chains of two to thousands amino acid subunits joined together by peptide bonds. There are 20 amino acids from which all proteins are synthesized. If these cannot be endogenously synthesized in sufficient amounts then dietary supply becomes essential. Classically, in healthy adults nine amino acids are regarded as dietary essential (or indispensable). During growth or during illness several other amino acids are regarded as conditionally essential (Table 68-3). If amino acids are not present in the appropriate proportions then protein synthesis will be reduced.[93,94] Furthermore, it has been shown that whole body protein breakdown is increased when less balanced mixtures of amino acids are fed.[95] In this case, the endogenous amino acids provide the missing amino acids for protein synthesis.[95,96]

TABLE 68-3 Essential, Conditionally Essential, and Nonessential Amino Acids

Essential Amino Acids	Conditionally Essential Amino Acids	Nonessential Amino Acids
Histidine	Arginine	Alanine
Isoleucine	Cysteine	Serinene
Leucine	Glycine	Aspartic acid
Lysine	Proline	Asparagine
Methionine	Tyrosine	Glutamic acid
Phenylalanine		Glutamine
Threonine		
Tryptophan		
Valine		

Clinical assessment of the adequacy of protein supply is done most easily in childhood through sequential height and weight measurements. Additional useful clinical tools are measurement of mid-upper arm parameters (mid-upper arm circumference and triceps skin-fold thickness) from which muscle area and circumference can be calculated. Body composition measurements using bone densitometry or bio electric impedance (BIA) are seldom done routinely and are usually part of a research protocol.

The classical approach to biochemical assessment of protein status has

been nitrogen balance studies in which excretion of nitrogen waste products in urine and feces are subtracted from dietary protein (nitrogen) intake.[97] This technique requires complete collections of urine and feces for three days and biochemical measurements which are not readily available in the clinical setting. A ‘‘partial nitrogen balance’’ can be obtained by measuring urea nitrogen in urine instead of total nitrogen. This wrongly assumes that urea nitrogen is a fixed proportion of total nitrogen.[98] For children, protein allowances were traditionally considered to be the amount of protein needed for sustaining positive nitrogen balance and therefore, growth. Recently, protein requirements have begun to encompass outcomes other than growth (i.e., immune function) and a more critical evaluation of protein requirements for children has been recommended.

Various blood proteins have been examined as possible markers of protein status. These include albumin, transferrin, prealbumin, and retinol-binding protein. Serum albumin represents the equilibrium between hepatic synthesis and albumin degradation and body losses. It is also influenced by intravascular and extravascular albumin compartments and water distribution (about one-third of the albumin pool is in the intravascular compartment, and two-thirds is in the extravascular compartment). Once albumin is released into plasma, its half-life is about three weeks and can be used for long-term monitoring. Serum albumin is a good predictor for outcome and thus reflects disease severity. However, albumin is a poor marker to assess nutritional status in inflammatory states. Prealbumin and retinol-binding protein, with half-lives of two days and 12 hours, respectively are regarded as being mostly reflective of acute protein intake. However, these markers also suffer from the influence of other nonnutritional factors such as hepatic and renal failure, hormone effects, infection, and inflammation.[99]

A number of different tracer techniques and protocols have been applied with the purpose of determining the requirements for specific indispensable amino acids. The advent of amino acid oxidation studies, and in particular, the indicator amino acid oxidation (IAAO), which is the current gold standard method, has been successfully applied to identify amino acid requirements in adults.[100] This method is based on the concept that when one indispensable amino acid is deficient in the diet, then all other amino acids, including the indicator amino acid, usually L-(1-^{13}C) phenylalanine, will be oxidized. With increasing intake of the limiting amino acid (or total protein), oxidation of the indicator amino acid decreases, reflecting increasing incorporation of the amino acid into

proteins. Once the requirement is met for the limiting amino acid, there will be no further change in the oxidation of the indicator amino acid. The inflection point at which the oxidation of the indicator amino acid stops decreasing and reaches a plateau is referred to as the “break point.” The break point identified with the use of two-phase linear regression analysis indicates the mean or estimated average requirement (EAR) of the limiting amino acid or total protein.[101] The initial application of IAAO to studies in humans involved intravenous indicator administration, blood sampling, and the use of up to nine days of amino acid–based experimental diet. To enable studies in children, the IAAO method has been adapted by administering the tracer orally, using urine instead of arterial blood sampling, and reducing the adaptation period to the experimental diet to four hour.[102] The minimally invasive IAAO have thus enabled the estimation of amino acid requirements in children[103,104] and neonates[105,106] over a shorter period of time and allowed the study of the test amino acid in 8–9-hour and over a range of 6–8 levels of the tested amino acid.

The amino acid utilization and therefore, requirements are different when provided via the enteral vs. the parenteral route. Although parenterally infused amino acids enter directly into the circulation, peptides and amino acids within the intestinal lumen undergo a variety of transformations, including utilization by enterocytes and conversion to other amino acids, within the enteric mucosa and liver.[107] Thus, the pattern of amino acids entering the circulation of the enterally fed individual reflects not only the pattern of the protein intake but also the extent of digestion and, subsequently, metabolism within the enteric mucosa and liver. In contrast, the pattern of individuals receiving only parenteral nutrients more closely reflects the amino acid pattern of the infused mixture.

The currently available pediatric parenteral amino acid mixtures were designed based on considerations of food protein composition (e.g., human milk proteins) and plasma pattern of amino acids observed in normally growing, breast-fed infants.[108,109] Their composition was designed to mimic the optimal amino acids profile based on fetal and neonatal cord blood amino acids concentrations (i.e., according to the factorial approach that uses estimations of weight gain and the composition of fetal tissues) (Primene) or based on plasma amino acids concentrations of healthy 30 days old breast-fed term infant (i.e., according to the approach that uses human breast milk as the gold standard) (TrophAmine). The rationale was

that this pattern reflects transformations of dietary protein and amino acids by enteric and hepatic metabolism as well as ongoing protein synthesis and breakdown of normally growing infants and, hence, should also be optimal for infants requiring parenteral nutrients.[110]

In addition to the eight classically indispensable amino acids and histidine, infants also require cysteine and tyrosine which most adults can synthesize from methionine and phenylalanine, respectively.[111] The requirement for cysteine is thought to result from low or absent hepatic activity of cystathionase, the rate-limiting enzyme for endogenous synthesis of cysteine from methionine. The hepatic activity of the rate-limiting enzyme for endogenous synthesis of tyrosine from phenylalanine, that is, phenylalanine hydroxylase, achieves adult levels early during gestation; thus, the reason for the apparent requirement for tyrosine in infants is not clear. The composition of different pediatric amino acids solutions compared to adult solutions is presented in Table 68-4.

Accretion of body protein in infants and children is dependent on the optimal intake of all of the indispensable and dispensable amino acids and adequate nonprotein energy. Energy supply of 30 to 40 kcal per 1 g amino acids is usually recommended. Stanley Dudrick originally conceived of PN as hyperalimentation, and provided nutrients in excess of normal requirements for patients with increased metabolic demands. The first infant to receive modern TPN, reported by Wilmore and Dudrick in 1968, was given 4 g/kg/d of protein hydrolysate.[9] Nitrogen retention of 0.200–0.300 g/kg/d and satisfactory weight gain were found in all patients when protein intake ranged from 2.0 to 5.0 g/kg/d.[112–115] Fox et al., however, reported optimal weight gain of 10–15 g/d in all babies with a protein intake of 1.5–2.7 g/kg/d.[116] As excessive supply of protein can have harmful effects it is important to achieve positive nitrogen balance with adequate amount and mixture of amino acids supply. The parenteral amino acids requirements for different age groups are presented in Table 68-2. No data endorse the common practice of gradually advancing either the amino acid or lipid dose.

Duffy et al. reported that amino acid and nitrogen utilization is enhanced in parenterally fed neonates when the energy intake is increased from suboptimal (60 kcal/kg/d) to optimal level (80–90 kcal/kg/d) by the addition of intravenous lipid to the amino acids and glucose.[95] However, other studies that investigated the optimal nonprotein fuel mix (glucose vs. lipid) for parenterally fed neonates showed no differences in nitrogen retention between the two energy sources.[117,118] Bresson et al., showed

however, that protein turnover, protein breakdown, and amino acid oxidation rates were significantly higher when glucose only was the energy substrate, compared to glucose-lipid supply, whereas protein-synthesis rates did not differ significantly.[91] These results suggest that the nature of energy substrates delivered to parenterally fed infants may affect protein metabolism.

TABLE 68-4 Amino Acid Composition of Several Parenteral Formulations for Infants and Children as Compared to Human Milk

	TrophAmine[a] (B.Braun)	Primene[a] (Baxter)	AminosynPF[a] (Abbott)	Travasol[b] (Baxter)	FreAmine[b] (B. Braun)	Aminoplasmal[b] (B. Braun)	Human Milk
Essential and Conditionally Essential Amino Acids							
Isoleucine	820	670	760	600	590	510	550
Leucine	1400	990	1200	730	770	890	1050

[a]Recommended for infants less than 1 year.

[b]Recommended for children older than 1 year through adulthood.

The knowledge about safe levels of enteral amino acid intakes is sparse, and similarly there is limited knowledge of parenteral amino acids toxicity, although hyperammonemia, acidosis, and seizures have been well described.[108,119] Moss and colleagues have demonstrated that methionine

is hepatotoxic in a rabbit model in which animals received large amounts of parenteral methionine with or without enteral feedings.[120] L-Arginine, through L-ornithine production, is known to induce necrotizing pancreatitis in a rat model,[121] and L-lysine at large doses induces renal failure in dogs.[122]

Specific amino acid requirements are altered in many diseases, and recommendations for the general population may not apply in these conditions. Furthermore, unnecessary restrictions may cause aggravation of malnutrition.[123] In a retrospective study, Verbruggen et al. compared the parenteral amino acids intake in 116 critically ill children, with essential amino acids intakes recommended by the Institute of Medicine (IOM). The study found that the amino acid compositions of commercially available parenteral amino acid formulas provided to critically ill children are variable and unbalanced to support inflammatory/immune protein synthesis, resulting in excessive or deficient supply of amino acids compared with IOM recommendations, breast milk, and mixed muscle proteins.[124] Because there is no tailor-made recipe for amino acid supplementation in various disease states, periodic assessment of protein nutritional status for adequacy, including anthropometry and serum biomarkers is recommended.

Protein Requirements in VLBW Infants

Early high protein intake is the cornerstone of "early aggressive nutrition" (discussed above as part of the general approach to PN in preterm infants). Early high protein intake during the first week of life induces positive nitrogen balance, protein accretion, and also increases endogenous insulin secretion, thus improving glucose tolerance and preventing hyperglycemia.[20] Recent recommendations suggest providing 2–3 g/kg/d of amino acids on the first day of life, and progressively increasing up to 3.5–4.0 g/kg/d by the end of the first week.[10] This intake promotes weight gain and growth and improves neurodevelopmental outcome.[24,25] In extremely low-birth-weight (ELBW) infants (<1000 g) amino acids intakes up to 4.5 g/kg/d have been well-tolerated and have been associated with weight gain and lower rates of bronchopulmonary dysplasia (BPD).[36] Optimal nitrogen (protein) and nonnitrogen energy intake and their appropriate ratios are essential to achieve positive nitrogen balance. High early PN amino acids intake is well-tolerated with no significant acidosis or hyperammonemia, and only moderately elevated blood urea nitrogen levels that are transient.[35,36,125] There are some concerns regarding the

safety of early high amino acids intake in very premature infants, related to the concentrations of the different amino acids and the possible side effects, mainly neurodevelopmental long-term outcomes.[126] Extremely premature LBW infants who receive early and higher parenteral amino acids have higher plasma amino acid levels.[127] However, there is no consensus regarding the optimal profile of amino acids in these infants and currently there is no data about toxicity. Nevertheless, the proven benefits of providing early high amino acids intake outweigh these concerns, although, more long-term studies are needed to ensure safety.

The metabolic immaturity of the neonatal population, especially those born prematurely, requires the provision of optimal amounts of both essential and conditionally essential amino acids that preterm infants have limited ability to synthesize (cysteine, glutamine, glycine, taurine, and tyrosine). Glutamine is an amino acid abundant in human milk and may be considered as a conditionally essential amino acid in premature infants. It is not included in available amino acid solutions because of stability issues. Glutamine contributes to the maintenance of small intestinal interepithelial junction integrity, intestinal epithelial cells growth and proliferation, inflammatory responses, and mucosal healing.[128,129] However, in a multicenter study and meta-analysis, supplementation of glutamine to standard PN did not improve protein retention, weight gain or growth and did not reduce the risk of mortality, late-onset sepsis or NEC.[125] Cysteine supplementation was suggested as a means to improve glutathione (a major intracellular antioxidant) synthesis, and to help premature infants to face the oxidative stress that they encounter on their unanticipated early transition to extrauterine life.[34] Glutathione is synthesized from glutamate, cysteine, and glycine. In a meta-analysis, cysteine supplementation was associated with improved nitrogen balance, although it did not improve growth.[130] Addition of cysteine to PN solutions (done as its hydrochloride base, 30–40 mg/g amino acids, up to a maximum of 120 mg/kg) lowers mixture pH. This increases calcium and phosphorus solubility and allows higher concentrations of these minerals to be provided.[131]

LIPID REQUIREMENTS AND INTRAVENOUS LIPID EMULSIONS

The introduction of the first successful intravenous lipid emulsion (ILE) in 1961 was a major breakthrough in PN support. Besides being a high-

density nonglucose source of energy, lipids are increasingly recognized to influence various immune functions, according to physicochemical characteristics of its FA and emulsifier (egg phospholipid) concentration.[132] Fat emulsions provide both energy and essential FAs. In addition, partial replacement of glucose by fat emulsions as the source of nonprotein calories minimizes hyperglycemia and its detrimental effects. Compared to glucose, intravenous administration of fat was shown to have equal[133] or superior[134] effects on nitrogen economy in surgical patients receiving PN. Furthermore, providing glucose and fat to infants is advantageous to protein metabolism compared to providing glucose alone as discussed above.[91] In premature infants, FAs are also necessary for central nervous system development and retinal maturation.[135]

lLEs consist of three components: an aqueous phase (glycerol), a lipid phase (FA), and an emulsifier. The lipid phase supplies FAs and the majority of the calories. FAs are categorized based on several different characteristics. First is the number of carbons in the FA chain: 2–4 carbons, short-chain FAs; 6–12 carbons, medium-chain FAs; and ≥14 carbons, long-chain FAs. Second is the number of double bonds in the FA molecule. Saturated FAs have no double bonds, monounsaturated FAs (MUFA) have 1 double bond, and polyunsaturated FAs (PUFAs) have 2 or more double bonds. Unsaturated FAs are furthermore categorized according to the carbon position at which the first double bond occurs, counting from the methyl end of the molecule (the ω carbon). There are three principal families of unsaturated FAs in humans: ω-3, ω-6, and ω-9 in which the first double bond occurs at the third, sixth, or ninth carbon, respectively. Essential FAs, ω-6 linoleic acid (LA,18:2 n6) and ω-3 α-linolenic acid (ALA, 18:3n3) are polyunsaturated FAs (PUFAs) that cannot be synthesized in humans but are metabolized through two different pathways, that use and compete for the same enzymes with preference for ω-3 > ω-6 > ω-9. With some exceptions, high conversion of LA to arachidonic acid (AA) may lead to overproduction of proinflammatory cytokines; in contrast, the cytokines derived from ω-3 FAs are considered to be anti-inflammatory.[136]

Soybean oil–based ILEs

The first safe and effective ILE became available in Europe in 1961 with the introduction of a soybean oil–based ILE. Until today, soybean oil, rich in ω-6 FAs, continues to be one of the main lipid sources in the various ILE on the market. Soybean oil contains high concentrations of PUFAs,

around 60% of the total FAs, with 8:1 ratio of LA (ω-6) to ALA (ω-3) ratio. Many experimental reports have raised concerns about the safety of ω-6 rich ILEs. ω-6 FAs promote the generation of AA–derived eicosanoids, which could, potentially exaggerate the inflammatory response when administrated to critically ill patients and patients with compromised immune function, sepsis, and trauma. Proinflammatory eicosanoids increase synthesis of potent proinflammatory mediators such as, tumor necrosis factor α and interleukin-6. ω-6 PUFAs have been correlated with unwanted immunosuppressive actions such as impaired reticular endothelial system function and inhibition of lymphocytes, macrophages, and neutrophil functions, although the data are not always uniform. In addition, the high number of double bonds in ω-6 PUFAs predisposes them to lipid peroxidation. The generated lipid peroxides can lead to cell death and cause damage to DNA, lipids, and proteins. Lipid peroxidation may further impair immune cells function and has been involved in the pathogenesis of intestinal failure associated liver disease (IFALD). Phytosterols, an isomer of cholesterol, another toxic component of soybean oil, has also been suggested among the etiologies of IFALD.[137,138] Furthermore, more questions have been raised about providing infants and children with soybean oil–based ILEs as their sole lipid intake. Soybean oil contains 50% or more of its triglyceride FAs as LA. This may represent a "linoleic acid overload" that may compete for and inhibit synthesis of longer chain ω-3 FAs such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Especially important to the growing infant is adequate provision of DHA for normal retinal and brain development.[139]

Concerns about the association of ILE with infectious morbidity were raised after a report of an increased risk of bacteremia related to the use of ILE in neonates.[140] A recent meta-analysis investigated the influence of timing and type of LE on rate of weight gain and several secondary outcomes in VLBW infants.[141] Analysis of the type of LE included 10 studies (499 infants; 249 in the intervention groups, 250 in the control group) which compared different LEs (combinations of soybean oil with medium-chain triglycerides (MCT) and/or olive oil and/or fish oil) with pure soybean oil. The rate of weight gain, death before discharge, duration of respiratory support, hypertriglyceridemia, and hyperglycemia were not affected by the type of LE. Pooled analysis of the studies (three studies, n = 197) which reported the incidence of sepsis showed that the use of a lipid source which was not purely soybean reduced by 25% the number of sepsis episodes (RR: 0.75; 95% CI: 0.56, 1.00; P = .05). This borderline

significant difference was, however, not significant in the individual studies. Moreover, the overall data regarding the effects of soybean oil–based ILE on immune responses have been disparate, as many investigators in numerous clinical and experimental settings found no evidence of an effect on a wide range of features and functions of immune cells, cellular signal transduction, or membrane characteristics. Taken together, the different experimental approaches applied in animal and human studies most probably play an important role in the ongoing controversy.[142,143]

MCT/LCT–based ILEs

In 1984, a second generation of ILEs consisting of a physical mix of equal parts of soybean oil and MCT oil (from coconut oil) was introduced in Europe. This emulsion (Lipofundin®) contains 50% less ω-6 PUFA, still adequate for meeting the needs of adults and infants. The new LCT/MCT combination has a similar ratio of LA (ω-6) to ALA (ω-3) of approximately 8:1. Compared to LCT, MCT has the advantage of greater solubility, lower accumulation in adipose tissues and liver, faster clearance, and improved resistance to peroxidation. Compared to LCT, MCT are rapidly taken up by mitochondria, largely independent of carnitine, and are oxidized faster and to a greater proportion. When prescribing MCT/LCT ILE one must remember that the energy content per gram MCT fat is lower than of LCT. From a functional point of view MCTs do not promote the synthesis of proinflammatory mediators and, unlike LCTs, have been suggested to improve immune function. The clinical relevance of these findings, however, remains to be established.[144,145]

There are indications that using emulsions containing MCT is advantageous in increasing lipid utilization, but also in decreasing the severity of chronic cholestasis syndromes and other hepatotoxicities that have been linked to PN.[146,147] In clinical studies, ILEs containing MCT/LCT have been well tolerated and safe in low-birth weight[148,149] and older children[150] in ICU patients[151] and HPN patients.[152] The use of MCT/LCT–based ILE in pediatric surgical patients has been shown to improve immune response and spare protein better than traditional LCT-based ILE.[150] Side effects including metabolic acidosis and increased energy expenditure have been reported after administration of MCT to animals. High levels of MCT have also been reported to delay the utilization of LCT. MCTs are, however, always used in combination with

LCTs because MCTs do not contain EFAs.[153,154]

Olive oil–based ILEs

In the 1990s, a third generation of ILEs, containing olive oil and soybean oil in a ratio of 4:1, was developed in Europe. The new olive oil–based ILEs have a high content of the monounsaturated (MUFA) oleic acid and of biologically active vitamin E (α-tocopherol). The ratio between LA (ω-6) and ALA (ω-3) in this ILE is 9:1.

Several in vitro animal and human studies have shown that the impairment of immune function, oxidative stress, glucose metabolism, endothelial function, and inflammation that occurs with soybean oil–based ILEs may be attenuated with olive oil–based ILEs. However, it is unclear whether the use of olive oil–based lipid emulsions in PN results in improved clinical outcomes compared to PN containing conventional soybean oil–based formulations.[155,156]

In randomized controlled studies in children and infants, the olive oil–based emulsion showed comparable tolerance and safety to a soybean oil emulsion (premature infants, ill neonates, and HPN) or MCT/LCT emulsions (children after bone marrow transplantation), but resulted in more favorable FAs levels in serum, reduced markers of lipid peroxidation, and higher serum vitamin E levels.[157–160] Use of olive oil–based lipid emulsions have been also shown to be safe in various adult patients groups: HPN patients,[161] hemodialysis,[162] severe trauma,[163] and in burned patients.[164] However, at this point of time there is insufficient data on oxidative stress markers, immune function, and clinical outcomes advantages of olive oil–based ILE.

Fish oil–based ILEs

Fish oil (FO) containing emulsions represent the most recent development in ILEs. FO is currently found in three PN lipid emulsions: Omegaven® (pure FO emulsion); Lipoplus® (50% MCT, 40% soybean oil, 10% FO) and SMOFlipid® (30% soybean oil, 30% MCT, 25% olive oil, 15% FO). FO is rich in ω-3 PUFAs, particularly EPA and DHA. Compared to MCT and olive oil, ω-3 FAs, are highly bioactive compounds. FO–based ILEs are not only nutrients and source of energy but also have anti-inflammatory properties with potentially important pharmacological and clinical benefits.[165,166] Pure FO emulsion (Omegaven®) has been developed as an adjuvant pharmacological—anti-inflammatory agent in critically ill patients, regardless of PN indication. The isolated use of

parenteral fish oil LE as a pharmacological agent has been investigated as an approach for quickly modulating immune functions and improving clinical outcomes in different clinical settings (rheumatoid arthritis, cancer, postsurgery, and critically ill patients).[165–168] Addition of FO has been associated with several effects: (1) Suppression of ω-6 FAs tissue content and increased incorporation of ω-3 FAs in the phospholipids of plasma, platelets, red blood cells (RBCs), and leukocytes, as well into lung tissue, liver cells, and the intestinal mucosa; (2) lower PGI2 metabolites, TXA2, 6-keto PGF1α, and TXB2 and decreased tendency for thrombosis and platelet aggregation; (3) inhibition of the proinflammatory cytokines (TNF-α, IL-6, and IL-1β) production and modulation of the anti-inflammatory cytokine IL-10.[169,170]

A recent meta-analysis in surgical and ICU adults, which included 23 studies (*n* = 1502 patients, *n* = 762 admitted to the ICU) found no statistically significant difference in mortality rate between patients receiving ω-3 PUFA-enriched lipid emulsions and those receiving standard lipid emulsions (RR = 0.89; 0.59, 1.33). However, ω-3 PUFA-enriched emulsions were associated with a statistically and clinically significant reduction in the infection rate (RR = 0.61; 0.45, 0.84) and the lengths of stay, both in the ICU (−1.92; −3.27, −0.58) and in hospital overall (−3.29; −5.13, −1.45). Other beneficial effects included reduced markers of inflammation, improved lung gas exchange, liver function, antioxidant status, and FA composition of plasma phospholipids, and a trend toward less impairment of kidney function.[171] A meta-analysis published in 2013 (six RCTs, *n* = 390 patients, critically ill adults only) reported that FO-containing emulsions were associated with a trend toward a reduction in mortality (RR 0.71; 95% CI: 0.49,1.04; *P* = .08) and a reduction in the duration of mechanical ventilation (weighted mean difference in days [WMD] −1.41; 95% CI: −3.43, 0.61; *P* = .17). However, no effect on infections and intensive care unit length of stay was observed.[168]

Besides these immunomodulatory properties, ω-3 PUFAs also exerts metabolic effects, which are well documented in humans.[172–174] PUFAs decrease plasma triglyceride levels in healthy and hypertriglyceridemic subjects and, increase lipid oxidation through upregulation of mitochondrial uncoupling proteins (UCPs'3) gene expression in liver and skeletal muscle in animal models.[175] Lipid profiles of the 79 children who developed PN-related cholestasis while receiving standard PN with a soybean oil–based ILEs were examined before and after the switch to a FO–based ILE (Omegaven®). After a median 18.3 (9.4–41.4) weeks of

receiving the FO–based ILE, serum triglyceride, total cholesterol, LDL, and VLDL concentrations significantly decreased by 51.7%, 17.4%, 23.7%, and 47.9%, respectively. A trend toward increase in the favorable cholesterol HDL was observed.[176] SMOFLipid® emulsion was evaluated in a double-blind randomized study in 28 children on HPN allocated to receive either SMOFlipid 20% (n = 15) or a standard soybean oil–based (Intralipid 20%, n = 13). ILEs were administered four to five times per week (goal dose, 2.0 g/kg/d). SMOFlipid emulsion was safe and well tolerated, decreased plasma bilirubin, and increased ω-3 FA and α-tocopherol levels without changing lipid peroxidation.[177]

Use of FO–based ILEs seems to be advantageous in treating infants and children with IFALD. FO–based ILE as monotherapy has been recently used in patients with IF and cholestasis, with promising results.[178] To date, no prospective RCT have compared equal doses of soybean oil–based with FO–based ILEs in preexisting IFALD. Concerns with the use of FO monotherapy have included the development of essential fatty acids deficiency (EFAD) or bleeding. Neither complication has been reported to date, although EFAD can occur if doses <1 g/kg/d are used.[179] Recent evidence in a murine model suggests AA and DHA provision alone is sufficient to prevent biochemical and physiologic evidence of EFAD.[180] The use of mixed ILEs with some FO for the prevention of cholestasis and hyperbilirubinemia in VLBW infants has not been evaluated in RCT but is increasingly used in neonates, thus, calling urgently for more well-designed RCTs.[181,182]

A recent meta-analysis reviewed the evidence on the benefits and safety of ω-3 FO compared with standard LE in children. The authors identified five RCTs and three prospective cohort studies in premature and LBW infants (n = 6), children with heart disease (n = 1), and IF (n = 1). The strength of evidence was consistently low or very low across all ILE comparisons and outcomes. In young children, ω-3 emulsions resulted in improvement in some biochemical outcomes of liver disease but no difference in mortality. Few studies examined patient-important outcomes, such as hospital length of stay or intensive care days and important safety parameters including the effect on growth and development remain to be evaluated.[183] Table 68-5 shows the composition and characteristics of several ILEs for parenteral supply in infants and children.

Carnitine

Carnitine facilitates transport of long-chain FAs across the mitochondrial

membrane, and thus makes the FAs available for beta-oxidation.[184] Preterm infants on PN have low carnitine levels, although the clinical significance of this finding is not clear. Meta-analysis of studies on carnitine supplementation to infants on PN showed no effects on weight gain, ketogenesis, or lipid utilization.[185] Thus, there is no benefit in routine parenteral carnitine supplementation to neonates requiring PN. Carnitine supplementation should be considered on an individual basis in infants receiving exclusive PN for long periods, probably for more than four weeks.[10]

Essential Fatty Acids Deficiency

Essential FAs cannot be synthesized in human tissues and must be obtained from the diet. Essential FAs are needed for processes including maintaining the integrity of the skin, structure of cell membranes, and the synthesis of prostaglandins and leukotrienes. Essential FAs include LA (ω-6) and ALA (ω-3) acids. The body can derive other FAs, such as AA (20:4 ω-6) from LA and EPA (20:5 ω-3) and DHA (22:5 ω-3) from ALA, but FO is a more efficient source as it does not rely on the conversion of ALA to DHA and EPA or LA to AA. In fact, FO contains mainly EPA and DHA, whereas vegetable oils predominantly contain LA or ALA. Requirements of EFAs are 1%–2% of dietary calories for children and 4%–5% for infants. Previous recommendations suggest a balance of 10:1 of ω-6 to ω-3 FAs, but emerging data indicate that a ratio as low as 2:1 would be beneficial in ill patients.[186] Soybean and olive oil–based emulsions contain a ratio of approximately 7:1 and 9:1, respectively.

[a]Data of commercial ILE according to the manufacturers.

Intralipid (Fresenius Kabi, Bad Homburg, Germany); Clinoleic (Baxter, Compton, United Kingdom), Omegaven 10% (Fresenius Kabi, Bad Homburg, Germany), SMOFLipid (Fresenius Kabi, Bad Homburg, Germany), Lipoplus (B. Braun Melsungen, Melsungen, Germany).

EFAD can develop when intake of EFAs is inadequate (<1%–2% of total calories). EFAD was prevented when at least 3.2% of total calories were given as intravenous fat or at least 15% as oral fat. To prevent EFAD a minimum LA intake of 0.25 g/kg per day should be given to preterm infants and 0.1 g/kg per day to term infants and older children.[187] Patients with EFAD may show adverse effects, including skin lesions, reproductive failure, growth retardation, reduced learning, impaired vision, and polydipsia, as well as susceptibility to infections.[188]

The decline in ω-3 and ω-6 FAs concentrations that is characteristic of EFAD is accompanied by a corresponding increase in the percentage of nonessential FAs (oleic acid, palmitic acid) derivates, produced as a result of the elongation and desaturation of oleic acid (to mead acid) and palmitic acid (to palmitoleic and vaccenic acid). This process occurs during de novo lipogenesis. As mead acid typically accumulates in the presence of EFAD, the ratio of this compound to AA (i.e., the triene:tetraene ratio, Holman's index) is used as a diagnostic marker for EFAD. Until recently, plasma values of triene:tetraene ratio above 0.2 were considered abnormal, whereas levels >0.4 were considered diagnostic for EFAD.[189] Using capillary-column-gas-liquid chromatography, Siguel et al. have developed

long ago a more sensitive criteria that suggests total essential FAs to total nonessential FAs <0.60 and mead acid to AA ratios >0.025 as more reflective of EFAD. It must also be noted that the triene:tetraene ratio does not reflect ω-3 FAs status.[190]

Biochemical abnormalities appear in 1–2 weeks in children, whereas physical signs and symptoms may not appear for 4–6 weeks. However, biochemical abnormalities occur within 72 hours of birth in neonates, and may manifest clinically in premature infants by the end of the first week of life.[191–193]

EFAD may be treated by a variety of modalities and the essential FAs may be administered orally, or intravenously. In the absence of ILEs, donor plasma has been administered to patients with EFAD. Topical application of safflower and corn oils has been used but is not currently recommended. These oils do not provide adequate LA, are associated with unpredictable results, may take 2–3 weeks to take effect, and requires permeable skin to be effective.[194,195] In the absence of enteral feedings, the most reliable therapy for EFAD consists of ILEs. The ILEs from soybean oil with or without safflower oils are rich in ω-6 FAs. Omegaven, consists of 100% FO and is rich in ω-3 FAs with very little ω-6 FAs. This lipid emulsion, however, dosed at approximately 1 g/kg/d, provides sufficient essential FAs to prevent EFAD.[179]

Lipids Dose

Lipid intake should usually provide 35%–40% of calories in fully parenterally fed patients. Age-based lipid intake requirements are presented in Table 68-2. The minimum lipid supply must cover the daily requirements of essential FAs. Excessive lipids supply, beyond the liver's ability to utilize CHO and fat can cause accumulation of by-products in the liver and is a risk factor for the development of IFALD. Although standard guidelines recommend administration of ILEs at a dose <2.5 g/kg/d, even a dose >1 g/kg/d has been associated with the development of IFALD.[196] A recent study showed that compared to a historical control group of infants receiving 3 g/kg/d, reduction of soybean-based ILE to 1 g/kg/d delivered twice weekly was associated with a significant reduction in total bilirubin levels. EFAD was however diagnosed in 8/13 infants in the intravenous fat emulsion reduction group, although clinical signs of EFAD were not detected.[197] Decreasing or withholding lipids for extended periods in neonates may be detrimental due to lack of fat reserves and the high risk of EFAD and growth retardation.[198] Furthermore, provision of 1 g/kg/d of a

soy-based ILE did not always prevent or delay the onset of cholestasis in neonates.[196]

Excess ILEs has also been associated with respiratory distress, coagulopathies, impaired reticuloendothelial system function, immunosuppression, and hypertriglyceridemia.[199,200] The upper limit of lipid administration is difficult to determine. In term infants, fat oxidation reaches a maximum at 4 g/kg per day, given that the maximum glucose intake does not exceed maximal oxidative glucose disposal of about 18 g/kg per day.[91] Fat oxidation depends on the total energy intake and expenditure, the total intake of CHO and triglycerides and the CHO/fat ratio administered. Maximal fat oxidation occurs when the ILE provides 40% of the nonprotein PN calories in newborns and 50% in infants.[91] In neonates and infants, assuming an intake of 2.5–3.0 g/kg/d amino acids and 18–20 g/kg per day glucose, the administration of 3 g/kg per day lipids would put the total calorific intake at ~110–120 kcal/kg per day. This would cover the needs in most cases. If there is need to achieve a total caloric intake of 140 kcal/kg per day and assuming an administration of 3.0 g/kg per day amino acids, there would be need to give 3–4 g/kg per day lipids with 24.5–22 g/kg per day glucose.[201]

The metabolic utilization of intravenous lipids varies with gestational and postnatal age, severity of disease, and other factors. Therefore, monitoring of indicators of lipid utilization such as plasma triglycerides (or ideally lipid oxidation) may help in defining adequate intakes. There is no need to withhold parenteral lipid administration for determining triglyceride serum levels. Upper triglyceride levels of 250 mg/dL during lipid infusion in newborns, and serum levels of triglycerides of 300–400 mg/dL in older children can be reached postprandially and are considered acceptable during infusion of lipid emulsions. Emulsions with a low phospholipid/triglyceride ratio, usually in 20% lipid emulsions, result in less hyperlipidemia than emulsions with a higher phospholipid/triglyceride ratio (10% emulsions).[202,203] Parenteral lipid intake should usually be limited to a maximum of 3–4 g/kg per day (0.13–0.17 g/kg per hour) in infants and 2–3 g/kg per day (0.08–0.13 g/kg per hour) in children.[10,204] In critically ill patients, with sepsis or acute respiratory failure, it might be prudent to limit lipid intake during the acute phase of respiratory failure. Closely monitoring plasma triglycerides and adjusting lipid infusion rate when necessary is recommended in septic patients. It is common practice to limit ILE intake to less than 3 g/kg/d in infants, especially premature, with extreme hyperbilirubinemia, approaching levels mandating exchange

transfusion.[205] This practice is based on a theoretical concern that FAs might displace bilirubin from albumin-binding sites thus increasing serum free unconjugated bilirubin levels that could increase the risk of kernicterus.[206]

Use of ILEs in VLBW Infants

For many years the use of ILEs in preterm infants, especially early within the first days of life, had been limited by concerns regarding impaired lipid tolerance that is increased with decreasing gestational age. Lipid infusion has been allegedly associated with an increased risk for sepsis,[207] increased albumin-bound bilirubin displacement and aggravation of hyperbilirubinemia,[206] impairment of oxygenation, and development of BPD.[207,208] However, recent data including meta-analyses suggest that the initiation of ILEs within the first two days of life, even on the first day of life, appears to be safe and well tolerated in VLBW infants.[209–211] Early initiation of ILE in this setting was not found to be associated with increased morbidity or mortality or with any significant short- or long-term sequels. Actually there is some evidence to suggest better long-term neurodevelopmental outcomes in these VLBW infants.[212]

A systematic review published in 2012 also found no differences related to the type of ILE used.[141] Using soybean oil–based ILEs and or mixed ILEs containing soybean oil in combination with other fat sources (olive oil, MCT, and/or FO) showed similar outcomes regarding weight gain, pulmonary morbidity, hypertriglyceridemia, hyperglycemia, or mortality before discharge. However, the use of non-purely soybean oil–based ILEs was significantly, although weakly, associated with reduced incidence of sepsis in preterm infants.[141] As sepsis in VLBW infants is associated with serious adverse long-term outcomes, this finding suggests that mixed ILEs that are not based only on soybean oil should be preferentially used in VLBW preterm infants.[181,182]

The recommended ILE dose in VLBW infants is 1 g/kg/d on the first day of life with gradual increase by 0.5–1.0 g/kg/d thereafter. If well-tolerated, without hypertriglyceridemia, the lipid dose can be increased up to maximum of 3.0–3.5 g/kg/d by the end of the first week of life.[10,213] A dose of 4 g/kg/d might be occasionally used in chronically ill infants with high energy needs.

Lipid Emulsions Stability

ILEs are complex, thermodynamically unstable pharmaceutical products manufactured as oil-in-water dispersions of individual oils or their mixtures that are emulsified with the aid of egg lecithin phospholipids. Each oil droplet is coated with a monolayer of phospholipids that aligns its hydrophobic tails toward the oil phase, whereas the negatively charged hydrophilic heads are oriented toward the water phase. Emulsion stability is maintained by mutual repulsion of the droplets' resultant negative surface charge (or zeta potential) from the hydrophilic part of the phospholipids. Emulsions are made isotonic (250–350 mOsm/L) by the addition of glycerol and thus can be infused directly by either peripheral or central veins. Parenteral emulsions have a mean droplet size of approximately 0.2–0.3 μm, which is similar to that of naturally occurring chylomicrons and a median pH of 7.5 (range, 6.0–9.0). The emulsions also contain other lipid soluble substances, such as vitamins E and K, lipid peroxidation products, and phytosterols.[214]

ILEs can be given either undiluted as a separate infusion or, more commonly, mixed together with other PN components (i.e., amino acids, glucose, electrolytes, vitamins, minerals) in a single container as an all-in-one (AIO) admixture. Industrially manufactured multichamber bags (MCB) containing the three macronutrient solutions (amino acids, glucose, and lipids) in separate chambers of a single closed plastic system are now rapidly gaining widespread acceptance around the world where standard PN regimens can be used.[215]

The use of in-line filters with all PN admixtures to prevent the passage of insoluble particulates and enlarged lipid droplets into the microvasculature, has been advocated. In-line 1.2-μm filters are preferred for AIO administration and adherence to maximum 24 hours hang-times is recommended. Light protection and oxygen exclusion by using multilayer bags are proven factors that can decrease lipid peroxides formation and improve stability, especially for long-term storage of AIO admixtures (e.g., home PN). It is recommended that all PN containers and infusion lines be protected from phototherapy light and daylight at all times, unless these are infused solely at night.

Structured ILEs

Structured-lipid emulsions are produced by mixing MCT and LCT, then allowing hydrolysis to form free FAs, followed by random transesterification of the FA into mixed triglyceride molecules. Studies in animals have shown an improvement in nitrogen balance with the use of these lipid emulsions. Few human clinical studies with these products have

been performed. The results of these studies have been less promising than the animal studies; however, an improvement in nitrogen balance and lipid metabolism has been reported with a physical mixture of LCT and MCT. Structured-lipid emulsion seems to induce less elevation in serum liver enzyme values compared with standard ILEs. In addition, structured-lipid emulsions seem to have no detrimental effect on the reticuloendothelial system. Further studies are necessary to recommend the use of structured lipid emulsions.[216]

CARBOHYDRATE REQUIREMENTS

Carbohydrates (CHO) are key ingredients of PN solutions, being the major and most immediate source of energy. CHO can improve the nitrogen balance by exerting a protein-sparing effect which is more effective when combining CHO with amino acids or CHO with amino acids and lipid emulsions.[217,218] In addition, glucose is an important carbon source for the de novo synthesis of FAs and nonessential amino acids. Under normal metabolic conditions, CHO metabolism is regulated predominantly by insulin and glucagon. Other important factors involved in the regulation of CHO metabolism, especially during stress, are the counter-regulatory hormones (epinephrine, cortisol) and cytokines (e.g., IL-6, TNF-α). In certain tissues, glucose uptake is insulin-independent (e.g., erythrocytes, renal medulla, bone marrow, leukocytes, and brain). Serum glucose level is influenced by various factors: glucose intake (enteral, parenteral); glucose oxidation via glycolysis or pentose phosphate cycle; gluconeogenesis mainly in the liver (but also occasionally in the kidneys); and glucose exchange with glycogen stores in the liver and muscles.

Generally, approximately 50%–70% of nonprotein energy should be supplied as CHO and blood glucose level should be maintained between 80–110 mg/dL. The upper and lower limits of CHO intake in infants and children are difficult to establish due to the paucity of available data. Acceptable intake of CHO may be however, inferred from the rate of endogenous production and utilization of glucose, response to glucose administration, glucose utilization by the brain, the relation between CHO intake and nitrogen sparing and the basal and total energy expenditure.

Estimation of the lower limit of CHO intake should take into consideration the energy needs of the brain and other glucose dependent organs, should avoid protein and nitrogen loss, minimize protein use for gluconeogenesis, and prevent ketosis. Glucose is the primary oxidative fuel for the brain. Compared to adults, infants are at danger during any

period of sustained fasting because of the high glucose demand of their nervous system. The minimum intake of dextrose, the CHO used in PN, required for normal brain function is about 2 mg/kg/min in adults and 5 mg/kg/min in neonate. Using published data on glucose metabolism in vivo, Kalhan and Kilic have published the estimates of glucose consumption by the brain in relation to age. These ranges probably reflect the amount of exogenous glucose required to prevent hypoglycemia under most circumstances.[219]

Hyperglycemia should also be avoided; serum glucose levels should be probably kept less than 130–150 mg/dL at any time (although there are no specific criteria for defining either hyper- or hypoglycemia among critically ill children), as higher levels have been associated with higher morbidity (infections rate and length of hospital stay) and mortality.[220,221] To avoid hyperglycemia, the exogenous glucose delivery should correspond to the normal endogenous glucose production and rate of substrate oxidation. The amount of glucose that can be infused safely depends on the clinical condition and maturity of the infant. The ability of neonates to metabolize glucose may be impaired by prematurity and low birth weight. The endogenous glucose production varies from about 2 mg/kg/min (3 g/kg/d) in adults to approximately 8 mg/kg/min (11.5 g/kg/d) glucose in premature infants.[219,222] During PN, the rate of parenteral glucose delivery must be kept constant without exceeding the maximum rate of glucose oxidation (RGO). Glucose administration to full term neonates and children up to 2 years of age should not exceed 12.5 mg/kg/min (18 g/kg/d).[223] The maximal rate of glucose infusion may exceed glucose oxidation rate during cyclical PN, but should not go beyond 20 mg/kg/min (1.2 g/kg/h) (Table 68-2).

Evaluation of substrate utilization by IC in normal infants has estimated oxidative glucose disposal rates to be 12.6 mg/kg/min. Studies using labeled glucose contradict these findings, revealing maximal rates of glucose oxidation similar to that of adults, even among preterm infants.[222,224] This difference could be explained by the fact that IC estimates energy utilization from the algebraic sum of glucose degradation and synthesis. By contrast, stable isotope glucose tracers facilitate closer inspection of glucose utilization beyond simple cellular uptake. By using this method, the fraction of parenterally infused glucose that actually is oxidized can be measured directly. In a study by Sheridan et al., 10 critically ill children (mean age: 5.2 years) with burns were evaluated by using a stable-isotope tracer technique. The authors found that maximal glucose oxidation occurred at glucose intakes of 5 mg/kg/min. An increase

in exogenous parenteral glucose infusion from 5 to 8 mg/kg/min reduced the fraction of total exogenous glucose being oxidized from 59% ± 5% to 48% ± 5% ($P < .05$).[225] The mechanisms behind this decreased capacity of glucose oxidation in critically ill patients are unclear. Hu et al. reported decoupling of the mitochondrial respiratory chain reaction after burn injury.[226] Demling et al. described relative hypoxia of liver parenchyma in critically ill patients, despite hemodynamic stability. This hypoxia could limit aerobic metabolism of glucose while other biochemical pathways for its degradation become favored resulting in tissue uptake of exogenous glucose, rather than increased oxidation.[227]

RQ expressed as the ratio between CO_2 production to O_2 consumption, reflects the proportion of substrate utilization in the body. The npRQ (nonprotein RQ) represents the ratio of glucose and fat utilization by excluding the participation of protein, and varies in value from 0.70–1.0, with values >1.0 indicating net fat biosynthesis from glucose (lipogenesis). It must be kept in mind that the RQ in healthy (enterally fed) infants and children with normal growth and development, is approximately 0.85. Studies of critically ill adults and children have shown that changes in the metabolic condition, or excessive energy intake in the form of glucose, modify the npRQ value.[220,228] Studies[220,221] have shown that 75% of the subjects who consumed high amounts of CHO had an npRQ value >1.0. Glucose provided in excess of oxidative capacity enters nonoxidative pathways including glycolysis, glycogenesis, and lipogenesis.[229] The risks associated with this process are many fold and include accumulation of the newly synthesized fat in the liver and aggravation of respiratory acidosis resulting from increased CO2 production, particularly in patients with compromised pulmonary function. In addition, infusion of excess glucose causes hyperglycemia, glucosuria, and dehydration and has been associated with higher risk of complications in adults and children alike.[230,231] Taking into consideration the complications associated with high glucose supply, Meguid et al. showed conclusively that substitution of 30% of glucose calories with fat avoids these complications.[232] Likewise, substitution of up to 50% of calories with fat appears equally safe and complication free. When the intake of glucose calories exceeds the REE, net fat oxidation is minimal regardless of fat intake.

Critically ill patients have major alterations in substrate utilization. Peripheral insulin resistance and accelerated hepatic gluconeogenesis are added to the preferential use of anerobic glycolysis in injured tissues. Although exogenous insulin can be used to achieve normoglycemia, forced

cellular uptake with insulin does not guarantee effective glucose utilization. In adults, maintenance of normoglycemia with insulin infusion has been shown to reduce morbidity of surgical and medical ICU patients, and reduces mortality of surgical ICU patients.[233] A randomized controlled study of 700 critically ill infants and children in PICU, showed that targeting blood glucose concentrations to an age-adjusted normal fasting concentration with insulin infusion improved morbidity and reduced mortality, despite a substantial risk of biochemical hypoglycemia. Intensive insulin therapy protected the cardiovascular system, prevented secondary infections, and attenuated the inflammatory response, reducing the need for extended stay in intensive care. Mortality was lowered by an absolute 3·1% (95% CI 0·2–6·0) due to prevention of lethal neurological and pulmonary damage, and possibly prevention of infection.[234] A recent study, however, showed that tight glycemic control after cardiac surgery in children can be achieved with a low hypoglycemia rate, but did not significantly change the infection rate, mortality, length of stay, or measures of organ failure, as compared with standard care.[235] Routine use of tight glycemic control in the PICU remains controversial, owing both to contradictory results of the trials evaluating this approach in adults as well as to concerns about potentially damaging effects of insulin-induced hypoglycemia on the developing brain of children. Glucose targets and insulin titration strategies to improve end points while avoiding harmful effects of hypoglycemia and glucose fluctuation are still to be established.

CHO in PN are provided in a hydrate form (dextrose), which provides 3.4 kcal/g of dextrose. Fructose use in PN solutions is not recommended as life-threatening complications may arise in the event of undiagnosed hereditary fructose intolerance. Glucose contributes substantially to osmolarity in the PN solution. The osmolarity of a glucose solution rises significantly with increasing concentration from 255 mOsm/L in a 5% glucose solution to 1020 mOsm/L in a 20% glucose solution. Glucose solutions higher than 12.5% must be administered via a central vein. Initiation of glucose infusion should occur in an incremental fashion to prevent hyperinsulinemia. The glucose infusion rate (GIR) in mg/kg/min can be calculated using the following equation: GIR = g/kg/d dextrose × 1,000/1,440 min/kg.

Parenteral Carbohydrate Supply in Premature Infants

Glucose is the major energy source in newborns because it is readily available for the brain.[20] In the fetus, glucose is transported across the

placenta from the mother. The amount of glucose transported across the placenta increases as pregnancy progresses, thus allowing glycogen and fat stores to be accumulated during the third trimester. In the healthy term newborn baby, hormonal and metabolic adaptation in the immediate perinatal period ensures that adequate fuel supply to the brain and other vital organs is delivered. However, in preterm infants glucose homeostasis is still immature on the first days of life, and hyperglycemia as well as hypoglycemia are common in these neonates. After initial hypoglycemia, due to limited glycogen and fat stores, VLBW preterm infants often become hyperglycemic because of insulin resistance combined with relative insulin deficiency.[20,236] Hyperglycemia is associated with increased morbidity and mortality in preterm infants. Although there is lack of agreement on the precise definitions of hypoglycemia and hyperglycemia, it is generally accepted that glucose blood levels should be maintained within the following range: above 40–45 mg/dL on the first day of life[237] and above 50 mg/dL thereafter; and below 200 mg/dL, preferably below 150–180 mg/dL.[238,239] There is great variation in terms of diagnosis and management of hyperglycemia in VLBW preterm infants.[239,240]

Approximately 4 mg/kg/min (7 g/kg/d) of glucose cross the placenta in the last trimester of pregnancy. Glucose production rate ranges from 5.5 mg/kg/min (8 g/kg/d) in full-term healthy newborns and up to 8 mg/kg/min (11.5 g/kg/d) in VLBW premature infants.[219,222,241] Accordingly, initial glucose infusion rates of 4–7 mg/kg/min are appropriate for most newborn infants, although extremely-low-birth-weight (ELBW) infants (less than 1000 g) may need higher rates of 8–10 mg/kg/min to match endogenous glucose production from the liver and preserve their limited CHO stores.[242] Unfortunately many of these ELBW infants will not tolerate these high glucose infusion rates in the first days of life without hyperglycemia. Thus lower glucose infusion rates of 4–5 mg/kg/min (6 g/kg/d) are initially given, usually by using solutions with 5% dextrose.[20] Initial glucose infusion rates as low as 3.5 mg/kg/min are used in VLBW, and more often in ELBW preterm infants, corresponding to 100/mL/kg of 5% dextrose-based PN solution.[243] Supply of balanced PN, including amino acids and lipids, with high amino acids intake of 2–3 g/kg/d from the first day of life was suggested as one of the contributing factors to the improved glucose tolerance in ELBW infants.[35] Providing lower glucose infusion rates as part of full early PN might be even more successful than administration of insulin, probably due to the relative

insulin resistance in VLBW infants during the first week of life.[20,240] Moreover, data on long-term outcomes including morbidity, mortality, and long-term neurodevelopmental outcomes comparing uncorrected hyperglycemia or insulin administration are lacking.[240] If low intake of intravenous glucose (4–5 mg/kg/min, i.e., 6 g/kg/d) is tolerated, glucose delivery may be gradually increased to 8, 10, and up to 12–16 g/kg/d over the first week of life.[20] This can usually be achieved with 10%–12.5% dextrose-based PN solutions. Infusion rate of 18 g/kg/d glucose is probably maximal, because higher rates will exceed glucose oxidative capacity.[243,244] If higher intakes of glucose are not tolerated, glucose intake should be reduced. Insulin administration should also be considered, according to the clinical and nutritional status of the infant, with an initial dose of 0.05 IU/kg/h. Insulin may help control plasma glucose concentration, achieve increased energy intake, and promote nitrogen retention and growth. However, the evidences on the use of insulin for decreasing hyperglycemia, especially in ELBW infants, are controversial, and currently do not support the routine use of insulin infusions to prevent hyperglycemia.[239,240] Early insulin administration to reduce hyperglycemia did not improve mortality, sepsis, growth, intracranial hemorrhage, NEC, or chronic lung disease.[245,246] Actually, there were some concerns regarding mortality at 28 days that might have been higher in the early-insulin group. Although early insulin was associated with decreased incidence of hyperglycemia, it was nevertheless associated with increased number of episodes of hypoglycemia.[244] Insulin administration has also raised concerns regarding the increased weight gain, probably FM, and not lean body mass; and regarding the fact that insulin infusion did not improve protein balance, yet caused unexpected lactic acidosis.[247] More data is required also on the safety and long-term consequences of insulin use, especially on growth and neurodevelopmental outcomes, compared to long-term effects of hyperglycemia.[245] Nevertheless, there are few ELBW infants on PN, who will remain hyperglycemic despite very low glucose infusion rates in the first days of life and in these infants exogenous insulin infusion seem to be justified for a short period to keep them normoglycemic. Close monitoring is mandatory to avoid hypoglycemia and provide the best possible balanced nutrition.

FLUIDS, ELECTROLYTES, AND MINERALS REQUIREMENTS FOR PN

The total body water (TBW) content is age-related and diminishes from about 90% in a preterm infant born after 24 weeks of gestation to 75% in a term newborn infant, less than 70% in a 1–year-old infant and about 50% in an adult.[10,248] TBW is divided into two compartments: intracellular fluid (ICF) and extracellular fluid (ECF). The total volume of ICF increases with body size during growth. ECF is subdivided into intravascular and extravascular components as well as a ‘‘third space’’ represented by the free fluid in preformed body compartments under physiological (such as urine in the bladder, cerebral spinal fluid, pleural, peritoneal, and synovial fluid etc.) and pathological conditions (such as ascites or pleural effusions). ECF decreases during growth.[249]

Fluid Requirements

Fluid requirements for infants and children are based on studies done half a century ago by Darrow.[250] These requirements are based on healthy infants and children and do not take into account the changes in losses that may occur during altered health states. Fluids provide the principal source of water; however, some water is derived from the oxidation of food and body tissues. Requirements for water are related to caloric consumption; therefore, infants must consume much larger amounts of water per unit of body weight than adults. In general, fluid requirements (mL/kg/d) are matched to calorie requirements (kcal/kg/d). Although there are several methods to estimate fluid requirements, the most commonly used is that of Holliday, based on weight.[251] This method of calculating fluid requirements is in very close agreement with several other methods based on formulas, body surface area, basal calories plus activity calories, and age:

100 mL/kg for an infant 3 to 10 kg
1000 mL + 50 mL/kg for every kg over 10 kg for a child 10 to 20 kg
1500 mL + 20 mL/kg for every kg over 20 kg for a child over 20 kg

Enteral and parenteral fluid requirements are essentially the same. Approximately 40 mL/100 kcal per 24 hours replaces insensible losses and 60 mL/100 kcal replaces urinary losses. In the absence of diarrhea, stool losses are minimal, however, if diarrhea is present, fluid loss can increase dramatically and fluids loss should be replaced milliliter for milliliter. Acute weight loss almost always reflects fluid loss; any acute weight deficit should be added to fluid requirements. Additional fluid losses (for instance from an ileostomy or biliary drain), should also be replaced on a daily basis. Fever increases insensible water loss via respiration and via the

skin. For each degree of temperature above 38°C, insensible water loss is increased by 10% to 12% per 24 hours. Monitoring of fluid status is vital, and should include assessment of clinical status, body weight, fluids intake and output, blood electrolytes, acid base status, hematocrit, urine-specific gravity, and urine electrolytes. As a remainder, urine osmotic load results from protein catabolism and electrolyte excretion, but is little affected by CHO and fat metabolism that produce metabolic water and CO_2.

Electrolytes Requirements

In an otherwise healthy child, essentially all electrolyte loss occurs via the urine. Therefore, recommendations for electrolyte requirements come from measurements of sodium, potassium, and chloride urinary losses in healthy children. As with fluids, unusual losses of electrolytes (diarrhea, stoma output, bums, exercise, diuretic therapy, renal abnormalities, etc.) need to be considered and replaced. Electrolytes are critically important in PN for the short term but also long term because normal muscle accretion cannot occur in the presence of insufficient electrolytes and minerals.[252]

Sodium (Na^+) is the principal cation of the ECF and modulates the maintenance of intravascular and interstitial volumes. Sodium intake can influence the ECF volume. Sodium excretion occurs primarily through urine, but also through sweat and feces. Chloride (Cl^-) is the major anion of the ECF. The intake and output of chloride usually parallels that of sodium, but external losses and excretion can occur independently, mainly in equilibrium with bicarbonate status. Potassium (K^+) is the major intracellular cation, and the potassium pool correlates well with the lean body mass. The potassium intake varies widely. Extracellular potassium concentration is not always related to intracellular concentration. Evidence concerning fluid and electrolyte needs in infants comes from relatively few well-performed studies. Recommended intakes,[10,253] based on recommended daily allowances (RDAs), endorsed by the ASPEN/ESPGHAN are shown in Table 68-6. In general, PN should not be used to correct acute fluid or electrolyte abnormalities. Maximum levels of 40 mEq/L of potassium through a peripheral line and 0.5 to 1 mEq/kg/h through a central line are generally accepted.

Calcium, Phosphorus, and Magnesium

In the context of pediatric PN solutions, calcium, phosphorus, and magnesium are termed “minerals.” Calcium, phosphorus, and magnesium provided in PN solutions are essential for various systemic functions.

Approximately 99% of total body calcium is found in bone, whereas 85% of phosphorus is in bone, and 50% to 60% of magnesium. Bone acts as a reservoir for calcium, phosphorus, and magnesium, therefore, serum levels often do not reflect total body content, which makes it difficult to identify deficiency states. The molar Ca:P ratio is 1.3 in the whole body and 1.67 in bone mineral apatite. Less than 1% of the total body calcium, phosphorus, and magnesium is found in the circulation. Because serum calcium is tightly controlled at the expense of bone, calcium deficiency is a chronic condition associated with bone loss. Calcium circulates in three forms: 45% is in the biologically active ionized form, 45% is bound to protein, mainly albumin, and 10% is complexed to phosphate, lactate, and citrate. Measurement of ionized calcium, because it is the active form, better reflects calcium homeostasis than does measuring total serum calcium. IOM updated recently dietary reference intakes (DRI) on calcium and vitamin D.[254] The recommendations for 0–12 months reflect AI value rather than the RDAs, as RDAs have not been established for infants. The amount of dietary calcium needed to satisfy the demand for skeletal growth and mineralization is greater than the theoretical accretion rate because of incomplete calcium absorption and losses from skin, urine, and gastrointestinal tract.

TABLE 68-6 Parenteral Electrolytes and Minerals Requirements

	Preterm	Term Newborn	Infants	1–2 Years	2–18 Years
Sodium, mEq/kg/d	2.0–5.0	2.0–3.0 (5.0)	2.0–3.0	1.0–3.0	1.0–3.0
Potassium, mEq/kg/d	1.0–3.0	1.5–3.0	1.0–3.0	1.0–3.0	1.0–3.0
Chloride, mEq/kg/d	2.0–3.0 (5.0)	2.0–3.0	2.0–3.0	1.0–3.0	1.0–3.0
Calcium[a], mg/kg/d (mEq/kg/d) 20 mg = 1 mEq = 0.5 mmol	60–100 (3.0–5.0)	60–80 (3.0–4.0)	20–40 (1.0–2.0)	20–40 (1.0–2.0)	10 (0.5) 10–20 mEq/d
Phosphorus[a], mg/kg/d (mmol/kg/d) 31 mg = 1 mmol	45–78 (1.5–2.5)	45–62 (1.5–2.0)	16–45 (0.5–1.5)	16–45 (0.5–1.5)	16–31 (0.5–1.0) 10–40 mmol/d
Magnesium, mg/kg/d (mEq/kg/d) 12.1 mg = 1 mEq	6–10.5 (0.5–0.8)	6–10.5 (0.5–0.8)	6–10.5 (0.5–0.8)	2.4–6 (0.2–	2.4–6 (0.2–

= 0.5 mmol		0.5)	0.5) 10–30 mEq/d

[a]Provide Ca:P ratio (mg/mg) in the range of 1.3–1.7 (1:1 mmol:mmol ratio) in the first year of life, thereafter equimolar Ca; P ratio is optimal.

Current recommendations include 0 to 6 months (M+F): 200 mg/d; 6 months to 1 year (M+F): 260 mg/d; 1 to 3 years (M+F): 700 mg/d; 4 to 8 years (M+F): 1000 mg/d; and 9 to 18 years (M+F): 1300 mg/d.

Phosphorus plays a vital role forming the high-energy bond within adenosine triphosphate (ATP), which fuels a wide range of physical and metabolic processes and acts as an essential regulator within the glycolytic pathway. Crucially involved in respiration as the integral part of 2,3-diphosphoglycerate for tissue oxygen supply, phosphorus also acts as a buffer for maintaining urinary and plasma pH. Fifty percent of phosphorus exists in circulation as free ions, 10% is protein bound, and 40% is complexed to calcium, magnesium, and sodium as salts. Phosphorus deficiency can be a serious acute problem when malnourished patients are refed and sufficient phosphorus is not provided. For PN, at least 10 to 15 mmol phosphate should be given for each 1000 kcal. Infants, neonates, and small babies require 1.5 mmol/kg per day. This requirement diminishes with increasing maturity, and after the third year of life it is around 1 mmol/kg per day. During phosphate therapy, care should be taken to monitor for hyperphosphatemia and hypocalcemia caused by a negative feedback effect on the parathyroid gland.[255] Magnesium is mainly an intracellular anion, therefore, serum magnesium levels may not accurately reflect total body magnesium status. Frequent monitoring of potassium, calcium, and magnesium status is essential in all clinical conditions.

Calcium and phosphate supplementation via PN is often limited by the lack of central venous access and calcium and phosphate solubility. The hypocalcemia associated with metabolic bone disease results from inadequate supply and from urinary calcium losses. Increased urinary calcium excretion has been noted to accompany high oral or parenteral protein, glucose, or sodium intake, acidosis, decreased phosphorus intake, or vitamin D deficiency, use of loop diuretics, corticosteroids, and insulin or cycling PN.[256–258] Hypophosphatemia resulting from phosphorus depletion and intracellular phosphorus shifting is a primary and potentially life-threatening manifestation of the refeeding syndrome. Many studies have evaluated the effects of different calcium and phosphate dosage and ratios on serum and urinary calcium and phosphorus concentrations, retention, and bone mineralization and it seems that sufficient bone

mineralization may occur in infants and children on PN. Optimal calcium to phosphate ratio depends on the route of administration, bone mineralization, and nitrogen retention. Optimal calcium phosphate ratio for PN is 1.3–1.7:1 Ca:P (weight:weight/mg:mg) and nearly 1:1 molar ratio.[10,259] Lower ratios result in elevated urinary and serum phosphorous that suggest inadequate utilization of phosphorous because of insufficient calcium intake. This Ca:P ratio appears to promote the highest retention of both minerals and to simulate in utero bone mineral accretion rates. This Ca:P ratio is typically provided throughout the first year of life or until the infant reaches approximately 10 to 12 kg in weight. Calcium and phosphate requirements decrease as children age. In older children, equimolar provision of calcium and phosphate is optimal. In adults, balance studies have reported that positive calcium and phosphate balances can be achieved with mean calcium intakes of 15 mEq per day and minimum phosphorus intake of 15 mmol per day.[260]

Calcium and phosphate precipitation is the primary limiting factor to delivering optimal amounts of these minerals via pediatric PN. Calcium phosphate precipitates can cause significant morbidity and even death. Calcium phosphate precipitates have been noted in the central line of a neonate and have been reported to cause microvascular pulmonary emboli and interstitial pneumonitis in patients receiving lipid-free HPN.[261–263] Attempts to circumvent this problem by providing separate infusions of calcium and phosphate failed and resulted in hyperphosphatemia and hypocalcemia during phosphate infusions and hypercalcemia and hypophosphatemia during calcium infusions.[264] The solubility and saturation point of a solution of calcium and phosphorus are determined by many factors including pH, temperature, time of storage, amino acid concentration, amino acid product, lipid emulsions, dextrose concentration, calcium, phosphate, and magnesium concentrations, type of phosphate salt (inorganic vs. organic: glucose-1-phosphate, glycerophosphate, and fructose-1,6-diphosphate), and the order of addition of calcium and phosphate.

At concentrations above the saturation point, the calcium and phosphorus form insoluble complexes identified as precipitates. The type of calcium salt used in compounding parenteral solution can increase the calcium ion concentration at which saturation occurs for a given phosphorus concentration. For example, calcium chloride is more soluble than calcium gluconate. Solution pH is another factor determining the solubility of calcium and phosphorus. Dibasic phosphate is the predominant ion when the pH increases above 6.5, with a low solubility of

30 mg/dL. Monobasic phosphate is the predominant ion at lower pH and has a solubility of 1800 mg/dL.[265] Amino acids vary in pH and have a buffering effect (titratable acidity) on parenteral solutions. Depending on the amino acid product and the concentration (ranging from 1%–4%), the pH can vary from 6.8 to 5.2. The addition of cysteine (pH 1) and fat emulsion (pH 9) also influences the solubility of calcium and phosphorus. Amino acid solutions designed for children under 1 year have added cysteine which lowers the pH enough to permit the addition of calcium and phosphorus in amounts that may meet daily requirements.[266] Increasing dextrose, amino acid, and magnesium concentration also lowers pH and increases calcium and phosphate solubility.[267] Temperature is another important factor for calcium and phosphate solubility. The higher the temperature, the more readily available the calcium ion becomes, increasing the probability of precipitation.[268,269] Calcium solubility is endothermic; solutions that are compounded and tested at room temperature differ in solubility from those tested at body temperature (room: 20–25°C; body: 37°C). In addition, the chances of precipitation are greater with increasing length of time the PN solution is stored and infused as well as with lower infusion rates.[270]

Many safeguards exist to prevent the infusion of calcium phosphate precipitates to patients receiving PN. The prescriber and the pharmacist responsible for compounding PN solutions should recognize the factors affecting calcium and phosphate solubility. Practitioners may predict solubility by using available software or by plotting the concentration of calcium and phosphorus in the compounded PN on a graph with a saturation curve specific for the amino acid concentration, temperature, and calcium and phosphorus concentration. These saturation curves can be approximated by a hyperbolic model and incorporated into computer-based PN ordering. These systems alert the pharmacy that the solution is over solubility limits, thereby allowing the prescriber to revise the formulation. A recent study that reviewed 38,019 hospital PN orders plotted the calcium and phosphate concentrations for each solution in relation to the published curves. In all solutions, calcium and phosphorus concentrations plotted below the precipitation limits predicted by the published curves despite a large range of concentrations of electrolytes and minerals, validating the solubility limits represented by published curves.[271] Generally, calcium and phosphate can be safely added to PN solution when the concentrations provided satisfy the following equation: Calcium (mEq) + Phosphate (mmol) < 30 (per 1000 mL of PN solution).

Recommendations for minimizing the risk of calcium phosphate precipitation in PN solutions have been published.[272,273] Recommended parenteral calcium, phosphorus, and magnesium intakes for infants and children are shown in Table 68-6.

Refeeding syndrome frequently accompanies the nutritional rehabilitation of malnourished individuals. The refeeding syndrome is a set of metabolic and functional complications that occurs as a result of intracellular shifts of elements. During rapid nutritional rehabilitation, profound hypophosphatemia, hypomagnesemia, and hypokalemia can precipitate acute respiratory and circulatory collapse. Neurologic manifestations of the refeeding syndrome include weakness, lethargy, paralysis, and confusion. Deaths have been documented. The pathophysiological results of phosphate deficiency are inadequate supplies of energy-rich phosphates and, in particular, inhibition of glyceraldehyde-3-phosphate dehydrogenase, which occupies a key position in glycolysis. The effect of this on the central nervous system, muscle, and erythrocyte energy metabolism is to reduce ATP and 2,3-diphosphoglycerate levels, leading energy deficit and left-hand displacement of the oxygen–hemoglobin dissociation curve with decreased peripheral oxygen uptake and transport. Phosphorus, magnesium, and potassium must be carefully monitored in malnourished patients. Aggressive supplementation and correction of low values before feeding initiation will prevent the adverse outcomes of refeeding syndrome.[274]

FLUIDS, ELECTROLYTES, AND MINERALS REQUIREMENTS IN VLBW INFANTS

Fluid volume per kg body weight is higher in newborn compared to older children. Handling fluids in VLBW is further complicated by renal immaturity and reduced ability to concentrate urine, higher energy expenditure, greater body surface area, skin immaturity, and thus increased insensible losses.[248] Immediately after birth a transition period that can extend from less than 12 hours to few days (up to 3–5 days) follows. During this transition period, water and electrolytes balance may be severely disturbed as a result of discontinuation of placental exchange, considerable increase in insensible water loss, and huge requirements for thermoregulation. This immediate postnatal phase is characterized by initial relative oliguria followed by a diuretic phase.[275] In these first hours of life, contraction of the ECF space should be allowed to take place, while

maintaining normal intravascular fluid volume and cardiovascular function, as well as maintaining as normal as possible serum electrolytes and urine output. Attention to avoiding fluid overload may be critical during this transition period in VLBW infants, because this was shown to decrease respiratory morbidity, patent ductus arteriosus (PDA), BPD, and chronic lung disease, later on.[276,277] This can be achieved many times by restricting fluid and sodium administration, even in face of very high urine output and urinary sodium excretion with net negative sodium balance. Fluid intake in the initial transition period should be started at 60–100 mL/kg/d and gradually increased over the next days.[10] VLBW and premature infants born at younger gestational age will require the higher fluid intakes within this range due to their increased losses. Weight loss during this transitional period is expected, yet it should be closely monitored, especially in VLBW infants, along with input and output balance and serum electrolytes. Subsequent adaptation involves the onset of autonomic renal regulation of fluids and electrolytes. Urine output will usually decrease and urine osmolarity will increase above serum osmolarity. By the end of this period which may extend up to 5–15 days in VLBW infants, birth weight will be regained. During this adaptation period, total fluid intake could already reach 150 mL/kg/d (range: 140–160 mL/kg/d), although some ELBW infants may need slightly more. The suggestion to avoid fluid overload, as discussed above, is still very applicable to this adaptation period. During the stable growing period that follows, fluid intake of 150 mL/kg/d (range: 140–160 mL/kg/d) for term and preterm infants should be appropriate, even for VLBW infants on PN.[10]

Sodium and potassium supplementation are usually not required during the early postnatal period in premature infants. This is because of their high initial ECF that needs to be decreased with sodium diuresis that occurs in the first 1–2 days. Most preterm infants born after 28 weeks gestation or less usually also get sodium from other sources, for example, transfusions, saline infusions for arterial line flushes, and drugs. At this stage, the ELBW infants are usually at risk of losing significantly more water than sodium with ensuing hyperosmolar hypernatremia.[10] ELBW are also at risk of developing nonoliguric hyperkalemia from immature distal tubular function.[10] Thus, close monitoring of serum electrolytes in the first days of life is mandatory even though Na and K are usually not given in PN during the first 1–3 days. Supplementation of Na and K is gradually started based on their decreasing serum levels. This usually coincides with the cessation of the initial weight loss, although it may be required earlier.

Maintenance intake of Na, K, and Cl are listed in Table 68-6. Sodium requirements may be higher in preterm infants due to renal immaturity with increased urinary Na excretion. Metabolic acidosis is quite common in preterm infants on PN. This is due to the relatively acidic amino acids admixtures (especially if cysteine is added) and to renal immaturity with decreased renal reabsorption of bicarbonate.[278] This can be corrected by adding acetate (1–2 mEq/kg/d) as sodium or potassium salt.[279]

Because most of the calcium and phosphorus transfer and retention occur during the third trimester of pregnancy, and because hormonal control systems (parathyroid hormone [PTH] and vitamin D) are also immature, preterm infants are at increased risk of hypocalcemia and hypophosphatemia. Inadequate intakes of calcium and phosphorus can lead to poor bone mineralization, osteopenia, and even frank rickets and fractures.[258,280] Calcium needs to be supplied to preterm infants from the first day because of the risk of early hypocalcemia. Phosphorous supplementation may sometimes be postponed for 1–2 days because initially phosphorus excretion maybe low due to low glomerular filtration rate resulting in normal or even slightly elevated serum phosphorus levels. However, phosphorus needs to be added soon after, to avoid hypophosphatemia thereafter.[281] Magnesium is rarely adjusted unless the infant has high levels secondary to magnesium treatment given to the mother before delivery, or persistent hypocalcemia secondary to hypomagnesemia. The currently recommended intakes of minerals for preterm infants on PN are shown in Table 68-6.[10,20] The parenteral calcium supply is 60%–80% of that deposited by the fetus during the last trimester of pregnancy (100–120 mg/kg/d), but quite similar to those provided by most currently available enteral preterm formulas.

VITAMIN REQUIREMENTS

In February 2009, at the annual ASPEN Research Workshop that focused on micronutrients in PN, a group of international experts reviewed the parenteral requirements of various nutrients.[282] The recommendations are similar to those found in the 2005 ESPEN/ESPGHAN guidelines[10] and the summary is presented here. Based on the recommended doses for the current parenteral multivitamin products, the daily dose of the fat-soluble vitamins is approximately the same as the oral RDA or AI for these vitamins, even though the bioavailability should be much greater when these vitamins are administered intravenously. The rationale for providing

a higher effective dose when given as part of PN therapy was that these patients have higher vitamin requirements due to malnutrition, baseline vitamin deficiencies, and metabolic changes secondary to acute and chronic illness. The current daily water-soluble vitamin parenteral doses are 2–5.5 times greater than the oral RDA or AI. The rationale for giving even higher relative doses for these vitamins was that in addition to the increased requirements, as discussed above, there is increased urinary excretion of water-soluble vitamins when administered intravenously. These relatively high doses of vitamins have been used in PN therapy for over 30 years, and no toxicity has been described. As the scientific data supporting the current dose recommendations for pediatric and neonatal parenteral vitamin administration are very limited, ASPEN Research Workshop concluded that there are insufficient data to make any recommended changes in the current pediatric and neonatal parenteral multivitamin dosages or products.

Vitamin A

The recommended amounts of vitamin A for the all pediatric age range is provided in Table 68-7. Vitamin A deserves special attention in premature infants.[283] Delivery of parenteral vitamin A to the preterm infant can be compromised by losses in the delivery system and photodegradation.[284,285] This can result in as little as 17%–66% of the expected amount being received. Greater plasma concentrations of vitamin A may be achieved when given mixed with the ILE.[286] In premature infants, vitamin A is necessary for normal lung growth and the integrity of respiratory tract epithelial cells. Preterm infants have low vitamin A status at birth, and this has been associated with increased risk of developing chronic lung disease (BPD). In a recent meta-analysis conducted to evaluate vitamin A supplementation on the incidence of death, neonatal chronic lung disease, and long-term neurodevelopmental disability in VLBW, it was found that vitamin A appears to be beneficial in reducing death or oxygen requirement at one month of age.[287]

Thiamine (Vitamin B1)

Thiamine is water soluble, stable at acidic pH, and unstable in alkaline solutions and with exposure to ultraviolet (UV) light. Urinary excretion is increased when serum levels are elevated and decreased when serum levels are low, with maximum excretion two hours after oral intake. The biological half-life of thiamine has been determined to be 9–18 days.[288]

Thiamine should never be omitted in PN regimens. Pediatric parenteral multivitamin solutions in the United States provide 1.2 mg thiamine per daily dose.[289,290] All of these products meet or exceed the RDA or AI levels. One recent study confirmed that current PN and EN regimens provide adequate thiamine for premature infants.[291]

Riboflavin (Vitamin B2) and Niacin (Vitamin B3)

The currently available pediatric parenteral multivitamin formulation provides 0.56 mg of riboflavin per day. In LBW infants, giving 0.56 mg/d, maintained riboflavin balance.[292] For 0–1 year, AI is 2–4 mg/d; age 1–8 years, 5–6 mg/d; age 9–13 years, 9–12 mg/d; and 14 mg and above, it is in the adult range which is 40 mg/d. Recommended intake for niacin is provided in Table 68-7. Although there are no good controlled studies to evaluate the exact need of riboflavin and niacin in PN, the available data suggest that the current formulation will meet requirements in stable patients.[293] For adults, the parenteral intake based on available formulations easily meets the requirements based on RDA, recommended daily intake (RDI) or DRI for riboflavin and niacin.[293]

TABLE 68-7 Daily Vitamins Recommendations for Parenteral Supply in Infants and Children

	Preterm Dose/kg/d	Term Newborn Dose/d	Infants Dose/kg/d	Children Dose/d
Fat-Soluble Vitamins				
Vitamin A[a], IU	700–1500	2300	500–1000	500
Vitamin D[b], IU	40–160	400	32	400
Vitamin E, IU	2.8–3.5	7	2.8–3.5	7
Vitamin K, µg	10	200	10	200
Water-Soluble Vitamins				
Vitamin B_1 (thiamine), mg	0.20–0.35	1.2	0.35–0.50	1.2
Vitamin B_2 (riboflavin), mg	0.15–0.20	1.5	0.15–0.20	1.4
Vitamin B_3 (niacin), mg	4.0–6.8	17	4.0–6.8	17
Vitamin B_5 (panthotenic acid), mg	1–2	5	1–2	5

Vitamin B_6 (pyridoxine), mg	0.15–0.20	1	0.15–0.20	1
Vitamin B_{12} (cyancobalamin), µg	0.3	1	0.3	1
Vitamin C, mg	15–25	80	15–25	80
Folate, µg	56	140	56	140
Biotin, µg	5–8	20	5-8	20

[a]1 µg RE (retinol equivalent) = 3.33 IU vitamin A.

[b]1 µg vitamin D = 40 IU vitamin D.

Source: Adapted from Koletzko B, et al.,[10] Laine L, et al.,[279] Levy R, et al.[292]

Pantothenic Acid (Vitamin B5)

RDA for pantothenic acid has not been established due to insufficient available scientific evidence. Pantothenic acid recommendations for PN are derived from the deliberations of expert panels.[10,294,295] Children, maintained on PN with commercial intravenous multivitamin products, showed no evidence of pantothenic acid deficiency or toxicity.[296,297] Pantothenic acid is stable in PN while stored in darkness at 2°C–8°C for 96 hours but only during 24 hours of simulated infusion initiated immediately after mixing.[298]

Pyridoxine (Vitamin B6)

For infants, the adequate oral intake (AI) is based on the amount of vitamin B6 in human milk. This dose was extrapolated, based on expected weight for older infants (7–12 months). For older children, EARs and RDAs are extrapolated based on adult data. The EAR of adults is 1.1 mg/d and DRI 1.3 mg/d.[299] As with other B vitamins, exposure of vitamin B6 to sunlight leads to destruction, although this has not been shown in all studies.[300,301] After intravenous infusion vitamin B6 reaches plasma steady-state concentration within 30 minutes. The serum half-life is only a few minutes; only 6.7% of the administered dose is detected unmetabolized in the urine.[302]

Cobalamin (Vitamin B12)

At birth, the liver of well-nourished babies contains only 25–30 mcg vitamin B12. If breast-fed from vegan mothers, these infants may develop B12 deficiency at 2–14 months.[303] The pediatric parenteral dose (1 mcg/d) is large enough to replenish the liver stores rapidly. There are no known

adverse consequences of providing this generous amount of B12.

Folate

The amount is expressed as mcg/kg/d (56 mcg/kg/d) for small infants (<3.0 kg), but thereafter the standard pediatric dose is expressed as mcg/d (140 mcg/d). The parenteral dose is 30% higher than the enteral dose until adulthood, whereas in adulthood enteral and parenteral recommendations are the same, 400 mcg/d.[295]

Biotin

RDA has not been set due to insufficient available scientific evidence. Daily AI of biotin levels has been established by IOM, Food and Nutrition Board based on extrapolation from the amount of biotin in human milk. Biotin deficiency has been reported in children on PN without biotin.[304] In children receiving HPN either total or partial, biotin deficiency was rare.[305] All plasma biotin levels normalized after supplementation with 60 mcg/d of parenteral biotin. The current recommended parenteral biotin supplementation is 20 mcg/d in infants and children and 8 mcg/kg/d in preterm infants. However, based on data on biotin-deficient children on biotin-free PN, some investigators have speculated that the biotin supplement currently recommended for pediatric patients (20 mcg/d) may not be adequate therapy for biotin deficiency and might not even be adequate to maintain normal biotin status during TPN.[306] Biotin is stable while stored in darkness at 2°C–8°C for 96 hours or during 24 hours of simulated infusion initiated immediately after mixing.[298]

Vitamin C

Ascorbic acid is a strong aqueous antioxidant, and it is a cofactor for several enzymes involved in formation of collagen, carnitine, iron, and sterol compounds metabolism, and neurotransmitters synthesis.[307] The 1998 ASPEN guidelines for full-term infants and children up to 11 years old, recommend a parenteral ascorbic acid dose of 80 mg/d for older children.[272] Friel et al., demonstrated that for most premature infants the recommended daily dosage of 25 mg/kg/d would be adequate.[308] Because antioxidant and anabolic requirements may vary, plasma concentrations of vitamin C should be monitored in long-term PN. In conventional bags stored at 4°C, the ascorbic content is reduced to 35% after 24 hours; at 21°C only 15% of vitamin C is left after 24 hours. Multilayered bags with

reduced gas permeability minimize the loss; at 4°C the loss is 5% at 48 hours and is 10% at 21°C for 48 hours.[309]

Vitamin D

Vitamin D is required throughout life for mineralization of the skeleton, prevention of rickets in childhood, and osteomalacia in the adult. In the last years, the finding of vitamin D receptor in other tissues, not involved with calcium and bone metabolism led to the discovery of new functions of vitamin D, mainly associated with immune system and cellular differentiation. Recently IOM published a new report on dietary requirements for calcium and vitamin D. Based on bone health, the RDA (covering requirements of 97.5% of the population) for vitamin D is 600 IU/d for ages 1–70 year, corresponding to a serum 25-hydroxyvitamin D level of at least 20 ng/mL (50 nmol/L). The recommendations for infants remain 400 IU/d.[254] For supply within PN, dosages of 400 IU/d have been recommended in children. In premature babies, the dosage of 160 IU/kg/d appears acceptable because this intravenous dose maintained plasma concentrations within the range recommended for normal term gestation infants consuming proprietary milk formulas.[310]

Vitamin E

Vitamin E (tocopherol) exists as several isomers, the most active being α-tocopherol. Vitamin E functions primarily as a biological antioxidant protecting the membrane phospholipids from peroxidation.[311] Toxicity in adults has not been described, but premature infants developed coagulopathy with progressive liver failure after one week of 25–100 mg/d of α-tocopherol.[312] A daily dose of 2.8 IU/kg α-tocopherol maintained plasma tocopherol blood levels within range of 23–58 μmol/L (1.0–2.5 mg/dL) in eight patients with birth weights between 450 and 1350 g. This dosage is therefore recommended in this population group.[313] The available data from term infants and children up to 30 kg indicate that blood levels between 12 and 35 μmol/L (0.5 and 1.5 mg/dL) can be achieved in all patients who received at least 7 mg/d of all-*rac*-α-tocopherol intravenously. This dose is therefore recommended for term infants and older children.[306] Vitamin E can be degraded by photooxidation in parenteral solutions.[314] The photooxidation of vitamin E may be prevented by the presence of ascorbic acid (competition for oxygen) and the type of bag used; multilayered bags substantially reduce oxidation reactions by preventing oxygen permeation from the air into the

solution. Skouroliakou et al. evaluated the stability of vitamin E in AIO mixtures for PN of neonates. In these AIO mixtures vitamin E (6.4 mg) remained stable (90%) within 24 hours, but started to decrease after 24 hours.[315]

Vitamin K

Phylloquinone of plant origin and menaquinone of bacterial origin are naturally occurring forms of vitamin K that are lipid soluble. Blood factors II, VII, IX, and X are dependent on the presence of vitamin K, which functions as posttranscription cofactor in activation of intracellular precursor proteins to plasma clotting proteins. The AAP recommends that 0.5–1.0 mg of vitamin K be given to all newborns and the Infant Formula Act requires that all formulas have a minimum of 27 μg/L.[316] For the past years, phylloquinone has been routinely supplied parenterally as 200 μg/vial of multivitamin infusion (MVI) pediatric. Because deficiency was not reported, based on plasma prothrombin time, or apparent toxicity from this dosage (the amount is much higher than that recommended enterally), the suggested daily intake should remain at 200 μg for infants and children. For preterm infants, doses of 130μg and 70μg/day have not been associated with abnormal prothrombin times or apparent complications. Therefore, the suggested daily dose for preterm infants is 100 μg phylloquinone/kg.

One potential problem with the introduction of vitamin K into the adult formulations is the possible interference with anticoagulants such as warfarin. Additionally, intravenous fat emulsions contain vitamin K in varying amounts (approximately 13–70 g/dL) which can make titrating anticoagulant therapy even more problematic.

Choline

Choline is an amine endogenously synthesized from the amino acid methionine. It is an essential component of all cell membranes and is necessary for DNA repair due to its role as a methyl donor. It also serves as the precursor for the neurotransmitter acetylcholine. Animal models have shown progression to steatohepatitis and even development hepatocellular carcinoma with long-term choline deficiency. Choline deficiency may cause or contribute to PN-associated hepatic steatosis. Currently, there is no commercially available parenteral choline product. The recommended daily choline doses for neonatal and pediatric PN supply are 0–6 months, 125 mg; 7–12 months, 150 mg; 1–3 years, 200 mg;

4–8 years, 250 mg; 9–13 years, 375 mg; >13 years, 550 mg/d (adult amounts).[317]

General Considerations

Vitamins are essential nutrients and must be provided by the PN solution, to avoid deficiency. The optimum time to begin vitamin supplementation in newborns and premature infants is not clear. It should be taken into consideration, that water-soluble vitamins, with the exception of vitamin B12, are inadequately stored. Insufficient thiamine intake can result in severe lactic acidosis within only a few days in children on PN. It is, therefore, recommended that vitamin substitution is started early with PN. Vitamin intake should be administered daily. All clinical studies have been carried out with commercially available vitamin preparations, therefore, existing intake recommendations are based on the composition of these available preparations. At this time there is no commercially produced vitamin supplement available on the market, which completely meets the current intake recommendations for premature infants as a supplement for long-term PN.

Vitamins can be degraded by oxygen, light, and heat. Degradation reactions can be accelerated by catalytically active TEs such as copper and iron. Fat-soluble vitamins can be adsorbed on specific synthetic materials, thus, the administered dose is uncontrolled and significantly reduced. Dissolving the vitamins in a lipid emulsion, reduce absorption on plastic. Furthermore, the formation of peroxides in lipid emulsions can be reduced by adding multivitamin preparations. Vitamin preparations should, if possible, be administered together with the lipid emulsion. The clinical impact of free radicals, which can develop in intravenous multivitamin emulsions when exposed to light, remains a concern.

Feed lines with light protection should be used when administering parenteral solutions with vitamins until the clinical significance of these results has been determined. Exposure to light of PN solutions increases oxidation products such as lipid peroxides and hydrogen peroxide and oxidative stress impairs glucose uptake and affects lipid metabolism. A prospective study in which preterm infants were allocated to light-exposed (n = 32) or light-protected (n = 27) PN solutions, blood glucose was higher and hypertriglyceridemia was twice as high in those who received the light-exposed solutions. The authors concluded that shielding PN solutions from light provides a potential benefit for preterm infants by avoiding hypertriglyceridemia and allowing increased substrate delivery.[318] Premature infants need higher amounts of some vitamins compared to term

infants, because of their increased requirements for growth, and possible greater losses.

Multivitamin formulations for parenteral use in infants and children are presented in Table 68-8.

Trace Elements

Routine addition of zinc, copper, selenium, chromium, and manganese to PN solutions is recommended to avoid deficiency. Although not a conventional addition, molybdenum supplementation may be appropriate in long-term TPN therapy.[319] In 1988, the subcommittee on Pediatric Parenteral Nutrient Requirements of The American Society for Clinical Nutrition published the recommendations on TEs requirements in the term infant and child for zinc, copper, selenium, chromium, manganese, and molybdenum. Intakes for preterm infants were also suggested.[295]

TE contamination must be considered when determining TEs supplementation. Blood concentrations of copper, chromium, and manganese may become elevated because of contamination of TPN solutions by these metals. Beginning in the late 1970s, several reports described contamination of PN formulations with zinc, copper, manganese, chromium, and selenium. Nonnutrient contaminants such as aluminum, arsenic, and strontium were also found. The greatest amounts of contamination were found in the amino acids, potassium chloride, calcium gluconate, and sodium chloride products.[320] Amounts varied between manufacturers and in different lots from the same manufacturer.

Pluhator-Murton et al. calculated the amount of TEs in a 2 L PN solution for adults made with the tested components, compared those numbers with the amounts expected to be provided in the same PN solution, and found an extra 1.1 mg zinc, 0.08 mg copper, 38 mcg manganese, 15 mcg chromium, and 21 mcg selenium. The amounts of contaminant manganese and chromium found in that study were approximately 63% of the current recommended daily requirement for manganese and 100% of the daily requirement for chromium.[320] Giving the change in the manufacturing processes over the years, ASPEN recommends that these contamination studies be repeated on the current PN component products.

Specific disease states will necessitate adjustments in the elements provided. Copper and manganese should be administered cautiously, if at all, in patients with impaired biliary excretion or cholestatic liver disease.[321–324] Because of renal excretion of these elements, dosage

reduction for selenium, molybdenum, and chromium should be evaluated in patients with renal dysfunction. Additional zinc supplementation is necessary in conditions of increased losses, such as persistent diarrhea or excessive ileostomy drainage.

The most recent ASPEN position paper (2012) has recommended several changes to the currently available parenteral TE products. These recommendations include greatly reduced daily doses of both copper and manganese based on the reports of manganese toxicity and excessive organ accumulation of both manganese and copper in patients who had received long-term PN.[282] TEs recommendations for parenteral supply in infants and children are shown in Table 68-9. TEs formulations for parenteral use in infants and children are presented in Table 68-10.

Zinc

Zinc is included in all the current parenteral TE products. There is strong data supporting the routine use of zinc supplementation.[325] Extra supplementation of zinc may be needed in patients with diarrhea, gastrointestinal fistulas, severe burns, and in preterm infants with NEC especially in the presence of bowel resection or ileostomy.[326,327]

Selenium

There is strong evidence that selenium should be routinely added to all PN formulas.[328] Selenium is especially important in VLBW preterm infants because it is a component of glutathione peroxidase.[329] Supplemental doses of selenium for VLBW preterm infants on PN should be provided early, probably from the first day and in higher doses than those currently used.[330] Selenium supplementation in VLBW preterm infants was associated with a significant reduction in sepsis episodes but not improved survival, neonatal chronic lung disease, or retinopathy of prematurity.[331]

TABLE 68-8 Multivitamins Formulations for Parenteral Use in Infants and Children

Content/Vial	M.V.I. Pediatric 5-mL Vial	Influvite PEDiatric 1-mL + 4-mL Vials	Vitalipid N Infant 10-mL Vial	Soluvit N Adult 10-mL Vial	Cernevit 5-mL Vial
Fat-Soluble Vitamins					
Vitamin A, IU	2300	2300	2300	—	3500

Vitamin D, Ergocalciferol (D_2), IU	400	400	400	—	220
Vitamin E, dl-α tocopherol acetate, IU	7	7	7	—	11.2
Vitamin K, phylloquinone (K_1), µg	200	200	200	—	—
Water-Soluble Vitamins					
Vitamin B_1(thiamine), mg	1.2	1.2	—	2.5	3.51
Vitamin B_2 (riboflavin), mg	1.4	1.4	—	3.6	4.14
Vitamin B_3 (niacin), niacinamide, mg	17	17	—	40	46
Vitamin B_5 (panthotenic acid), 15 mg dexpanthenol, mg	5	5	—	15	17.3
Vitamin B_6 (pyridoxine), mg	1	1	—	4	4.5
Vitamin B_{12} (cyancobalamin) µg	1	1	—	5	6
Vitamin C, mg	80	80	—	100	125
Folate, µg	140	140	—	400	414
Biotin, µg	20	20	—	60	69

M.V.I. Pediatric (Hospira); 5 mL is the dosage for infants and children from 3 kg to 11 years, for infants weighing 1–3 kg the daily dosage is 65% (3 mL) of the 5-mL vial, and for infants weighing less than 1 kg the daily dosage is 30% (1.5 mL) of the 5-mL vial.

Influvite PEDiatric (Baxter); is supplied in two single-dose vials, vial 2 (1 mL) contains folic acid, biotin, and vitamin B_{12}, and vial 1 (4 mL) contains all the other vitamins. 5 mL is the daily dose for infants and children from 3 kg up to age 11 years; for infants weighing 1–3 kg, the daily dosage is 65% (2.6 mL vial 1 and 0.65 mL vial 2); and for infants weighing less than 1 kg, the daily dosage is 30% (1.2 mL vial 1 and 0.3 mL vial 2).

Vitalipid N Infant (Fresenius Kabi); The dosage is 1 mL of Vitalipid N Infant per kg bodyweight per day up to a maximum of 10 mL.

Soluvit N Adult (Fresenius Kabi); supplement the water-soluble vitamins in adults and children 11 years of age and older. Soluvit N is not recommended for use in children under 11 years. Contains as preservative 500 µg methyl hydroxybenzoate.

Cernevit (Baxter); multivitamins supplement for children after 11 years.

However, not all the currently available parenteral TE products contain selenium. Selenium is also available as an individual parenteral product

that can be added to PN separately. ASPEN recommends that selenium be routinely added to PN formulas, either in a multiple TE product or as a separate component. The current recommended pediatric parenteral intake is 2 mcg/kg/d. The current parenteral dose of 20–60 mcg/d in adults seems to be too low, because patients receiving this level of daily intake frequently have low plasma concentrations of selenium.[328] It is recommended that the adult daily parenteral selenium requirement should be increased to 60–100 mcg/d.[282] Selenium is excreted in the kidneys, thus its intake should be reduced in patients with impaired renal function.

Manganese

Hypermanganesemia has been reported in 389 patients (17 studies) on PN (265 adults and 124 children). Most patients had no clinical symptoms, but few developed neurological symptoms (Parkinson-like syndrome, confusion, irritability, seizures). Serum and RBC manganese and basal ganglia magnetic resonance image (MRI) abnormalities regressed after discontinuation of manganese supply.[332] Additional patients were reported in 2008 by Hardy et al. Hypermanganesemia occurred particularly in infants with cholestasis, often within three weeks of the initiation of PN.[333] Manganese content in autopsy tissues were reported from eight patients who lived 2–21 years on PN, showed significant manganese elevation in liver and kidney samples, especially in patients who died of liver or renal failure.[323]

Currently, multiple TE products provide between 265 mcg to 500–800 mcg manganese per day (adults) and 2–10 mcg/kg/d (pediatric/neonatal TE products). Most patients who developed hypermanganesemia had received doses within these ranges. A dose-finding Japanese study showed that adult PN patients maintained a stable whole-blood manganese level on a supplement of 55 mcg/d, whereas an increase in RBC manganese and in MRI signal intensity was likely if 110 mcg or more was supplemented.[334]

TABLE 68-9 Daily Trace Elements Recommendations for Parenteral Supply in Infants and Children

	Preterm	Term Newborn	Infants	Children
Zinc, mg/kg/d	0.4	0.25	0.25 < 3 months 0.1 > 3	0.05 (max 5 mg/d)

			months	
Selenium, µg/kg/d	5–7	2	1–3	1–3 (max 30-60 µg/d)
Manganese[a], µg/kg/d	1	1	1	1 (max 50-100 µg/d)
Copper[b], µg/kg/d	20	20	20	20 (max 500 µg/d)
Chromium[c], µg/kg/d	0.05–0.2	0.2	0.2	0.2 (max 5–15 µg/d)
Molybdenum, µg/kg/d	0.25	0.25	0.25 (max 5 µg/d)	0.25 (max 5 µg/d)
Iron[d], mg/kg/d for PN >2 months	0.1–0.2	0.25–0.67	0.05–0.1	0.05–0.1 (max 1mg/d)
Iodine	1 µg/kg/d	0–1 µg/kg/d	0–1 µg/d	1 µg/d

[a]Regular monitoring rather than provision is recommended.

[b]Check serum copper and ceruloplasmin in children with cholestasis in order to decide whether copper should be reduced or removed from PN. There is insufficient data for PN supplementation in premature infants.

[c]ESPGHAN, ESPEN and ASPEN position papers states that chromium contamination of PN ingredients makes additional supplementation unnecessary and suggests regular monitoring rather than addition.

[d]Not usually added to PN solutions.

Multitrace-4 Neonatal (American Regent), supplied as 2-mL vial. Does not contain selenium and iodine.
Multitrace-4 Pediatric (American Regent), supplied as 3-mL vial. Does not contain selenium and iodine.
Trace Elements Injection 4, USP—Pediatric (American Regent), supplied as 10-mL vial. Does not conta
Peditrace (Fresenius Kabi), supplied as 10-mL ampoule. Dosage 1 mL/kg up to 10 kg.
Inzolen-Infantibus sine NaK (Kohler), supplied as 10-mL ampoule. Does not contain selenium and iodin
Oligoelements Aguettant Pediatrique (Aguettant), supplied as 10-mL ampoule.

Current recommendations suggest that the dose of manganese in parenteral multiple TE products be decreased to 55 mcg/d for adults and 1 mcg/kg/d in pediatric and neonatal products with a maximum daily total dose of 55 mcg suggested by ASPEN[282] and 50 mcg suggested by ESPGHAN/ESPEN. Manganese dose should be further decreased or withheld in patients with significant cholestasis or hepatic dysfunction, elevated whole blood manganese levels, or in those with signs and symptoms of manganese toxicity.[282] In addition, ASPEN recommends the amount of manganese contamination in a standard adult composite PN formulation be limited to <40 mcg/d.[282] Contamination data for pediatric and neonatal PN formulas are not available and require further research.

Copper

Wilson's disease, an inborn error of copper metabolism leading to high concentrations of copper is the prototype of copper toxicity. Elevated hepatic copper, within the diagnostic range of Wilson's disease (copper >250 mcg/g dry weight), have been reported in 8/28 patients with cholestasis on PN, although the copper supply was not reported.[335] Autopsy studies reported significantly elevated copper in liver and kidney tissue, especially in patients who died of liver failure although receiving recommended 0.5–1.5 mg/d of copper within PN solution.[323] By analogy with cholestatic infants, it is likely that copper accumulates as a result of liver disease, but it is also possible that hepatic copper overload enhances the liver damage. However, two recent studies including neonates and premature infants on PN did not find elevated serum copper levels on standard 20 mcg/kg/d supplementation, although most of them were cholestatic. Moreover, most infants had low serum copper levels, therefore, regular monitoring of copper levels even in cholestatic children should guide the decision on copper supply or discontinuation.[336,337]

The adult parenteral multiple TE products currently available in the United States provide approximately 1 mg/d of copper. ASPEN recommends that the dose of copper in adult parenteral multiple TE

products be lowered to 0.3–0.5 mg/d and limit the amount of contamination in a composite PN formulation to less than 0.1 mg/d. Copper requirements are increased in severe burn patients.[338] No contamination data are available for pediatric and neonatal parenteral TE products; investigation of copper contamination in these products is desirable.

Chromium

Chromium toxicity varies depending on the chromium valency. Chromium IV, V, and VI are carcinogenic. Chromium in PN formulations, food, and oral supplements is trivalent and considered nontoxic.[339] There are several reports in PN patients, both adults and children, of serum and urine chromium concentrations 10–100 times normal values.[340,341] Autopsy tissue data found similar elevations in heart, muscle, liver, and kidney samples.[323]

A normal adult diet provides approximately 35 mcg/d of chromium but the absorbed amount of chromium from a standard adult oral diet is only 0.4–0.9 mcg/d. Therefore, the parenteral requirement is likely to be only one-tenth or less of the previously recommended amounts of 10–15 mcg/d. According to Pluhator-Murton et al. data, chromium contamination of a 2-L PN composite formula is approximately 15 mcg per day, mainly from the 70% dextrose solution, in addition to the 11 mcg/d intentionally added from a multiple TE product.[320] This amounts a parenteral chromium dose that is 30–60 times greater than the current estimated requirement.

The key question is whether these high chromium doses have clinical consequence or are potentially toxic. There are no reported cases of chromium toxicity in adult patients on long-term PN, suggesting that these high chromium concentrations are not toxic. Chromium toxicity may be more of a concern in pediatric patients. In 1992, Moukarzel et al. reported that glomerular filtration rates (GFR) in PN-dependent children were inversely correlated with their serum chromium concentration, cumulative parenteral chromium intake, and PN duration. One year later after discontinuation of parenteral chromium supplementation, serum chromium concentrations were lower but still elevated, and their reduced GFR was still below control patients who did not receive PN.[342] Renal tubular damage and high renal chromium deposits were also reported in rodents after receiving one week of PN.[343] Because PN components have significant chromium contamination, some investigators have stopped adding chromium to PN formulations, but the consequences of such

actions have not been evaluated.[344,345]

The current adult multiple TE products provide 10–15 mcg/d of chromium. Based on oral absorption in healthy individuals, the parenteral requirements may be as low as 0.14–0.87 mcg/d.[346] ASPEN recommends that in addition to the current TE products that deliver 10–15 mcg/d of chromium, a TE product without added chromium should be made available. Research on chromium requirements during PN and the effects of contamination on requirement for supplementation is urgently needed.[282] The pediatric and neonatal multiple TE products available provide 0.05–0.2 mcg/d of chromium. Studies of pediatric and neonatal PN patients on this level of supplementation report serum chromium concentrations 4–42 times that of normal.[347] Moukarzel recommended that the daily parenteral dose of chromium for neonates and pediatric patients should be radically reduced. In view of preliminary studies in newborns on PN that demonstrate chromium nephrotoxicity, and because PN formulations have significant chromium contamination, ASPEN recommends that the daily dose of chromium be reduced to the levels recommended by Moukarzel and that a pediatric/neonatal multiple TE product without added chromium should be available for use in this patient population.[342]

Molybdenum

Molybdenum functions as a cofactor for a limited number of enzymes in humans. The IOM's Food and Nutrition Board has developed AIs for infants (2–3 mcg/d) and RDAs for children and adults (17–50 mcg/d).[344] The published, estimated daily molybdenum PN requirements are listed in Table 68-9. Most professional groups indicate the need for molybdenum in long-term, home PN patients. While there are no reports of molybdenum deficiency in term infants, LBW infants might be at risk because they are born before adequate stores can be acquired, have rapid growth requiring increased intakes, and frequently receive PN. Friel and coworkers performed a molybdenum balance study in 16 LBW infants on PN. They speculate that an intravenous intake of 1 mcg/kg/d would be adequate for the LBW infant.[348] There are no significant data to warrant changes in molybdenum supplementation in PN formulas. Thus, no changes are recommended for adult, pediatric, and neonatal products. Molybdenum is present in most of the adult and some of the pediatric parenteral multiple TE products in Europe but none of the products in North America.

Iron

Some TEs products contain iron, but some do not. Instability of total nutrient admixtures containing iron has prevented its addition to TE mixtures. For patients not able to take oral iron supplements, addition of iron dextran to fat-free PN or separate infusions of IV iron have been recommended. Further research is required to examine the stability of iron additives to fat emulsion–containing admixtures.

Iron supplementation in pediatric and neonatal patients on PN is important in long-term therapy, and these infants should be monitored for iron status prior to and during parenteral therapy. Iron is probably not needed in preterm infants in the first few weeks, especially if they were transfused.[349] There are also some concerns regarding its possible contribution to oxidative stress.[350]

Iodide

Iodide is currently included in the parenteral multiple TE products available on the market in Europe, but not in the North America. The amount of iodide contamination in PN components is unclear but appears adequate to meet basal requirements as thyroid function remains normal in most long-term PN patients on iodide-free regimens.[351]

However, one study of 15 pediatric PN patients in Europe found an inverse correlation between duration of PN and urinary iodide concentrations. Although 9/15 (60%) of these patients had iodide deficiency based on urinary iodide concentrations, thyroid function tests remained normal. Use of povidone-iodine solutions for skin cleansing of catheter sites in the past may have maintained a normal iodide status due to iodide skin absorption.[352] As skin cleansing has widely moved to the use of 2% chlorhexidine, the risk of iodide deficiency and the need for parenteral supplementation need to be investigated. Routine supplementation of PN with iodide could be beneficial, but more research is needed for adult, pediatric, and neonatal products.

Fluoride

Fluoride is also present in the multiple TE products used in Europe but is not included in any products available in North America. The amount of fluoride contamination in PN is variable. Supplementation of PN with fluoride could be beneficial, but more research is needed for adult, pediatric, and neonatal patient populations.[353]

Trace Element Requirements

TEs should be supplemented in long-term PN. When PN is used partially, or is limited to one or two week, only Zn need be added to the infusate. If PN continues for >4 week, addition of selenium is advisable and in the absence of cholestasis, copper and manganese may also be added. Iodide and chromium may also be added at this time and iron supplementation needs to be determined. In the presence of suspected preexisting deficits or rapid growth, earlier use of TE supplements may be desirable. Requirements for some TEs have been narrowed down lately. There is no TE supplement for long-term PN, which meets the current recommendations.

TEs requirements and optimum time to begin supplementation in premature and full-term infants are not completely clear. Premature and ill full-term infants have an increased risk of developing TE deficiency. Premature infants are born with lower TEs stores as the accumulation of these stores occurs during the last trimester of the pregnancy. Rapid growth, unidentified requirement levels, and variable absorption are further risk factors contributing to the development of a TE deficiency in premature infants. Probably, the only TEs that need to be provided from the first day of life, when PN is initiated in VLBW premature infants, are zinc and selenium.[295,331] Supplementation with other TEs is probably not needed up to two weeks, although these are usually supplied with the TE preparations.

VASCULAR ACCESS

PN solutions are administered either via a central venous catheter (CVC) or over short term via peripheral venous access, depending on the condition of the patient (type of illness, current state of health, etc.), composition of the infused solution, amount of energy to be administered, and duration of PN.

Long-term vascular access is an essential component in the management of pediatric patients with a wide variety of chronic clinical conditions requiring IV blood sampling, drug therapy, or PN. PN is usually administered via a CVC because of the high osmolarity of nutrient admixtures and the inability to provide the prescribed amount of PN when using peripheral veins. The broad array of devices and techniques available highlights the importance of disease- and patient-specific selection to properly address the clinical needs of the child. In addition, the appropriate care of the device is crucial to decrease the risk of morbidity

and mortality due to device-related complications. Current CVC types, materials, and connectors and alternative access choices for delivery of long term PN are as follows:

1. Tunneled catheters (e.g., Hickman/Broviac silicone catheters with or without Groshong valve) offer acceptable rates of sepsis and thrombosis and ease of use. These catheters have a Dacron cuff attached to the outer surface and located near the proximal end. This cuff is meant to be placed in a subcutaneous tunnel and allows for the ingrowth of surrounding tissue during several weeks after placement to secure the catheter in place. This tissue ingrowth also putatively provides a physical barrier against bacterial migration along the catheter tract into the bloodstream. These catheters are available in single- and double-lumen variety and range in size from 2.7 to 12 Fr for pediatric patients. The visible length may be repaired if damaged.[354–356]
2. Fully implanted catheters: (e.g., Port-a-cath): These CVCs are accessed through the skin by a needle and are favored by some patients for functional and cosmetic reasons, for example, bathing and swimming, and could be considered for patients with a coexistent stoma. These catheters consist of a reservoir attached to a catheter. Most reservoirs have a compressed silicone self-sealing septum that is estimated to be able to maintain its integrity through approximately 2000 punctures. The port is accessed transcutaneously using a 90° angle 20–22 gauge noncoring (Huber) access needle. These catheters are better suited for intermittent rather than daily use.[357]
3. Peripherally inserted CVCs (PICCs): These are acceptable for short-term PN (can provide access for up to 12–18 months) and provide the advantage of avoiding general anesthesia and vein manipulation. These catheters are made of either Silastic or polyurethane, are single or double lumen, and come in sizes from 1.1 to 7 Fr, 40–60 cm in length. In a prospective study in adults, PICCs for the administration of HPN were found to be similar in terms of catheter-related complications (catheter-related blood stream infections [CRBIs] and thromboembolic complications) to other CVCs.[358,359] Recently, a retrospective study in infants with IF reported that the use of PICC was associated with low prevalence of CRBIs and venous thrombosis.[360]

4. Arteriovenous fistulae: This type of access can be useful when central venous access becomes impossible.

CVC Material

Standard silicone catheters are robust and soft and can last for 10–15 years. There is insufficient evidence to currently recommend alternative CVC materials (Teflon, antibiotic impregnated lines).

CVC Line Connectors

All connections should be Luer-locked to prevent accidental disconnection and air embolus. All external tunneled catheters should have a clamp and be locked under positive pressure.

CVC Placement and Positioning

To minimize complications or side effects, the smallest single-lumen catheter should be inserted into the largest possible vein. Surgical or radiologically guided percutaneous insertion using an aseptic technique should be used to insert a CVC. The location of the catheter tip should be radiologically documented. The recommended CVC tip position is just above the SVC–right atrium junction, parallel to the SVC to prevent complications such as arrhythmia, thrombosis, tricuspid valve damage, and cardiac tamponade.[361] Various helpful radiographic landmarks for safe positioning have been described. The carina is always located above the pericardial sac in adults and recommended as a landmark to guide the CVC placement. Although, the radiographic diagnosis may be more difficult in children (e.g., because of a large thymus gland), the carina seems a safe radiographic landmark for CVC positioning even in small children. The tip of the right sided CVC catheter should ideally lie just above the level of the carina.[362–364]

Exit Site Dressings

Dressings for the CVC exit site are recommended for about the first 10 days. Highly permeable transparent dressings or dry gauze are acceptable. The former should be changed weekly in the absence of a specific indication (blood, pus) and the latter daily. With a dry healed exit site, dressings are not necessary except for peripherally inserted CVC lines.[365]

Catheters' Flushing

In adults, routine flushing of nonused CVCs or port systems with heparin

is not recommended,[366] and there is no need for heparinization when the catheter is closed for a short period of time (<8 h). In children or when recommended by the manufacturer, implanted ports or opened-ended catheter lumens should be flushed and locked with heparin sodium flush solutions. The usual dosage based on patient weight is 1 U/mL for patients in the neonatal ICU, 10 U/mL for children less 15 kg; and 100 U/mL for children >15 kg.[367]

Infusion Pumps

PN should always be administered by an infusion pump in neonatal and pediatric patients. The advantage of such devices is first of all safety (precise control of the flow rate) and the ability to gradually start and stop the infusion, which may enhance PN tolerance.

Filters

The use of in-line filters during PN administration is effective for the mechanical removal of larger particles, precipitates, bacteria, fungi, larger lipid particles, and air. The greatest concern relates to AIO admixtures containing calcium phosphate precipitates, which can cause diffuse microvascular lung embolisms. The 1.2-µm filters should be used for the administration of lipid-containing solutions including AIO admixtures and changed every 24 hour. The 0.2 µm endotoxin-retaining filters should be used for the administration of non-lipid–containing solutions and can be changed every 96 hours. No evidence has been found to support the use of in-line filters for preventing infusate-related CRBSIs.[368,369]

Infusion Sets

The risk of colonization, and therefore CRBSI, is higher if the infusate administered supports proliferation of contaminating organisms. The administration of PN has been associated with an increased risk of catheter-related infection, as lipid emulsion is particularly suited to the growth of a wide range of microorganisms. A Cochrane systematic review concluded that administration sets that do not contain lipids, blood, or blood products may be left in place for intervals of up to 96 hours without increasing the incidence of infection. Administration sets that contain lipids should be changed every 24 hours, and is currently recommended.[370] A study in neonates has shown that microbial contamination of infusion sets is significantly more frequent with 72- than with 24-hour set changes in neonates receiving lipid solutions.[371]

The placement and long-term use of IV catheters exposes the patient to a wide variety of risks, which generally can be grouped into mechanical, infectious, and metabolic categories. The infectious and metabolic complications and how to avoid them are extensively discussed in the other sections of this chapter.

Mechanical complications can occur intraoperatively or postoperatively. Intraoperative complications include erroneous catheter tip positioning, arterial puncture (with possible subsequent soft tissue hematoma and hemomediastinum), lung puncture (with possible pneumothorax and hemothorax), thoracic duct injury, guide wire-induced arrythmia (stimulus in the area of the tricuspid valve), myocardial perforation, nerve palsy, air embolus, misplaced catheters, and, if the catheter is infused after erroneous placement in the pleural space, hydrothorax. Postoperative complications include thrombosis, fibrin sheath formation, catheter occlusion, catheter erosion through the vein or the heart, arteriovenous fistula formation, catheter embolus, and clot embolus. Retrieval of fragmented catheter emboli can now be safely and effectively accomplished percutaneously.

Long-term (>3 months) home parenteral nutrition (HPN) requires a long-term venous access device, such as a cuffed tunneled central catheter (Hickman, Broviac, Groshong, and Hickman-like catheters such as Lifecath, RedoTPN, etc.) or a totally implanted port. An alternative to central venous cannulation is a PICC using an ultrasound-guided cannulation of a peripheral vein in the upper arm. The advantages of these peripheral access sites are lower rates of acute complications such as pneumothorax, life-threatening bleedings, and vein manipulation even in small infants.[372]

INITIATION AND MONITORING OF PN IN HOSPITAL

An individualized plan for initiation, advancement, and nutritional support goals should be formulated before starting PN. A multidisciplinary team including pediatrician or surgeon, dietitian, pharmacist, and nurse (nutrition support team) should be involved in the process of patient' assessment and planning the nutrition support strategy. Exhaustion of all possible modalities of advanced enteral nutrition support (specialized formulas and diverse delivery protocols) should be attempted before the initiation of PN. PN is not indicated in patients with adequate small intestinal function in whom nutrition may be maintained by nasogastric

tube or gastrostomy feeding.

Baseline nutritional assessment including clinical examination and anthropometry, review of enteral nutrition supply and baseline laboratory parameters should be performed before planning PN therapy. The plan is based on estimates of fluids, energy, and protein requirements, should account for increased or decreased needs of each patient and consider other fluid requirements for intravenous drugs. Evaluation of energy requirements and goals should be defined, either using conventional equations or better by IC, especially for children in PICU.

The initiation protocols regarding timing and composition of PN in premature and VLBW infants are related to the general principles of early aggressive nutrition, as discussed in the previous sections. PN should be administered within the first day of life to provide adequate nutrition and minimize early weight loss and protein breakdown. Initial protein intake should be at least 2–3 g/kg/d, and preferably 3–3.5 g/kg/d. Glucose should be administered immediately after birth, preferably at rates of at least 6 mg/kg/min, but rates as low as 3.5 mg/kg/min are acceptable in the presence of hyperglycemia. Lipids should be provided from the first day at 1 g/kg/d to supply energy for protein metabolism and growth. Most advocate some fluid restriction on the first days of life as outlined in the section on fluid intake. Calcium and multivitamins should be provided from the first day, but other electrolytes are not included in the initial PN solutions. Close monitoring of weight loss and laboratory tests should dictate the rate of fluid intake and the timing for the addition of electrolytes. Protein and lipid intake should be gradually increased to meet the target intakes. Close monitoring of blood glucose levels should guide the increase in glucose infusion rates that can be achieved either by increasing volume (fluid intake), or by increasing the percent of dextrose in the PN solution (from 5% up to 10%, and possibly up to 12.5%). This approach may allow minimization of the cumulative nutrient deficits and reduction or even elimination of postnatal extrauterine growth restriction in VLBW preterm infants.[39,373]

The steps in devising a PN prescription are as follows:

1. Determine the amount of protein to be given and calculate the caloric/nitrogen ratio, infants 150–200 kcal/1 g nitrogen, in older children 100–150 kcal/1g nitrogen (or 30–40 kcal for each 1 g protein).
2. Determine the energy requirements and distribution between glucose and lipids. The distribution of calories derived from macronutrients depends on the clinical setting: 10% to 20% of

calories in the PN solution can be derived from protein, CHO and lipids may supply between 50%–70% and 30%–50% of nonprotein energy respectively.

3. Calculate the amount of dextrose to be used initially, during advancement, and for maintenance.
4. Determine the dose of lipid, no data endorse the common practice of gradually advancing the amino acid or lipid dose in pediatric PN.
5. Determine fluid volume and rate, based on the patient' fluid requirements.
6. Calculate the electrolytes and mineral requirements.
7. Determine the amounts of vitamins and TEs.

Suggested ranges for macro- and micronutrient supply in pediatric PN solutions are given in each section of the chapter.

To be able to correct dosages early and to minimize complications such as fluid and electrolyte imbalances, disturbances of acid-base balance, hyperglycemia, and hypertriglyceridemia, clinical and laboratory monitoring of the patients receiving PN is mandatory. Periodic nutritional assessment including weight, height, and mid-upper arm circumference (MUAC) should guide short-term and long-term nutritional support.[374–376] An in-hospital monitoring schedule is shown in Table 68-11.

Nutritional assessment of preterm infants in the stable growing phase, especially if they are on prolonged PN, should include the following:

- Growth parameters
  - Daily weight gain:
    - ≤35 weeks: 15 g/kg/d
    - >35 wks: 20–30 g/d
  - Once a week head circumference ~0.7–1.0 cm/week
  - Consider also once week length ~1 cm/week
- Daily follow-up of urine glucose (glycosuria can be present without hyperglycemia) Nutritional Lab (at least once a week for infants on PN):
  - Glucose
  - Complete Blood Count: Hemoglobin, Reticulocytes.
  - Electrolytes
  - Minerals: Calcium, Phosphorus, Alkaline Phosphatase (sensitive markers for mineralization and chemical osteopenia of prematurity)
  - Urea/BUN (as markers for protein status and amino acids intake)
  - Triglycerides (as marker of lipid tolerance ~up to 150–200 mg/dL,

may accept up to <250 mg/dL)
  - Urinary phosphorus
  - Consider also:
    - Creatinine (as marker of renal function)
    - Total protein, albumin (or preferably prealbumin, a better indicator of protein status)
    - Total and direct (conjugated) bilirubin and liver function tests, especially if PN-associated cholestasis is suspected
    - Zinc
- Further tests that may be occasionally considered, especially if there is evidence of chemical osteopenia of prematurity (because the maximum intake of calcium and phosphate in PN does not supply the minimal requirements, preterm infants on PN are at increased risk for osteopenia of prematurity):
  - X-Rays
  - Bone density/Ultrasound

TABLE 68-11 In Hospital Monitoring After PN Initiation

Timing	Monitoring
Baseline	Nutritional assessment including: 1. Evaluation of enteral nutrition support adequacy 2. Anthropometry 3. Biochemistry: electrolytes, blood urea, calcium, phosphorus, magnesium, albumin/prealbumin, liver enzymes, serum triglycerides, hemoglobin/Ht
Daily	Weight, input-output, urine glucose Glucose monitoring 2 times daily initially Inspection of catheter site
3–4 times/week initially	Biochemistry: electrolytes, blood urea, calcium, phosphorus, magnesium, albumin/prealbumin, liver enzymes, serum triglycerides Hemoglobin/hematocrit Urine glucose and electrolytes
Weekly thereafter	Idem and follow-up nutritional assessment

As stated earlier, multidisciplinary and qualified pediatric nutrition support teams are of paramount importance for provision of high quality nutrition care. Nutrition support teams should be involved in the initiation and monitoring of enteral and PN therapy in the hospital and at home. Several studies have documented that nutrition support teams improve

clinical and economic outcomes by reducing the incidence of PN–associated complications, encouraging the use of alternative feeding routes, and by reducing wastage of PN solutions and resources.

At the Royal Children's Hospital in Melbourne, the introduction of a formal Nutrition Support Service in 1994 was associated with a 61% reduction in PN costs over five years, despite a 23% increase in hospital admissions and a 24% increase in surgical procedures over the corresponding period.[377]

METABOLIC COMPLICATIONS

Liver, Biliary, Bone, and Renal Complications

Since its introduction, more than fifty years ago, PN has benefited and saved the lives of many patients with a variety of clinical conditions. PN, however, has been associated with a large spectrum of possible complications related to both the PN solution (metabolic complications) as well as the technique of intravenous delivery (catheter-related complications). Metabolic complications of PN can be divided into acute metabolic complications and chronic (long-term) metabolic complications. A comprehensive list of PN-related short-term metabolic complication is presented in Table 68-12. Acute complications, such as hypoglycemia or electrolytes disturbances may be life-threatening but can be easily managed. Chronic, long-term metabolic complications are however, more problematic, as the etiology of these long-term side effects is multifactorial and often not fully understood.

Intestinal Failure Associated Liver Disease

The reported prevalence of IFALD varies widely, but is estimated to be 40% to 60% in children and as high as 85% in neonates receiving PN for prolonged periods of time.[378,379] A recent survey from the United States, Pediatric Intestinal Failure Consortium reported that cholestasis was present in 75% of 272 infants included in the analysis.[380] In adults, serious hepatic dysfunction is much less common, occurring in 15% to 30% of patients.[381]

TABLE 68-12 Short-Term Metabolic Complications Associated with PN

	Cause	Prevention/Interventi

Fluid disturbances	Fluid overload	Refeeding syndrome	Reduce fluids supply at the start
	Osmotic diuresis	Cardiac or renal insufficiency or excessive infusion rate Hyperglycemia and glycosuria	Decrease fluid, increase nutrient concentration Reduce dextrose infusion ra or concentration and monitc give insulin
Acid-base disturbances	Metabolic acidosis	Renal or gastrointestinal losses; infusion of hydrogen	Increase acetate in solution Avoid excessive protein and/or calories; postinjury phase, increased metabolic rate
	Metabolic alkalosis	Base intake or gastric drainage	Provide additional fluid and NaCl, KCl, or NH_4 Cl
	Respiratory acidosis	Increased supply of calories as dextrose	Decrease fraction of calorie from dextrose and increase fraction of calories from lipic
Electrolytes and minerals abnormalities	Hyponatremia	Gastrointestinal or renal losses; inadequate supply	Increase sodium in solution decrease fluid volume; monitor intake and output,serum and urinary sodium and urine-specific gravity
	Hypokalemia	Gastrointestinal or renal losses; refeeding syndrome; high dextrose infusion; hypomagnesemia	Increase potassium up to 4 mEq K/kg/d; monitor serum levels, check and correct metabolic alkalosis, hypomagnesemia
	Hypomagnesemia	Inadequate magnesium in solution; refeeding syndrome; gastrointestinal or renal losses	Increase magnesium in solution; monitor serum leve
	Hypocalcemia	Refeeding syndrome; inadequate calcium	Increase calcium in solution monitor serum levels
	Hypophosphatemia	Inadequate phosphate; refeeding syndrome; high dextrose supply	Increase phosphate in solution; monitor serum leve
	Hyperphosphatemia	Renal insufficiency	Decrease phosphorus in nutrient solution but do not

			omit; eliminate other phosphate source
Glucose metabolism abnormalities	Hypoglycemia	Abrupt interruption of glucose/PN infusion	Graduate decrease of PN infusion rate during cycling
	Hyperglycemia	Excessive infusion rate or dextrose concentration	Reduce rate or concentratio of dextrose; rule out sepsis; concurrent steroid therapy; diabetes mellitus
Protein metabolism disturbances	Azotemia	Dehydration; calorie-nitrogen imbalance; renal dysfunction	Correct dehydration; increas nonprotein calorie-to-nitroge ratio or reduce amino acid concentration
	Hyperammonemia	Hepatic dysfunction; excessive amino acids infusion; insufficient arginine	Reduce protein concentration; increase nonprotein calorie-nitrogen ratio
Lipid metabolism	Hypertriglyceridemia	Lipid infusion dose too high; excess glucose supply; acute inflammatory state	Decrease total lipid supply o rate of infusion; decrease caloric/glucose supply
	EFAD	Fat free PN	Provide at least 2–4% of calories as fat (0.5–1.0 g/kg/d)
	Rash	EFAD or allergy to egg	The first time PN should be delivered in hospital under medical supervision
Vitamin disorders	Vitamins' deficiencies or excess	Inadequate intake	Provide vitamins from the fi day of PN; monitor serum levels
Trace elements disorders	Deficiency or excess	Inadequate or incomplete trace element supply; gastrointestinal losses (zinc)	Routine trace element supplementation, monitor a make changes according to medical condition

The development of IFALD significantly increases the risk of additional morbidity and mortality. Recent studies have shown that liver disease in patients on long-term PN is strongly correlated with survival; in a cohort of 78 children with short bowel syndrome (SBS), the survival rate among those with cholestasis (conjugated bilirubin >2 mg/dL), was close

to 20% compared with 80% in those without cholestasis.[382] Overall, approximately 15% of patients with IFALD progress to end-stage liver disease requiring either isolated or combined liver–small bowel transplantation, a treatment that is associated with a high morbidity and mortality.[383]

IFALD is a multifactorial entity with poorly understood pathogenesis and multiple risk factors. Contributing factors to PN-associated liver disease (PNALD) are patient related and PN related. These include prematurity and LBW, lack of enteral nutrition, immature bile secretion, inflammation, oxidative stress, infection, nutrient deficiencies or excesses, and the underlying disease. Prematurity and CRSBIs have been shown to be the most important factor involved in the development of IFALD. Successive episodes of sepsis have been shown to result in a 30% increase in the serum bilirubin level. Sepsis often results in inflammation and oxidative stress, but both of these processes can also occur without an underlying infectious etiology and are thought to have a role in the development of PNALD. The proinflammatory cytokines are potent inhibitors of hepatobiliary transporter genes expression, which may be responsible for impaired bile secretion resulting in hyperbilirubinemia and cholestasis. In addition, highly reactive oxygen species are capable of cell injury through lipid peroxidation, oxidation of proteins, and destruction of DNA.[384,385] Lack of EN lead to a decrease in the release of counterregulatory hormones secreted from the gut, thereby decreasing bile flow and delaying gut maturation. Deficiencies or excess of PN macro- and micronutrients and bacterial overgrowth are all contributing to the etiology of IFALD.

The clinical spectrum of IFALD includes hepatic steatosis (more prevalent in adults), cholestasis (more frequent in infants and children), fibrosis, and, in some, progression to hepatic cirrhosis with portal hypertension and end-stage liver disease.[386] A late occurrence of hepatocellular carcinoma has been also reported in children with IFALD. Clinically, hepatic dysfunction is manifested by jaundice, hepatomegaly, splenomegaly, ascites, edema, and signs of portal hypertension in children with cirrhosis (spider nevi, palmar erythema, and caput medusae). The laboratory diagnosis of IFALD is characterized by hyperbilirubinemia/conjugated hyperbilirubinemia (>2mg/dl), abnormal international normalized ratio (INR; hepatic synthetic function), alanine aminotransferase (ALT; hepatic injury), gamma-glutamyl transferase (GGT; cholestasis), alkaline phosphatase (biliary or bone disease), and reductions in platelet count and absolute neutrophil count. Sepsis can have

a confounding effect on these laboratory values, specifically causing increases in serum bilirubin, INR, and aminotransferase concentrations while lowering the platelet count, therefore, the presence of an infection at the time of laboratory studies should be taken into consideration.

The gold standard for diagnosis of IFALD is liver biopsy, but this is seldom done due to the invasive nature of this procedure and the critical condition of many of these children. Histology picture of IFALD shows usually cholestasis with periportal inflammation and bile duct proliferation and fibrosis progressing to cirrhosis in severe cases. However biochemical reversal of IFALD had been reported even in the presence of significant fibrosis.[387] Cholestasis should be, however, attributed to PN only after other causes have been excluded. Infection should always be considered in any patient receiving PN who develops hyperbilirubinemia. All infants with sustained conjugated hyperbilirubinemia should be evaluated for biliary obstruction (i.e., biliary atresia, choledochal cyst, cholelithiasis). In addition, metabolic, genetic liver disease and toxicity secondary to pharmacologic agents should be considered and investigated.

Prevention of IFALD should address all the possible amendable risk factors. This includes prompt treatment of CRBSIs and bacterial overgrowth, early institution of enteral nutrition/timely weaning from PN, PN cycling and balanced PN supply, considering the need for sufficient nutrient supply while avoiding excess of calories/fat/glucose.

There are no definite or proven treatments after the development of IFALD. The use of ursodeoxycholic acid (UDCA) has been examined in a systematic review which confirmed that administration of UDCA is generally followed by improvement in biochemical indices. However, the review also highlights the serious limitations of the currently available studies, including small sample sizes, absence of randomization and controls, short duration, and lack of control for confounding variables. There is no evidence that routine use of UCDA will improve clinical outcomes such as survival, rate of hospitalization, incidence of sepsis, or progression to cirrhosis. No definite data on prophylactic benefits of UDCA exist.[388] Erythromycin has been used to promote upper gastrointestinal motility and has been shown effective in promoting feedings in neonate. This agent has also been shown to lower significantly the incidence of IFALD.[389,390] Other medications that have been used empirically, including cholecystokinin, cholestyramine, corticosteroids, and phenobarbital, have little to no evidence to support their routine use.

Parenteral Nutrition Ingredients and IFALD

Unbalanced nutritional supply of energy and macronutrients, deficiencies as well as excesses, and toxicities have been associated with the developments of IFALD and all PN components have been implicated. Changes in PN composition and regimen (cycling) are key strategies for the reversal of established cholestasis.

Excess of energy delivered either as dextrose or fat calories may promote hepatic steatosis by stimulating insulin release, which inhibits FA oxidation and promotes lipogenesis.[391] In the presence of hypertriglyceridemia, fatty liver, or developing IFALD, reduction of energy supplied by PN while increasing the enteral nutrient intake, whenever possible, is advised. The development of IFALD has been also related to the toxicity or deficiency of several amino acids.[392] One study showed that premature infants with parenteral protein intake of 2.5 g/kg/d or 3.5 g/kg/d had similar incidence of cholestasis. Increasing parenteral protein intake, however, was associated with earlier onset and increased magnitude of cholestasis whereas increased dextrose intake increased the prevalence of cholestasis.[393] It seems that high cumulative amino acid doses may be associated with development of IFALD in children, although a definitive relationship has not been demonstrated. It is not clear what role the kind and dose of amino acids play in the development of IFALD in older children and adults, but this does not seem to be as significant as it is in the full term and more so in the premature infant. Deficiency of specific amino acids such as taurine and cysteine may play a role in the development of IFALD especially in premature infants.[394] Yet, studies found no significant differences between cholestasic and noncholestatic infants with respect to the relative percentages of protein, glucose, and lipid calories in the PN infusates.[395]

The role of ILE in the development of liver complications has been related to the fat dose, source of FA, and the phytosterol content. Both liver steatosis and cholestasis have been associated with excessive ILE supply. Multivariate analysis demonstrated that cholestasis and severe IFALD are strongly associated with ILEs supply above 1 g/kg/d.[396] Evidence of the value of lipid minimization comes only from retrospective or uncontrolled studies, however, all these studies reported improvement or disappearance of cholestasis when ILE were discontinued or lipid dose reduced to less than 1–1.5 g/kg/d.[397] A recent study showed that reduction of soybean-based ILE to 1 g/kg/d delivered twice weekly was associated with a significant reduction in total bilirubin levels compared to infants

receiving 3 g/kg/d (historical control).[398] However, in a retrospective study in neonates, provision of 1 g/kg/d of a soy-based ILE compared to 2–3 g/kg/d did not prevent (cholestasis incidence 51.7% in 1-g group; 43.8%, in 2- to 3-g group, not significant), or delayed the onset of cholestasis (32.6 ± 24.1 days, in 1-g group; 27.7 ± 10.6 days in 2- to 3-g group, not significant).[399] Soybean-based ILE, historically the most commonly used fat emulsion, contains mainly ω-6 PUFAs. Clinical and experimental evidence suggested a role for soybean oil–based ILE in the onset of IFALD.[400,401] Alternative ILEs based on combinations of soybean oil with MCT or olive oil–based ILE have been developed to reduce the ω-6 PUFA content. Animal studies have shown that ω-3 FAs reverse hepatic steatosis, reduce oxidative stress, have less proinflammatory effects and do not impair bile flow. Omegaven and SMOFlipid have both been used for the treatment of IFALD. Gura et al. have published the first report of two children with severe IFALD who achieved complete resolution of cholestasis after two months treatment with Omegaven.[178] To date, several case series from Boston and Canada have reported that use of Omegaven 1 g/kg/d or a combination of Omegaven (1 g/kg/d) with Intralipid (1 g/kg/d) improves cholestasis and hyperbilrubinemia in children with established IFALD.[402,403] The results of an ongoing trial on term and near term (>34 weeks) neonates comparing SMOFlipid with olive oil–based lipid emulsion are expected to provide new evidence of the advantage of the newer FO–based ILEs over other than soybean oil–based ILEs.[404]

Early reports of FO–based ILE used outcomes based on clinical presentation and biochemical markers of cholestasis (AST, ALT, total bilirubin, and direct bilirubin) and not based on liver biopsy results. Investigators from Boston have now reported 83 biopsy results taken in 66 children. Of the 83 biopsies, 74 demonstrated fibrosis; 8 of these also demonstrated cirrhosis. Forty-one of the 74 fibrotic biopsies (55%) were obtained in patients without biochemical evidence of cholestasis. Seventy percent of these patients were treated with FO–based ILE during their clinical course.[405]

Cyclic infusion of PN implies daily supply of PN components over less than 24-hour period, usually 8–12 hours. Allowing each day a period off PN may reduce the risk of liver complications, especially in patients requiring long-term PN. Metabolic studies have shown that 24-hour lipid oxidation was higher and 24-hour dextrose utilization lower during cyclic vs. continuous TPN. Compared with continuous infusion, cyclic infusion of PN has been shown to result in a reduction of serum liver enzyme and

conjugated bilirubin concentrations associated with reduced hyperinsulinemia as well as fat deposition in the liver in both adults and children.[406]

The role of carnitine and choline in the etiology, prevention, and treatment of PN-associated liver complications remains to be established. Previous studies showed that patients on long-term PN had carnitine deficiency, but the prophylactic effects of carnitine supplementation on hepatic steatosis have not been well documented.[407] Studies in humans have shown that choline supplementation can reverse hepatic abnormalities and even liver steatosis.[408] A decrease in antioxidants such as vitamin A, vitamin E, and selenium has also been reported in IFALD, although supplementation with antioxidants to normalize their levels does not guarantee a clinical improvement. With modern solutions, there is little evidence that other components of PN solutions such as aluminum, chromium, or other micronutrients are anymore responsible for PNALD.[409]

Progression to full enteral feeds remains the primary goal for all patients with IFALD. Surgical interventions may assist to improve gut absorptive capacity and shorten the duration of PN. Surgical procedures considered useful in a patient with SBS or associated IFALD include placement of a feeding tube (i.e., gastrostomy or jejunostomy tube) to allow for enteral feeds, tapering enteroplasty (in children with dilated loops and bacterial overgrowth) and several types of intestinal lengthening procedures: Bianchi and the serial transverse enteroplasty procedure.[410,411]

Patients with liver and IF who fail to achieve intestinal rehabilitation and for whom death is otherwise unavoidable may be offered a combined liver and intestinal transplant despite the formidable immediate and long-term risks. The University of Pittsburgh, a large transplant center, has recently reported its 5-year patient survival (for isolated intestinal transplants and combined liver/small intestinal transplants) at 77% with a corresponding graft survival rate[412,413] of 58%.

Biliary Tract Complications

The loss of enteric stimulation occurring in the absence on enteral intake impairs the gallbladder motor function, favoring the development of a sluggish gallbladder. This explains the frequent association of PN administration with gallbladder dysfunction, including abnormal gallbladder dilatation and the development of acalculous cholecystitis, biliary sludge, and gallstones. Ileal disease or resection, surgery, rapid

weight loss, drugs, and bacterial overgrowth have also been shown to have a role. Biliary sludge may disappear spontaneously, but frequently evolves into gallstones. Sludge may persist or recur in 50% of cases, and gallstones may form in up to 14% of affected subjects over the age of 3 years.[414]

Prevention of gallbladder stasis, avoiding drugs that decrease gallbladder contractility and slow small bowel transit, promoting enteral nutrition (protein and fat/LCTs), prevention and treatment of small bowel bacterial overgrowth, and use of UDCA are the currently available therapeutic options for prevention of biliary complications.

Bone Complications

Patients on long-term PN are at significantly increased risk of developing metabolic bone disease. Bone disease in patients on long-term PN can be asymptomatic or associated with bone pain or with fractures which may occur with no or minimal trauma. Examination of bone histology or bone mineral density (BMD) in patients on long-term PN reported 40% to 100% prevalence of bone disease.[415]

Studies of bone metabolism have found increased bone turnover at the start of PN which diminished in time in concert with decrease in bone mineralization.[416] Others showed an increase in the amount of osteoid, similar to the defect seen with osteomalacia.[417] Shike et al. showed in a long-term PN cohort of patients that osteoporosis was present rather than osteomalacia.[418]

The pathogenesis of the bone disease is not completely understood, but it is probably related to several factors. Some are PN-related, some are related to the primary disease (malabsorption of calcium and vitamin D, chronic inflammation, medication, in particular corticosteroids) or general lifestyle (sedentary lifestyle, smoking, and alcohol abuse). The possible PN-related factors are changes in the balance of calcium and phosphorus intake, acidosis, excess or low parenteral intake of vitamin D, deficiency of vitamin K, fluoride or copper, and aluminum toxicity.

A small number of the initial cases of PN-associated bone disease were likely related to aluminum contamination of amino acid solutions prepared from protein hydrolysates.[419] Aluminum is still present in calcium gluconate, phosphate salts, vitamins, and TE solutions; however, the amounts are far less than those encountered in casein hydrolysates, and they are not believed to make a significant contribution to bone disease.[420] Hypercalciuria is a frequent occurrence during PN and has been associated with excessive amino acids, dextrose, and sodium delivery. Low

phosphorus supply and cycling PN infusion also increase the renal loss of calcium.[421–423]

Evaluation of bone metabolic status should include a thorough history, physical examination, anthropometry, and laboratory assessment. Laboratory studies should include a complete blood count, serum chemistry panel to exclude kidney and liver disease, and a thyroid-stimulating hormone study (TSH) to evaluate for hyperthyroidism. Evaluation of parathyroid hormone (iPTH) and 25-hydroxyvitamin D is also mandatory. Baseline and periodical dual-energy absorptiometry (DEXA) should be considered in patients on HPN.

Providing adequate amounts of minerals and vitamins form the foundation for maintaining the integrity of bone. Optimizing the composition of PN infusion to avoid the development of negative calcium balance and minimize the risk of developing or exacerbating underlying bone disease is imperative.

Various attempts have been made to treat IF–associated bone disease, both by modifying PN composition and by administering substances such as calcitonin, iPTH, sex hormones, and bisphosphonates. Several reports and a placebo controlled study have shown that spinal and hip BMD can be improved in both adults and children, by administration of intravenous bisphosphonate, especially in the absence of corticosteroid treatment.[424–426]

Renal Complications

The etiology of renal dysfunction is most probably multifactorial and includes recurrent dehydration and electrolytes abnormalities, excessive protein load, solutions' contamination, and recurrent central line infections.[427,428] Impairment of glomerular and tubular function has been documented in both adults and children receiving PN.[429,430] Moreover, cycling delivery of PN has been shown to influence urinary volume and electrolyte excretion and has been associated with diurnal hypercalciuria in several studies published so far in adults.[431]

CATHETER-RELATED COMPLICATIONS

Catheter-Related Blood Stream Infections

The incidence of nosocomial CRBSIs in PICU patients, is reported to be as high as 9 per 1000 CVC-days.[432] In children on chronic PN, investigators have reported incidence rates of CRBSI of 2.1 per 1000 HPN days.[433] In

most children, CRBSIs typically arise from bacterial colonization of the internal surface of the intravascular catheter from migration of skin flora. In children with IF, however, bacterial translocation from the injured gut or small bowel bacterial overgrowth represents additional sources of bacteria that can result in catheter infection. Furthermore, daily catheter manipulation for PN or fluid administration increases the risk of the catheter serving as a port of entry for infection.[434] The most commonly reported causative pathogens are coagulase-negative staphylococci, *Staphylococcus aureus*, enterococci, and *Candida* spp. Gram negative bacilli account for 19% and 21% of CRBSIs reported to Center for Disease Control (CDC).[435,436]

Diagnosis of CRBSIs

In the presence of fever (38°C) in a child with a central line, whether or not another source of infection has been identified, central and peripheral cultures should be obtained, and the child should be treated with intravenous antibiotics covering both gram positive cocci and gram negative bacteria. Diagnosis of CRBSI is best achieved (a) by quantitative or semiquantitative culture of the catheter (when the CVC is removed or exchanged over a guide wire), or (b) by paired quantitative blood cultures or paired qualitative blood cultures from a peripheral vein and from the catheter, with continuously monitoring of the differential time to positivity (if the catheter is left in place).[437]

Treatment of Catheter-Related Infections

For salvage of the device in patients with uncomplicated CRBSI, two weeks antibiotic treatment with standard systemic therapy for catheter-related bacteremia due to *Staphylococcus aureus*, coagulase-negative staphylococci, and gram negative bacilli is recommended. Exit site infection (tenderness, erythema, or purulence at exit site or on dressing) should be treated for two weeks with empiric antibiotics for *Staphylococcus aureus.* The antibiotics should be adjusted based on culture and sensitivity. If no improvement is present after a second course of antibiotics, catheter removal is needed and replacement at other site.[437] Removal of the long-term venous access is required in case of (a) tunnel infection or port abscess, (b) clinical signs of septic shock, (c) paired blood cultures positive for fungi or highly virulent bacteria, and/or (d) complicated infection (e.g., evidence of endocarditis, septic thrombosis, or other metastatic infections). Reinsertion of long-term devices should be

postponed until after appropriate systemic antimicrobial therapy is begun, and after repeat cultures of blood samples yield negative results. If time permits, insertion of a new device in a stable patient ideally should be done after a systemic antibiotic course of therapy is completed, and repeat blood samples drawn 5–10 days later yield negative results.[437]

CRBSIs Prophylaxis

Reducing the risk of CRBSIs may have a significant impact on the rate of readmission, cost of care, and quality of life (QOL), and the progression of IFALD in patients on long-tem PN. Evidence indicates that the risk of catheter-related infection may be reduced by using particular devices (tunneled and implanted catheters, antimicrobial coated catheters, and single-lumen catheters dedicated only to PN). Additional recommendations are use of peripheral access whenever possible, ultrasound-guided vein puncture, and maximal barrier precautions during insertion as well as appropriate nurse stuff and patient training on proper catheter care (hand washing technique, use of 2% chlorhexidine as skin antiseptic, appropriate dressing of the exit site, disinfection of hubs, stopcocks, and needle-free connectors, and regular change of administration sets).[437] In-line filters, routine replacement of central lines, systemic or antibiotic lock prophylaxis, and the use of heparin have not been shown to be effective in reducing the risk of infection, and should not be adopted for this purpose according to ESPEN guidelines.[437]

The 2011 report from Centers for Disease Control and Prevention recommend, however, the use of antibiotic locks in patients with long-term catheters who have multiple line infections despite adherence to basic principles of infection prevention. There is no recommendation regarding what type of antibiotic or the duration of therapy. One of the main concerns with the routine use of antibiotic locks is the development of resistant strains of bacteria.[438] A systematic review that looked at the evidence on the effectiveness of antibiotic-based catheter lock solutions found 16 trials: nine in hemodialysis patients, six in oncology patients (mainly children), and one study on critically ill neonates. Three hemodialysis patients needed to be treated with antibiotics to prevent one CRBSI, given an average baseline risk of 3.0 events per 1000 catheter-days. In the oncology patients, the calculated number needed to treat (NNT) was of eight patients to prevent one CRBSI, given average baseline risk of 1.7 events per 1000 catheter-days. The conclusions of the systematic review favored the use of antibiotic-based lock solutions over

heparin lock for prevention of CRBSI in hemodialysis patients and were marginally effective in oncology patients.[439] A recent randomized controlled trial conducted in pediatric patients that compared taurolidine citrate to heparin locks in children receiving chemotherapy reported a significant decrease in CRBSIs incidence from 1.3 per 1000 catheter-days in the heparin group to 0.3 per 1000 catheter-days in the taurolidine/citrate group.[440]

An alternative to antibiotic locks are ethanol locks (ELs). ELs were first introduced in 2003 by Ball et al. and Danneberg et al. as treatment of frequent CRBSIs in PN-dependent and pediatric oncology patients.[441,442] Ethanol has two desired effects of a lock solution: it is antimicrobial and anti-fibrinolytic. It is readily available and has not shown antimicrobial resistance. Sherertz et al. characterized the antimicrobial efficacy of ethanol in an in vitro study: Ethanol concentrations of at least 30% for an incubation time of two hours, four hours, and 24 hours were shown to be similarly efficient in killing *Staphylococcus aureus*.[443] Mukherjee et al. reported that 10 minutes and 30 minutes of 70% ethanol exposure were enough to inhibit biofilm formation and *Candida albicans* growth.[444] Studies on the effect of ethanol on silicone or polyether urethane catheters integrity have shown only minimal changes in catheters quality most likely not clinically relevant.[445]

Several retrospective studies confirmed the effectiveness of ELs in CRBSIs treatment and prevention in mixed pediatric and home PN populations. ELs dwell time ranged from >2 hours per day to four hours three days per week. Lately, most studies use a 70% ethanol solution. The volume used for the catheter lock range from 0.2 mL to 3.0 mL. A recommended upper limit of absolute ethanol dosage of 1 mL/kg per day was ascertained. The CVC is flushed before and after administration of PN or other medications with 5 to 10 mL normal saline and the ethanol solution is withdrawn after the initial dose to avoid potential intoxication in pediatric patients. All studies reported significantly decrease in CRBSIs during EL prophylaxis from 8.0 mean CRBSIs rate per 1,000 catheter days before EL treatment to 1.3 after EL treatment ($P < .01$).[446–450] A recent meta-analysis of four prospective observational studies have revealed a mean rate difference (MRD) of CRBSIs of 7.67 (95% CI 5.87 to 9.47; $P = .00001$). ELs significantly reduced the risk of CRBSIs by 81% (RR 0.19, 95% CI 0.12, 0.32; $P = .00001$).[451] Adverse events were infrequent, but included serious complications, such as disseminated intravascular coagulation and catheter and deep vein thrombosis.[446,448,449] Two studies

also reported CVC-associated thrombus formation.[448,449] Infectious Diseases Society of America, however, states that although the role of ELs for CRBSIs prevention is becoming clearer, not enough evidence is available to promote ELs as a standard CRBSIs treatment or prevention option.[452]

Additional measures to prevent CRBSI in patients with recurrent infections that have been evaluated are antibiotic impregnated catheters or chlorhexidine dressing. The impregnated catheters are not widely used because of the associated increased cost and because of the CDC recommendation that these catheters should only be implemented for short-term use, particularly when there is need to enhance prevention of CRBSI after standard evidence-based strategies have been executed.

Retrospective analysis of the incidence of sepsis rates in a small group of patients on long-term PN, using cycled enteral antibiotics (CEA) reported significantly reduced rate of sepsis from 2.14 to 1.06 per 100 PN days (P = .014, median effect size 1.04, CI 95% 1.93 to 0.22), whereas the controls had no significant change (from 1.91 to 2.36 per 100 PN days (P = .402, median effect size 0.92 CI 95% 1.96 to 4.17).[453]

CVC-Related Mechanical Complications

CVC-related mechanical complications represent significant life-threatening events, for example, misplaced lines, lines that move, fall out, are pulled out, break, kink, or become occluded. CVC occlusion can be caused by anatomical or mechanical obstruction, drug precipitation or lipid residue, or thrombosis.[454]

Anatomical or mechanical obstructions can occur as a result of malpositioning of the catheter, catheter damage, or fracture due to traumatic insertion or kinking.

Calcium phosphate, diazepam, phenytoin, heparin, bicarbonate, mannitol, pentobarbital, and phenobarbital are all drugs that have been reported to be associated with precipitation. AIO PN solutions can produce a lipid residue that can result in CVC lumen occlusion.[455] When drug-precipitate occlusion is suspected, hydrochloric acid and sodium bicarbonate are used to alter the intraluminal pH to try to dissolve the drug precipitate.[456,457] Drugs with a pH > 7 are more soluble in an alkaline solution whereas drugs with a pH < 6 are more soluble in an acid solution. A 70% ethanol solution has been used to try and dissolve occlusions attributed to lipid residue.

Catheter occlusion due to thrombus formation is more frequent in

children than in adults and has been reported in 10% in children receiving HPN, 13% to 16% of oncology patients, and 31% of infants.[454] The differences in the reported incidence of CVC thrombosis are dependent on the population and setting studied and whether clinical or venographic evidence of thrombosis was reported. Clot may form as a fibrin sheath at the catheter tip, or a thrombus may form on the outside wall of the catheter, and/or on the wall of the vessel adjacent to the catheter. The various risk factors suggested for CVC-related thrombosis can be categorized into those related to the catheter, those related to the individual, and those related to the underlying disease and its treatment. The contribution of inherited and acquired thrombophilia to CV-related thrombosis is controversial.[458,459]

Most catheter-related thrombi develop in the upper extremities, as most catheters are located in the upper venous system. Patients with venous thrombosis may develop symptoms of pain, swelling of the arm and neck, edema, and discoloration of the arm. SVC syndrome may occur if thrombosis develops in the SVC or in both jugular veins. Symptoms of SVC syndrome include facial, extremity, and neck swelling, and dilated chest, neck, and facial veins. Most of the catheter-related thrombi are, however, asymptomatic and diagnosed solely by radiographic tests. The development of catheter-related thrombosis is usually a gradual process, permitting collaterals to form, which minimizes the acute symptoms. Although catheter-related thrombi are asymptomatic in most patients, serious complications may occur, including pulmonary embolism, increased risk of catheter infections, postthrombotic syndrome (limb pain and heaviness, swelling, cramps, edema, and varicosities), and loss of venous access.[454]

Diagnosing the cause for occlusion involves both clinical judgment based on recent medical history, review of medications and fluids received, and radiological investigations such as chest X-ray, venogram, and ultrasound. Ultrasonography is adequate for jugular thrombosis but inadequate for diagnosis of subclavian or SVC thrombosis. If the result is negative and clinical suspicion is high, venography is the method of choice.

Treatment of Catheter-Related Occlusion and Thrombosis

Many publications of nonrandomized, clinical studies, and case series suggest that thrombolytic drugs such as streptokinase, urokinase, and

tissue plasminogen activator are both safe and effective in treating CVC lumen occlusion caused by a thrombus, in adults and children alike. Treatment of thrombotic occlusions with tissue plasminogen has been shown to be more successful (90%) and has a lower complication rate compared with treatment with either streptokinase or urokinase. These agents catalyze the conversion of plasminogen to plasmin, which cleaves fibrin into fibrin degradation products to dissolve the thrombus. The major drawback of thrombolytic therapy is the increased number of major bleeding complications.[460,461] A recent Cochrane systematic review that assessed the efficacy and safety of different interventions used to restore patency of occluded CVC lumens in adults and children, identified only seven (two in children) randomized or quasi-randomized controlled trials (RCTs).[462,463] None of the included studies investigated chemical or surgical interventions for treating occluded CVCs. All seven studies investigated different comparisons or strengths of thrombolytic or anticoagulant therapies for treating CVC occlusion caused by a thrombus. There was some low evidence from two studies that investigated urokinase vs. placebo (RR 2.09, 95% CI 1.47 to 2.95) and tissue plasminogen activator 2 mg/2 mL vs. placebo (two studies, RR 4.19, 95% CI 2.44 to 7.20) that these two drug interventions may be effective in treating occlusion of CVC lumens caused by thrombosis.[464]

The recommended management of acute and symptomatic CVC-related thrombosis depends on the need to preserve the CVC, otherwise CVC removal is recommended. If the CVC is still required and is functioning, the CVC may be left in place, and anticoagulation therapy including low-molecular-weight heparin (LMWH) subcutaneously or unfractionated heparin (UFH) intravenously, started as the main initial therapy. The aims of initial anticoagulant therapy are to prevent thrombus extension and subsequent pulmonary embolization. After completion of the first three months of anticoagulant therapy, both vitamin K antagonists and LMWH can be used for long-term anticoagulation to prevent recurrent venous thrombosis. The American College of Chest Physicians recommends to treat catheter-related thrombosis for at least three months and if the catheter remains in place to continue anticoagulation treatment at a prophylactic dose. The recommended management of radiographically detected asymptomatic CVC related thrombosis is less clear.[465]

Prophylaxis

The prevention of catheter-occlusion is focused on methods to keep blood

out of the catheter. This can be obtained by flushing of the catheter and by use of antireflux valves. Many centers use routine flushing of the catheters with UFH or other solutions. Most studies in adults and children have shown no difference in efficacy between saline or heparin flushes. The 8th American College of Chest Physicians consensus conference on antithrombotic therapy recommends against routine primary prophylaxis for children of all age groups with central line catheters. Given potential safety concerns with the use of heparin (heparin-induced thrombocytopenia and loss of bone mineral), 0.9% sodium chloride may be the preferred flushing solution for short-term CVC maintenance.[466–468] In adults, three different meta-analyses of randomized controlled trials evaluating the effect of heparin on duration of catheter patency have concluded that intermittent flushing with heparin is no more beneficial than flushing with normal saline alone.[469–471]

Nevertheless, manufacturers of implanted ports or open-ended catheter lumens recommend heparin flushes for maintaining catheter patency and many clinicians feel that heparin flushes are appropriate for flushing devices that are infrequently accessed (less than eight hours). No randomized clinical trials have ever established the usefulness of heparinization or the ideal heparin concentration, though most authors suggest using a range of concentration between 10 and 100 units/mL in children.

In children on long-term PN, most on cycling regimen, consideration should be given to prophylactic flushing with heparin, or systemic anticoagulation (LMWH) that might decrease the rates of CVC-related thrombosis and thromboembolism, although there is no conclusive data on the benefit of these interventions.[472] A recent retrospective study in 18 children on long-term PN reported a 5-year cumulative thrombosis-free survival of 48% and 93% in the nonprophylaxis and prophylaxis (LMWH 16 children, vitamin K antagonists two children) groups, respectively (P = .047).[473] Further research is needed for more clearly defined guidelines and recommendations with regard to prophylaxis, treatment, and management of thrombosis and thromboembolism.

Needleless, antireflux devices can be attached to the hubs of most CVCs. These devices maintain positive pressure within the lumen of the catheter, which prevents backflow of blood. These devices have been studied mainly in adult and pediatric patients with non-tunneled CVCs and shown to decrease catheter-occlusion rates.[474]

CYCLING PN

Patients who are acutely ill or require short-term PN typically receive PN as a 24-hour continuous infusion. In stable patients, who are expected to have a longer course of PN or receive HPN, PN is often administered on a cyclic (discontinuous) schedule. Cycling implies that PN solution is administered over a shortened period, usually 8–16 hours, to allow patients a window of time off the infusion. Essentially, patients receive the same fluid volume, electrolytes, and nutrient load over a shorter period by increasing the infusion rate.

This technique, specifically nocturnal PN, was first proposed in adults in 1970 by Scribner et al. as a method to improve lifestyle.[475] The practice has subsequently been shown in both children (1.5 months to 20 years old) and adults to be a safe and effective means of nutritional support. Studies in adults have shown that cyclic and continuous PN infusions result in similar nitrogen balance and circulating counterregulatory hormone concentrations.[476] Furthermore, cyclic PN may be of benefit in the prevention and treatment of IFALD. Continuous PN infusion leads to continuously high serum insulin levels. This hyperinsulinemia causes hepatic lipid deposition and increased hepatic lipogenesis. Furthermore, EFAD may occur because insulin inhibits the release of free FAs from adipose tissue. These physiologic effects of continuous PN are reversed by cycling. The major proposed benefit is that of mimicry of normal physiology by altering circulating hormones and fuel source utilization. In adults, cyclic PN has been shown to induce variability in substrate utilization (as evidenced by measured RQ) that mimics more closely both the natural fasting state and the natural postprandial state as compared to traditional continuous PN. Following PN infusion, CHO oxidation decreases, fat oxidation increases, and the RQ decreases.[477–479] Diurnal variability in REE, circadian patterns of apolipoproteins, and a cyclic pattern of human growth hormone and insulin secretion have been demonstrated in children receiving cyclic PN.[480,481]

The use of cyclic PN as a means to normalize hyperbilirubinemia has been reported in both adults and children.[482,483] Cyclic PN was associated with a decreased incidence and delayed onset of hyperbilirubinemia in infants with SBS and after surgery for gastroschisis but not in a prospective RCT in VLBW infants.[406,484,485] A prospective study in infants who were switched from continuous to cyclic PN infusion demonstrated stabilization and possible decreases in serum bilirubin levels with initiation of cyclic PN infusion.[486] Cycling PN has been associated

with adverse events, too. These include hyperglycemia and respiratory distress due to the increase in the rate of dextrose and fluid infusion, hypoglycemia, and hypercalciuria. Therefore, cycling is more challenging in patients with underlying diabetes or renal, cardiac, or pulmonary dysfunction and in young children.

Cyclic PN in adults is usually performed in 12-hour intervals, but this is not generally possible in the neonatal population due to diminished glycemic reserves, which limits safe cycling to much shorter time intervals of up to six hours. Abrupt PN discontinuation in 15 children 2.4–11.4 years old led to no symptomatic hypoglycemia in a before–after study.[487] A randomized crossover study of 10 patients 1.5–36 months old showed significantly greater decreases in blood glucose levels with abrupt discontinuation compared with tapered discontinuation and higher rates of hypoglycemia (55% vs. 20%, *P* value not reported).[488] Blood glucose levels should be monitored following cessation of high glucose infusions. If not done by the infusion pump automatically, PN should be tapered by decreasing to half the rate for one hour and to one-fourth the original rate for another hour before complete discontinuation.[483] Although data are limited, cyclic PN infusion has not been associated with increased daily losses of calcium, phosphorus, magnesium, or vitamin D compared with continuous infusion.[489,490] Although calcium loss increases during cyclic PN infusion, there is no evidence that this contributes to metabolic bone disease.

Clinical data support the current widespread use of cyclic PN infusion in most populations. Generally, practicality is the primary drive for cyclic PN infusion and likely its greatest benefit. However, precautions must be taken to avoid hypoglycemia, particularly in young children and acutely ill patients who may not be suited to this modality.[491] The clinical significance of PN cycling-associated hypercalciuria should be further investigated.

HOME PARENTERAL NUTRITION

IF is defined as a reduction of functional gut mass below the minimum amount necessary for adequate absorption of nutrients, fluids, and electrolytes, to maintain health in adults and growth in children. The causes of IF include SBS, congenital or as a consequence of surgical resection; neuromuscular intestinal disorders, such as total aganglionosis or chronic intestinal pseudo-obstruction syndrome (CIPO); and severe protracted diarrhea syndromes due to congenital intestinal mucosal

disease, severe food allergies, enteroendocrine cells disorders, or immunologic diseases. The incidence of IF is estimated at 1 to 2 per million population.[492]

PN is the established therapy for chronic IF; it can be total or partial, permanent or temporary. In children and adults who depend on long-term PN, HPN is the only alternative to prolonged hospitalization and offers patients the best possible QOL. HPN offers children who would be otherwise institutionalized, the possibility of achieving their growth and developmental potential and best possible QOL at a reduced risk of nosocomial infections. As they get older, most can attend school and take part in normal social life. QOL scores from HPN-dependent children and siblings have been shown to be the same as those of healthy peers, suggesting effective use of coping strategies.[10] The increase in HPN use in the United States and in Europe has been demonstrated by several surveys performed over the past decade. A national point prevalence survey of HPN in United Kingdom in 2010 reported a fourfold increase in the number of children on HPN patients since 1993 (66 to 167). This reflects both increasing numbers and survival of patients with SBS, in addition to developments in home care.[493]

HPN Indications

SBS remains the main indication for HPN in children, accounting for 30% to 50% of the cases in most published surveys.[494] Pediatric studies have reported a mean HPN duration of about 2 to 10 years. Neonates with SBS had the best prognosis. Even after an extensive small bowel resection at birth, more than 80% of the children survive and acquire intestinal autonomy. The increase in the incidence of other indications, such as intractable diarrhea of infancy or CIPO, has led to an increase in the mean duration of HPN programs, some of which are “definitive,” the only possible alternative treatment being small bowel transplantation. Cancer, which is the main underlying diagnosis in adults on HPN in the United States and in Europe, is a marginal indication for HPN in children.[495,496]

Complications in HPN

Although PN is lifesaving to many pediatric patients and grants patients the ability to lead a life outside of the hospital, it is also a high-risk therapy with potential immediate and long-term complications:

IFALD

An increased risk of IFALD is associated with young gestational age, low birth body weight, young age at the start of PN, frequent episodes of bacterial infections or sepsis, long duration of PN, low enteral intake, very short intestinal length <10%, the presence of SBS with a stoma, and the presence of gastroschisis or intestinal atresia.[497–499] An appropriate PN regimen is also important as high parenteral energy intake, use of lipid emulsion at a dose of >1 g/kg, dextrose infusion >7 mg/kg/min, high amino acid load in premature infants, and deficiency of transsulfuration pathway products, most notably choline, have been reported to contribute to the development of IFALD.[500,501] Progression of IFALD to liver failure represents the greatest concern in terms of potential mortality for the long-term HPN patient. The risk of development of liver failure appears to be higher in children, specifically very young children, than in adults. In children, death due to IFALD accounted up to 36%, with a mortality rate greater in premature infants and in babies <1 year (38%) than in older children (30%).[502] Gupte et al. evaluated the survival rate of children referred for intestinal transplantation (ITx) and observed a significant difference depending on the severity of the cholestasis. The 6-year survival of children on HPN was 80% when the pretransplant total serum bilirubin concentration was <100 mmol/L, but when >100 mmol/L survival was only 40%.[503] The U.S., Pediatric Intestinal Failure Consortium also reported that the cumulative percentage of survival in children with cholestasis was lower, 79% vs. 95% at 1 year and 73% vs. 88% at 3 years, compared to infants without cholestasis.[380]

Catheter-Related Blood Stream Infections and Thrombosis

CRBSIs are common complications of HPN in children. The incidence of CRBSIs in most series is around 2/1000 HPN days (1/476 days, or 0.78 per patient-year). An increased risk for CRBSIs was found when HPN was begun during the first year of life, when first episode of CRBSI occurred shortly after starting HPN, in children with SBS and autoimmune enteropathy as the underlying disease.[433] Published series have shown that the death rate from CRBSIs was higher in children (up to 30% of total death in patients with SBS or CIPO) than in adults (8% of total death in mixed population). However, the CRBSI-related risk of death is reassuringly low. Pironi et al. observed 2.3% of deaths from 298 episodes of sepsis occurring in 527 patients, including 138 children who received a total of 1154 catheter-years of HPN.[495,496]

CVC-related deep vein thrombosis may cause HPN failure through the loss of venous access for CVC placement. The incidence of this is quite low (0.02–0.09 per catheter-year), with the highest rates reported in children.[495] In both adults and children, CVC-related deep vein thrombosis have accounted for a few deaths while on HPN. Mortality from CVC-related thrombosis is very rare (0%–3.9%), and represents a substantial risk only in those with a SVC syndrome (6.8%).[504] A study of 34 children reported a mortality rate of 11.8%, of which 26% had fatal pulmonary embolism.[505] CRBSIs may also be associated with CVC thrombosis as the clot becomes a nidus for bacteria. Loss of venous access is an important concern, although complete or impending loss of venous access has not been reported.[506]

Prognosis

Weaning of PN

Three studies in children have shown that the ability to successfully wean from HPN was greater in those with SBS (54%, 42%, and 73%), than for those with CIPO (38%, 25%, and 29%).[494,507–509] The U.S., Pediatric Intestinal Failure Consortium reported 47% cumulative percentage of intestinal autonomy at 3 years.[380] In children with SBS, the minimum required healthy residual small bowel was 40 cm in one study,[510] 15 cm in another,[511] or 10% of the expected normal length for a given gestational age in a third report.[512] In children with CIPO, neonatal onset, acute onset, urinary tract involvement, and requirement for surgery all predict a low probability of reaching intestinal autonomy.[513] In children with intractable diarrhea, Colomb et al. reported weaning in 48% of 25 children (40% with congenital mucosal disease, 60% protracted diarrhea of other causes), whereas Diamanti et al. observed weaning off HPN in 83% of 39 patients (18% with congenital mucosal disease and 82% with other types of protracted diarrhea).[494,508]

Survival and Prognostic Factors for Survival

Generally, the mean survival rate in children on long-term PN is better than in adults, with approximately 90% survival at 5 years.[494,508] However, the survival rates were only 49% at 1 year and 35% at 3 years in children referred for ITx.[503,514] Survival probabilities on HPN for SBS seem to differ on the basis of patient age and clinical condition at time of enrolment in the survey. The 5-year survival rate was 95% in children and

slightly lower, 88%, in neonates or infants <1 year old.[494,512] Starting PN at an early age, particularly in the neonatal period, was associated with greater mortality.[494,503,514] Primary non-digestive disease and NEC were the underlying conditions associated with the greatest mortality risk.[494,503] The mortality rate was highest in children with a very short small bowel remnant (duodenostomy or jejunostomy) and in the presence of a stoma.[512,513] Survival is slightly greater in patients with SBS, than in those with CIPO.[512,515] In patients with CIPO or aganglionosis, the risk of death was increased in cases with onset at birth, acute onset of the disease, myopathy as etiology, with intestinal malrotation, and in the presence of urinary tract involvement, and repeated surgery with or without resultant SBS.[515–517] Children with congenital mucosal disease or other types of protracted diarrhea had a lower survival than those with IF due to primary non-digestive disease.[494] The absence of a specialized nutrition care team was also a significant risk factor for mortality. The best outcome was described for patients with Crohn's disease.[494] Overall, CRBSIs, IFALD, and venous thrombosis remain the most common of potential serious risks.

Causes of Death in HPN

HPN-related causes (IFALD, infection, thromboembolic, and metabolic complications) accounted for the majority of deaths in three studies, whereas a fourth study reported that most deaths were related to underlying disease.[494,507,518,519] In those surveys where PN-related deaths prevailed, treatment had started within the first year of life. In the survey reporting underlying disease as the primary cause of death, the mean age at the beginning of HPN was 3 years. This suggests an increased risk of life-threatening HPN complications during the first years. PN-related death was the main cause of death in children with SBS or CIPO. In patients with protracted diarrhea, the cause of death was related to the underlying disease or to PN. The underlying disease was the main cause of death in patients with IF due to primary non-digestive disease (cancer).[494,507,518,519]

Discharge on HPN

PN dependency no longer mandates inpatient management. Clinical stability and severity of underlying disease must be taken into account when planning for HPN, including fluid losses, enteral tolerance, comorbidity, and the ability to tolerate cyclic PN. Children on HPN are provided binary admixtures (lipids being administered separately) or "all-in-one" admixtures. PN is usually infused over night for 12 hours and the

CVC heparin-locked during the day. This “cyclical” PN is important not only for protecting against IFALD but also for the psychosocial development of the child.

With the development of hospital nutritional support teams (NST) and commercial home care companies, HPN has become a practical option. However, the necessary organizational infrastructure remains complex. Parents need to be highly motivated wishing to assume responsibility for the medical care of their child. They must cope not only with the emotional demands of HPN, but also master the technical aspects of catheter and infusion care. Assessment of whether a family is able to take on the responsibility of HPN should be undertaken by a NST staff member in conjunction with the hospital ward staff and community team. A teaching program should be implemented to ensure that parents are confident and competent in all aspects of their child’s care. This includes hand washing and aseptic technique, knowledge of CVCs, catheter care and dressing changes, care of the infusion pump, running of infusion solutions through and connection to the CVC, setting up the feed and making the necessary corrections, urine testing, temperature taking, blood glucose monitoring, problem solving, and what to do in an emergency.[520]

Patients on HPN must be seen and assessed on a regular basis by the multidisciplinary team (optimally a nurse, dietitian, pharmacist, and physician). The timing will depend on the status of the patient and may range from weekly to every 4–6 months. Supervision by a multidisciplinary NST can optimize outcomes and facilitate HPN. Suggested schedule for monitoring during long-term PN is shown in Table 68-13.

Long-Term PN Monitoring

Patients receiving long-term PN must be monitored to optimize nutrition outcomes and to prevent complications that may develop over time, either related to their disease state or the PN. For patients who remain on long-term PN, it is important to monitor growth and pertinent laboratory assessments to ensure that nutrition and outcome goals are being met.[10,521] A comprehensive review of the evaluation and monitoring that should be considered for pediatric patients receiving specialized nutrition support is available.[522]

TABLE 68-13 Suggested Schedule and Monitoring During Long-Term PN

Interval	Clinical Assessment	Tests
1–3 months	Physical examination	Complete blood count, acid-base balance, and serum electrolytes
	Weight, height, head circumference in children <2 years	Nutritional biochemistry: glucose, urea, creatinine, albumin, prealbumin, lipid profile
	Enteral assessment	Calcium-phosphorous metabolism: calcium, phosphorus, magnesium, alkaline phosphatase
	Extra renal losses (e.g., stoma losses)	
	Line status and adequacy of care	Liver enzymes and bilirubin: alanine amino transferase, γ-glutamyl transpeptidase, total and direct bilirubin
	Functional status	Urinanalysis and Na, K, PO_4, Ca, creatinine
6–12 months	Idem	PT, PTT, ferritin
		Vitamin A, D, E, B_{12}, folate
		Zinc, copper and iron status
		Parathormone and thyroid hormones
		Hepatobiliary and renal ultrasound
12–24 months	Idem	Aluminium, chromium, manganese, selenium
		Chest X-ray (catheter location)
		Echocardiogram (if recurrent CRBSIs)
		Bone densitometry (DEXA scan)

Quality of Life

Three studies evaluated the QOL of children on HPN and their families. The first study found that the QOL scores were high in patients of all ages and were not significantly different from scores in a reference population of healthy children and adolescents. Lower QOL scores were recorded in the spheres related to hospital, health, doctors, medications, and obligations. The QOL was not affected in siblings but was significantly impaired in parents, especially in mothers, who showed a lower level of satisfaction for items related to work, inner life, and freedom. Presence of an ileostomy was the only factor that influenced QOL, especially of adolescents.[523] Overall the studies found that despite the problems they may face, it is possible for pediatric patients on long-term PN to develop and maintain a positive outlook, and cope well with illness-related

demands. The ability to cope so well may be related to the lack of experience with any other way of life. Children were also enabled to cope by support from parents, siblings, friends, and household pets. Participation in normal childhood activities and possession of a good understanding of their illness was also helpful.[524,525]

Cost

HPN is one of the more expensive ambulatory therapies, but the only possible alternative for many patients would be long-term hospitalization. The few cost-benefit studies have demonstrated that HPN is more cost-effective (by 50%–75%) than inpatient hospital PN. In the absence of published economic appraisals of pediatric HPN, one must consider costs to be similar to those of adult HPN. The annual cost of HPN, including nutrients, pump, and disposable equipment, has been estimated in 1990, to be approximately UK£ 60,000 pounds (about US$ 100,000) per patient in the United Kingdom, and ranges from US$ 80,000 to US$ 140,000 in the United States.[526–528] The HPN costs rise significantly in the presence of complications. A pediatric study, however, showed that HPN was associated with a fourfold decrease in the incidence of septic episodes as compared to hospital, leading to major savings.[529]

PERIPHERAL PN

Peripheral parenteral nutrition (PPN) is now regarded as a safe and effective alternative to central vein administration of nutrients for many patients. It avoids the risks of central venous catheterization, simplifies nursing care, reduces cost, and may shorten the time to initiation of nutritional support. PPN is useful for supplementation of inadequate oral or tube feeding intake, or transitional support until central access can be obtained. In general, it is difficult to provide adequate support via PPN for a patient with severe metabolic stress or nutritional depletion requiring electrolyte replacement and high calorie or protein intake. Other major limitations to the use of PPN are the availability of suitable peripheral veins, the development of peripheral vein thrombophlebitis, and the frequent need to replace the vein access, which limits the effective delivery of fluids and nutrients.

PN administered via peripheral vein catheters should last for no more than 10–14 days as the rate of complications increases after this period. Thrombophlebitis is one of the most significant complications limiting PPN support. There are many factors involved in its pathogenesis. There is

no consensus about optimal feed composition, choice of cannula, infusion technique, or pharmacological adjuncts. The incidence of thrombophlebitis is related to the osmotic content of infused solutions as well as to osmolality rate (product of osmolality and infusion rate). In most nutrient solutions, the major osmotic components are glucose, amino acids, and electrolytes. Early studies of PPN using crystalline amino acid and glucose-based solutions found phlebitis rates of almost 100% when the osmolarity was increased above 600 mOsmol/L.[530,531] Correlation between hyperosmolality and phlebitis is not, however, apparent when lipid-based solutions are used. Lipid emulsion appears to provide protection to the vein and allows tolerance of higher osmolarity infusates. Kane et al. randomized 36 patients to receive lipid-based PN solutions of osmolarity 1700 or 1200 mOsmol/L. They found no difference in the incidence of thrombophlebitis.[532] In adults, Everitt et al. have used successfully lipid-based formulations with an osmolality greater than 1100 mOsmol/kg, with phlebitis rates[533] ranging between 7% and 26%. Vein tolerance to hyperosmolar formulations may be further improved by admixture of the lipid emulsion with the dextrose-amino acid solution, AIO admixture.[534]

Addition of low-dose heparin and hydrocortisone to PPN formulations may increase tolerance to hyperosmolar formulations.[535] The incidence of vein thrombosis appears to be reduced by addition of low-dose heparin (1 unit/mL) to peripherally administered fluids. Premature infants receiving one unit of heparin per milliliter of PPN had about one-third the incidence of thrombophlebitis (5.7% vs. 17.2%) and nearly double duration of catheter patency compared to those without heparin.[536] Significant reduction of peripheral vein thrombophlebitis has been reported in randomized placebo controlled trials with use of transdermal glyceryl trinitrate in both PPN and non-PPN patients.[537] In healthy subjects, application of a topical nonsteroidal anti-inflammatory agent to the cannulation site on one arm reduced the incidence of phlebitis by nearly half in comparison with the site on the other arm, which served as a placebo.[538]

The risk of phlebitis seems lower when the cannula is placed on the back of the hand compared to venous access sites in the wrist or upper arm.[539] A Cochrane systematic review and a recent randomized, non-blinded equivalence trial showed that, in adults, there is no evidence of benefit in changing catheters every 72 to 96 hours.[540,541] Taking into consideration the small number of peripheral vascular access sites, pain,

and distress associated with sites changes, and the limitations in delivering optimal nutrition (osmolarity constraints and frequent interruptions) make routine change of vascular access in children, in the absence of clinical indications, an unwarranted practice favoring the use of CVCs.

Composition of PPN

Macronutrient concentrations are typically limited in PPN formulations. The final concentration of amino acids is generally between 2.5% (25 g/L) and 5% (50 g/L) for PPN. The generally recognized upper limit for dextrose concentrations in PPN formulations is 10% for adults (approximately 500 mOsm/L) and 12.5% for pediatric patients (625 mOsm/L). At these concentrations, dextrose provides 340 kcal/L in adults and 425 kcal/L in pediatric patients. The micronutrient components of PPN are similar to those of centrally administered PN formulations, with a few exceptions. Electrolytes such as sodium chloride, potassium, magnesium, phosphate, and calcium are essential for muscular and central nervous system functions, as well as for metabolism and maintenance of fluid status. All these and vitamins should be administered daily. TEs can be routinely added to all PN formulation, although the short duration of most PPN therapy makes this unnecessary unless the patient has preexisting deficiencies.

Monitoring of PPN therapy is essentially in the same way as for PN administered via a central venous access device. Metabolic complications parallel those associated with central PN. The typical duration of PPN therapy and limitations on CHO provision in PPN—with a subsequent increase in calories from lipid emulsion—may alter the incidence of hyperglycemia and hypertriglyceridemia. The frequency of monitoring should be based on the overall condition of the patient, on the presence of factors that may contribute to complications, and response to alterations in the nutrient prescription. As PPN patients tend to be under less metabolic stress than patients who require full support, the frequency of laboratory monitoring may be reduced.

Standard vs. Individually/Tailored Parenteral Solutions

PN can be provided as a standard, usually commercial, formulation that is designed to meet the nutritional needs of most patients of the same age group with a similar condition. Alternatively, an individually tailored PN compound, adapted to the individual patient’s nutritional needs, can be prescribed and prepared, usually on a daily basis and in the hospital

pharmacy. Both types of PN preparations have advantages and disadvantages associated with their use.

The main advantage of individually prescribed PN solutions is that they are tailored to suit a specific patient, and to achieve the best possible nutrition and precise biochemical control needed. The prescription can be changed on a daily basis, reflecting the medical condition and most recent laboratory tests.[31] In contrast to individualized prescriptions, standardization carries the risk of turning into "cookbook medicine" that lacks continuous clinical judgment of the patients' changing nutritional requirements.[542] This risk may be increased when the patient is a tiny fragile VLBW premature infant with enormous nutritional requirements and tendency for developing major nutrient deficits and sometimes life-threatening, metabolic disturbances (e.g., hypo- or hyperglycemia, hypo- or hypernatremia, hypo- or hyperkalemia). Studies in VLBW infants as well as in pediatric patients suggested that compared to infants on standard PN, infants who got individually tailored PN got more optimal nutrition, achieved better growth without clinical or laboratory complications, had a shorter period of exclusive PN, and required less electrolyte corrections.[542–544] Furthermore, Smolkin et al. suggested that individualized PN preparations were more optimal for the current more aggressive nutritional approach for PN in VLBW infants.[544] Yet, these authors admitted that the currently available standardized PN admixtures with adequate nutritional composition should be considered as appropriate alternatives. This is in contrast to "historical" standardized PN solutions that did not meet all the nutritional requirements of neonates, and could have resulted in inadequate nutrition and poor growth if used beyond short periods.[545]

PN is an intravenous medication, with more than 50 ingredients and additives, and as such is very liable to medication errors, especially in pediatric patients, where all the calculations are weight based.[546] The complexity of providing the nutritional requirements to children and neonates turns the task of ordering PN into a difficult process for the inexperienced clinician. Development of an optimal PN order form, including age and weight-specific nutrient requirements with guidelines for advancing substrates may aid the clinician, improve PN prescriptions, and decrease prescribing errors.[547,548] The stability and compatibility of PN solutions is also a safety topic of great concern. The most significant pharmaceutical issues involve the stability of ILE and the compatibility of calcium and phosphate salts to avoid precipitates. The existence of a

hospital NST, well-established communication channels between the prescribing clinicians, and the pharmacy team dedicated to PN preparation, and the use of compounding devices decrease these risks, but do not abolish them.[548–551]

Recent technology has advanced computerized PN ordering systems based on the guidelines contained in the program.[552] Such computerized nutritional software provides low cost and easy to use effective data of correctly calculated nutrient dosages. When data is both updated and reliable it results in better growth and better biochemical control, as evidenced in blood samples from the newborn studied.[553] In addition, electronic ordering systems can still allow individualization of PN prescription for each patient, thus improving biochemical control and decreasing wastage. Computer-assisted PN prescribing programs are also a valuable educational tool for the junior clinician, not experienced in clinical nutrition. These tools also facilitate the communication between the prescribing clinical team and the pharmacy department. Puangeo et al. found that automating the process of writing and delivering PN orders saved time and resulted in improved nutrient content of the PN solutions. This helped achieving caloric and protein goals earlier, and improving mineral status in premature infants.[554] However, in practice not all the alleged advantages of individualized computer-assisted prescriptions could be proved in premature infants.[555] A possible disadvantage of a computer-based prescription program is that it might encourage trivial adjustments in PN prescriptions, based on laboratory results that in clinical practice are irrelevant.[543] Based on these observations, it was suggested that higher proportion of PN could be standardized, if modified to reflect the practice pattern.

Krohn et al. evaluated the use of standard PN solutions in a PICU, and found that standard PN orders could be used in the majority of the patients. These solutions were usually nutritionally adequate and the intake of most macronutrients and electrolytes was similar to individually prescribed PN. Actually, calcium and phosphate intakes were better with standard PN compared to the individualized PN, and electrolyte imbalances occurred less frequently with the standard PN.[556] Yeung et al. evaluated retrospectively the difference in nutrient intakes and biochemical responses in premature infants who received standardized versus individualized PN between days 2–7 of life. They could not demonstrate any clinical advantage or improved biochemical control with individualized PN regimes.[557] In that study, the increase in protein was

accompanied by proportional increases in the intakes of glucose, electrolytes, and acetate. They also found that in infants who were on standardized PN, the cumulative deficit in protein intake by the end of the first week was 35% less compared to those who were on the individualized regimes. Infants on standardized PN had also higher intakes of calcium and phosphate, resulting in less commutative deficits and better bone mineralization. Lenclen et al. also showed that in premature infants standardized parenteral formulations provided higher early intakes of amino acids and glucose, and better calcium phosphate ratio during the first week of life while maintaining the same biochemical parameters.[558] In addition, it was suggested that the standardization strategy should be considered as part of the approach for improving quality control and good professional practice for the preparation of PN solutions. Batch-produced standardized PN bags can be readily available as ward stocks in the neonatal intensive care units, thus allowing initiation of early PN immediately after the delivery of a premature infant.

Commercially prepared standard PN bags decrease the risk of ordering errors, as well as the risk of compounding errors in the hospital pharmacy that has to deal with many different PN prescriptions on a daily basis. Large-scale commercial production of standard PN bags can be further eased by using automated compounding technology that can assure better pharmaceutical control of the physicochemical stability and compatibility of PN admixtures. This can decrease the risk of potentially adverse outcomes from infusion of incompatible nutrient admixtures (e.g., precipitated calcium phospate).[549–551] Large-scale commercial production of standard PN bags can also offer better aseptic manufacturing conditions than the average pharmacy hospital, thus decreasing the risk of PN-associated infections.[546] Commercially batch-produced standardized PN bags may also reduce the large costs of individualized PN production.[559] The need to add the parenteral multivitamins to the standard PN bag shortly before infusion is a limitation, that requires proper handling to assure aseptic conditions and avoid errors.

Based on European guidelines on pediatric PN, we suggested that standard PN solutions can be used safely in most pediatric and newborn patients, including VLBW premature infants for short periods (up to 2–3 weeks).[10,560] A range of standard regimens to suit different clinical conditions should always be available. Adequate monitoring of the metabolic and nutritional status of an infant on standardized PN should be assured, and the most suitable available standard PN formulation for the infant’s condition should be ordered at least once daily. Individually

tailored PN solution should be preferred when the nutritional needs cannot be met by the available range of standard PN formulations (i.e., in very sick and metabolically unstable patients [such as those with abnormal fluid and electrolyte losses]; and in infants and children requiring PN for prolonged periods [such as those with SBS]). Computers-assisted prescribing software for PN should become readily available, as they can save time, decrease prescription and compounding errors, and improve the quality of nutritional care. Such computerized programs should guide the physician to the most adequate standardized solution and optimize the use of individualized solutions.

Recently, Rigo et al. evaluated the efficacy, safety, flexibility, and ease of use of industrially manufactured ready-to-use (RTU) multichamber PN bag system containing three sterilized macronutrient solution chambers (for amino acids, glucose, and optional lipid bag activation system) specially designed for administration to preterm infants.[561] This technologically advanced multichamber PN bag system was easy to use, guaranteed sterility and longer shelf life, and provided well-balanced and safe nutritional support. Nutritional intakes and weight gain were within the recent PN recommendations for preterm infants. The combination of computerized prescription and the use of multichamber PN bags may enhance our ability to rely on standardized PN with minimal usage of individualized prescriptions.

SAFETY OF PN

PN is one of the most complex prescription drug preparations used for routine patient care. A single patient PN admixture contains macronutrients and micronutrients, solubilizers, preservatives, and other excipients. Giving this complexity, PN is classified among the “high-alert medications,” a term that describes drugs that can place patients at risk for significant harm when used in error.[562]

The options for delivery of pediatric PN solutions are RTU compounded bags prepared either by the hospital pharmacy or an outside service provider, and standard formulations prepared by the hospital pharmacy or outside service, to be modified on the ward according to the patient’s needs. All of these formulations are subject to human error. Isolated cases have reported of tragic but preventable outcomes from PN prescription errors. Otherwise, there is scant data in the literature describing PN-related medication errors.[563] Flynn and colleagues reported a significant error rate in manually and partially automated compounded

PN of 37% and 22%, respectively.[564] Other risks, such as stability issues and contamination and prescribing errors, have also been reported with compounded PN.[564] A recent retrospective analysis of adverse drug events in pediatric patients found that replacement preparations and total PN represented the largest category of adverse drug events (37%).[565]

PN fits easily into the model of regular medical decisions: decision to use drug therapy; selecting the best regimen for a patient; preparing, dispensing, and administering the drug; and then monitoring the patient and reassessment of the initial decision. Many relevant practice recommendations, guidelines, and standards for PN prescription and use are available for clinicians.[566–568] These include the following:

1. Use of a standardized PN ordering process that can reduce prescribing errors, provide prescriber education, and improve the efficiency of patients' nutrition care and the clinicians' follow-up. Although computerized order entry may reduce errors (e.g., associated with legibility), it does not eliminate errors, including those leading to an adverse drug event. Handwritten, and in some cases, nonstandardized forms are still being used in many centers, despite expert guidelines that have addressed mandatory components of the PN order form.
2. Verifying and reviewing the submitted PN order by a knowledgeable pharmacist. The review process includes two aspects: a *clinical* review verifies that dosing of each PN component is appropriate for the individual patient and a *pharmaceutical* review that the ordered components are compatible and that the preparation is expected to be stable.
3. Strictly adherence to the recommendations of professional organizations on PN compounding. Use of electronic interface offers the benefit of automatization and build in dose-warning limits that should remain active for all PN orders.
4. Standardization of the dispersing process involves labeling, delivery, and storage of the PN admixture prior to administration. The label should match all the elements of the PN order using the same terms and in the same order, with all ordered ingredients included. A beyond-use date and storage directions for the admixture should also be included.
5. Connection of PN solution to the patient should be made only after patient identification and corroboration of the label components and dosage with the written order from the patient'

file.

6. Each step along the PN use process needs to be readily documented in the patient's chart or in the pharmacy system as appropriate, whether using electronic medical record or paper documentation.

PN DELIVERY BAGS

All-In-One

In the past, lipids, amino acids, and glucose were administered in separate bottles and infused through separate intravenous lines (multi-bottle system). Presently, health-care institutions increasingly use AIO systems, with which nutrients are mixed in a single bag and infused simultaneously through a single intravenous line. The hypothetical advantage is that AIO systems reduce the manipulations. This system results in reduced manipulation and savings of material, time, and personnel workload. AIO admixtures require only one intravenous line, and the risk of infection is lowered by the closed system. The complete and simultaneous administration of all substrates reduces the risk for metabolic complications. AIO admixtures offer a convenient system for patients, clinicians, and nursing staff. The associated savings may overcome the higher manufacturing costs of the multi-compartment bags.

AIO PN bags can be compounded by hospital pharmacies (hospital-compounded AIO) and their composition can be standardized or tailor-made. These allow for the provision of patient-specific RTU admixtures, individually adapted according to energy, volume, and substrate needs. AIO bags can also be manufactured industrially, in a standardized way, as two or three-compartment bags. Industrially manufactured standard AIO can be provided as two- or three-chamber bags: in the case of a two-chamber bag, a lipid emulsion is admixed with a transfer set shortly before its administration to the patient, thus creating an AIO admixture, or through a separate line. Three-chamber bags contain all the macronutrients and electrolytes in three separate compartments. The substrates are mixed together immediately prior to intravenous delivery by breaking the separation seals between the bag chambers. Vitamins and TEs are injected into the bag prior to administration or infused by a separate intravenous line. When not mixed together, these standard MCBs have usually a shelf life of more than 12 months.

Multichamber Bags

Industrially prepared MCBs, with established standard compositions, often are an attractive method of providing PN. They are predominantly used in the short-term PN treatment of hospitalized adults. Individual compounding is, however, still required.[552] Colomb et al. described the use of the first pediatric triple-chamber PN bag (Ped3CB) in a prospective, open-label, multicenter, phase III clinical trial. The study enrolled 46 children, who were treated for five consecutive days with formulations designed for term infants and toddlers up to 2 years of age (Ped3CB-B) or for children and adolescents 2–18 years of age (Ped3CB-C). The volume of Ped3CB administered was based on the patient's individual needs. Majority of pharmacists and nurses found the Ped3CB system easy to use, and favored Ped3CB formulations over bags compounded on the ward, RTU compounded bags, and premixes prepared by the pharmacy and tailored to patient needs. Ped3CB delivered 91% of the PN energy intake among the Ped3CB-B group and 68% in the Ped3CB-C group. PN administered using the Ped3CB system was well tolerated in both groups. Four adverse events, all of which occurred in the Ped3CB-B group, were related to study treatment, two cases of hypertriglyceridemia and two cases of mild hyperglycemia. No serious adverse events considered to be related to study treatment were reported.[569]

The safety of an industrially manufactured three-chamber PN system specially designed for preterm infants was evaluated in a recent prospective, multicenter, open-label phase III clinical trial. The researchers used Ped3CB-A three-chamber PN that provide 3.1 g amino acids, 13.3 g glucose, 2.5 g lipid, and 91 kcal/100 mL with the ternary admixture and 3.9 g AA, 16.7 g glucose, and 83 kcal/100 mL with the binary admixture. Additional supplementation of sodium, potassium, calcium, and organic phosphate may be added to the basic admixtures, increasing concentrations by 78%, 67%, 118%, and 78%, respectively. Vitamins and TEs are not included in the Ped3CB-A bag and were added to the activated bag or provided separately, according to the general practice of the NICU. One hundred and thirteen preterm infants were enrolled in the study from five centers. The triple-chamber PN system was easy to use, has the flexibility required to meet the varied and changing nutritional needs of preterm infants, provided levels of nutrients within the ranges of recent recommendations, and resulted in appropriate weight gain rates. The majority of prescription days were successfully fulfilled using Ped3CB-A as is, with the addition of vitamins and TEs as usually performed in adult patients. Few additional supplementations into the bag, mainly sodium,

were necessary, representing only 23.1% of the perfusion days. Few abnormal biological parameters were reported as adverse events, including hyperglycemia, hypertriglyceridemia, and electrolytes deviation, but no serious adverse events related to PN supply. In conclusion, the triple-chamber bag for premature infants was easy to use and provided well-balanced and safe nutritional support in premature infants.[561]

CONCLUSIONS

Pediatric IF or immaturity is a complex and unique problem. Nutritional support in these children should be met by balancing both parenteral and enteral routes, while maintaining adequate growth and development. Efforts must be made to deliver a balanced PN solution, avoid catheter-related infections, and the development of IFALD. Additional research is needed to refine the enteral formulas and parenteral macro- and micronutrients for this pediatric population.

Nutrition in the Athlete

69

Kathryn E. Ackerman, MD, MPH and Madhusmita Misra, MD, MPH

INTRODUCTION

Approximately 35 million children in the United States ages 5 to 18 years are involved in organized sports, including 66% of boys and 52% of girls in this age range (http://www.statisticbrain.com/youth-sports-statistics/). In Europe, depending on the country, sports participation rates among children reach as high as 98% for at least occasional involvement in sports activities.[1] In general, physically active children and adolescents tend to have healthier nutritional habits than their nonathletic peers.[2] However, many are unaware of the effects of dietary choices on performance, injury prevention or recovery, much less the effects on growth, maturation, and overall health. Some attempt excessive caloric supplement and protein ingestion in an effort to bulk up for sports. Others take their dietary habits to the other extreme, restricting caloric content and suffering nutritional deficiencies with a goal of achieving a thin, lean physique. Although many nutritional issues in the young athlete are similar to those of the adult athlete, there are several physiologic and metabolic characteristics that distinguish child and adolescent athletes from adults.[3] Therefore, specific nutritional issues need to be addressed.

This chapter will review the nutritional needs for normal growth and development of children and adolescents and the special considerations for athletic youth. It will discuss macro- and micronutrient requirements, vitamin and mineral recommendations, special dietary restrictions (such as vegetarianism), in addition to hydration, supplementation, and appropriate timing of meals to optimize health and performance. It will also review some of the negative sequelae of energy imbalance and the importance of fueling for sport.

GROWTH

Infancy and early childhood are typically times of rapid growth. Later childhood is associated with a slowing, but consistent gain in stature and weight, with adolescence being a time again of rapid growth. A general rule is that a child grows 25 cm in the first year of life, half that in the second year, and then 5–6 cm until puberty.[4] Girls average a peak height velocity of 9 cm/year around age 12, with a total height gain of 25 cm during the pubertal growth period.[4,5] Boys have a later but greater peak height velocity of 10.3 cm/year around age 14, with a total height gain of 28 cm during the pubertal growth period.[4,5] Approximately 90% of peak bone mass is attained by the second decade in boys and girls, with 26% of adult bone mineral content acquired during the 2 years around peak height velocity.[6–8]

School-aged children and adolescents require adequate caloric intake to ensure appropriate growth and maturation, and these caloric needs are generally higher in active children versus their sedentary counterparts. Although it is difficult to provide specific caloric recommendations because of large individual variability, on average, during growth spurts, adolescents should consume an additional 500 kcal/d above their usual intake.[9] Growth and maturation are influenced by numerous factors that act independently or synergistically to impact any individual's inherent potential for these parameters. Worldwide, the most common cause of growth retardation is poverty-related malnutrition. In the United States, in upper-middle and upper-class teens, the most common cause for poor growth and delayed pubertal development is self-induced energy restriction.[4]

Participation in sports activities that do not require weight control does not delay puberty or alter growth. In fact, children involved in sports not associated with weight control are normal if not advanced in their rates of growth and maturation. It is quite possible that because strength and power advantages associated with earlier development are beneficial for such sports, the earlier maturing athletes are self-selected for participation.[10,11]

However, there are activities associated with an increased risk for prolonged inadequate energy intake (EI) relative to expenditure. These include wrestling, gymnastics, distance running, and dance.[12] A sustained energy-deficit state may result in short stature, delayed puberty, menstrual irregularity or amenorrhea, poor bone health, and increased rates of injury.[13] Roemmich et al. found that statural growth and advancement of skeletal maturation of wrestlers was similar to controls both during and

after wrestling season. However, increase in fat-free mass and other soft tissues slowed during wrestling season, followed by catch-up growth postseason when caloric intake increased.[14,15]

A muscular and short frame provides competitive advantage in gymnastics. Performance often declines after the onset of puberty secondary to increases in height and fat mass, and development of secondary sexual characteristics. Thus, gymnasts may try to modify activity levels and caloric consumption to maintain a lean physique, maximize their strength to weight ratio, and potentially to delay puberty and growth.[12] Studies of gymnasts have found reduced insulin-like growth factor-I (IGF-I) concentrations, relatively shorter lower limbs in both males and females, and delayed age of menarche in female gymnasts.[16–20] Delay in growth and sexual maturation is most notable in gymnasts, dancers, and long-distance runners 10. However, there are few longitudinal studies of such athletes, and it is also important to consider the role of genetic predisposition, with short stature often being familial, and menarchal age correlating positively between mothers and daughters.[10,21]

Many of the hormones most strongly linked to pubertal development [such as growth hormone (GH), IGF-I, and sex steroids] are also linked to energy metabolism during exercise.[22] The antiquated theory that elevations in pubertal hormones (GH and testosterone) during exercise cause increased growth and development during adolescence is yet to be confirmed through controlled, longitudinal studies. Transient increases in hormones have been documented in exercising adolescents, but their long-term effects have not been determined.[22–25]

MACRONUTRIENTS

Carbohydrates

The daily recommended intake for carbohydrates in children is based on the amount of carbohydrate needed to provide sufficient glucose for brain function and does not take into account the amount needed for muscle glycogen repletion.[1,3] In adults, carbohydrates are the dominant fuel source for maintaining prolonged or high-intensity exercise. As exercise intensity decreases, a greater proportion of energy is derived from oxidation of free fatty acids, particularly from muscle triglycerides. In addition, with more aerobic training, the energy derived from fat increases, while that from carbohydrates decreases,[26] as seen in better trained athletes. Of note, children are more dependent on fat oxidative pathways

than adults. This may be due to higher intramuscular triglyceride levels, higher free fatty acid turnover during exercise, or an underdeveloped glycolytic system in children compared with adults.[27] Fat may play as important a role as carbohydrates for child athletes, whereas adolescent athletes behave more like adults.[28] In a study of 13- to 15-year-old teens, there was no significant difference in muscle glycolytic enzymes compared to adults.[29]

It is well-established that puberty is associated with a period of insulin resistance. Although the exact cause in unclear, increases in GH and sex steroids are thought to oppose the effects of insulin in skeletal muscle, adipose tissue, and liver, leading to a decrease in insulin sensitivity of about 30%.[3,22]

Parts of the human body that almost exclusively require glucose for metabolic functions (such as the brain, red blood cells, and a few other tissues) have a daily need in adolescents and adults of about 180 g of carbohydrates/day. Gluconeogenesis from noncarbohydrates (e.g., fat, protein, lactate) generates about 130 g/day. Most child athletes get at least 200–500 g/day of carbohydrate.[1,3] However, female athletes, particularly endurance athletes, are less likely than their male counterparts to consume recommended amounts of carbohydrate, often due to restriction of total EI from a desire to achieve or maintain a lower body weight and/or body fat level.[30]

The Institute of Medicine's Dietary Reference Intakes (DRIs) are the recommended dietary allowances for food types. The DRI of carbohydrates for children and adults to maintain brain function is 130 g/day, with a suggestion that 45%–65% of total calories be derived from carbohydrates (http://fnic.nal.usda.gov/dietary-guidance/dietary-reference-intakes/dri-tables). It is important to remember that during heavy exercise, adolescents may utilize up to 1–1.5 g/kg/h of total carbohydrates.[31]

Fat

Fat is a necessary component of any diet, providing energy and essential elements of cell membranes, in addition to facilitating the absorption of fat-soluble vitamins such as vitamins A, D, E, and K.[32] Children and early and mid-pubertal adolescents oxidize relatively more fat than carbohydrate at a given relative exercise intensity compared to late pubertal adolescents and adults.[27,33] This is based on studies using the respiratory exchange ratio during and after bouts of exercise, in addition to blood byproducts of fat oxidation (such as plasma-free glycerol and free fatty acids) and of

carbohydrate metabolism (such as lactate). As mentioned above, the phenomenon appears to be inversely correlated with maturation, with an adult-like metabolic pattern observed by the end of puberty.[27,29,33]

Yet even with this increased reliance on fat as a fuel source, there is no evidence that young endurance athletes benefit from higher fat content in their diets.[33,34] In fact, ingestion of high-fat food prior to exercise may decrease GH secretion during exercise from an increase in free fatty acids. If GH secretion during exercise is important for muscle adaptation and hypertrophy, high fat ingestion could have negative consequences.[33]

The American Heart Association recommends that dietary fat constitute 25%–35% of the daily calories of individuals ages 4–18 years.[35] There are no Institute of Medicine DRIs for fat other than recommending amounts of linoleic (10, 12, and 16 g/d for ages 4–8 years, 9–13 years, and 14–18 years, respectively) and α-linolenic acid (0.9, 1.2, and 1.6 g/d for ages 4–8 years, 9–13 years, and 14–18 years, respectively) (http://fnic.nal.usda.gov/dietary-guidance/dietary-reference-intakes/dri-tables).

Protein

Children and adolescents must maintain a positive nitrogen balance for growth and development. Although it is important to ingest enough protein, particularly essential amino acids, it is just as important to ingest enough calories, to spare protein from being used as a substrate for energy. Amino acids contribute 5%–15% of the fuel burned during exercise. There have been few studies to determine the optimal protein intake in child/adolescent athletes. In a recent study by Aerenhouts et al.,[36] 60 adolescent sprint athletes were followed over 2 years. Body height, weight, and skeletal muscle mass increased in the participants throughout the study, and it was concluded that about 1.5 g/kg/d of protein (1.46 g/kg/d for girls and 1.35 g/kg/d for boys) was sufficient to maintain a positive nitrogen balance, even during periods of peak growth.[36]

MICRONUTRIENTS

Micronutrients are required in small amounts for normal bodily functions including hemoglobin synthesis, bone health, immune defense, and protection from oxidative damage. They include vitamins and minerals such as vitamins A, C, D, E, K, the B vitamins, calcium, iron, zinc, magnesium, β-carotene, and selenium. A few of those of most concern to

young athletes will be discussed below.

Antioxidants

Antioxidant vitamins C and E, β-carotene, and selenium protect cell membranes from oxidative damage.[26] Because of increased oxygen consumption with exercise, it has been hypothesized that long-term, intense exercise may increase oxidative stress on the body, resulting in lipid peroxidation of membranes.[26] However, studies in well-trained adult and adolescent athletes have demonstrated enhanced antioxidant systems.[37,38] Whether or not adolescent athletes truly benefit from increased antioxidant consumption remains to be determined.

B Vitamins

The B vitamins, namely thiamine (vitamin B_1), riboflavin (vitamin B_2), niacin (vitamin B_3), pantothenic acid (vitamin B_5), pyridoxine (vitamin B_6), and biotin (vitamin B_7) are important for energy production during exercise, while folate (vitamin B_9) and vitamin B_{12} are important for red blood cell production, protein synthesis, and tissue repair and maintenance, including of the central nervous system.[26] Research in adults suggests that exercise may increase requirements for riboflavin and vitamin B_6, but data for folate and vitamin B_{12} are limited,[39] and there are no confirmatory studies in otherwise healthy child/adolescent athletes. Any increased needs in young athletes can likely be met with appropriate EI. However, those on restrictive diets or with low EI may potentially suffer from severe B_{12} and folate deficiency, resulting in anemia, with subsequent endurance performance impairment.[26,40] Young amenorrheic athletes with the female athlete triad have been shown to benefit from folate supplementation, with improved endothelial vascular function.[41]

Vitamin D

Vitamin D is critical for absorption of calcium, regulation of serum calcium, phosphorus, and parathyroid hormone levels, and promotion of bone health. Vitamin D is also important for nervous system and skeletal muscle function.[42] As little as 10–15 minutes of direct sunlight can generate 10,000 to 20,000 IU of vitamin D. However, many factors can significantly affect vitamin D synthesis, including latitude, amount of skin exposed, and skin pigmentation.[43] Children with darker skin pigmentation

require 5–10 times more sunlight exposure to achieve the same serum concentrations of 25-hydroxy (25-OH) vitamin D as those with lighter skin.[43,44] Vitamin D intake reduces the risk of stress fractures, infections, inflammation, and impaired muscle function[45]; however, adolescent athletes often consume less than the recommended amount of vitamin D.[46–48] In 2008, the American Academy of Pediatrics increased their recommendations for daily intake of vitamin D from 200 to 400 IU for adolescents,[49] and the Institute of Medicine has recommended a daily intake of 600 IU of vitamin D in this age group. Most bone experts consider 25-OH vitamin D concentrations <20 ng/mL (50 nmol/L) to represent vitamin D "deficiency," with levels of 21–29 ng/mL (52–72 nmol/L) considered "insufficient," and levels >30 ng/mL (>70 nmol/L) "sufficient."[45,48] Some believe that current recommendations for daily vitamin D intake are still not quite adequate and suggest that up to 1000 IU daily intake may be necessary to maintain 25-OH vitamin D levels in an optimal range.[50] Vitamin D levels should be checked in adolescent athletes, particularly those living in northern latitudes, training primarily indoors (such as gymnasts and figure skaters), and those who do not consume foods fortified with vitamin D.[26,51]

Calcium

The Institute of Medicine's recommendations for daily calcium intake in children ages 9–18 is 1300 mg daily (http://fnic.nal.usda.gov/dietary-guidance/dietary-reference-intakes/dri-tables). The maximal absorption of elemental calcium in a single dose is approximately 500 mg; therefore, calcium intake needs to be divided into multiple doses over the course of the day. Prospective, placebo-controlled calcium supplementation trials (1000 mg calcium/d) in otherwise healthy adolescents with inadequate baseline calcium intake have reported increases in total body bone mineral density (BMD).[52,53] Although dairy products are obvious sources of calcium, many foods including juices, cereals, and cereal bars contain added calcium with the percent recommended daily allowance (%RDA) listed on foods being based on 1000 mg daily. Of note, in amenorrheic athletes, calcium intake per recommendations by itself is not sufficient to optimize BMD.[52]

Iron

During rapid growth and maturation, iron stores are influenced by changes in muscle mass and nutrition. Exercise affects body composition and

increases iron loss in urine, stool, sweat, and by hemolysis. In addition, young female athletes may have increased iron losses with the onset of menses.[3] Overt iron deficiency anemia is rare, but depleted iron stores (low serum ferritin) without decreased hemoglobin is prevalent in 25%–50% of male and female adolescent athletes, particularly endurance athletes.[3,54,55] Animal studies have demonstrated impaired endurance with iron deficiency even without associated anemia. Human studies have shown that iron supplementation maintains the ventilatory threshold and improves aerobic capacity and energy efficiency in iron deficient, nonanemic young athletes.[3,56]

Food sources of iron include enriched grain products, meat, fish, poultry, vegetables, legumes, nuts, and soy. However, adolescents need to consume up to 3000 kcal in order to achieve the RDA for iron of 18 mg/d[3] (http://fnic.nal.usda.gov/dietary-guidance/dietary-reference-intakes/dri-tables). Iron occurs in food in two separate forms: heme and nonheme. Heme iron comprises about 40% of the iron in meat, fish, and poultry. It is more efficiently absorbed than nonheme iron, which comprises the remaining iron in meat, fish, and poultry, as well as all iron in other foods.[57] Nonheme iron absorption is enhanced by tissue protein factor (in meat, fish, and poultry), vitamin C, alcohol, and potentially retinol and carotenoids, but is inhibited by phytic acid (in whole grains, legumes, lentils, and nuts), polyphenols (in tea, coffee, red wines, and certain vegetables), soy protein, eggs, and calcium and phosphate salts.[58,59] Thus, while vegetarian diets often have enhancers that include increased vitamin C and carotenoids, this frequently does not make up for the increase in inhibiting substances and the absence of tissue protein factor.[58]

Adolescent athletes may have higher iron needs than the RDA and should be encouraged to consume iron-rich foods. Nutritional restrictions, declining performance, and/or fatigue should alert medical providers to check ferritin levels of athletes.

FLUID AND ELECTROLYTES

Hydration (thermoregulation)

Prior reports suggested that exercising children do not adapt to extremes of climatic temperature as effectively as adults, and need more time to acclimatize. Reasons include children's greater surface area-to-body mass ratio, which could lead to greater heat gain on a hot day and more heat loss on a cold day. Children are also believed to produce more heat per kg of

body weight than adults during physical activity, and to have a lower sweating capacity, thus reducing the ability to dissipate body heat effectively by evaporation. Therefore, higher air temperature and humidity would potentially lead to lower exercise capacity of a child.[60] However, recent studies in 9- to 12-year-old children and similarly fit and heat-acclimatized adults exposed to similar relative intensity exercise workloads and environmental conditions (while minimizing dehydration) have demonstrated similar rectal and skin temperatures, cardiovascular responses, and exercise-tolerance time during exercise in the heat in the two groups. Thirst-driven drinking behavior also appeared to be similar, as *ad libitum* fluid intake was comparable.[61–65]

In children, maturation, body size, diet, medications, illnesses, and chronic health conditions all play a role in the amount of water needed to maintain optimal cardiovascular, thermoregulatory, and other physiologic functions.[66] With exercise, individuals sweat in order to mitigate rises in core body temperature, thus losing water, sodium, potassium, iron, calcium, and magnesium, in addition to other trace elements. Significant dehydration can lead to premature fatigue, impaired sports performance, cognitive changes, electrolyte abnormalities, and increased risk of heat illness.[66] For the average child engaged in routine physical activity, water and a healthy diet should suffice in replenishing losses in sweat. When a child drinks in response to thirst alone during exercise, he/she experiences a fluid deficit of 0%–35% of incurred fluid losses. It is also possible that the inexperienced young athlete will not respond to normal thirst cues because of distraction, sympathetic stimulation, and/or lack of motivation to drink.[65] Therefore, coaches and athletic trainers should encourage appropriate hydration before, during, and after exercise. Weight checks before and after exercise are also helpful to assess fluid status, minimizing risk of both dehydration and overhydration.

The American Academy of Pediatrics recommends that fluids be available and consumed at regular intervals before, during, and after physical activities to offset sweat loss and to maintain adequate hydration while avoiding overdrinking. The Academy suggests about 3–8 oz. every 20 minutes for 9- to 12-year-olds and up to 34–50 oz. per hour for adolescents. In addition, long-duration (≥1 hour) or repeated same-day sessions of physical activity might warrant electrolyte-supplemented beverages.[61]

Sports Drinks

"Sports drinks" are typically beverages containing carbohydrates, electrolytes, minerals, and flavoring, and are intended to replenish water and electrolytes lost through sweat during exercise. "Energy drinks" are very different types of beverages, as they also contain non-nutritive stimulants, such as caffeine, guarana, taurine, ginseng, l-carnitine, creatine, and/or glucuronolactone, with claims of ergogenic or performance-enhancing benefits.[66]

As mentioned above, there may be utility in young athletes consuming sports drinks that contain carbohydrates and electrolytes during prolonged, high intensity, and/or frequent exercise sessions. Sports drinks contain 2–19 g of carbohydrates (glucose and fructose) per 8 oz., whereas energy drinks contain 0–67 g per 8 oz. In addition, the caloric content of sports drinks range from 10 to 70 calories, with that of energy drinks ranging from 10 to 270 calories.[66] Excessive intake of carbohydrate-containing beverages beyond what is needed to replenish blood glucose and muscle glycogen stores should be discouraged, as such excessive intake can increase the risk of overweight and obesity in children and adolescents, as well as dental erosion.[66]

Caffeine has been shown to improve physical performance in adults by increasing aerobic endurance and strength, improving reaction time and delaying fatigue. However, effects are quite variable and have not been studied in children or adolescents. Caffeine can increase heart rate, blood pressure, diuresis, temperature, and anxiety, and may have a negative impact on the developing neurologic and cardiovascular systems in children, in addition to causing physical dependence and addiction.[66,67] Therefore, there is no role for caffeine or other stimulants in the diet of the child or adolescent athlete.

Other legitimate ingredients in energy drinks marketed to enhance performance, such as amino acids/protein and vitamins/minerals can usually be obtained adequately from diet. Thus, although there may be utility in some sports drinks due to carbohydrate, caloric, and electrolyte needs, energy drinks are not warranted in this population.

Performance-enhancing Substances

A "performance-enhancing substance" (PES) or "performance- enhancing drug" is defined by the American Academy of Pediatrics as "*…any substance when taken in non-pharmacological doses specifically for the purposes of improving sport performance. A substance should be considered performance enhancing if it benefits sports performance by*

increasing strength, power, speed or endurance (ergogenic) or by altering body weight or body composition."[68] Sports activities require varying levels of strength and power. As with adults, children and adolescents may be tempted to use what they believe to be a PES to help them achieve the Olympic motto, "*faster (citius), higher (altius), stronger (fortius).*" This motto was introduced by the father of the Modern Olympics, Pierre de Coubertin, and often overshadows another Olympic concept introduced at the 1908 Games, "*The most important thing is not to win, but to take part!*" Our society places a huge emphasis on sports, with children getting scouted at an earlier and earlier age, and regional, state, national, and international competitions becoming a bigger and bigger industry. Parents and coaches are often dissatisfied with the rate of growth, ability to gain lean mass, and/or the predicted adult height of a child. Children may want to please the adults in their lives and also feel the thrill of victory. Thus, some will seek an athletic advantage at any cost.

In a study of preadolescent athletes, 3% admitted to experimenting with doping agents in the prior 6 months,[69] and reports suggest that 4%–12% of adolescent high school athletes use anabolic steroids.[70] Although the perceived benefit of such substances is beyond the scope of this chapter, suffice it to say that athletes use PES often with little information regarding associated risks. Such substances are often obtained illegally, do not meet Food and Drug Administration standards, and have potential serious adverse effects. Examples include a theoretical risk of cancer with human GH and IGF-I; decreased blood flow and increased blood clots from erythropoietin; and psychological disturbances, premature growth plate closure, and liver dysfunction from steroids.[70]

SPECIAL DIETS AND SUPPLEMENTS

As with adults, young athletes may follow specific diets for health, ethical, or religious reasons. Examples include gluten-free diets for those with celiac disease, modified carbohydrate diets for those with diabetes, vegetarian diets for those who oppose consumption of animals and/or animal products, and so on. Regardless of the reason for the food type omission, it can be very instructive for a young athlete following a restrictive diet to meet with a dietician/nutritionist. No research to date has shown that if well-planned and followed properly, any of the above types of dietary restrictions inhibit performance. However, there are special considerations and challenges to keep in mind. Those with celiac disease may have issues with malabsorption of vitamins and minerals.[71] Those

with diabetes have to strike a delicate balance with carbohydrate ingestion and insulin administration to avoid hyper- and hypoglycemia, the latter being a risk up to 15 hours postexercise.[72] Vegetarians are at risk for nonanemic iron deficiency and typically have lower mean muscle creatine stores.[58] Additionally, it is important to consider that some athletes choose specific diets (e.g., vegetarianism) for weight control and this practice may, therefore, be used to conceal disordered eating.[58]

Although most adolescent athletes can obtain the requisite macro- and micronutrients through food sources, some on restrictive diets may benefit from supplementation. Examples include iron and/or calcium supplementation in those who have difficulty obtaining appropriate amounts of these micronutrients through food. Decisions about supplements should be made on a case by case basis after careful dietary analysis.

TIMING OF MEALS

Although timing, size, and type of meal can vary greatly depending on the preferences and gastrointestinal characteristics of each athlete, there are some general principles to follow. There is more tolerability to a variety of meals and snacks prior to a low-intensity workout compared to a high-intensity training session or competition. Eating prior to exercise, rather than working out in a fasting state, has been shown to correlate with performance improvement.[73,74] The meal or snack consumed prior to intense exercise should fuel the athlete for the upcoming activity, while leaving him/her neither hungry nor with undigested food in the stomach. Most athletes do not like to compete on a full stomach; therefore, the pre-exercise meal should be small in order to allow for gastric emptying, while a larger meal may be consumed many hours prior to competition. The pre-exercise meal or snack should include enough fluid to maintain hydration, food relatively low in fat and fiber to facilitate gastric emptying and minimize gastrointestinal distress, food high in carbohydrates to maintain blood glucose and maximize glycogen repletion in muscles, and food with moderate protein to provide a positive net protein balance. Most importantly, the meal should be familiar to the athlete, so that he/she has experienced the consistent effects of such fueling in past similar exercise bouts.[42] This is important both physiologically and psychologically.

During exercise, fluid and glycogen losses can be replenished with water and easily digested carbohydrate sources that may include fruits,

sports gels, and bars.[75] The amount varies depending on duration and intensity of exercise. Postworkout recovery snacks that include carbohydrate and protein shortly after exercise have been shown to positively affect subsequent exercise performance and could specifically be helpful for athletes involved in multiple training or competition sessions on the same or consecutive days.[76]

ENERGY BALANCE

Energy balance is achieved when EI equals energy expenditure (EE). To achieve this, athletes need to appropriately replenish the calories expended during athletic activity in addition to maintaining their basal needs.

Obesity

Although the prevalence of childhood obesity and its consequences are at an all-time high in the United States, adolescent athletes suffer from body weight concerns at both extremes of the nutritional spectrum. These extremes include the morbidly obese, adolescent, offensive lineman with type 2 diabetes, and the adolescent dancers and runners suffering from anorexia nervosa. Emphasis on size for sports performance has driven young athletes to extremes of weight-related behavior.

In a study of 653 male American football players 8.7–14.6 years of age, 45% were overweight or obese according to Centers for Disease Control and Prevention body mass index (BMI) criteria, with the prevalence being highest in early maturing boys and more commonly in offensive and defensive linemen.[77] In the 1960s, National Collegiate Athletic Association (NCAA) Division I collegiate linemen averaged about 90.7 kg (200 lbs).[78] Now they average 136.1 kg (300 lbs).[79] Noel et al.[80] found that Division I offensive and defensive linemen average >25% body fat, with much of that fat being concentrated in the abdominal region, putting these young athletes at higher risk for the metabolic syndrome, heart disease, and stroke.79, When anthropometric measurements and blood biomarkers were obtained in 70 NCAA Division I, II, and III football lineman, 49% were found to have the metabolic syndrome.[81] Larger athletes often generate more force, thus contributing to increased musculoskeletal injuries and concussions.[79] Increased BMI also leads to increased oxygen demand and a decreased ability to dissipate heat, thus making larger players more susceptible to heat-related injuries.[82] It is paramount that larger athletes are educated about health consequences of

obesity and are given the tools to maintain healthier weight both during their competitive years and after retirement.

Energy Restriction

Energy restriction refers to decreased caloric intake often for the purpose of weight loss or relative to EE. In athletes, energy restriction may be a means to achieve a perceived ideal sports physique (as in gymnastics, figure skating, and dance) or to make a weight class (as in wrestling or lightweight rowing). Mild energy restriction may be beneficial in those who are overweight or those who need to lose only a small percentage of weight to make a weight class. However, all too often, energy restriction for sports may lead to detrimental health consequences.

Wrestling is often cited as the classic example of the dangers of rapid energy restriction combined with dehydration. For a perceived competitive advantage, wrestlers may plan to compete in a weight category lower than their preseason weight and utilize rapid weight-losing techniques to achieve this goal. Collegiate wrestlers have died from restricting food and fluid intake and exercising vigorously in hot environments prior to weigh-ins.[83] In 2005, the *British Journal of Sports Medicine* reported the case of a 5-year-old boy who had already learned dangerous habits for weight-making. On the day of weigh-ins for the final competition, the boy was overheard saying to his teammates, ‘‘Why are all of you eating before weigh-ins? I bet that I was the only one in the sauna last night. I haven’t had anything to eat today, or yesterday.” The boy, who weighed 22.7 kg, had been pressured by his father to wrestle in a lower weight class, which would require a weight loss of 2.27 kg or 10% of his usual body weight.[84,85] Thus, it’s never too early to discuss nutrition, disordered eating, and health consequences of bad habits for sport.

Female Athlete Triad

The female athlete triad (Triad) is the interrelatedness of low-energy availability, menstrual dysfunction, and low bone density.[86] Energy availability is the amount of dietary energy available after accounting for resting EE and that needed for exercise, standardized for lean body mass. Energy availability of greater than 30 kcal/kg lean body mass is believed to be necessary for normal reproductive function. In athletes with restrictive eating habits and/or those who overexercise, caloric intake may not be sufficient to meet the energy needs for the individual’s normal bodily functions, causing suppression of the reproductive axis.

Gonadotropin-releasing hormone pulsatility is diminished, leading to decreased levels of the gonadal steroids estradiol and testosterone, both of which are important antiresorptive hormones with possible bone anabolic effects. In addition, other bone anabolic hormones, such as IGF-1 and leptin, are decreased in conditions of energy deficit.[46] Thus, athletes with decreased energy availability and subsequent menstrual dysfunction are at higher risk for decreased BMD, stress fractures, and fragility fractures.[86]

Sometimes adolescent female athletes inadvertently slip into an underfueled state, because they are unaware of how much energy they are expending through physical activity. In other cases, they are trying to lose too much weight, lose weight too quickly, or maintain a low weight in an attempt to look a certain way or perform better. In a recent review of 65 studies on Triad prevalence, it was noted that only a small percentage of athletes exhibited all three components of the Triad simultaneously (0%–15.9%), but 2.7%–27.0% had two Triad conditions, and 16.0–60.0% had one condition.[87] It is important to note that having one component of the Triad is a risk factor for developing the other two components.

The greatest bone mass accrual occurs during puberty.[88] In general, healthy weight-bearing athletes should have higher BMD than their nonathletic counterparts.[89] However, low bone density has been noted in 22%–50% of female athletes, compared to 12% of the general population.[90] In young female athletes with the Triad, a compromise in bone strength and impaired bone accrual can result in short-term injuries (e.g., stress fractures) and long-term consequences (e.g., osteoporosis and fragility fractures).[86]

Disordered eating and more serious eating disorders, such as anorexia nervosa, can also lead to non-bone-related problems. These include decreased speed, strength, and exercise recovery. More serious consequences include depression, anxiety, electrolyte abnormalities, cardiac arrhythmias, and even death.[91] Because disordered eating behaviors often start in childhood or adolescence, it is important to monitor growth and dietary behavior, coupled with good nutrition and body image education, during these critical years.

DIETARY COUNSELING

When helping a young athlete determine energy requirements, a variety of questions should be asked: Does the athlete need to gain or lose weight to achieve a healthy BMI? What type of activity and how much is the athlete

performing? Is the athlete at risk for over- or undernutrition because of preconceived notions about physique and his/her particular sport? Does the athlete fear body changes during maturation and adolescence? Is there an optimal caloric and fluid intake before, during, and after training sessions and competition? Does the athlete use PES and/or follow specific diets (high protein, vegetarian, vegan, gluten free)?

Laboratory methods and equations are available to help calculate energy needs. In the laboratory, indirect calorimetry may be employed during both rest and exercise to measure EE. Outside a laboratory setting, the Harris–Benedict[92] equation is often used. The Harris–Benedict equations for males and females is detailed below:

MALE: basal energy expenditure (BEE) in kcal = 66.47 + 13.75 (weight in kg) + 5.00 (height in cm) − 6.76 (age in years)

FEMALE: BEE in kcal = 655.10 + 9.56 (weight in kg) + 1.85 (height in cm) − 4.68 (age in years)[92]

Total Caloric Requirements equal the BEE multiplied by the sum of stress and activity factors. Stress plus activity factors range from 1.2 to over 2. Activity levels include:

Little to no exercise: BEE × 1.2

Light exercise (1–3 days per week): BEE × 1.375

Moderate exercise (3–5 days per week): BEE × 1.55

Heavy exercise (6–7 days per week): BEE × 1.725

Very heavy exercise (twice per day, extra heavy workouts): BEE × 1.9

(http://www.myfitnesspal.com/topics/show/256851-harris-benedict-equation-for-maintenance)

Modifications to these equations as well as other formulas have also been utilized. Individual nutritional assessments should be performed with frequent adjustments, as these equations and methods only serve as guides.

CONCLUSION

When providing nutritional guidance to young athletes, it is essential to keep in mind the age, growth rate, level of physical maturity, specific sports involvement, and special dietary restrictions or preferences of the individual child or adolescent. This knowledge helps guide the athlete, parents, and coaches involved in the athlete's sports participation. To achieve change in fueling behavior, rather than overemphasizing effects on growth and maturation, focusing on the relationship between good dietary habits and athletic performance, injury prevention and recovery can be a powerful and effective approach in the child/adolescent athlete.

Special Diets

70

Sharon Evans, MSc, Tracey Johnson, BSc, SRD, Katharina Dokoupil, MSc, and Anita MacDonald, BSc, PhD

INTRODUCTION

Nutritional intervention and therapeutic diets play a central role in the treatment of many pediatric disorders. The aims and principles of the dietary management include the following:

1. Obtaining relief of symptoms by avoidance of the "offending" or source of the substrate food/additive
2. Preventing inadvertent exposure to the "offending" foods
3. Preventing unnecessary avoidance of foods
4. Supporting normal growth and development for age and gender in children
5. Ensuring that the diet is safe and does not lead to metabolic instability
6. Providing an adequate, healthy, nutritionally dense and balanced diet with appropriate alternatives for the excluded food allergens to minimize the impact on quality of life

Dietary treatment may be used as a monotherapy or in combination with drug or exercise therapy. Additional emergency treatment (EpiPen [epinephrine] Auto-Injector for anaphylaxis in food allergy or administration of emergency glucose solutions either orally or intravenously in some inherited metabolic disorders [IMDs]) may be necessary. The diet may require exclusion of one or more substrate "offending" foods or a controlled and regular food intake to maintain normoglycemia and prevent secondary complications. Some patients may require additional nutritional support with dietary supplements or tube feeds. Diet therapy is often arduous and unrelenting and may create

additional anxieties and difficulties for caregivers. Feeding problems may be more common in children on special diets than in healthy children.

This chapter describes commonly used special diets for selected pediatric disorders. Special diets for clinical conditions such as food allergy, gastrointestinal (GI) disease, faltering growth, hyperlipidemia, selected inborn errors of metabolism, weight control, and mineral deficiency are found in this chapter.

PRINCIPLES OF MANAGEMENT OF FOOD ALLERGY AND INTOLERANCE

The only treatment of any food intolerance is the avoidance of the causative allergen or offending food or ingredient. Individuals will tolerate different thresholds to offending foods; the most sensitive food allergic individuals will experience reactions from exposure to trace quantities only.

In general, the following stringent dietary advice is necessary:

- Avoidance of food/ingredient sources containing allergenic ingredients, even in small amounts.
- Avoidance of cross-contamination from allergen food sources.
- Avoidance of unrefined oil derived from allergenic foods.
- Advice on meals or foods of uncertain composition (meals eaten in restaurants or “Takeaways”).
- Meal planning and appropriate food choices.
- Monitoring nutritional adequacy of diet therapy.
- Regular observation of symptom control, dietary adherence/indiscretions and associated consequences, growth.

Targeted information may also be required about lactation diets, infant feeding and choice of special formula, and solid food introduction for lactating mothers and infants.

Individuals require verbal and detailed written advice about reading and interpreting food labels and understanding how to avoid cross-contamination during food preparation,[1] with regular updates and retraining. It is important to effectively liaise and teach the caregivers at nurseries, school, and school meal services to eliminate or reduce exposure to food allergens. All those involved with caring or teaching a child need to be aware of the food allergy, treatment, and any emergency treatment procedures in case of food reactions. A training program for school nurses with educational materials is important so they can help cascade

information to teachers and other caregivers at school.[2] Children also require education about which foods should be avoided. Role-play with plastic foods, about foods permitted and not permitted, is helpful. Also teaching a child that they should not accept food from others is important.

Many food allergy reactions are caused by allergens eaten from unlabeled sources. Detailed information is required about purchasing unpackaged food from retail outlets, from restaurants, or travelling abroad. There can be no venue considered a completely safe place to eat for those with food allergies.[3] Accidental exposures to food allergens can lead to reactions at home, school, work, and restaurants.

Some patients or caregivers may choose to avoid too many foods and therefore over restrict their diets. This may be caused by anxiety regarding unfamiliar foods and fear of inadvertent allergy reactions.[4] Patients with milk allergy may unnecessarily avoid nuts and soy or with peanut allergy may avoid all tree-nut sources too.

There is evidence that persistent food allergy and food hypersensitivity may be an important cause of anxiety[5] and negatively impact on quality of life.[6] Disrupted family activities include family social events, sleepovers, and visits to friend's houses without parental supervision. Children report anxiety about going on holiday, attending parties, and using public transport. Activities such as eating out are seen as frightening.[7] Parents often become hypervigilant but worry about the effect this overprotectiveness may have on their child. More than 30% of parents of children with food allergies make more than one visit per month to school to discuss issues surrounding their child's allergy.[8]

Allergen Food Labeling and European Legislation

The EU (EC 2003[9]; Food Labelling Regulations EC 2006[10]) state that the common food allergens or ingredients made from them should be identified on prepackaged food including alcoholic drinks. These foods include:

- Cereals containing gluten, that is, wheat, rye, barley, oats, spelt or their hybridized strains and products.
- Eggs and egg products.
- Fish and fish products.
- Crustaceans.
- Mollusks.
- Peanuts and peanut products.
- Soybeans and products.

- Lupin.
- Milk and milk products (lactose included).
- Tree-nuts and nut products.
- Celery and products.
- Mustard and products.
- Sesame seeds and products.
- Sulfur dioxide and sulfites in concentrations of >10 mg/kg or 10 mg/L.

Similar labeling laws have been adopted by the United States.[11]

These commonly allergenic foods account for over 90% of all moderate to severe allergic reactions to foods, although more than 160 foods are associated with sporadic allergic reactions.[12] Allergic reactions to fresh fruits, the so called oral allergy syndrome, are also rather common,[13] but these foods are not included on the EU list because the symptoms are typically mild and confined to the oropharyngeal region and the allergens are unstable to heating and digestion.

The EU[14] (Commission Directive 2007/68/EC) further published a very highly processed list of food ingredients that are unlikely to be associated with adverse reactions in susceptible individuals. These ingredients are exempt from EU labeling requirements and include the following:

- Wheat-based glucose syrups including dextrose
- Wheat-based maltodextrins
- Glucose syrups based on barley
- Cereals used for making distillates or ethyl alcohol of agricultural origin for spirit drinks and other alcoholic beverages
- Fish gelatin used as a carrier for vitamin or carotenoid preparations
- Fish gelatin or isinglass used as fining agent in beer and wine
- Fully refined soybean oil and fat, vegetable oils derived from phytosterols, esters from soybean sources, plant stanol ester produced vegetable oil, sterols from soybean sources
- Whey used for making distillates or ethyl alcohol of agricultural origin for spirit drinks and other alcoholic beverages
- Lactitol
- Nuts used for making distillates or ethyl alcohol of agricultural origin for spirit drinks and other alcoholic beverages

A further EC Directive[15] (No 1169/2011) will introduce a new requirement for allergen information to be provided for foods sold

nonpacked or prepacked for direct sale. At the end of 2014, allergy information on food sold unpackaged in catering outlets, deli-counters, bakeries, and sandwich bars should be provided.

The EU also request that mandatory information will be clearly visible on food labels, and identification of mandatory allergens should be in a type set that clearly distinguishes it from the rest of the ingredients. In the United Kingdom, the mandatory allergens will be identified in **bold type** on the label.[16]

Also in the United Kingdom, many manufacturers have provided information about the possible and unintentional presence of substances or products causing allergies or intolerances that may be in a food product. The EU suggests that in many cases such voluntary food information is provided to the detriment of the clarity of the mandatory food information. In the United Kingdom, such statements will be replaced with an Allergy Advice box containing the following statement: 'for allergens, see ingredients in bold.' There will also be consistent presentation of information about cross-contamination.

EGG-FREE DIET (Tables 70-1 and 70-2)

- Egg allergy usually presents in infancy with a prevalence of approximately 2% in children and 0.1% in adults. It is induced by egg protein (usually ovalbumin and/or ovomucoid).[17]
- Ingestion of raw or undercooked egg may trigger more severe clinical reactions than well-cooked egg. Children with mild egg allergy may be able to tolerate extensively heated egg products.[17]
- Ingredients and allergy warning labels on prepackaged foods should be checked. Non-prepackaged foods may be a hazard, particularly bread and pastries that may have been glazed or cross-contaminated with egg.[17]
- Breast-feeding: egg protein from the maternal diet is detectable in breast milk.[18] Therefore, eczema in breast-fed babies with egg allergy may improve if their mothers avoid eating eggs.

TABLE 70-1 Egg or Egg Derivatives

Egg proteins: Albumin, globulin, ovalbumin, ovomucin, ovomucoid, ovovitellin, livetin,
Egg white, egg yolk
Dried egg, egg powder, egg solids, pasteurized egg
Lysozyme

Egg lecithin (E322)

TABLE 70-2 Egg-Free Diet

Foods Allowed	Foods to Avoid
Milk, milk products and milk derivatives Cows, goat, sheep and other animal milks (including whole, skimmed, dried, evaporated and condensed milk). Yogurt, cream, sour cream, crème fraiche, fromage frais, cream cheese, whipped toppings Rice drink, soy drink, almond drink, hazelnut drink, potato drink, coconut milk, (cream made from these milks). Soy cheese, soy yogurt, soy desserts	*Milk, milk products and milk derivatives, Greek yogurt*
Cheese All cheese	*Cheese* Blue cheese, cream cottage cheese
Fats and oils Butter, margarines Vegetable oils Lard, dripping, suet	*Fats and oils* Butter, salad dressing with egg, mayonnaise, tartar sauce, hollandaise sauce
Meat and fish Plain beef, lamb, veal, pork, wild game, poultry, liver, kidney, offal, fish, shellfish (fresh or frozen)	*Meat and fish* Commercially breaded meats, fish, or poultry. Meatballs, meat loaf, croquettes, some sausages, rissoles, pâté, prepared meat dishes containing egg
Egg-free substitutes only	Eggs Eggs from all birds Scotch eggs, quiche, scrambled or omelette, meringue, soufflés, egg curry
Non-meat alternatives Peas, beans, lentils (dried, canned, or frozen e.g. dhal or hummus); all nuts and seeds, tofu, peanut butter.	*Non-meat alternatives* Quorn products, vegetarian burgers or sausages and other similar vegetarian products
Cereal, flour, pasta All grains; wheat, oats, corn, cornmeal, barley, maize, sago, rye, tapioca, bulgar, quinola, millet, arrowroot. Custard power (original), semolina Carob	*Cereal, flour, pasta* Egg noodles or pasta. Fried rice containing eggs Pancakes, crepes, doughnuts, waffles, muffins, bread crumbs and pretzels. Baking mixes, fritter batter, or batter-fried food. Yorkshire pudding

Breakfast cereals Most are suitable, e.g. Weetabix, Cornflakes, Rice Krispies	*Breakfast cereals*
Bread and yeast products Plain bread, white, wholewheat, rye bread (without egg products or brushing with egg for glazing).	Bread and yeast products French toast, waffles, muffins, egg glaze on bread, bread rolls, croissants, egg roll wrappers
Cakes, biscuits, crackers Egg-free biscuits. Oatcakes, Rye crackers	*Cakes, biscuits, crackers* Many cakes and biscuits contain egg, cream filled pies, pastries, scones, choux pastry, pastry glazed with egg, fruit flans. *Royal icing, Icing or frostings*
Desserts Sorbet, jelly, yogurt	*Desserts* Many desserts contain egg in some form. Ice cream (especially fresh and deluxe types), custard containing egg, dessert powders, Mousse, some sorbets, Bread and butter pudding, custard tart, egg custard, cream caramels, frittata, tiramisu
Fruit All fresh, frozen, tinned or dried fruit All fruit juices	*Fruit*
Vegetables All fresh, frozen, tinned or dried vegetables (without added milk or milk products) Most dried and tinned pulses, e.g. red kidney beans, chick peas, lentils Tomato paste and puree All vegetable juices Olives	*Vegetables* Coleslaw, potato salad, vegetables with mayonnaise and salad cream. Any vegetables prepared with a sauce or breaded that contains eggs in any form (such as hollandaise sauce, vegetable soufflé, or batter style vegetables)
Savoury snacks Plain popcorn, plain pretzels, plain potato and tortilla chips, fruit crisps	*Savoury snacks*
Seasonings Herbs, spices, salt, pepper, vinegar, mustard	*Seasonings*
Soups, gravies and sauces Bouillon, broth, meat, or vegetable stock soups; bisques and chowders made with water or milk. Stock cubes/concentrates, gravy granules, ketchup, sauces made without egg, salsa, relish, pickles.	*Soups, gravies, and sauces* Mayonnaise, Aioli, Remoulade, Béarnaise sauce Hollandaise sauce, tartar sauce, salad cream Any stock cleared with egg (consommé, broth, bouillon), canned soups Cream sauces made with egg.

Sugar, sweet spreads Sugar, honey, jams, jellies, maple and corn syrup, fruit based pouring syrup, molasses.	Sugar, sweet spreads Lemon curd
Confectionery Boiled or hard sweets/candy, most mints, plain fruit lollies, chewing gum, gum drops	Confectionery Chewy sweets, marshmallow, jelly beans brushed with egg white, chocolate bars (e.g. Mars Bar, Snickers, Wagon Wheel), nougat
Drinks Milk shake syrup or powders Carbonated, squash, fruit juice Cocoa powder, tea, most coffee Flavored water	*Drinks* Malted beverages, eggnog
Miscellaneous – used in baking Baking powder, yeast, gelatine Food essence and food coloring	*Miscellaneous—used in baking* Marzipan Alcohol clarified with egg
Food labels should always be checked because ingredients might change.	

Possible Sources of Egg

- A shiny glaze or yellow baked goods may have been brushed with an egg wash. Simplesse is a protein-based fat substitute derived from egg whites and milk (or whey protein) that allows energy reductions of up to 80%. It may be used in ice cream, yogurt, cheese spread, salad dressings, margarine, mayonnaise, coffee creamer, soups, and sauces.
- Egg shells or whites may have been used to clarify soup stocks, consommés, wine, and coffee drinks.
- Breaded foods may be dipped in egg before dipping in breadcrumbs.

Egg-Free Ingredients and Substitutions

Cake, muffin, and other recipes can be adapted by using egg replacers or replacing a teaspoon of baking powder for each egg. Alternatively, replace one egg with one teaspoon of Xantham gum or gelatin. Egg replacers have little nutritional value and are based on potato, tapioca starch, and raising agents. They can be purchased from health food shops or large supermarkets. Egg-free mayonnaise, cake and muffin mixes, omelets, and quiche mixes are available.

Nonfood Items Containing Egg

These can be identified by reading the ingredient label. U.K. law requires

cosmetics, toiletries, perfumes, finger paints, and medications to include a list of ingredients on their packaging.

Vaccines

Yellow fever vaccine and influenza vaccine should be avoided by those with egg allergy.

SOY-FREE DIET (Tables 70-3 and 70-4)

- The soy bean belongs to the legume family, which includes peas, beans, carob, liquorices, and peanut. Reactions to more than one member of the legume family are rare. It is usually unnecessary to avoid all foods from the plant family as cross-reactivity is uncommon.
- Soy is widely used in foods and so is difficult to avoid. As many as 60% of manufactured foods contain soy. Soy can be ingested as whole beans, soy flour, soy sauce, or soy oil. Soy can also be used in foods as a texturizer (texturized vegetable protein), emulsifier (soy lecithin), or protein filler. Soy flour is widely used in foods including breads, cakes, processed foods (ready meals, burgers and sausages), and baby foods.
- Soy lecithins are commonly used in the food industry as emulsifiers. Lecithin is a lipid, which stabilizes foods that contain water and fats, which do not normally mix. Evidence suggests that proteins present in soy lecithin and soy oil have low allergenicity[19] and most individuals with soy allergy should tolerate it.
- In the United Kingdom, the Food Standard Agency advises that refined soy oil (the main component of vegetable oil) should be safe for people with soy allergy, because the proteins that cause allergic reactions are removed during the refining process. However, cold pressed soy oil, usually sold from delicatessen counters or health food shops, may contain soy protein and should be avoided.
- Most soy sauces contain very small amounts of soy, with most of the protein in the sauce being derived from fermented wheat.[20] Soy sauce is well known as a Japanese traditional seasoning, namely shoyu.

TABLE 70-3 Soy Derivatives
Soy protein isolate
Soy protein concentrate
Soy shortening
Soy protein
Soy albumin
Soy beans
Soy flavoring
Soy flour
Soy gum
Soy lecithin (E322)
Soy milk
Soy nuts
Soy oil
Soy starch

Terms That May Indicate the Presence of Soy

Vegetable broth, vegetable oil, vegetable protein, vegetable paste, textured vegetable protein (TVP), hydrolyzed vegetable protein (HVP), hydrolyzed plant proteins (HPP), vegetable starch, vegetable gum.

Foods That Contain Soy

Miso, soy infant formula, soy margarine, soy or Shoyu sauce, Tamari, soy flour, grits, soy nuts, soy drink, soy sprouts, soy yogurts, soy cheese, soy desserts, tempeh, tofu/tofutti, TVP, Edamame, Natto, bean curd, Kinako, Nimane, yuba, and Okara.

Foods That May Contain Soy

Baby foods, bread, breakfast cereals, cakes and biscuits, confectionary with a biscuit base, cheese substitutes, canned and tinned soup, Chinese foods, chocolates (especially cream centers), commercial fruit products, crackers, crisps, dessert mixes, flavored crisps, frozen dessert, ice cream, liquid meal replacers, margarine, meat products (cold meats, beef burgers, meat pasta/pies, minced beef, sausages, hotdogs, coffee whiteners or cream replacers, pancake and waffle mixes, pasta, pizza bases, ready meals, sauces (including Worcester sauce, sweet and sour, Teriyaki sauce, stock cubes, gravy powders, and some cook in sauces), seasoned salt, snack bars, soups (canned or packet), sandwich spread, mayonnaise, salad creams, vegetable products, and vegetarian meals.

Alternatives to Soy

- Avocado, tahini (sesame paste), and nut butters can make useful alternatives to margarine for spreading on sandwiches and toast.
- Olive oil, sunflower or safflower oil, canola oil can be used as alternatives to undefined vegetable oil.

PEANUT-FREE DIET

- Peanut allergy is an IgE-mediated allergic disease, associated with fatal anaphylaxis. It typically presents with symptoms after one of the first few exposures to the peanut source. Only about 20% of individuals acquire tolerance[3] but about 8% may then experience a resensitization. The prevalence rate of peanut allergy is estimated to be 1% of the population.[3,21] There are no parameters that can reliably predict with certainty those at risk of anaphylaxis.[22]
- Peanut (*Arachis hypogaea*) is a member of the legume family but not nut family. Legumes are edible seeds enclosed in pods; others include soy beans, lima beans, carob, and sweet clover.
- Eight peanut allergens have been identified that are termed as Ara h 1 to Ara h 8.[23] Individuals may react to minute amounts of peanut allergen (100 μg–50 mg). The protein fraction of peanuts makes up 25%–30% of the kernel. The allergenicity of peanut proteins is very resistant to thermal, chemical, and proteolytic denaturation.
- Long-term management consists of complete avoidance of all sources of peanut. It requires constant vigilance.
- Unrefined (crude) peanut oil should be avoided by peanut allergic people as the process by which the oil is made means that low levels of protein can contaminate the oil. Highly refined peanut oils are unlikely to cause a reaction for the majority of people with peanut allergy[24] but it may be difficult to identify the type of oil used in a product.
- Roasting and heating of peanuts (not boiling) may increase allergenicity.[25]
- Some individuals who are peanut allergic may also react to lupin.[26] Lupin flour may be added to some baked goods. Under European law, lupin must be labeled when it is added to prepacked food.
- In the United Kingdom, in the past, the Department of Health

advised against the consumption of peanuts during pregnancy, breast-feeding, and weaning. Since 2009, the advice is that peanuts can be consumed during pregnancy or breast-feeding. However, peanuts should be avoided in the following situations: if a mother suffers from peanut allergy, if there is a history of allergy in the immediate family, or if the child already has an allergy. Medical advice should be sought before giving peanut for the first time.[27]

TABLE 70-4 Soy-Free Diet

Foods Allowed	Foods to Avoid
Milk, milk products and milk derivatives Cows, goat, sheep and other animal milks (including whole, skimmed, dried, evaporated and condensed milk. Yogurt, cream, sour cream, crème fraiche, fromage frais, cream cheese made from animal milk Rice drink, almond drink, hazelnut drink, oat drink, quinola drink and hemp drink, coconut milk, (cream made from these milks).	*Milk, milk products and milk derivatives* Soy drink, soy infant milk, non-dairy creamers, Soy yogurt, soy desserts, soy cheese, some processed cheeses.
Fats and oils Butter Pure sunflower or olive oil margarines Home-made salad dressings	*Fats and oils* Vegetable oil, margarine, salad dressing, mayonnaise, vegetable oils, vegetable sprays, shortening unless the type of oil is specified as non-soy oil.
Meat and fish Plain beef, lamb, veal, pork, wild game, poultry, liver, kidney, offal, fish, shellfish (fresh or frozen)	*Meat and fish* Commercially breaded meats, fish, or poultry, sausages, hamburgers, rissoles, pate, prepared meat dishes, hot dogs, meat loaf containing soy, Deli meats
Eggs Plain eggs	*Eggs*
Non-meat alternatives Peas, beans, lentils (dried, canned, or frozen e.g. dhal or hummus); all nuts and seeds.	Non-meat alternatives Textured vegetable protein, vegetarian ‘meat’ or ‘chicken’ burgers or sausages and other similar vegetarian products, soy nuts, peanut butter and peanut butter substitutes, sandwich spread, commercial Seitan.

Cereal, flour, pasta All grains; wheat, oats, corn, cornmeal, barley, maize, sago, rye, tapioca, bulgar, quinola, millet, arrowroot, pasta, semolina.	*Cereal, flour, pasta* Soy containing noodles, pasta, commercial pasta and rice in sauces, dry pizza mixes Pancake mixes
Breakfast cereals Commercial cereals not containing soy	Breakfast cereals Granolas and natural cereals containing soy.
Bread and yeast products Plain bread, white, whole-wheat, rye bread (without soy flour or soy milk).	*Bread and yeast products* Breads, bread rolls, stuffing, doughnuts, waffles containing soy flour.
Cakes, biscuits, crackers Soy-free biscuits, oatcakes and wheat and rice crackers	*Cakes, biscuits, crackers* Cakes, biscuits, cookies, muffins containing soy.
Desserts Home-made ice cream. Pastries, puddings, pies without soy. Frostings, sauces, without soy.	*Desserts* Many desserts contain soy in some form. Ice cream, dessert powders, ice cream cones, pies, puddings, pastries, frostings, creamy desserts containing soy.
Fruit All fresh, frozen, tinned or dried fruit All fruit juices	*Fruit* Fruits in commercial baked goods, fruit bars
Vegetables All fresh, frozen, tinned or dried vegetables (without added milk or milk products) Most dried and tinned pulses, e.g. red kidney beans, chick peas, lentils Tomato paste and puree All vegetable juices Olives	*Vegetables* Soy sprouts, commercially prepared vegetables that are breaded or contain soy sauce, canned and frozen Oriental style vegetables, canned and frozen vegetables in any sauce.
Savoury snacks Plain popcorn popped with corn, sunflower, rice cakes	*Savoury snacks* Pretzels, crisps, corn chips
Seasonings Herbs, pure spices and seasonings	*Seasonings* Seasoned salt
Soups, gravies and sauces Home-made soup made with fresh ingredients and vegetable/meat stock.	*Soups, gravies, and sauces* Commercial soups, canned and dry mixes, noodle soups, soups containing tofu or nondairy creamer, pesto, cook in sauces, curry sauces, marinades. Worcester sauce, Oyster sauce, Teriyaki sauce, stock cubes, gravy powders

Sugar, sweet spreads Sugar, honey, jams, jellies, maple and corn syrup, molasses.	*Sugar, sweet spreads*
Confectionery Home-made sweets without soy.	*Confectionery* Sweets containing soy oil/undefined oil.
Drinks Carbonated, squash, fruit juice Cocoa powder, tea, most coffee *Flavored water*	*Drinks* Soy drink
Food labels should always be checked because ingredients might change.	

Possible Sources of Peanuts (Table 70-5)

- Foods that could contain peanuts or peanut products include African, Chinese, Indonesian, and Thai dishes, peanut brittle, peanut slab, dried fruit mixes, trail mix, baked goods (pastries, cookies), sweets, chili and spaghetti sauce (which may be thickened with peanut butter); chocolate spread, chocolate bars, egg rolls (may be sealed with peanut butter), hydrolyzed plant vegetable protein, vegetable burgers and sausages, nutmeats, ice cream, desserts, marzipan (which can be a mixture of nuts), and nougat. Foods most likely to contain hidden peanut products include cakes, cupcakes, fruit cakes, delicatessen cakes containing vegetable oil, cereal/granola bars, some breakfast cereal, granola, satay sauce, peanut sauce, confectionery, curries, salad dressings, breakfast cereals, sweet mincemeat, salad dressings, flavorings (natural), blended oils, and curries. Restaurant and takeaway meals may be a particular risk. Peanut shoots may be used in stir-fry dishes.
- Contamination can occur through the use of shared production lines or the same utensils. Manufacturers will commonly voluntarily identify on food labels if a product has been produced in the same factory as other foods containing peanuts to indicate possible cross-contamination. However, some of this advice may be disregarded by parents or patients. Research has indicated that many parents or patients are unlikely to purchase food products if the label indicated “not suitable for nut allergy sufferers” or “may contain nuts” but if the label stated “this product does not contain

nuts but is made in a factory that uses nuts," "cannot guarantee is nut free," and "may contain traces of nut" this would only be avoided by 50%. Large numbers of parents did not read labels for the presence of nuts in nonfood products. There is an assumption that risk is dependent on the wording of the label warning.[28] Teenagers in particular are shown to take risks with label interpretation and continue to eat foods labeled as "may contain" an allergen as they perceive the food is very unlikely to contain an allergen.[29]

- The peanut allergen appears to persist on the tabletop surface for at least 110 days if no cleaning occurs.[30] Therefore, regular cleaning of surfaces before and after eating should be reinforced as a safety measure for all individuals with peanut allergy.
- Foods sold in catering outlets or at in store bakeries and delicatessen counters, are generally unlabeled and so are problematic. Also there is inadequate knowledge about peanut allergy in restaurant staff.[31] A study undertaking chemical analysis of the peanut content of meals sold on food premises found that one in five provided a meal that could have triggered a fatal reaction. Most "front of house" staff did not check the allergy status of the meal with those doing the cooking.[32]
- Even cases of peanut allergy reactions via kissing are reported.[33] A study assessing the risk of peanut antigen in the mouth, found one hour after ingestion of peanut butter that 13% of participants had detectable levels.[34]
- Cosmetics, shampoos, medications, creams, and other topical products may contain arachis oil.

TABLE 70-5 Peanut Sources

Peanut flour, peanut meal
Peanut butter
Peanuts
Beer nuts
Mixed nuts
Ground nuts
Monkey nuts
Earth nuts
Goober nuts/peas
Mandalona nuts
Cold, pressed, expressed or expelled peanut oil
Arachis oil

TREE-NUT-FREE DIET (Table 70-6)

- Tree-nut allergy is less clearly characterized than peanut allergy.[3] The prevalence of allergy to tree-nuts is about half that of peanut allergy but it is associated with fatal anaphylaxis.[35] Only about 10% of children achieve tolerance to their tree-nut allergy.
- Accidental exposure to tree-nut allergens are common[36,37] and are predominantly associated with eating food outside the home, particularly restaurants, school cookies, and confectionary.
- In the United States and United Kingdom, the most common tree-nut allergies are walnut, cashew, almond, pecan, Brazil nut, hazelnut, macadamia nut, pistachio, and pine nut.[37,38] It has been reported that 45% of tree-nut allergic patients react to more than one nut.[37]
- The most common tree-nut allergies reported are walnut, cashew, almond, pecan, Brazil nut, and macadamia nut.[37]
- 25%–50% of peanut sensitive individuals are also allergic to tree-nuts.[37,39]
- Tree-nuts are available in their natural state (with or without shells) as ingredients in dishes or processed into butters, flours, oils, pastes, milks, or coffees.
- The tree-nuts identified by European/US legislation on prepackaged product food ingredient labels are almond, hazelnut, walnut, cashew, pecan nut, Brazil nut, macadamia, or Queensland nut.
- Although not mandatory, many manufacturers also use voluntary labeling (may contain tree-nuts) to indicate possible cross-contamination with tree-nuts.
- The following foods may contain tree-nuts: vegetarian sausages and burgers, Caponata, salads (commonly as garnishes), marinades, barbeque sauce, pesto, baked goods, cakes, biscuits, granola bars, pastries, Baklava, Macaroons, Amaretto biscuits, confectionery, praline (confectionery products made with nuts), fudge, trail mix, cereals, ice cream, desserts, marzipan, mortadella, natural flavoring, nougat, Turron, Nutella (or other chocolate nut spread), sweet mincemeat, and flavored coffee. Salad dressing, flavored natural extracts (e.g., almond), and nut distillates/alcoholic extracts are potential sources of tree-nuts.
- Specialty oils such as walnut oil contain significant levels of protein and should be avoided.

- Artificial nuts (e.g., Nu-Nuts) are ground and reshaped tree-nuts and should be avoided.
- Many African, Chinese, Indonesian, Mexican, Thai, and Vietnamese dishes contain tree-nuts.
- Coconut, nutmeg, water chestnuts, butternuts are not in the tree-nut family. Coconut is classified as a fruit. Although allergic reactions to coconut have been documented, most people allergic to tree-nuts can safely eat coconut.
- Lotions and sunscreens may contain shea butter or other nut butter. Nut oils such as almond may be used for massage.

TABLE 70-6 Tree-Nuts

Acorns
Almonds/almond paste
Artificial nuts
Beechnuts
Brazil nuts
Cashews
Hazelnuts (filberts)
Hickory nuts
Macadamia nuts (Queensland nut)
Pecans (mashuga nuts)
Pine nuts (pignoli)
Pistachios
Shea nut, shea butter
Walnuts
Nut oils, e.g., walnut oil
Natural nut extract (e.g., almond, walnut)
Nut meal
Nut meat
Nut paste
Nut liquors (Frangelico, Amaretto, and Nococello)
Nut butter (e.g., almond butter, hazelnut butter, brazil nut butter, macadamia nut butter, pistachio nut butter, shea nut butter, karike butter) Gianduja: a sweet chocolate hazel nut paste

SHELLFISH-FREE DIET

- Shellfish allergy affects about 1% of the population with significant consumption of shellfish. About 60% of people with shellfish allergy develop it in adulthood and it is usually lifelong.
- Tropomyosin, a heat stable muscle protein, is the major allergen in shellfish.[40]
- Edible shellfish are usually divided into two categories: mollusks

and crustaceans. Mollusks, such as clams and mussels, have two shells, but also include the abalone, which has a shell covering and a soft under part; crustaceans such as the lobster have segmented bodies that are covered with armor-like sections of thick and thin shells.

- Elimination of the following ingredients is necessary:
  – Mollusks: abalone, calamari, clams, cockle, cuttlefish, escargot/snails, mussels, octopus, oysters, periwinkle, sea urchin, scallops, sea cucumber, squid, and whelk.
  – Crustaceans: barnacle, crab, crawfish, crayfish, ecrevisse, krill, lobster, shrimp, prawn, and crevette.
- Caution should be exercised at salad bars where cross-contamination may occur, as well as restaurants with deep fryers shared with shellfish. It may be found in fish stock, seafood flavoring (crab extract), oyster sauce, fish sauce, sea food dips, sushi, sashimi, surimi, and prawn crackers. In the United States, many pasta sauces contain crustaceans.
- A shellfish allergy is distinct from allergy to fish. Those who are allergic to shellfish do not necessarily react to fish and vice versa.
- Individuals with shellfish allergy should avoid seafood restaurants where cross-contamination may occur.
- When shellfish is cooked, its proteins may become airborne and for some sensitive individuals inhalation of the cooking vapors (especially grilling and on the barbecue) may cause a reaction. Some people have an allergy reaction just with the smell of shellfish.
- The medication glucosamine is derived from the outer coating of shellfish such as crustaceans. Sometimes, chondroitin sulfate is added, usually derived from shark cartilage.

FISH ALLERGY

- Fish is a relatively common and important cause of food allergy, presenting with a high rate of anaphylaxis. The prevalence of fish allergy is dependent on amount of fish eaten in the local diet. In Spain, it is the third most frequent allergy, after milk and eggs in children under 2 years of age.[41] Fish allergy affects about 0.4% of populations with significant consumption of fish.
- Most cases are IgE-mediated due to ingestion, contact, or

inhalation of cooking vapors.[41]

- The major fish allergen across fish species is parvalbumin, which is resistant to thermal and enzymatic degradation. There are reports of sensitization to multiple species (50%–92% of individuals) or monosensitization to a single fish type.[42]
- Cross-reactivity between crustaceans and fish is not reported, so those with fish allergy do not need to avoid shellfish. However, up to 50% of individuals may be sensitive to both shellfish and fish.[43]
- Fish is often found in Worcester sauce and Caesar salad, and is sometimes found in imitation crab products in the form of surimi, a processed food mainly from Alaskan Pollack. Fish is also prevalent in Asian cuisine, which uses fish-based stock for many dishes.

SULFUR DIOXIDE AND SULFITES

- Sulfur dioxide and sulfites are preservatives widely used in food industry as antibrowning agents, antioxidants, and preservatives.
- Sulfites can cause allergy-like symptoms in people with underlying asthma and allergic rhinitis and is as high as 3%–10%.[44] The severity of the reactions varies and steroid-dependent asthmatics, those with marked airway hyperresponsiveness, and children with chronic asthma appear at greater risk.[44] Skin reactions through both topical exposure and ingestion of sulfite additives can also occur.
- EU food labeling rules require prepacked food sold to indicate on the label if it contains sulfur dioxide or sulfites at levels above 10 mg/kg or 10 mg/L (or if one of its ingredients contains it).

Possible Sources of Sulfur Dioxide and Sulfites (Table 70-7)

Drinks: Bottled soft drinks and fruit juice, cordials, cider, beer, wine (including sparkling wine), tea.

TABLE 70-7 Food Additives Containing Sulfites

E220: sulfur dioxide
E221: sodium sulfite
E222: sodium hydrogen sulfite

E224: potassium metabisulfite
E223: sodium metabisulfite
E225: potassium sulfite
E226: calcium sulfite
E227: calcium hydrogen sulfite
E228: potassium hydrogen sulfite
E150b: caustic sulfite caramel
E150d: sulfite ammonia caramel

Other liquids: commercial preparations of lemon and lime juice, vinegar, grape juice, vegetable juices.

Fruit: dried apricots, fruit bars.

Commercial foods: canned vegetables, dried or precut potatoes, gravies, bottled sauces, dressings, guacamole, fruit toppings, maraschino cherries, pickled onions, sauerkraut, pickles, jams, maple syrup, sugar syrups, jellies, biscuits, bread, pie, pizza dough, soup mixes, potato crisps, tomato paste, and tomato puree.

Meats: delicatessen meats, mincemeat, sausages.

Other foods: gelatin, coconut.

- Sulfites may be present in hair colors or bleaches, skin lighteners, fake tanning lotions, shampoos, and shower washes, antiageing creams, facial cleansers, body washes, and moisturizers. They may be found in topical creams and ointments, eye drops, and parenteral medications such as adrenaline.
- There may be individual, varying tolerance to sulfite-containing foods. Some people with mild sensitivity may need to avoid foods with the highest sulfite content only.

LACTOSE-FREE DIET (Tables 70-8–70-12)

NB: This diet is not intended for those with cow's milk protein intolerance.

- The lactose-free diet is intended for individuals with lactose intolerance (with low levels of the enzyme lactase) or the IMD, galactosemia (requiring a lifelong lactose-free diet).
- Patients with lactose intolerance experience GI symptoms such as bloating, flatulence, abdominal pain, and diarrhea which may occur when undigested lactose reaches the colon and is fermented by gas-producing bacteria.[45]
- Galactosemia is a disorder of galactose metabolism causing abnormal glycosylation of glycoproteins and glycolipids, causing

liver failure and cataracts if untreated.

- Intolerance to lactose is individual and people will vary in their ability to absorb lactose-containing foods depending on the degree of lactase deficiency and the form of food substance in which the lactose is ingested.[46] Individuals with galactosemia require a lifelong low-lactose diet.
- Cow's milk contains 4.5%–5.5% lactose. All milk, milk products, and manufactured foods containing milk need to be avoided.
- Constituents of milk are also likely to be found in foods such as biscuits, some sweets, and tinned and processed meats. Many spreads (including reduced fat) and mayonnaise include milk components to improve their flavor. The lactose content of whey derivatives such as whey powder is high, comprising 70% of total solids. In contrast, the lactose content of casein is low, with the U.K. Casein and Caseinates Regulations[47] stating the maximum anhydrous lactose content of casein should not exceed 1% by weight.[48] Butter oil and ghee contain only minimal lactose, but the recommendation is to avoid these.
- Lactose powder is added to a diverse range of food products including bakery goods, confectionery, dry mixes, dried vegetables, and crisps. It is often added to prepared foods to prevent caking or as a coating. It may be used in bakery goods for enhancing browning and, as it has one sixth the sweetness of sucrose, it is added instead of sucrose to reduce the sweetness. It is commonly used as a filler and flowing agent in seasoning mixes for foods such as instant pot noodles. It may act as a carrier for flavors and seasonings and may be added to ham, bacon, and salami. It may also be added to some artificial tabletop or tablet sweeteners.

TABLE 70-8 Lactose Content of Foods[48]

Food	Lactose Content (g/100 mL or g/100 g)
Milk, skimmed	4.4
Milk, whole	4.5
Cream, single	2.2
Yogurt, low fat, fruit	4.4
Butter	0.6
Chocolate, milk	10.1
Ice cream, dairy	5.2

Lactofree milk (Arla)[a]	0.02

[a] Data analyzed by UK Galactosemia Support Group (unpublished data)

TABLE 70-9 Milk, Milk Products, and Milk Derivatives

Milk and milk products
Cow's milk, goat's milk, sheep's milk
Cheese, cream, butter
Ice cream, yogurt, fromage frais, crème fraiche
Chocolate
Milk derivatives
Skimmed milk powder, milk solids, milk protein, non-fat milk solids, separate milk solids
Whey, hydrolysed whey protein, margarine or shortening containing whey, whey syrup sweetener, casein, hydrolysed casein, sodium caseinate, calcium caseinate
Lactose
Buttermilk, butterfat, butter oil, milk fat, animal fat (may be butter), ghee, artificial cream
Cheese powder
Lactose as a filler may be used in:
Flavorings
Table top or tablet artificial sweeteners
Medicines

Milk Substitutes

Breast milk and cow's milk-based infant formulas are contraindicated because they contain lactose. It is important that infants and young children are provided with a suitable nutritionally adequate formula. Several factors influence the choice of milk substitute including its nutritional composition, the child's clinical and nutritional status, safety and palatability of the product, ease of preparation, cost, and availability.

Low-lactose Cheeses Allowed for Galactosemia

A small number of hard mature cheeses are very low in lactose and are considered suitable for galactosemia by the U.K. medical advisory panel for galactosemia. Most cheese types have high levels of casein (which contains no more than 1% lactose) and low levels of whey (which contains 70% lactose). In the United Kingdom, the following low-lactose cheeses are permitted in galactosemia: Emmental, Gruyere, Jarlsberg, Parmigiano Reggiano, and Grana Padano Italian Parmesans with an EU PDO (Protected Designation of Origin) seal on the label. All of these cheeses have been extensively tested for their lactose and galactose content[49] and have been shown to contain minimal lactose and galactose on repeated

analysis. *All other dairy cheeses are not permitted.*

Vitamin and Mineral Supplementation

- It is important to ensure that patients meet the reference nutrient intake (RNI) for all bone-related nutrients. Calcium intake is commonly low in galactosemia[50–52] and lactose-free diets.
- Wherever possible, calcium requirements should be achieved from food sources. Soy infant formula normally provides adequate calcium in the first one to two years if sufficient amounts are taken, but it may be necessary to change to a calcium-enriched soy drink (preferably supplemented with vitamin D), encourage low-lactose cheese, soy yogurts, sardines, mackerel, sesame seeds, lentils, and milk-free fortified bread to ensure adequate calcium intake.
- Dietary assessment should be performed annually to ensure sufficiency. If calcium intake is low, it is necessary to give a calcium supplement and vitamin D to aid calcium absorption.

Lactose in Medications

- Lactose is an excipient with properties that make it ideal as a tablet filler or binder and it is found in many medications including laxatives.
- Some toothpastes and shampoos may contain milk derivatives. No recommendation is given to avoid these. Although a little of these may be swallowed by young children, the amount is unlikely to be significant.

TABLE 70-10 Lactose-Free Diet Guidelines

Foods Allowed	Foods to Avoid
Soy milk and soy products Infant soy formula Liquid soy milk – calcium enriched (not before 1 year of age), rice milk, almond milk, hazelnut milk, potato milk, coconut milk, (cream and soy made from these milks). Soy cheese, soy yogurt, soy desserts	*Milk, milk products and milk derivatives* Cows, goat, sheep and other animal milks (including whole, skimmed, dried, evaporated and condensed milk, breast milk) Yogurt, cream, sour cream, crème fraiche, fromage frais, cream cheese, whipped toppings
Cheese Dairy free cheese	*Cheese* Some hard cheeses
Fats and oils	*Fats and oils*

Milk free margarine Vegetable oils Lard, dripping, suet Salad dressing without cheese or milk	Butter, many margarines and low fat spreads contain milk
Meat and fish Plain beef, lamb, veal, pork, wild game, poultry, liver, kidney, offal, fish, shellfish (fresh or frozen)	*Meat and fish* Many processed meat or fish products such as sausages, salami, frankfurters, burgers, pies, luncheon meat, pates, breaded or battered foods or in sauce may contain lactose Ham and bacon (lactose may occasionally be used as a flavor enhancer – see ingredient label) Breaded/battered/creamed fish
Eggs	*Eggs* Egg custards, crème caramels
Non-meat alternatives Peas, beans, lentils (dried, canned, or frozen e.g., dhal or hummus); all nuts and seeds, tofu, peanut butter.	*Non-meat alternatives* Quorn based products, roasted nuts
Cereal, flour, pasta All grains; wheat, oats, corn, cornmeal, barley, maize, sago, rye, tapioca, bulgar, quinola, millet, arrowroot. Pasta, spaghetti, macaroni, dried noodles, cous cous, rice (plain, boil in the bag, rice noodles) Flour: plain, self-raising; cornflour, rice flour, soy flour Custard power (original), semolina Carob	*Cereal, flour, pasta* Tinned pasta such as spaghetti hoops may contain cheese. Dried pasta mixes. Instant custard powders Pancakes, doughnuts
Breakfast cereals Most are suitable, e.g., Weetabix, Cornflakes, Rice Krispies	*Breakfast cereals* A few cereals may contain chocolate derivatives or milk (muesli and chocolate flavored—particularly) Instant cereals
Bread and yeast products Most bread is suitable Pitta, chapatti, water-based breads (Italian [focaccia, ciabatta]), French, Jewish rye, bagels, wraps, plain rice cakes, Pareve-Jewish bakery products.	*Bread and yeast products* Brioche, naan breads, milk bread, bread rolls, sweet rolls, waffles, muffins, crumpets, teacakes, croissants, may not be suitable.
Cakes, biscuits, crackers Oatcakes, Rye crackers	*Cakes, biscuits, crackers* Many cakes, biscuits and crackers contain milk. Cheesy crackers, cheese thins, cheese oatcakes, cheese cakes, commercial cake

	and cookie mixes.
Desserts Sorbet, jelly, soy desserts, soy ice cream, soy yogurt Homemade soy milk custard or rice pudding	*Desserts* Most desserts contain milk in some form. Ice cream.
Fruit All fresh, frozen, tinned or dried fruit All fruit juices	*Fruit* Fruit bars Chocolate and yogurt dried fruit
Vegetables All fresh, frozen, tinned or dried vegetables (without added milk or milk products) Most dried and tinned pulses, e.g., red kidney beans, chick peas, lentils Tomato paste and puree All vegetable juices Olives	*Vegetables* Baked beans and ready-made vegetable dishes such as coleslaw, potato salad, vegetables in mayonnaise and salad cream. Potatoes or vegetables: creamed, scalloped, mashed with milk or breaded/battered vegetables, packaged dried potato mixes, sauces with milk or cheese sauce.
Savoury snacks Plain popcorn, plain pretzels, plain potato and tortilla chips	*Savoury snacks* Butter popcorn, toffee/chocolate popcorn, ranch-style or cheese-flavored snack pretzels, flavored crisps may not be suitable because they contain cheese or lactose as a filler in the flavoring Dry roasted nuts and popcorn may contain milk/butter
Seasonings Herbs, spices, salt, pepper, vinegar, mustard	*Seasonings*
Soups, gravies and sauces Bouillon, broth, meat, or vegetable stock soups; bisques and chowders made with water or lactose free milk. Stock cubes/concentrates, gravy granules, ketchup, sauces made without milk, salsa, relish, pickles. Sauces made without milk.	*Soups, gravies, and sauces* Tinned, packet, carton soups may contain lactose. Creamed soups. Gravy granules and stock cubes may contain milk Cook–in sauces, guacamole Mayonnaise and salad cream
Sugar, sweet spreads Sugar, honey, jams, jellies, maple and corn syrup, fruit based pouring syrup, molasses.	*Sugar, sweet spreads* Powdered and tablet artificial sweeteners may contain lactose
Confectionery Boiled or hard sweets/candy, most mints, marshmallow, plain fruit lollies, chewing gum, gum drops	*Confectionery* Milk chocolate, most plain chocolate, butterscotch and fudge, toffee Plain or carob chocolate
Drinks Soy milk	*Drinks* Drinking chocolate may contain milk

Milk shake syrup or powders Carbonated, squash, fruit juice Cocoa powder, tea, most coffee Flavored water	Instant milk drinks and malted milk drinks – avoid Instant iced tea, chocolate drink mixes, instant coffee (latte and cappuccino mixes) Milk based nutritional supplements Coffee whiteners
Miscellaneous – used in baking Baking powder, yeast, gelatine, marzipan Food essence and food coloring,	*Miscellaneous – used in baking* Sugar substitutes (sweeteners with added lactose) *Flavorings* Lactose may be used as a 'carrier' for flavorings particularly in crisps and similar snack foods. In sweets lactose is rarely used for this purpose except in some dairy flavors.
Food labels should always be checked because ingredients might change.	

COW'S MILK PROTEIN-FREE DIET

- Cow's milk allergy is the most common food allergy in infants and children. It usually presents in infancy when cow's milk formula or weaning solids containing cow's milk are introduced. The incidence in infants is approximately 2%–3% in developed countries.[56]
- Cow's milk allergy is also seen in 0.5% exclusively breast-fed infants.
- 45%–50% children will outgrow cow's milk allergy by 12 months of age, 60%–75% by 2 years, and 85%–90% by 3 years.[57]
- Approximately 50%–60% infants and children have cutaneous symptoms, 50%–60% have GI symptoms, and approximately 20%–30% respiratory symptoms.[56] Symptoms are diverse and can occur immediately (IgE mediated) or may be delayed (non-IgE mediated).
- Cow's milk allergy should not be confused with lactose intolerance which can present with similar GI symptoms.
- Due to the high possibility that children will grow out of cow's milk allergy, a formal challenge should be considered around 12 months of age or at least by 2 years.

TABLE 70-11 Lactose-Free Formula and Drinks

Lactose-Free Infant Formula Suitable for Infants	
Infant soy formula	Nutritionally complete soy infant formulas, e.g., InfaSoy and Wysoy, are lactose free. One potential disadvantage of soy infant formula is that it is a rich source of isoflavones, particularly genistein and daidzein, and this was identified as a concern by the UK Food Standards Agency.[53]
Infant low-lactose formula	There are a number of low lactose and casein/whey hydrolysate infant formula. All low lactose and protein hydrolysate formulas based on cow's milk protein will undoubtedly contain some residual lactose and the amounts vary. Manufacturers of low lactose casein based formula declare their lactose content at <10 mg/100 kcal (420 kJ) as defined by the European Food Safety Authority (EFSA).[54] Whey hydrolysate formulas are likely to contain a higher concentration of residual lactose and are unsuitable.
Infant amino acid–based formula	These are suitable providing lactose-free infant formulas are used. There are some products designed for children from the age of 6 months which are not nutritionally complete. Weaning products based on L-amino acids and pre-gelatinized rice starch are available from the age of 6 months. These provide a source of supplemental nutrition but are not designed to replace infant formula.
Lactose-free drinks suitable for children >1 year of age	
Vegetable/cereal milks for children over 1 year of age	There are a number of commercial nutritionally enriched plant-, cereal-, and nut-based drinks that can be purchased in supermarkets, specialist shops, or on the internet. Most of them contain approximately 120 mg/100 mL calcium and 0.8 µg/100 mL vitamin D but are low in energy content. There are also nutritionally enriched follow-on soy milks designed for children >1 year with added calcium, iron, vitamin D, some B vitamins and an energy profile similar to cow's milk. Generally, commercial soy drinks cook similarly to cows' milk and are a useful substitute in lactose intolerance. Oat drink is excellent for cereals and savoury dishes, but quite strongly flavored for desserts. Rice drink is thinner and sweetener than cow's milk. It is useful for desserts and sweet drinks. In the UK, it is not recommended for children under 5 years of age, as it contains a trace of arsenic. Coconut milk can be used in most cooked dishes but has a strong coconut flavor.
Milks suitable for lactose intolerance but not galactosemia	
Lactofree	Lactofree *(* Arla), low-lactose dairy drink. About half the lactose is removed by filtration and the remainder is removed enzymatically. It contains a significant quantity of galactose, rendering it unsuitable for galactosemia[55] and for those with cow's milk allergy. It may be useful for lactase deficiency. Lactase enzyme drops, which reduce the lactose content of cow's milk, are also unsuitable for galactosemia and cow's milk allergy but may be useful in lactose intolerance due to lactase

deficiency.

TABLE 70-12 Lactose-Free Sources of Calcium

	Calcium (mg/100 mL/100 g)	Vitamin D (µg/100 mL/100 g)
Calcium/vitamin D–enriched soy drinks	100–140	0.8
Soy dairy-free yogurts	120	Variable
Low-lactose hard cheese	730	0.3
Whitebait	860	Not available
Sardines in oil/brine	500	5
Pilchards	250	14
Sesame seeds	670	0
Red kidney beans	100	0
Bread	170	0
Spinach	170	0
Apricots	73	0

Source: *Roe MA, et al*[48]

Milk Substitutes (Table 70-13)

Removing cow's milk from the diet of an infant whose sole source of nutrition is provided by milk requires careful dietetic management.

Breast-fed infants can react to food allergens secreted in their mother's milk. These sensitive infants can continue to breast-feed if their mother eliminates all dairy foods in her diet. This requires great commitment from the mother and careful dietary management to ensure dietary adequacy, particularly calcium.

It is important that infants who are formula fed commence a suitable nutritionally adequate formula. The choice of milk substitute will depend on the clinical history, the age of the infant, palatability, cost, availability, and cultural restrictions and will vary between individuals.

Older children will continue to require a milk substitute although they remain sensitive to cow's milk protein. A range of products based on soy, rice, oats, almonds, hazelnuts, coconut, and hemp are available. Products fortified with calcium are more suitable for children. See section on lactose-free diets for more detail.

Goat's milk and sheep's milk are often tried as an alternative to cow's milk but because of the high cross-reactivity between cow's milk and other

mammalian milks, they frequently cause similar symptoms.

TABLE 70-13 Cow's Milk-Free Infant Formulas

Type of Formula	Example	Additional Information
Hydrolyzed whey	Pepti (Cow and Gate) Pepti-junior (Cow and gate) Althera (Vitaflo) Alfare (Nestle)	Contains lactose Clinically lactose free / 50% MCT Contains lactose Clinically lactose free / 50% MCT
Hydrolyzed casein	Nutramigen Lipil (Mead Johnson) Pregestimil (Mead Johnson) Similac Alimentum (Abbott)	Clinically lactose free Clinically lactose free / 55% MCT Clinically lactose free / 33% MCT
Amino acid	Nutramigen Puramino (Mead Johnson) Neocate LCP (Nutricia) Aptamil Pregomin AS (Milupa)	Clinically lactose free Clinically lactose free Clinically lactose free
Hydrolyzed soy and meat	Peptide (Nutricia) MCT Peptide (Nutricia)	Clinically lactose free Clinically lactose free/ 75% MCT
Soy	Infasoy (Cow and Gate) Wysoy (SMA) Enfamil Prosobee (Mead Johnson)	Due to the the potential risk associated with phytoestrogens soy formulas are not recommended for infants under 6 months with the exception of infants who refuse hydrolyzed protein formulae or if a vegan formula is required (Food Standards Agency 2003)[53]

	Similac Soy Isomil (Abbott)

Milk-Free Diet (Table 70-14)

All cow's milk, cow's milk products, and manufactured foods containing cow's milk must be removed from the diet. The list of ingredients on tins and packets of processed foods should always be checked. Some sources of milk may not be obvious, so parents and carers need to be taught to recognize the ingredients that may indicate the presence of cow's milk. EU[14] (Directive 2007/68/EC) and United States (Food Allergen Labeling and Consumer Protection Act, 2004[11]) food labeling legislation state that milk should be clearly labeled on food packaging. Any foods containing the following ingredients should be avoided:

Milk	Casein and caseinates
Milk solids	Buttermilk
Nonfat milk solids	Butter
Milk powder	Margarine
Skimmed milk powder	Shortening
Cream	Whey powder
Cheese and cheese powder	Hydrolyzed whey protein
Lactose	Hydrolyzed whey sugar
Yogurt	Whey syrup sweetener

Most major supermarkets will provide a list of their own products that are free from milk but ingredients sometimes change, so checking the labels is still necessary.

Parents and carers should be educated on the importance of strict adherence to the diet. Children should also receive age-appropriate education to aid understanding and compliance. Education should include possible sources of cross-contamination, meal planning, and advice for school and childcare. Many favorite children's foods contain milk, so advice on suitable alternatives and meal plans is helpful (Table 70-15).

TABLE 70-14 Cow's Milk-Free Diet

Foods Allowed	Foods to Avoid
Milk substitutes Infants: breast milk, hydrolysate formulas, amino acid formulae, soy formulas (over 6 months only)	*Milk, milk products, and milk derivatives* Normal infant formulae Cows, goat, sheep and other animal milks (including whole, skimmed, dried, evaporated

Over 12 months: Liquid soy milk–calcium enriched, rice milk, almond milk, hazelnut milk, hemp milk, coconut milk	and condensed milk) Yogurt, cream, sour cream, crème fraiche, fromage frais, cream cheese, whipped toppings
Cheese Dairy-free cheese	*Cheese* All cow's, goat and sheep cheeses
Fats and oils Milk-free margarine Vegetable oils Lard, dripping, suet Salad dressing without cheese or milk	*Fats and oils* Many margarines and low fat spreads contain milk
Meat and fish Plain beef, lamb, veal, pork, wild game, poultry, liver, kidney, offal, fish, shellfish (fresh or frozen)	*Meat and fish* Many processed meat or fish products such as sausages, salami, frankfurters, burgers, pies, luncheon meat, pates, breaded or battered foods or in sauce may contain milk Breaded/battered fish and fish in sauce
Eggs	*Eggs* Scrambled egg, omelette, scotch egg, egg custards, crème caramels
Non-meat alternatives Peas, beans, lentils (dried, canned, or frozen e.g., dhal or hummus); all nuts and seeds, tofu, peanut butter.	*Nonmeat alternatives* Quorn-based products, roasted nuts
Cereal, flour, pasta All grains; wheat, oats, corn, cornmeal, barley, maize, sago, rye, tapioca, bulgar, quinola, millet, arrowroot. Pasta, spaghetti, macaroni, dried noodles, cous cous, rice (plain, boil in the bag, rice noodles) Flour: plain, self-raising; cornflour, rice flour, soy flour Custard power (original), semolina Carob	*Cereal, flour, pasta* Tinned pasta such as spaghetti hoops may contain cheese. Macaroni cheese Dried pasta mixes. Instant custard powders Pancakes, doughnuts
Breakfast cereals Most are suitable, e.g., Weetabix, Cornflakes, Rice Krispies	*Breakfast cereals* A few cereals may contain chocolate derivatives or milk (muesli and chocolate flavored – particularly) Instant cereals
Bread and yeast products Most bread is suitable Pitta, chapatti, water-based breads (Italian [focaccia, ciabatta], French, Jewish rye, bagels, wraps, plain rice cakes, Pareve-Jewish bakery	*Bread and yeast products* Brioche, naan breads, bread sticks, garlic bread, milk bread, bagels, bread rolls, sweet rolls, waffles, muffins, crumpets, teacakes, croissants, may not be suitable.

products.

Cakes, biscuits, crackers Homemade biscuits and cakes made with cow's milk free ingredients Oatcakes, Rye crackers	*Cakes, biscuits, crackers* Many cakes, biscuits and crackers contain milk. Cheesy crackers, cheese thins, cheese oatcakes, cheese cakes, commercial cake and cookie mixes.
Desserts Sorbet, jelly, soy desserts, soy ice cream, soy yogurt Homemade soy milk custard or rice pudding	*Desserts* Yogurt, milk puddings, ice cream, fromage frais, mousse, instant desserts, blancmange, pies, crumbles and sponges
Fruit All fresh, frozen, tinned or dried fruit All fruit juices	*Fruit* Fruit bars Chocolate and yogurt dried fruit Fruit pie fillings
Vegetables All fresh, frozen, tinned or dried vegetables (without added milk or milk products) Most dried and tinned pulses, e.g., red kidney beans, chick peas, lentils Tomato paste and puree All vegetable juices Olives	*Vegetables* Baked beans and ready-made vegetable dishes such as coleslaw, potato salad, vegetables in mayonnaise and salad cream. Potatoes or vegetables: creamed, scalloped, mashed with milk or breaded/battered vegetables, waffles, potato shapes, wedges, packaged dried potato mixes, sauces with milk or cheese sauce.
Savory snacks Plain popcorn, plain pretzels, plain potato and tortilla chips	Savory snacks Butter popcorn, toffee/chocolate popcorn, ranch-style or cheese-flavored snack pretzels, flavored crisps may not be suitable because they contain cheese in the flavoring Dry roasted nuts and popcorn may contain milk/butter
Seasonings Herbs, individual spices, salt, pepper, vinegar, mustard	*Seasonings* Blended spices
Soups, gravies, and sauces Bouillon, broth, meat, or vegetable stock soups; bisques and chowders made with water. Stock cubes/concentrates, gravy granules, ketchup, sauces made without milk, salsa, relish, pickles.	*Soups, gravies, and sauces* Tinned, packet, carton soups may contain milk, creamed soups. Gravy granules and stock cubes may contain milk Cook-in sauces, guacamole Mayonnaise and salad cream
Sugar, sweet spreads Sugar, honey, jams, marmalade, jellies, treacle, maple and corn syrup, fruit-based pouring syrup, molasses.	*Sugar, sweet spreads* Lemon curd, chocolate spread, sandwich spread, peanut butter

Confectionery Boiled or hard sweets/candy, most mints, marshmallow, plain fruit lollies, chewing gum, gum drops Some plain chocolate, carob chocolate	*Confectionery* Milk chocolate, butterscotch, toffee and fudge
Drinks Milk substitute Milk shake syrup or powders Carbonated, squash, fruit juice Cocoa powder, tea, coffee Flavored water	*Drinks* Drinking chocolate may contain milk Instant milk drinks and malted milk drinks Instant iced tea, chocolate drink mixes, latte and cappuccino mixes Milk-based nutritional supplements Coffee whiteners
Miscellaneous – used in baking Baking powder, yeast, gelatin, marzipan Food essence and food coloring	*Miscellaneous – used in baking* Artificial sweeteners unless known to be milk free Blended spices

TABLE 70-15 Example of Meal Planning for a 5-Year-Old Child

Normal food intake	Milk-free menu
Breakfast	*Breakfast*
Weetabix with cow's milk	Weetabix with soy milk
Toast and butter with jam	Toast and milk free margarine with jam
Fruit juice	Fruit juice
Lunch	*Lunch*
Cheese sandwich	Chicken sandwich
Flavored crisps	Plain crisps
Chocolate bar	Milk-free cereal bar
Dinner	*Dinner*
Roast chicken	Roast chicken
Mashed potato with milk and butter	Mashed potato with soy milk and milk-free margarine
Vegetables	Vegetables
Yogurt and fruit	Soy yogurt and fruit

Nutritional Adequacy

Calcium: calcium supplements may be necessary if a calcium-enriched milk substitute is not taken or taken in adequate amounts. Other nondairy foods contain calcium but often cannot provide sufficient amounts to meet requirements. Table 70-12 illustrates other sources of calcium.[48]

Energy: a cow's milk-free diet can be low in energy. Dairy foods are major components of children's diets and provide a significant percentage of energy intakes. Elimination of milk, cheese, cream, milk-containing

desserts, snacks, and chocolate can lower energy intakes. Suitable alternatives need to be included and close monitoring of weight gain and growth is advisable.

Tablets and Medicines

Some tablets and medicines contain milk products. Parents and carers should be advised to check with their doctor and pharmacist to ensure medicines are suitable.

Cow's Milk Challenge

Due to the high possibility that children will grow out of cow's milk allergy, a formal challenge should be considered around 12 months of age or at least by 2 years. Informal challenges can sometimes occur at home before scheduled if children inadvertently or intentionally consume milk or a milk-containing food and this sometimes supersedes the need for a formal challenge. If there is a possibility of a severe reaction, the challenge should take place in hospital under medical supervision otherwise milk can be introduced gradually into the diet in incremental amounts to assess tolerance.

DIETS FOR GI DISEASE

In GI diseases, dietary manipulation and special diets are frequently the primary treatment. This may be a short course of treatment, a temporary requirement for a special diet, or sometimes a lifelong change.

CELIAC DISEASE

Celiac disease is an autoimmune condition triggered by a reaction to gluten. It is a relatively common condition with the prevalence estimated at 0.5%–1.0% in Europe. In children with celiac disease, ingestion of gluten damages the villi of the small intestine and the only treatment is a lifelong gluten-free diet.

Gluten-Free Diet (Table 70-16)

- Gluten is a protein found in certain cereal grains. All wheat, rye, and barley needs to be excluded from the diet, and in some cases oats. These grains form the base of bread, pasta, biscuits, cakes, and many breakfast cereals so excluding them from a child's diet

can be challenging. Oats contain a similar protein but are safe for most children with celiac disease but there remains controversy. Pediatric studies suggest no adverse effects but the quantity eaten may have been lower than prescribed.[57] Oats can generally be consumed but care must be taken to ensure oats are free from contamination with wheat, rye, or barley from the milling process.

- A gluten-free diet should be started as soon as possible after the diagnosis of celiac disease has been made. Until recently this diagnosis required endoscopic and histological confirmation. European and British guidelines suggest that endoscopy can be avoided in selected symptomatic children with raised tTG > 10 times upper limit of normal and either DQ2 or DQ8 HLA typing.[58,59]
- A gluten-free diet requires extensive dietary changes and parents and carers need careful education to ensure strict adherence. In turn, this leads to resolution of symptoms and normal growth and development.
- Many foods are naturally gluten free and are included in the diet freely. These include fresh meat, eggs, dairy products, fruit, vegetables, and other cereals including rice, maize, tapioca, and buckwheat.
- As well as the obvious sources (bread, pasta, biscuits, cakes, breakfast cereals), gluten may unexpectedly be found in processed foods where flours are used as thickening agents, fillers, and as carriers for flavorings. Other manufactured foods can become contaminated with gluten during production processes and may also need to be avoided as even the smallest amounts of gluten may cause symptoms and gut damage. As a result, all manufactured foods need checking to confirm they are gluten free. Similar foods made by different manufacturers may differ, so it is important that this is checked and the correct brands are used. Celiac UK produce a Food and Drink Directory annually for members that is regularly updated listing suitable gluten-free foods. This is available electronically and has recently been supplemented by a mobile phone app.
- Contamination can also occur during food preparation at home where gluten-containing foods are eaten by other members of the family. Advice needs to be given to avoid this including using separate bread boards for gluten-containing and gluten-free

breads, using a separate toaster or toaster bags, and avoiding contamination of butter and jam with knives and spoons. All surfaces and cooking utensils also need to be washed well to remove crumbs.

- A wide range of commercially produced gluten-free foods are available. These include staple food items such as breads, pasta, plain biscuits, crackers, and flour as well as other luxury items such as cakes, chocolate biscuits, pizza bases, cookies, muffins, cake mixes, and seasonal foods. In 2009, legislation reduced the permitted level of gluten in foods to be labeled as "gluten free" from 200 ppm (parts per million) to 20 ppm which came into effect in 2012.[60] In the United Kingdom, a range of gluten-free products are available free on prescription. The quantities available are often at the discretion of the prescribing doctor, but guidelines suggest the approximate monthly requirement for children of different ages.[61]

School and Nursery

The school should be made aware that a child has celiac disease, particularly for young children gluten-free school lunches can usually be arranged or packed lunches can be taken. Schools should ensure that children do not swap foods at mealtimes and particular care needs to be taken for any cooking lessons, school trips, or parties.

TABLE 70-16 Gluten-Free Diet

	Gluten Free	Check Ingredients	Gluten Containing
Milk and dairy products	Milk, cheese, cream, plain yogurt, plain fromage frais	Flavored yogurts and fromage frais, rice milk and soy milk, soft and processed cheeses	Yogurt with muesli or wholegrains
Meat and Poultry	Fresh meats and poultry, cured and smoked meats	Meat or poultry in sauce, processed meats eg sausages and burgers	Meat or poultry cooked in batter or breadcrumbs, breaded ham, faggots, rissoles, meat pie
Meat alternatives	Plain tofu	Marinated tofu, soy mince, Quorn products	

Fish and shellfish	Fresh fish and shellfish	Tinned fish, fish in sauce	Fish in breadcrumbs and batter
Eggs	Boiled, fried, smoked and scrambled egg, omelette		Scotch eggs
Fats and oils	Butter, cooking oil, ghee, margarine and low fat spreads		Suet
Fruit and nuts	Fresh, dried, canned and frozen fruit Plain or roasted salted nuts	Fruit pie fillings, dry roasted and coated nuts	Fruit pies
Vegetables	Fresh, frozen, dried and tinned vegetables	Baked beans, vegetables in sauce, cauliflower cheese, potato waffles and potato shapes, vegetable burgers,	Battered vegetables, samosas, vegetable pies, croquette potatoes
Flours and Grains	Buckwheat, corn, millet, rice, sago, tapioca, polenta, quinoa, Gluten free flour, gram flour, potato flour, chestnut flour, cornflour	Oats	Barley, wheat, rye, semolina, bulgar wheat, couscous, spelt, durum wheat
Bread, Cakes and Biscuits	Gluten free bread, rolls, pizza bases, muffins Gluten free cakes, biscuits and crackers Gluten free bread and cake mixes	Meringues, macaroons, rice cakes	Bread, cakes and biscuits made with wheat, rye or barley flour
Breakfast cereals	All cereals labeled as gluten free	Porridge oats, Corn and rice based cereals and those containing barley malt	Wheat-based cereals, muesli
Pasta and Noodles	Gluten free pasta and noodles, rice noodles and pasta		Fresh, dried, canned wheat pasta and noodles
Savoury snacks	Plain potato crisps, plain rice cakes, homemade popcorn	Flavored crisps, flavored popcorn and flavored rice cakes	Wheat rye and barley based snacks Pretzels
Soups and sauces	Homemade soups, mint sauce, Worcestershire sauce, tomato puree	Brown sauce, ketchup, ready-made mustard, mayonnaise, salad cream,	Soy sauce

		packet and jars of sauce, pickles, canned and packet soups, gravy, peanut butter, sandwich spread	
Desserts	Jelly, fresh and tinned fruit, homemade gluten free pies, puddings and desserts	Ice cream, mousse, instant desserts, custard powder, imitation cream	Sponge puddings, pies, semolina and macaroni pudding, ice-cream wafers and cones
Sweets and Chocolate		All sweets and chocolate, seaside rock	Chocolate bars containing biscuit
Beverages	Tea, coffee, milk, fruit juice, cordials, cocoa	Drinking chocolate, milkshake flavorings, vending machine hot drinks, fizzy drinks (especially if cloudy)	Horlicks, Ovaltine and other malted milk drinks, barley waters
Miscellaneous	Honey, jam, marmalade, golden syrup, treacle, yeast extract, vinegar, herbs, pure spices, cream of tartar, bicarbonate of soda, salt, freshly ground pepper	Mincemeat, Mustard powder, blended spices, baking powder, curry powder, ground pepper, stock cubes and powders, gravy granules	

Eating Out

Eating out at restaurants and takeaway food can be challenging for children with celiac disease. Popular children's foods such as pizzas, burgers, sausages, and breaded fish and meat products are unsuitable. Careful planning and discussion with the chef are needed to identify gluten-free menu choices and to ensure that there is no cross-contamination. Some restaurants offer the option to take in gluten-free pizza bases or gluten-free burger buns, but care must be taken that these are not contaminated by gluten-containing foods prepared and cooked in the same kitchen. Deep fat fryers used to cook gluten-containing foods should not be used to fry gluten-free options. Many chefs are happy to provide a gluten-free option if there is nothing suitable on the menu.

Adherence

Adherence to the diet is influenced by a number of factors including accurate information about the diet and the availability and cost of gluten-free foods. The dietitian needs to provide individual advice for children to aid compliance. If children are unwell at the time of their diagnosis, compliance is often helped when the gluten-free diet is associated with resolution of troublesome symptoms. Children who have less troublesome symptoms or who are identified through screening may find compliance harder, particularly if they feel no difference after commencing a gluten-free diet. Inadvertent or intentional exposure to gluten may cause abdominal pain and diarrhea, which acts as an aid to compliance. However, many children will have no symptoms after gluten consumption and find compliance harder to achieve. In these cases, discussions about the importance of compliance and the long-term risk of complications are needed. Education for the extended family may also be helpful.

Diabetes and Celiac Disease

Celiac disease is more common in children that have type 1 diabetes. Between 2% and 10% of people with celiac disease will also have type 1 diabetes. Usually, the diagnosis of diabetes is made first and later children are found to have celiac disease either through screening or investigation of GI symptoms. After diagnosis, absorption of nutrients improves, including carbohydrate, and so, blood glucose levels should be monitored closely and it may be necessary to adjust insulin doses.

Gluten Challenge

Routine rechallenge is not required if diagnosis is secure. If initial diagnosis is uncertain and the child is on a gluten-free diet, then further testing is recommended.[59] HLA testing can identify when a challenge may be required. If HLA-DQ2 or HLA-DQ8 is positive, a formal gluten challenge will be required for clarification of the diagnosis. A normal diet containing gluten should be consumed for three months, or a minimum of four to six weeks if symptoms are troublesome. It may be confusing for a young child to comprehend why they can temporarily eat gluten-containing foods when they usually have a gluten-free diet. This can potentially affect compliance if the restricted diet needs to be resumed after a challenge. For these children, gluten powder can be used for the challenge, with the child continuing to follow a gluten-free diet. The amount of gluten required will vary with age, but it is estimated that an intake of 10–15 g gluten a day is sufficient. Biopsy is repeated if serology

becomes positive or children are symptomatic.

Support Groups

There are a number of support groups worldwide. These groups provide educational materials, practical tips, and support and recipes for children and their families and also fund research into celiac disease.

United Kingdom: www.celiac.org.uk
United States: www.celiac.org
Worldwide: www.celiac.org/celiac-disease/resources/celiac-associations-around-the-world/

CARBOHYDRATE INTOLERANCE

Carbohydrate intolerance in infants and children may be a primary or secondary disorder. Malabsorbed carbohydrate results in diarrhea that may be mild or severe leading to dehydration.

LACTOSE INTOLERANCE

- Lactose is a disaccharide sugar present in milk. It is broken down by the enzyme lactase to glucose and galactose. Lactase enzyme is normally found in the intestinal brush border.
- Lactose intolerance is the result of a lactase deficiency and should not be confused with cow's milk allergy. Congenital lactase deficiency is rare and high levels of the enzyme are found in infants who rely on milk as a primary source of nutrition. After the age of 2, when breast-feeding or bottle-feeding has stopped, children are less reliant on milk and dairy products and lactase levels decline. In some population groups, particularly East and South East Asians, Africans, and native Americans, hypolactasia is significant enough to cause lactose intolerance. Secondary lactose intolerance can occur at any age and results from an injury or insult to the intestinal mucosa and is often transient. This commonly occurs after gastroenteritis but also in other GI disease states such as celiac disease and inflammatory bowel disease.
- Symptoms of lactose intolerance result from maldigestion and fermentation of lactose and include diarrhea, bloating, flatulence and acidic stool, and perianal excoriation.

- Dietary lactose restriction is required to manage the symptoms of lactose intolerance, although commercially produced lactase substitutes are available. Details of the lactose-free diet are covered earlier.
- Commercial lactase substitutes are available to help digest the lactose in food and drinks. The lactase substitute comes in liquid form and can be taken before a meal or added to milk. Both lactase enzyme drops and capsules are available from most health food shops.

SUCRASE ISOMALTASE DEFICIENCY

This is a rare autosomal recessive condition characterized by an absence of the disaccharidase sucrease and an absence or reduction in isomaltase activity. Malabsorption of carbohydrate results in diarrhea, distension, flatulence, and abdominal pain. Breast milk and normal infant formulae are tolerated well so presentation is usually at the time of weaning after the introduction of foods containing sucrose and starch. Diagnosis can be made with a positive hydrogen breath test or low-disaccharidase activity in intestinal biopsy specimens.

TABLE 70-17 Sucrose Content of Fruits and Vegetables

Low Sucrose (≤0.1 g/100 g)	Moderate Sucrose (0.2–0.5 g/100 g)	High Sucrose (>0.5 g/100 g)
Grapes, avocado pear, currants, raisins, sultanas,dates, pomegranate, lime, lemon, blackberries, blueberries, rhubarb, William's pear, kiwi, cranberries, lychees, gooseberries, Sharon fruit Asparagus, aubergine, baby sweetcorn, beansprouts, broccoli, cabbage, cauliflower, celeriac, cress, cucumber, endive, garlic, kale, lettuce, marrow, mushrooms, peppers, radish, frozen spinach, swede, tomato, watercress	blackcurrants, cherries, raw figs, grapefruit segments in juice, raspberries, strawberries, guava, Commice pear, fruit cocktail in juice Celery, courgettes, fresh and canned spinach, spring onions, turnip, pumpkin, yam, leeks, green beans, runner beans, lentils, fresh garden peas, mange tout, processed peas	Apple, banana, pear, orange, peach, nectarine, pineapple, honeydew melon, apricot, tangerine, Satsuma, plums, melon, dried figs Brussel sprouts, corn on the cob, frozen and canned corn, carrots, broad beans, onions, squash, frozen and canned peas, frozen mixed vegetables

Source: Holland B et al.[62]

- Dietary management usually requires a low-sucrose diet and a restriction in starch foods. The tolerance of starch is variable and starchy foods can be included by some children but restricted in others.
- Sucrose (white sugar) is added to many foods but is also found naturally in many fruits and vegetables. Sucrose is initially excluded from the diet to resolve symptoms then introduced to the level of tolerance. Added sugar should be avoided and sugary drinks, confectionary, cakes, biscuits, and desserts should also be excluded. Care should be taken to read the labels of manufactured foods, drinks, and medicines that may unexpectedly contain large amounts sucrose. Fruit and vegetables high in sucrose should be avoided and replaced with lower sucrose alternatives (Table 70-17).
- Starch restriction should be advised initially and then starch reintroduced to tolerance. An exchange system of measured amounts of starch-containing foods can be helpful to ensure tolerance is not exceeded. Tolerance increases with age and many older children consume a normal amount of dietary starch with no side effects.
- Patient noncompliance is common. Children may relax their diet in order to consume a wider variety of foods. They will tolerate some symptoms that are not dangerous but should be avoided if this practice leads to diarrhea and weight loss.
- Enzyme replacement therapy with Sucraid® offers a pharmacologic alternative to sucrose-free diets. Sucraid is an effective option for the management of sucrase deficiency that reduces the need for dietary restrictions and the symptoms of sucrose isomaltase deficiency.[63]

GLUCOSE–GALACTOSE MALABSORPTION

Glucose–galactose malabsorption is an inherited disorder characterized by the small intestine's inability to transport and absorb the monosaccharides, glucose and galactose. Infants fed breast milk or normal infant formulae containing lactose will present in the first few days of life with severe watery diarrhea, dehydration, and failure to thrive.

- The diarrhea stops when feeds are withheld, but unlike in other congenital and secondary carbohydrate intolerances, diarrhea will continue when the infant is given oral rehydration solutions

containing glucose.

- Dietary management requires the exclusion of glucose and galactose from the diet and all carbohydrate sources containing these monosaccharides (Table 70-18). This includes lactose, sucrose, dextrose, maltose, starch, and glucose polymer. Fructose is the only carbohydrate tolerated and infants should be swapped to the formula Galactomin 19 (Nutricia). Weaning should start at the usual time with very low carbohydrate foods. The diet is extremely restricted, although tolerance may increase slightly with age.

Oral rehydration solutions containing glucose cannot be given to infants and children with glucose–galactose malabsorption. If a child develops gastroenteritis and Galactomin 19 is not tolerated, it is important that either an oral solution containing fructose is substituted or intravenous fluids are given until feeds are tolerated.

All medicines should be free of carbohydrate. The ingredients should always be checked by the pharmacist before given.

CROHN'S DISEASE

Crohn's disease is a chronic incurable inflammatory disease of the GI tract. Approximately 25% of cases of Crohn's disease are diagnosed during childhood and adolescence.[64] Nutritional problems are common in pediatric Crohn's disease. Studies show weight loss in 88% and growth failure in 19% children at diagnosis.[65]

Treatment strategies in pediatric Crohn's disease are needed to manage acute exacerbations and for maintenance of remission and nutritional therapy has an important role both as a primary treatment and as an adjunct to medical and surgical management.

Exclusive Liquid Diet Therapy (LDT) is often the first-line treatment for children with active Crohn's disease (Table 70-19). Normal food is discontinued and replaced with a nutritional complete liquid formula usually for a period of six to eight weeks, but sometimes up to 12 weeks.[66] Full feeds are achieved in the first three to four days with an initial goal for volume based on expected energy requirements. This requires regular review and adjustment throughout the treatment to achieve timely nutritional rehabilitation and to satisfy hunger. A prospective study concluded that the median energy intake of children receiving an exclusive liquid diet for management of Crohn's disease was nearer 120% expected

requirements.[67]

TABLE 70-18 Low-Glucose/Galactose–Containing Foods

	Foods Allowed
Milk substitute	Galactomin 19 (Nutricia)
Protein Sources	Meat, poultry, fish, egg
Fruits	Avocado pear, rhubarb, lemon juice
Vegetables	Asparagus, bamboo shoots, beansprouts, broccoli, celery, cucumber, fennel, lettuce, mushrooms, marrow, spinach, watercress, spring greens
Miscellaneous	Fructose, sugar-free jelly, sugar free drinks, Marmite, Bovril, salt, pepper, herbs, spices

- All solid food should be stopped for the duration of the treatment to induce remission.[68] Some centers only permit additional water whereas others permit clear fluids, boiled sweets, chewing gum, and ice lollies.
- At the end of the course of treatment, food is reintroduced. There is no evidence to exclude single or multiple foods while reintroducing diet after LDT.
- Once in remission, it is important to maintain the nutritional benefits, prolong remission, and achieve prolonged linear growth. There is no evidence to suggest that eating or avoiding specific foods influences the severity of the disease or the frequency of relapses and a balanced diet with adequate calories, protein, fluid, and micronutrients is usually recommended.
- A high energy diet with food fortification, nutritional complete sip feeds, energy supplements, and homemade “milkshakes” can all be used to improve nutritional intakes. Overnight nasogastric feeding may also be necessary and has been shown to improve linear growth[69] and to maintain remission.[70]

INBORN ERRORS OF METABOLISM

Common IMDs treated by lifelong dietary management are responsible for a collection of diverse clinical conditions. Each condition may present at different ages with variable severity and outcome. Examples of dietary treatment orders will be given for the following disorders:

1. Avoidance/reduction of dietary precursors of toxic metabolites includes phenylketonuria (PKU), galactosemia (example of low-lactose diet given in section on lactose intolerance), and minimal fructose, sucrose, and sorbitol diet.
2. Modified low-fat diet, use of medium-chain triglyceride (MCT) supplements, and prevention of fasting for long-chain fatty acid disorders (very long chain acyl Co-A dehydrogenase deficiency, long chain acyl CoA dehydrogenase deficiency).

LOW-PHENYLALANINE DIET IN PKU

- Dietary treatment is essential in PKU (see Table 70-20).
- It aims to correct abnormal biochemistry by (1) decreasing the phenylalanine load on the affected pathway and (2) supplementation with tyrosine that is deficient due to the metabolic block.
- Diet may be the sole therapy or used in combination with the cofactor sapropterin.
- The diet is constructed from a combination of a phenylalanine-free L-amino acid supplements, a restricted and controlled amount of phenylalanine, and low protein foods (natural and specially manufactured foods), with appropriate vitamin and mineral supplementation. Application of dietary management varies between countries and centers.

TABLE 70-19 Suitable Products for Exclusive Liquid Diet

Type of Formula	Examples
Elemental formula:	Elemental 028 Extra (Nutricia)
Disease specific polymeric formula:	Modulen IBD (Nestles) Alicalm (Nutricia) *1 kCal/mL* Paediasure (Abbott) Fortini 1.0 (Nutricia) Frebini (Fresenius) Ensure (Abbott) Fresubin (Fresenius) Resource (nestles) *1.5 kCal/mL*
Standard polymeric sip feed:	Paediasure Plus (Abbot) Fortini (Nutricia)

Standard polymeric tube feed:	Fortisip (Nutricia) Resource Energy (Nestles) Ensure Plus (Abbot) *1 kCal/mL* Nutrini (Nutricia) Paediasure (Abbot) Frebinbi (Fresenius) Ensure (Abbot) Tentrini (Nutricia) Nutrison (Nutricia) Clinutren Junior powder (Nestles) *1.5 kCal/mL* Nutrini Energy (Nutricia) Paediasure Plus (Abbot) Frebini Energy (Fresenius) Tentrini Energy (Nutricia) Ensure Plus (Abbot) Nutrison Energy (Nutricia) Clinutren Junior powder (Nestles)

TABLE 70-20 Goals of Dietary Treatment in Phenylketonuria

To restrict foods high in natural protein to prevent excess accumulation of phenylalanine. Foods such as meat, fish, eggs, cheese, nuts and seeds are not permitted (except patients with a mild PKU phenotype).
To limit the amount of natural protein to maintain phenylalanine within the target treatment range. The types of natural food sources allocated for substrate amino acids are usually from cereal, potato and potato products, some vegetables and milk products.
Provision of phenylalanine-free L-amino acids to meet at least safe levels of protein/nitrogen requirements.
Provision of the conditionally indispensible amino acid tyrosine that may become deficient as a result of the enzyme block and dietary treatment.
To maintain a normal (but not excessive) energy intake by encouraging use of foods naturally low in protein and specially manufactured low protein foods such as bread and pasta.

Source: Adapted from MacDonald et al.[71]

High Protein/Phenylalanine Foods to be Avoided

Foods that are high in protein and so avoided include all kinds of meat, fish, eggs, cheese derived from animal milk (cow, goat, sheep), nuts, seeds, foods made from flour or Quorn (a meat substitute made from protein of fungal origin), and anything containing aspartame sweetener (aspartame consists of phenylalanine and aspartate linked together, and is metabolized to these separate amino acids). Sweets and jellies containing gelatin should also be avoided.

Phenylalanine Tolerance and Prescription

- Phenylalanine tolerance is the amount of phenylalanine that maintains the blood phenylalanine concentrations within a target treatment range. The amount of dietary phenylalanine tolerated from natural food sources will vary depending on the severity of the patient's phenotype, age, target blood phenylalanine concentrations, and adjunct drug therapy. The amount of phenylalanine from breast milk, infant formula, or food should be systematically titrated until phenylalanine is stable and within the target treatment range. Most patients with severe PKU tolerate between 4 and 10 g/d natural protein (150–500 mg/d phenylalanine).
- Systems for allocating phenylalanine vary throughout Europe.[72] Some countries allocate phenylalanine in daily amounts where all phenylalanine-containing foods are estimated in the diet.[72] In the United Kingdom, the amino acid is allocated in the form of a 50 mg phenylalanine exchange system (50 mg ≅1 g natural protein). The protein content of most foods contain 5% phenylalanine (vegetables and fruits are an exception, with the protein content in most vegetables containing 3%–4% phenylalanine and 3% in fruits).[73] Other countries may use a variation of the phenylalanine exchange system.[72]
- Exchange foods are generally sourced from low-biological protein foods such as potatoes, peas, sweet corn, rice, pasta, and breakfast cereals, although sometimes milk products such as yogurt and cream cheese may be used depending on phenylalanine tolerance. It is recommended that "counted" sources of phenylalanine are weighed.

TABLE 70-21 Foods That Can be Eaten Without Measurement/Restriction in PKU

Food Groups	Examples of Suitable Foods That Can be Eaten Without Measurement
Fruits and vegetables	Studies suggest the fruit and vegetables that can be given without measurement are those containing ≤ 50 mg/100 g phenylalanine[74,75,76] although practices vary from country to country.
Fats	Butter, margarine, ghee, lard, dripping and vegetable oils.
Starches	Cassava flour, arrowroot, cornflour, custard powder, potato starch,

	sago, tapioca, and tapioca starch. Some protein-free low protein cheese replacements based on food starches and oils are available.
Sugars	Sugar, glucose, jam, honey, marmalade, golden syrup, maple syrup, fruit sorbets, ice lollies, sweets containing <0.3 g protein/100 g.
Miscellaneous	Vegetarian jelly, agar-agar, salt, pepper, herbs, spices and vinegar; food essences and coloring; fruit/vegetable 'table top' sauces and 'cook in sauces' containing <1.0 g protein/100 g.
Drinks	Water, squash, lemonade, cola drinks and fruit juice, black tea, fruit tea, green tea, coffee, tonic water, soda water and mineral water, providing all are aspartame free. Rice drink is very low in protein but is unsuitable for children under 5 years of age due to trace amounts of arsenic. Other plant drinks e.g., oat milk, contain some phenylalanine which should be calculated in the diet.
Low-protein special foods	A selection of low protein breads, flour mixes, pizza bases, pasta, biscuits, egg replacers, and milk-replacements are available. Other low-protein specialist products contain some natural protein/amino acids e.g., low protein cheese substitutes, snack pots, burger mixes, milk replacements, but can be incorporated into the diet but as part of the natural protein exchange system. Any special food containing ≥0.5 g/100 g of protein should be calculated into the natural protein allowance.

Foods That Can Be Eaten Without Measurement

There are some foods that are naturally very low in protein so can be eaten without measurement (Table 70-21). It is a good practice to encourage five portions of low-phenylalanine fruits and vegetables daily. The range and availability of low-phenylalanine vegan foods (through supermarkets and the internet) is extending, thereby, increasing the choice of foods available.

Phenylalanine-Free L-Amino Acids

- The provision of additional phenylalanine-free L-amino acid supplement is essential to prevent protein deficiency and optimize metabolic control. In the majority of patients, *it is likely that precursor-free amino acids will supply >75% of the total protein intake.*[77] The optimal protein intake in PKU, accounting for inefficiency of precursor-free amino acids, is not agreed.
- It is best to give L-amino acids in small frequent doses, three to four times spread evenly throughout the day rather than only once or twice daily,[78] and ideally together with natural protein and a carbohydrate source.
- Most supplements contain additional vitamins, minerals, and

trace minerals. Many also contain essential fatty acids and omega-3 LC-PUFA's such as docosahexaenoic acid (DHA). If phenylalanine-free L-amino acids do not contain micronutrients, supplements should be administered separately, although adherence may be suboptimal.[79]

- Blood phenylalanine concentrations are monitored regularly to ensure they are maintained within target treatment range. Growth, clinical, and biochemical nutritional status is also monitored carefully.

VERY LOW-FRUCTOSE DIET FOR HEREDITARY FRUCTOSE INTOLERANCE

- Hereditary fructose intolerance (HFI) is a rare, inherited disorder of fructose metabolism, resulting from deficiency of aldolase B, the main enzyme responsible for hepatic metabolism of dietary fructose.[80] It is reported to affect 1 in 20,000 to 1 in 30,000 newborns in Europe.[80]
- Children with HFI develop symptoms after the introduction of fruits, vegetables, and particularly table sugar (the fructose–glucose disaccharide sucrose) to their diet. This is often between 4 and 8 months of age.[81] In HFI, accumulation of fructose-1-phosphate causes inhibition of glycogen breakdown and glucose synthesis, thereby, causing severe hypoglycemia following fructose ingestion. It can lead to hepatomegaly, jaundice, bleeding tendency, and renal tubular dysfunction.
- Some patients may not be diagnosed until later in life. Older patients may develop an aversion to fructose-containing foods after experiencing abdominal pain, nausea, and vomiting after fructose ingestion. Some may remain asymptomatic into adulthood, with significant absence of dental caries and a positive family history as only disease indicators.[82]
- It is treated by a very strict exclusion of dietary fructose, sucrose, and sorbitol but it is not possible to exclude these sugars completely (Tables 70-22 and 70-23).
- Different thresholds of fructose intake leading to the development of symptoms vary from 40 to 250 mg/kg/d.[81] Some have suggested it should be as little as 1500 mg/d.[83] The diet suggested in Table 70-24 provides less than 2 g/d.[84] The average

amount of fructose consumed in a “normal” Western society diet is 1–2 g/kg/d.

- Sucrose, sorbitol, and artificial sweeteners may be used in medicines, tablets and syrups, and toothpastes.
- Starch, glucose, and lactose can be included in the diet. Glucose can be used as an alternative sweetener, although many individuals with HFI dislike the taste and avoid sweet tasting foods.
- Cooking of vegetables causes a loss of free sugars, and they therefore have a lower fructose content than raw vegetables. Newer potatoes have higher fructose content than older potatoes.[84]
- Sucrose and fructose may be used as a carrier for flavorings.
- Individuals with HFI are at risk of vitamin C and possibly folic acid deficiency due to the exclusion of the major sources of these vitamins (fruits and vegetables). Therefore, suitable supplementation of these vitamins is important.
- With a careful diet, people with HFI should remain symptom free and be able to live normal lives.
- Intravenous fructose and sorbitol are potential lethal sources of fructose.[85]
- HFI is not the same condition as fructose malabsorption or dietary fructose intolerance, which is a cause of GI discomfort. This is an uncomfortable but benign condition.[87]

TABLE 70-22 Dietary Sources of Fructose

Fructose	Fructose or fruit sugar is a simple monosaccharide found in many plants. Commercially, fructose is frequently derived from sugar cane, sugar beets and corn.
Sucrose	Sucrose, is composed of fructose and glucose linked by a glycosidic bond.
Sorbitol	Fructose can be synthesized endogenously from sorbitol (a polyol synthesized from glucose). Hepatic sorbitol dehydrogenase converts sorbitol to fructose.
Isomalt and Lycasin	Isomalt is an artificial sweetener. Its hydrolysis yields glucose, sorbitol and mannitol. Lycasin is a trade name for hydrogenated glucose syrup. It contains maltitol, derived from the hydrogenation of maltose.

LONG-CHAIN FATTY ACID DISORDERS

- Mitochondrial long-chain fatty acid oxidation disorders (LCFAOD) are a rare group of inherited metabolic autosomal recessive disorders due to enzyme deficiencies in fatty acid oxidation and transport proteins.[87] They require attentive diet therapy.
- These disorders *demonstrate an abnormal response to fasting adaptation.*[88] *They* lead to accumulation of fatty acids and a decrease in cell energy metabolism. *They* are an important cause of disturbed energy homeostasis.
- Fatty acids are a major fuel source for most tissues of the body, especially during fasting, when glucose supply is limited. They are the principal energy source for cardiac muscle and skeletal muscle in the resting state and during prolonged exercise. Fatty acid oxidation is also important for the production of ketone bodies.
- LCFAOD conditions vary in severity and may present at any time from the neonatal period to adulthood. The organs affected are heart, liver, and skeletal muscles.
- *Several disorders of long*-chain fatty acid oxidation have been described including:
  – Carnitine transporter deficiency
  – Carnitine palmitoyl transferase 1 (CPT1) and 11 (CPT11) deficiency
  – Carnitine acylcarnitine translocase (CACT) deficiency
  – Very long-chain acyl CoA dehydrogenase deficiency (VLCADD)
  – Long-chain 3 hydroxyacyl CoA dehydrogenase deficiency (LCHADD)
- Clinically, patients may present in infancy with acute life-threatening hypoketotic hypoglycemia, hypotonia, hepatic dysfunction, hyperammonemia, and cerebral edema. Cardiomyopathy is common. Chronically, there may be muscle involvement with hypotonia or exercise intolerance with or without cardiomyopathy and rhabdomyolysis. In milder variants, skeletal myopathy with intermittent myoglobinuria may develop later in life.
- The aims of diet therapy are too:
  – To minimize fat lipolysis
  – To reduce accumulation of toxic intermediates
  – Ensure normal growth

– To help maximize exercise tolerance

- These aims are achieved by (1) adhering to a limited long-chain fatty acid intake, (2) avoiding prolonged fasting by regular daytime feeding and, usually, overnight tube feeds (3) replacing long-chain dietary fat with medium-chain triglyceride fat (MCT Oil), and (4) during illness, administering emergency, high carbohydrate feeds throughout 24 hours.
- A low-fat, high-carbohydrate diet with limited long-chain fatty acid intake (10% of total energy) is beneficial.
- Addition of MCT oil treatment (providing 10%–30% of energy requirements) is reported to be beneficial with improvement in dicarboxylic aciduria and a normalization of the plasma level of long-chain acylcarnitines.
- Coordinating MCT supplementation (0.5 g/kg of lean body mass) with periods of increased activity will help improve exercise tolerance.
- Supplementation with linoleic acid and linolenic acid to provide minimal essential fatty acid requirements. DHA supplementation (100 mg/d) may help visual function, particularly with LCHADD.
- Prevention of fasting with frequent feeds is crucial.
- A daily multivitamin and mineral supplement that includes all fat-soluble vitamins is required.

TABLE 70-23 E Numbers That are Sources of Fructose and Should Be Avoided

E420: Sorbitol
E473 and E474: Sugar esters
E491–E495: Sorbitol esters, some sorbitol may be liberated
E953: Isomalt

TABLE 70-24 Low-Fructose Diet (Containing Less Than 2 g/d Fructose)

Foods Allowed	Foods to Avoid
Sugars, sweeteners and preserves Glucose, glucose polymers, glucose syrup, dextrose, lactose, starch, maltodextrin, malt extract, saccharin, aspartame	*Sugars, sweeteners and preserves* Sugar or sucrose (cane or beet)- white, brown, caster, icing. Fruit sugar, fructose, laevulose Honey, treacle, molasses Sorbitol, Lycasin, Isomalt Golden syrup, corn syrup, invert syrup, high fructose or isoglucose syrups,,

	hydrogenated glucose syrup Jam, marmalade, lemon curd.
Fruit Avocado, rhubarb (occasionally)	*Fruit* All other fruit and fruit products
Vegetables Cook, boil and discard water Seaweed, vine leaves, allowed freely Fructose from vegetables should not exceed 1–1.5 g/daily. *Group 1 (<0.5 g fructose/100 g)** Celery, globe artichokes, mango tout, mushrooms, spinach, watercress Beans: haricot, mung, red kidney Dried split peas, lentils Potato: old potato, plain potato crisps (potato waffle, potato croquette-check food label) *Group 2 (0.5–1.0 g fructose/100 g)** Aubergine, asparagus, beansprouts, broccoli, cabbage, cauliflower, courgette, cucumber, fennel, artichoke, leeks, lettuce, marrow, new potato, pumpkin, radish, spring greens, swede, turnip. Beans: black-eye, broad, butter, soy Marrowfat peas, processed peas canned in water, chick peas.	*Vegetables* Beetroot, Brussels sprouts, carrots, gherkins, green beans, kohlrabi, okra, onion, parsnip, peas, pepper, plantain, shallots, spring onion, squash, sweetcorn, sweet potato, tomato, tomato puree. Beans: green, French, runner Baked beans, tinned vegetables with added sugar, mayonnaise or salad cream, coleslaw Flavored crisps Pickles, chutney
Milk Cow’s milk, Cream, cheese, plain cottage cheese Natural yogurt	*Milk* Flavored milk, condensed milk, milk shake powders/syrups Liquid soy milks Aerosol cream Cheese with added ingredients e.g., nuts, fruit Fruit and flavored yogurt, fromage frais Ice cream
Eggs Allowed	*Eggs*
Meat and poultry All fresh meat and poultry If processed read label to check for added sucrose, fructose, or honey	*Meat and poultry* Processed meats which have added sucrose e.g., meat pastes, frankfurters, salami, pate, sausages, tinned meat. Tender sweet meats, e.g., ham Honey cured meals Readymade meat meals- possible sources are the gravy, sauces, vegetables, breadcrumbs, batter, pastry.
Meat substitutes Soy meat, tofu, Quorn	*Meat substitutes*

Fish Fresh and frozen fish, shell fish, fish tinned in brine	Fish Fish tinned in tomato sauce, fish paste, fish cakes, fish oil or fish fingers Ready-made fish meals, possible sources are the sauce, vegetables, breadcrumbs, batter, pastry.
Flour and cereals Flour (white in preference to wholemeal), buckwheat, cornflour, custard powder, sago, semolina, tapioca, oatmeal, barley Flaky pastry, shortcrust pastry (not sweetened).	*Flour and cereals* Bran, wheatgerm
Pasta and rice Spaghetti, macaroni, other pasta (white in preference to whole meal) Noodles, egg noodles Rice (white in preference to brown)	*Pasta and rice* Pasta tinned in tomato sauce Pot Noodle
Breakfast cereals Porridge, puffed wheat, Original Ready Break, Shredded Wheat (Kallo) puffed rice cereal	*Breakfast cereals* Most manufactured breakfast cereals
Bread and crackers White bread(pre-packed) Baker's bread- check if sugar is added to dough mixture. Cream crackers, Matzo crackers, water crackers, original Ryvita (not sesame), plain rice cakes, crumpets	*Bread and crackers* Wholemeal bread, sweetened breads e.g., malt bread, soda bread, currant bread NB: Sucrose is present in wheat germ and bran. Savoury snack biscuits
Cakes, biscuits and pastries Home-made using permitted ingredients and sweeteners	*Cakes, biscuits and pastries* All cakes, biscuits, and pastries
Desserts Home-made using permitted ingredients and sweeteners	*Desserts* Most desserts, e.g., jelly, meringue, mousse, gateaux, fruit pie, or crumble, ice cream, yogurts
Fats and oils Butter, margarine, vegetable oils, lard, suet	*Fats and oils*
Drinks Soda water, mineral water (without fruit flavor) Some low energy drinks may be suitable (check the label for fructose, sucrose, sorbitol, polyols, or comminuted fruits). Tea, coffee, cocoa, herbal teas (no sugar)	*Drinks* Fruit juices, vegetable juices, fruit squash, fizzy drinks, diabetic squash containing sorbitol or fructose, low energy drinks, tonic water. Drinking chocolate, malted milk drinks. Instant tea mixes, coffee essence

Confectionary	*Confectionary* Sweets, chocolate, toffee, jelly. Ice lollies, chewing gum, diabetic sweets (sweetened with fructose, sorbitol, or other polyols). Glucose tablets, e.g., orange flavor Lucozade tablets.
Gravies, sauces and soups Marmite, Bovril White or cheese sauce, made with milk, flour, fat and cheese only	*Gravies, sauces and soups* Gravy granules, stock cubes Bottled sauces and dressings, e.g., tomato ketchup, horseradish sauce, mint sauce, soy sauce Sauce mixes e.g., sweet and sour, curry Mayonnaise, salad cream All soups (packet, tinned, or fresh)
Herbs, spices, nuts and seeds Pure herbs, mustard and spices, salt, pepper. Sesame seeds Pumpkin and sunflower seeds maximum of 10 g/day total	*Herbs, spices, nuts and seeds* Nuts, peanut butter, marzipan
Baking products Baking powder, bicarbonate of soda, yeast, arrowroot, food coloring, food essences, gelatin	*Baking products*

Source: Adapted from Dixon.[84]

TABLE 70-25 A Very Low-Fat Diet

Low-Fat Foods: Permitted	High-Fat Foods to Avoid
Milk and milk products Skimmed milk, very low fat yogurt, low fat cottage cheese, egg whites	Any other milk, yogurt, cheese, and egg yolks
Meat and fish Chicken, turkey (white breast meat) White fish, e.g., haddock, sole. Prawns	Fatty meat, duck, skin and dark meat from chicken and turkey, red meat, processed meats and meat products, meat pastries, meat in breadcrumbs and batter, meat paste or pate, ham Oily fish
Fats and oils MCT oil	Butter, margarine, vegetable oils, mayonnaise
Vegetables/fruit/nuts/seeds Pulses, fruit and vegetables, fat-free fruit crisps, potatoes mashed with skimmed milk, baked beans	Avocado pears, olives, potato fries/chips, processed potato, potato waffle, and crisps, nuts, seeds, vegetable burger, vegetable sausage
Cereals/breads White pasta, cous cous and rice, white	Naan bread, croissants, crackers, pastry, cakes, biscuits, Muesli, Cereal

flour, semolina and tapioca, white bread (in moderation), chapatti made without fat, 99% fat free crackers, rice cakes, Rice Krispies, Cornflakes.	containing added nuts
Sugar, desserts, confectionary. Jelly, meringue, marshmallows, ice lollies, sorbet, boiled sweets, jelly sweets, gummy sweets, fruit gums, jelly sweets, jam, honey, fruit dessert syrups, sugar	Chocolate, fudge, toffee, sweets containing oil, chewy sweets, chocolate spread, ice cream, milk puddings, cakes, biscuits/cookies made with ordinary fat/butter, sweet pastries
Drinks Fruit juice, squash, fizzy drinks, flavored water, tea, coffee	Hot chocolate, milk shakes, yogurt drinks
Soups, sauces, and spreads Clear soup/vegetable soup Low energy soups Stock cubes, ketchup, brown sauces Pickles in vinegar, vinegar Herbs and spices Cooking sauces (<0.5 g/100 g fat)	Cream of soups, meat soups, peanut butter, gravy made with meat sauce. Salad cream, mayonnaise Cream sauces, French dressing/vinaigrette, jar sauces.

Low-Fat Diet

- There is evidence that long- chain fat should be restricted to no more than 10% of total energy intake for LCHADD *and 10%–15% of energy intake for severe patients with VLCADD.* However, the degree of fat restriction varies according to the severity of the condition and age of presentation. By comparison, a normal diet contains on average approximately 35%–40% of its total energy from fat- containing foods.
- Foods that are permitted in the diet include skimmed milk, egg whites, chicken, turkey, white fish, fruit, vegetables, potatoes, pasta, rice, lentils, low fat yogurt, cottage cheese or minimal fat cheese (1% fat), jam, sugar, sweets, and fruit juices (Table 70-25).

MCT Oil

- Replacing long-chain fat with medium- chain fat is particularly beneficial for patients with LCHAD and VLCAD deficiency. It is thought that the metabolism of MCT bypasses the long- chain enzymes of the β-*oxidation spiral and only requires* β-oxidative enzymes with shorter chain-length for further breakdown and energy production. *MCT is converted to ketone bodies by the*

liver, which acts as an energy source for other organs including the brain and heart muscle. This may even help reduce the risk of heart complications. There is also evidence that MCT oil may reduce body fat breakdown and prevents the accumulation of potentially toxic chemicals.

- Between 10% and 30% of energy from MCT has been recommended for patients with LCHAD and VLCAD deficiency. MCT oil should be used in cooking. It may be used to make margarine, salad dressings, mayonnaise, cakes, biscuits, and chips helping make the diet far more palatable. However, this oil should not be heated to very high temperatures because it will oxidize and break down, affecting the taste and smell of food. Some children may take a special MCT supplement powder two or three times during the day.

MCT–Based Infant Formula

- Babies are usually given a nutritionally complete infant formula that is high in carbohydrate, low in long- chain fats, and supplemented with MCT oil. Some children may continue to take this product for many years either in their overnight tube feeds, bottles, or drink it via a cup.

Regular Feeds

- Children with LCFAOD deficiency require feeds at frequent intervals day and night. Frequency of feeding should be individually assessed according to severity of disorder and metabolic stability, but as a starting point, in children who present symptomatically in the first 1–2 years of life, feeds should be given three to four hourly during the day with continuous overnight tube feeding (either via a gastrostomy or nasogastric pump).

Exercise

- Exercise management also needs consideration. Fatty acid oxidation is increased during times of increased energy use (e.g., prolonged exercise). Some children will choose to limit their exercise activities but some who enjoy exercise may develop muscle pain and weakness following prolonged activities. MCT

supplements or glucose drinks before exercise in LCHAD patients is important.

Illness Management

- It is well recognized that poor food intake due to infection or energy losses due to vomiting or diarrhea causes rapid body fat breakdown, which can quickly cause metabolic instability. An emergency regimen should be started early in order to try and prevent or limit body fat breakdown. The first stage of any emergency plan consists of giving high carbohydrate drinks at least every three hours day and night or via a continuous tube feed over 24 hours. This ensures an adequate intake of carbohydrate and fluid. If high carbohydrate feeds are not tolerated, intravenous fluids providing 10% dextrose are administered immediately.

HIGH-ENERGY DIET IN GROWTH FAILURE

Growth failure and failure to thrive are terms that describe the condition of infants, children, and adolescents whose physical growth deviates significantly from standards or from their individual growth pattern. Nutritional support is the cornerstone of therapy for these individuals (Table 70-26). Oral nutritional support by a high-energy diet is indicated for promoting weight gain and catch up growth under the condition that the child can swallow safely and the GI tract is functional. Dietary advice to improve dietary intake from normal food can be accompanied or preceded by the use of oral nutritional supplements containing a balanced mixture of macro- and micronutrients. Problems such as severe loss of appetite, swallowing problems, or obstructive and motility problems of the GI tract may limit the use of oral nutritional support. Under these circumstances, more invasive nutritional support, in the form of enteral tube feeding or parenteral nutrition, should be considered. The patient should follow a well-balanced diet based on a wide variety of food from all the food groups. A high-energy intake could be achieved by increasing meal frequency and/or increasing energy density of the meals. Table 70-26 gives practical suggestions for increasing the energy content of the diet.

Practical Tips for Increasing Meal Frequency

- Eat small, frequent meals distributed throughout the whole day

- Add a small late meal before going to bed (in form of a snack or a high-energy beverage)
- Include snacks (e.g., chips, nuts, ice cream, chocolate bar)

Practical Tips for Increasing Energy Density

- Prefer foods with high energy content:
  – Full-fat milk and milk products (whole-milk yogurt, cheese)
  – High-fat meat or sausage, high-fat fish, for example, salmon, trout, mackerel, sardines
  – Peanut butter
  – High-energy beverages
- Add carbohydrate or fat to food
  – Maltodextrin or sugar in tea, fruit juice, lemonade, milk, or yogurt
  – Maltodextrin in soups, sauces
  – Cream in milk or milk products
  – Oil or butter to pasta, rice, vegetables

Recipes (Always Calculated for 500 mL)

Shake With Neutral Taste

100 mL cream (30% fat)
50 g maltodextrin
350 mL cow's milk (3.5 % fat)
Total kcal: 706

TABLE 70-26 High-Energy Diet

Food Group	Choose
Cereals, bread, pasta and other grain products, rice and potatoes	Breakfast cereals with cream and nuts Rice or pasta with butter or oil Potatoes as fried potatoes or chips Bread with generous butter or margarine
Vegetable and legumes	Vegetables with added butter, margarine, bacon or sauce, e.g., hollandaise. Dip sticks of carrot or pepper in mayonnaise or cream cheese.
Fruit and nuts	Prepare fruit salad with nuts and whipped cream. Add cream, full fat yogurt or vanilla sauce to fruit. Mix Fruit Smoothies with sugar and cream.

	Prepare avocado as a spread.
Beverage	Add sugar or honey to tea. Add maltodextrin to tea, fruit juice or lemonade.
Milk and milk products	High fat cheese or cream cheese Add cream to yogurt or curd cheese Full cream milk Milk shakes with cream, sugar or ice cream Use sour cream for cooking (e.g., soups, sauces) Cheese au gratin Add grated cheese to casseroles or pasta
Egg, meat, and fish	High fat meat Fried sausage, salami, bacon Fried breaded meat or fish Poultry with skin High fat fish (e.g., salmon, tuna, herring)
Fats and oils	Generous use of butter or margarine on bread. Generous use of vegetable oil for cooking and preparing dishes.
Sweets and snacks	Nuts and seeds Bars with or without chocolate Marzipan. Salty snacks like potato chips or peanut snacks Cakes with nuts, chocolate or cream Salty or sweet pastries
Formula/drinks	High-energy (≥ 1.5 kcal/mL), ready-to-use drinks based on milk protein in different flavors.

Chocolate Shake

100 mL cream (30% fat)
50 g maltodextrin
25 g cocoa
325 mL cow's milk (3.5 % fat)
Total kcal: 776

Fruit Shake

100 mL cream (30% fat)
50 g maltodextrin
120 g fruit (e.g., banana)
160 mL cow's milk (3.5% fat)
Total kcal: 735

CONGENITAL HEART DISEASE AND

HYPERLIPIDEMIA

Pediatric patients with congenital heart disease or hyperlipidemia require careful nutritional monitoring to ensure optimal growth and development. Growth failure in congenital heart disease is common and can be attributable to anorexia, hypermetabolism, frequent respiratory infections, decreased peripheral blood flow, malabsorption, or pulmonary hypertension, among other factors. Patients requiring dietary fat restriction because of hyperlipidemia are placed at greater risk for energy deficits, as well as deficits in calcium and iron. Nutrition education with frequent monitoring is necessary to prevent these deficiencies.

Fluid-restricted and sodium-restricted diets are often used in the management of congenital heart disease.

Fluid-Restricted Diet

The fluid-restricted diet is a modification of the normal diet in which all fluids are limited to a prescribed level. Individuals with renal, liver, or cardiac insufficiency might require it.

Noteworthy Points

- All foods contain water in varying amounts. All foods that are liquid at room temperature are considered to be fluids. These include water, tonic, coffee, tea, fruit and vegetable juices, milk, ice, ice cream, sherbet, Popsicles, fruit ices, gelatins, soups, gravies, sauces, cream, and alcohol.
- Fluid from solid foods is not routinely restricted in a fluid-restricted diet. Solid foods with the highest water content are fruits and vegetables. Excessive consumption of these foods should be avoided.
- Liquid medications and fluids consumed while ingesting medications must be accounted for in the fluid-restricted diet.
- The following measurements are useful in calculating daily fluid allowance:
  - 1 oz = 30 mL = two tbsp
  - 4 oz = 120 mL = half cup
  - 8 oz = 240 mL = one cup
  - 32 oz = 960 mL = four cups = 1 quart
  - 1L = 1,000 mL = 1kg

Sodium-Restricted Diet

The sodium-restricted diet is a modified, healthy, balanced diet. The sodium content is limited to a prescribed level. It may be indicated in children with hypertension, congestive heart failure, liver disease, renal disease, and corticosteroid therapy. Table 70-27 includes foods that should be preferred and avoided if a strict sodium restriction is recommended.

Practical Tips for Limiting Sodium Intake

- Do not use salt for cooking.
- Do not spread salt over food at the table.
- Prefer freshly prepared dishes instead of convenience foods that often contain a high salt content.
- Read labels carefully on all canned, frozen, and packaged foods. Avoid products with added sodium or salt. Ingredients are listed on the package by weight, from the largest amount to the smallest.
- Use low-sodium or sodium-free canned soups, broth, potato crisps/chips, crackers, and fresh nuts.
- Instead of salt try to flavor food with spices and flavorings such as herbs, onion powder, thyme, or lemon juice.
- Limit fast foods and restaurant foods that are high in sodium. They often contain added salt or salt-containing ingredients such as monosodium glutamate or soy sauce.

CHOLESTEROL-LOWERING DIET

Cardiovascular disease is associated with a variety of risk factors, including hypercholesterolemia.

Longitudinal studies report a reduction of low-density lipoprotein (LDL) cholesterol concentration of about 7%–15 % by dietary therapy.

In children and adolescents with hypercholesterolemia, from the age of 3 years dietary therapy including nutrition education by qualified dietetic experts should be the basis of treatment. No restriction of fat or cholesterol is recommended for children less than 2 years of age when rapid growth and development require high energy and nutrient intake per kilogram body weight.

Effects of Dietary Fats on Serum Lipoproteins

There are four types of fatty acids in the diet: saturated, polyunsaturated,

monounsaturated, and *trans* fatty acids.

Saturated fatty acids have the strongest influence on blood cholesterol. As they increase blood cholesterol the most, an important step is to limit the amount of saturated fat in the diet. Animal fats have a high content of saturated fatty acids. Examples are butter, shortening, meat fats (suet, lard, salt pork, bacon fat), chicken fat (including skin), whole milk, cheese, yogurt, and cream. But also some vegetarian fats have a high saturated fat content: for example, coconut oil or palm oil.

Polyunsaturated fatty acids lower total blood cholesterol, LDL, and high-density lipoprotein (HDL) cholesterol. A high content is found in corn, safflower, sunflower, soybean, cottonseed, walnut, and sesame oils, as well as fish, which contains long-chain omega-3 polyunsaturated fats.

Monounsaturated fatty acids lower serum LDL while maintaining or even increasing HDL cholesterol levels. Olive, canola, and peanut oil have a high content.

Trans **fatty acids** raise LDL and lower HDL cholesterol levels. They are found in fat of ruminant animals (e.g., milk fat, beef). They are also formed when liquid oils are hydrogenated into a solid form. So called partially hardened vegetable fats are found in margarine, cookies, crackers, pastries, baked goods, and many other processed foods, and snack foods.

Recommendations for Dietary Intake

The intake of saturated and *trans* fatty acids (from partially hardened vegetable fat or fat from ruminant animal) should not exceed 8%–12% of energy intake. The intake of fat should be mostly from monounsaturated fat (> 10% of energy); whereas the consumption of polyunsaturated fat should not exceed 10% of energy. In normal-weight children, total fat intake should not differ from the recommendation for healthy children (30%–35% of energy). A lower fat intake is usually not necessary and for some children and adolescents such a restriction may not provide sufficient energy for optimal growth and development.

Intake of dietary cholesterol should not exceed 150 mg/d in children and 250 mg/d in adolescents. Complex and slowly digested carbohydrates should be preferred. Soluble fiber (oat bran, psyllium), but not insoluble fiber (wheat bran), can contribute to reduced blood cholesterol. If triglyceride concentration is high, it is additionally necessary to decrease simple carbohydrate intake including glucose, saccharose, and fructose. However, it has to be considered that a diet high in fiber and low in sugars is less attractive for children and may lead to poor compliance with dietary therapy.

Due to the potential risk of insufficient energy intake, careful monitoring is necessary to ensure normal growth and development in all children. As no single food item provides all the essential nutrients in the amounts needed, choosing a wide variety of food from all the food groups will ensure an adequate diet.

Table 70-28 provides recommended intakes with the goal to prevent coronary heart disease. Table 70-29 includes foods that should be allowed and avoided in hyperlipidemia.

TABLE 70-27 Sodium-Restricted Diet

Foods Allowed	Foods to Avoid
Milk, milk products, and cheese Milk, fresh milk Yogurt Curd cheese (natural without salt)	*Milk, milk products, and cheese* Buttermilk Processed cheese Hard and soft cheese Curd cheese with added salt
Breads and cereals Low-sodium special breads, cereal products, bread mixes, rolls and crackers. Cooked cereals without added salt: pearl barley, cracked wheat, plain farina, rolled oats, and rice. Dry cereals: puffed rice, puffed wheat, shredded wheat; macaroni, spaghetti, noodles (cooked without added salt)	*Breads and cereals* Breads and rolls made with salt or commercial mixes; quick breads (pancakes, waffles, cakes, pastries, muffins) made from baking powder, baking soda, salt, monosodium glutamate or commercial mixes; quick cooking and enriched cereals that contain a sodium compound (read label); cornflakes and dry cereals (except those allowed); crackers (except low sodium)
Fruits and juices All fresh, frozen, canned, or dried to which salt, sodium benzoate, or sodium sulfite has not been added (read labels)	*Fruits and juices* Regular tomato and vegetable juices, maraschino cherries, any fruit or fruit product that contains salt or sodium benzoates, sodium-preserved dried fruits
Vegetables Fresh, frozen, or dietetic canned without salt: asparagus, green beans, dried lima beans, dried navy beans, brussels sprouts, cabbage, cauliflower, corn, cucumbers, parsley, parsnips, peas (fresh), peppers, potatoes, sweet potatoes, pumpkin, radishes, rutabaga, soybeans, squash (winter, summer), tomatoes, turnip greens	*Vegetables* All regular canned vegetables: beets, beet greens, carrots, celery, dandelion greens, hominy, kale, mustard greens, pickles, sauerkraut, spinach, white turnips, frozen peas or lima beans if processed with salt; commercially seasoned frozen vegetables, frozen mixed vegetables
Fat Lard, vegetable oil, shortening,	*Fat* Salted butter or margarine, bacon fat, salt

salt-free butter or margarine	pork, commercial mayonnaise or other salad dressing (except low sodium)
Sugar and sweets Sugar, honey, syrups, jams, marmalades, and jellies that contain no preservatives, marshmallows, chocolate marshmallow, gummy bear, ginger bread	*Sugar and sweets* Molasses, commercial jams containing sodium benzoate or other sodium preservatives (read labels)
Beverages Fruit juices, lemonade, milk (regular or low sodium as allowed), coffee, tea, coffee alternative, cocoa (made with allowed milk or water), mineral water with < 20 mg Na/L	*Beverages* Fountain beverages, “Dutch process” cocoa, instant cocoa mixes, powdered milk, prepared beverage, mixes including fruit-flavored powders, mineral waters with > 20 mg Na/L
Seasonings and condiments All spices, extracts, herbs, except those with sodium as an ingredient; lemon juice, vinegar, salt substitute (with doctor’s approval), low-sodium bouillon/stock cube	*Seasonings and condiments* Salt, celery salt, onion salt, garlic salt, prepared mustard, ketchup, horseradish prepared with salt, barbecue sauce, chilli sauce; meat extracts, gravies, and tenderizers; monosodium glutamate, soy sauce, Worcestershire sauce, regular bouillon/stock cubes, relishes, mixed pickles
Miscellaneous Unsalted nuts	*Miscellaneous* Canned, dehydrated, or frozen potato; spaghetti, macaroni, or noodle products (ready to eat); pre-prepared gravies; canned or dehydrated soups, except low sodium; salted popcorn, potato chips, pretzels, and other snack items such as corn chips or Doritos; party spreads and dips; regular baking powder, baking soda (sodium bicarbonate), rennet tablets, laxatives, Chinese/ Asian food, Italian food, fast foods; salted nuts, olives

Practical Tips for Lowering Cholesterol, Saturated and *Trans* Fat Intake

- Use only lean cuts of meat. Cut away any visible fat from meat before cooking.
- Remove skin from poultry.
- Do not fry foods.
- Eat no more than two egg yolks per week. Substitute two eggs whites for a whole egg in recipes. Use egg whites to batter meats and vegetables, coat with crumbs moistened with acceptable oil, and then bake. Use low-cholesterol commercial egg substitutes in

place of whole eggs.

- Read labels of commercially prepared products to identify hardened vegetable fats in cakes, spreads, and so on.
- Avoid fast fried foods that could be high in saturated fat (e.g., fried chicken, French fries).
- Increase fish intake, especially oily sea fish (herring, mackerel, salmon), to two servings per week.
- Try some meatless dishes, such as pasta with tomato sauce or vegetarian burgers.
- Use high-protein vegetables such as legumes (kidney, red, or pinto beans) and soy products (bean curd) to supply protein.
- Limit high-fat sauces such as cream, cheese, and Alfredo sauce.
- Eat low-fat dairy products daily.
- Encourage nuts or popcorn instead of chocolate or potato crisps as a snack.
- In case of high triglyceride levels:
  – Avoid sweetened drinks such as lemonade, fruit juices, and ice tea
  – Get used to drinking water, mineral water, or tea without sugar
  – Avoid large or frequent servings of foods with high sugar content such as cookies, candy, or ice cream

TABLE 70-28 Recommended Dietary Intakes of the European Society for Paediatric Gastroenterology, Hepatology, and Nutrition for Children (>2–3 y) and Adolescents

Nutrient	Recommendation
Total fat	30%–35% of energy intake
Saturated fatty acids	~8%–12% of energy or less
Trans Fatty acids	Low intake
Polyunsaturated fatty acids	~6%–10% of energy
Monosaturated fatty acids	No limitation
Cholesterol	~300 mg/d or less
Antioxidant vitamins	Generous intake
Sodium	Low intake
Complex carbohydrates	Generous intake

MINERAL-RICH DIETS

Children on any type of special diet (whether prescribed or self-imposed) may be at risk of deficiencies of vitamins and minerals due to restricted intake of certain foods or food groups. This in turn can contribute to delayed growth and development. As a result, nutrient intake should be monitored regularly by way of diet histories or food records and where appropriate nutritional biochemistry. A multivitamin and mineral supplement can be administered if the diet is lacking in several nutrients, or individual vitamins or minerals can be given to rectify specific deficits.

HIGH-CALCIUM DIET

Calcium is a mineral that is essential for the normal development and functioning of bones, teeth, muscles, and the nervous system. Growing children in particular have high requirements for calcium due to higher rates of bone formation. Most calcium in the body is stored in the bones and teeth with less than 1% circulating in the blood, muscles, and tissues.[89,90] Dietary deficiency of calcium does not usually result in obvious symptoms because the body maintains calcium levels in the blood by resorbing it from the bone. However, in the longer term, this may result in reduced bone density (osteopenia) and risk of bone fracture.

As milk and dairy products are the main source of calcium in the Western diet, any diet that omits or reduces the intake of these foods is likely to low in calcium. There is evidence to suggest that for diets habitually low in calcium, the body does adapt by improving the rate of absorption from foods. This is because calcium absorption decreases with increasing intakes. Other factors that aid absorption include Vitamin D (from sunlight and food sources), protein, and exercise. Conversely, phytic acid (found particularly in high-fiber breads and cereals and legumes) and oxalic acid (found in leafy green vegetables) may reduce absorption, although the effect in people eating a varied diet is minimal. High sodium intakes may also increase excretion of calcium.[91,92]

Dairy products, leafy green vegetables, and fish with soft bones (e.g., sardines, salmon) are the best food sources of calcium although bioavailability from vegetable sources is lower. The bioavailability of calcium from dairy products is about 30% compared with 5% for spinach due to the oxalic acid in the latter.[90] Many foods such as breakfast cereals are often fortified with calcium by the manufacturer and because they are consumed in relatively large amounts, they make a significant contribution

to calcium intake. For a list of foods high in calcium see Table 70-30. (See Appendix II for UK Dietary Reference Values, US Dietary Reference Intakes, and EU Reference Intakes).

Calcium supplements are best taken in divided doses as absorption of calcium decreases as intake increases.

TABLE 70-29 Diet for Hyperlipidemia

Foods Allowed	Foods to Avoid
Fats and oils Rapeseed and olive oil are vegetable oils of the first choice (high amount of monounsaturated fatty acids). Soybean, wheat germ, peanut and walnut oil (ratio of n-6 to n-3 fatty acids: <7:1) in small amounts. Diet margarine (low in *trans* fatty and saturated fatty acids). Salad dressings made with vegetable oils listed above. Seeds and nuts—peanut butter, other nut butters	*Fats and oils* Coconut oil, palm kernel oil, palm oil Butter, lard, shortening, bacon fat Coconut Cocoa butter Dressings made with egg yolk, cheese, sour cream, whole milk
Breads and cereals Breads—whole grain (if accepted) Cereals—oat, wheat, corn, multigrain Pasta (100% Durum) Rice *Dry beans and peas* Low fat crackers Homemade baked goods using unsaturated oil, skim or 1% milk, and egg substitute e.g., quick breads, biscuits, cornbread muffins, bran muffins, pancakes, waffles	*Breads and cereals* Bread in which eggs are a major ingredient, croissants and other puff pastry Granola made with coconut Egg noodles and pasta containing egg yolk
Sauces	*Sauces*

Ketchup, barbecue sauce	Mayonnaise, cheese sauce
Fruits and Vegetables Fresh, frozen, canned or dried Fruit juice—fresh, frozen, or canned	*Fruits and Vegetables* Fruits or vegetables fried or prepared or served with butter, cheese, or cream sauce
Sweets, desserts and snacks (*if triglyceride level is normal*) Sugar, syrup, honey, jam, Candy made without fat (gumdrops, hard candy, marshmallow), fruit-flavored gelatin Frozen desserts - sherbet, sorbet, fruit ice, water ice. Cookies, cake, pie, pudding prepared with egg whites, low fat milk, and rapeseed oil or margarine. Popcorn, nuts	*Sweets, desserts and snacks* (*if triglyceride level is normal*) Candy made with chocolate, coconut oil, palm oil Ice cream and frozen treats made with ice cream Commercially baked pies, cakes, donuts, high-fat cookies, cream pies Chocolate, potato crisps/chips
Meat, poultry, and fish Beef, pork, lamb-lean cuts well trimmed before cooking Poultry without skin Processed meat - prepared from lean meat (e.g., turkey ham, tuna, wieners) Sea fish and low-fat freshwater fish	*Meat, poultry, and fish* Beef, pork, lamb - regular ground beef, fatty cuts, spare ribs, organ meats, sausage,bacon Poultry with skin, fried chicken Fried fish Regular luncheon meat (e.g., bologna, salami, sausage, wieners) High-fat freshwater fish Shellfish
Eggs Eggs whites (two whites equal one whole egg in recipes), cholesterol-free egg substitute	*Eggs* Egg yolks; includes egg used in cooking
Dairy products Low-fat milk (≤1.5% fat), skim milk (<0.1% fat) Buttermilk Yogurt /yogurt beverages - non-fat or low-fat Cheese - low-fat natural or processed cheese, e.g., part-skim mozzarella, ricotta Cottage cheese - low fat, non-fat, or dry curd (0%–2% fat) Frozen dairy dessert—low-fat or nonfat ice milk, frozen yogurt	*Dairy products* Whole milk (fluid, evaporated, condensed), Whole-milk yogurt, whole-milk yogurt beverages Regular cheese (American,Blue,Brie,cheddar, Colby, Edam, Monterey Jack, whole-milk mozzarella, Parmesan, Swiss), cream cheese, Neufchatel cheese Cottage cheese (> 4% fat) Ice cream, cream, half and half, whipping cream, nondairy creamer, whipped topping, sour cream

IRON-RICH DIET

Iron is a mineral essential as a component of the protein hemoglobin in red blood cells, which transports oxygen to the muscles and tissues and takes carbon dioxide back to the lungs for excretion. Iron is also part of enzyme reactions that produce energy and has a role in the immune system.[94] About two-thirds of the body's iron is stored as hemoglobin, the remainder is found in the body organs and tissues in the form of ferritin.[99]

Insufficient dietary intake of iron leads to reduced levels in the blood and subsequently reduced levels of hemoglobin, which can lead to iron

deficiency anemia with symptoms of tiredness, lethargy, weakness, and decreased immunity. In children, it can affect cognitive function, concentration, and school performance. Frequent eating of nonnutritive substances such as ice, chalk, dirt, or sand (known as “pica”) can also be a sign of iron deficiency.

An iron-enriched diet may be recommended if there has been a diagnosis of anemia due to insufficient dietary intake of iron, excessive blood loss, or impaired absorption.

There are two forms of dietary iron: heme iron and nonheme iron. Heme iron is derived from hemoglobin and so is found in animal products. About half the iron in meat, poultry, fish, and seafood is heme iron and between 15% and 35% of this is absorbed.[100] Nonheme iron is derived from plant sources (cereals, vegetables, fruits) and makes up a larger portion of our iron intake but is less readily absorbed by the body (2%–20%)[100] and is more sensitive to inhibitors and enhancers of iron absorption. Nonheme iron absorption can be enhanced by consuming foods at the same time or with the same meal as foods containing Vitamin C (citrus fruits or juices, tomatoes, and green leafy vegetables) or heme iron (e.g., meat). Iron is also absorbed more readily when body stores are low, such that fussy eaters with poorer dietary intakes will absorb a higher percentage of available iron. Conversely, absorption may be impaired by phytic acid (found particularly in high-fiber breads and cereals and legumes), oxalic acid (found in leafy green vegetables), and the tannins found in tea. There is evidence to suggest that individuals may adapt to lower intakes of iron over time resulting in increased absorption and decreased losses.[101]

Full-term healthy babies are born with iron stores that last for the first 4–6 months of life. After this time, introduction of iron-enriched solid foods helps to ensure iron requirements are met. The iron in breast milk is well absorbed compared with that in formula milk; hence the iron content of the latter is much higher. Older infants, toddlers, and young children are particularly at risk of iron deficiency as requirements are high and fussy eating and a lack of variety in the diet can exacerbate the problem.

The main sources of iron in the Western diet are red meat, poultry, fish, cereal products, pulses and beans, green leafy vegetables, eggs, nuts, and dried fruit.

Iron supplements are available but the form of iron is less well absorbed than that in food sources, as a result, larger amounts need to be consumed and this can cause constipation and nausea in some people. As the amount of iron absorbed decreases with increasing intake, supplements

are best taken in divided doses.

For a list of foods high in iron see Table 70-31. (See Appendix II for UK Dietary Reference Values, US Dietary Reference Intakes, and EU Reference Intakes).

HIGH-FIBER DIET

Dietary fiber is a component of plant foods that is largely undigested by the acids and enzymes in the stomach or small intestine. Absorption of water by undigested contents increases the bulk and softens the stools, helping to prevent constipation. The breakdown of dietary fiber occurs mostly in the large intestine due to fermentation by bacteria, which produce short-chain fatty acids and gases (carbon dioxide, methane, and hydrogen). The bacterial mass and absorption of water contribute to stool bulk and consistency.

Different types of dietary fiber have different properties. Some absorb water in the intestines and are fermented by bacteria in the intestines, producing acids and gas. For example, pectins (found mostly in fruits, vegetables, and legumes), gums (mostly in oats, legumes, seeds and seaweed), some plant oligosaccharides (fructo- and galacto-oligosaccharides: found mostly in onions, Jerusalem artichokes, and chicory), and polysaccharides such as inulin (found mostly in vegetables, legumes, and fruits). These types of fermentable fiber help lower cholesterol by binding to bile acids and aiding their excretion and may also aid the absorption of some minerals, particularly calcium[102,103] in contrast to the effects of phytates.

Other types of less fermentable fiber absorb water and pass through the bowel largely undigested, providing satiety, contributing bulk to the stools, and speeding up transit time. For example, celluloses and lignin (found in grains, wheat bran, vegetables, legumes, fruits, nuts, and seeds). Resistant starch (found in legumes, whole grains, seeds, and potato) also passes through the small intestine undigested into the large intestine where it is fermented by bacteria. These types of dietary fiber have been associated with a reduced risk of diabetes.[104,105]

[a] Organ meats are high in cholesterol and should be eaten in moderation; liver and liver products should also be avoided.

Source: Roe MA et al.[48]

Foods high in dietary fiber also tend to have a lower energy density, may reduce hunger, improve satiety, improve glycemic control, and reduce the intake of other high fat foods, thereby reducing the risk of overweight and obesity. Dietary fiber that is fermented by bacteria in the bowel may also have beneficial effects on gut microflora and the short-chain fatty acids produced may help to regulate cholesterol and blood glucose levels and enhance the intestinal environment and immune function.[106]

Current fiber recommendations in the United States suggest for children an intake of 14 g/1000 kcal.[105] Whereas in the United Kingdom,

Dietary Reference Values [97] suggest children consume proportionately less than the 18–24 g/d recommended for adults. Williams et al[107,108] recommends for children over the age of 2 years an intake equivalent to the child's age in years plus 5 g/d. For example, a 5-year old should receive 10 g/d (5 g + 5 years).

Care does need to be taken that too much fiber is not consumed by children as the bulky nature of high-fiber foods can reduce appetite and subsequently reduce energy and nutrient intake.

During commercial processing, the fiber content of some foods, notably breads and cereals, can be significantly reduced. For this reason, wholegrain and wholemeal varieties are better sources of dietary fiber than white or refined. Raw and freshly cooked fruits and vegetables also tend to be higher in fiber than canned varieties.

Fiber supplements are available for those unable to take in sufficient fiber from food.

Tips for Increasing Dietary Fiber Intake in Children

- Include different types of dietary fiber including that from fruits and vegetables and wholegrain/wholemeal breads and cereals;
- Include raw fruit and vegetables with skins where possible;
- Increase fiber intake slowly to reduce the risk of excessive gas and bloating;
- Increase fluid intake, as an increase in fiber without extra fluid can contribute to constipation;
- If high-fiber foods are refused, continue to offer them, as children often need to be given the taste of new foods several times before they accept them;
- Give children choices about what to eat but make sure they are appropriate and healthy options;
- Add a few tablespoons of a high-fiber cereal to their favorite cereal;
- Add unprocessed bran to cereals, soups, pasta, casseroles, and desserts;

For a list of foods high in fiber see Table 70-32.

VEGETARIANISM

A vegetarian is generally defined as a person who does not eat meat or the flesh of any animal (including poultry and fish) and may include

abstinence from foods that are derived from animals such as eggs, milk, and dairy products. The choice to be vegetarian may be for cultural, religious, or ethical reasons such as the support of animal welfare. It may also be a lifestyle choice for health, environmental, or economic reasons. There are generally four types of vegetarians:

1. Vegans are vegetarians that eat no animal flesh or products derived from animals (including meat, poultry, fish, seafood, eggs, dairy products, and honey).
2. Lacto-ovo vegetarians consume eggs and dairy products but no meat, poultry, fish, or seafood.
3. Ovo-vegetarians consume eggs but no dairy products, meat, poultry, fish, or seafood.
4. Lacto-vegetarians consume dairy products but no eggs, meat, poultry, fish, or seafood.

Source: Roe MA et al.[48]

However, vegetarian diets vary the world over and what is included or excluded from the diet is often based on individual preference. Some vegetarians, for example, may avoid red meat but will eat fish and seafood (pescetarians). A macrobiotic diet consists mostly of grains and beans and occasionally fish. Semi-vegetarians or flexitarians may eat meat but only occasionally. Many processed foods contain ingredients derived from animals, which some people may choose to avoid. For example, rennet in cheese (derived from stomach enzymes) and gelatin (derived from animal bones or tissues).

Initially, babies can be given breast milk or formula exclusively for the first 6 months and then as the main drink in addition to solid foods until 1 year. Alternatively, lacto-ovo and lacto-vegetarian infants can use standard cow's milk based-infant formula. Vegans and ovo-vegetarians will require a nondairy-based infant formula such as soy formula. Soy milk and rice milk are not appropriate before the age of 12 months as they contain insufficient protein and/or energy and micronutrients. After 12 months of age, infants can be weaned onto cow's milk or fortified (with calcium, Vitamins B12 and D) dairy-free alternatives such as soy milk. Solid foods can be introduced in much the same way as in nonvegetarian children, for example, starting with iron-fortified rice cereal. Substitute puree/mashed tofu or beans/lentils for meat and for vegans and ovo-vegetarians, soy-based milk, yogurt, and cheese.

If a wide variety of foods are eaten, a vegetarian diet should provide adequate nutrients for normal growth and development. However, there are some nutrients that require consideration.

Energy and Dietary Fiber

Vegetarian diets are often lower in energy than diets containing animal products and higher in dietary fiber. A high-fiber diet can be bulky and fill

children up before they have consumed sufficient energy. As children have high energy requirements, care needs to be taken to ensure adequate energy-containing foods are consumed for growth. This may mean using some refined grains, breads, and cereals rather than just wholegrain varieties. Fat-containing foods should not be limited (e.g., avocado, nut butters, nuts, vegetable oils, margarine) before the age of 2 years.

Protein

Vegetarian diets are often lower in protein and children have higher requirements per kilogram of bodyweight than adults. Although proteins from animal sources contain all the essential amino acids for growth, most plant foods (except soy beans, quinoa and hemp) are deficient or low in at least one essential amino acid. So eating a variety of plant foods is important to ensure all essential amino acids are consumed. Good sources of protein for vegetarians include soy beans and soy bean products (e.g., soy milk, tofu), legumes (e.g., lentils, baked beans, chickpeas), nuts (including peanut butter), seeds, grains (e.g., cereals, pasta, rice, and bread), manufactured meat substitutes (e.g., mycoprotein or Quorn, seitan) and if eaten, eggs, milk, and dairy products. Combining protein sources in a meal will maximize protein quality. For example: beans on toast, lentil soup with bread, peanut butter sandwich, cereal with milk, vegetable soup with lentils or barley, chilli con carne with rice, pasta and cheese, hummus with bread or crackers.

Calcium

Breast- and formula-fed infants will get sufficient calcium. However, after weaning, vegans and ovo-vegetarians may not receive sufficient calcium from foods due to the avoidance of dairy products. Vegetarians may also absorb less calcium due to the consumption of more plant products that contain oxalic and phytic acids. Calcium can be obtained from calcium fortified milk replacements such as soy milk and soy yogurt, tofu, rice or oat-based drinks, green leafy vegetables such as broccoli, bread, dried fruit, nuts, and seeds. Adequate intakes of protein and Vitamin D will aid absorption of calcium.[109]

Iron

Vegetarians are also at risk of iron deficiency as iron is less well absorbed from plant sources than it is from animal based sources. The lower bioavailability of iron in a vegetarian diet means that iron requirements

may be almost twice that of the average population.[111] However, a well-balanced diet should provide adequate iron from legumes, cereals, bread, leafy green vegetables, dried fruit, nuts, and seeds. Consuming these with a source of Vitamin C (e.g., orange juice, fruit, or vegetables) will help the body to absorb the iron from plant foods.

Zinc

Absorption of zinc, like iron, is impaired by phytates. Animal protein also aids absorption of zinc; therefore, the bioavailability of zinc on a vegetarian diet is lower than for nonvegetarians. However, a good intake of legumes, tofu, grains, fortified cereals, and nuts will ensure an adequate intake of zinc.

Vitamin B_{12}

Vitamin B_{12} may be deficient in the vegan diet as there is no reliable plant source of this vitamin. Eggs and/or dairy products will provide sufficient for other types of vegetarians, but vegans will need to rely on fortified foods such as soy milk and soy yogurt, breakfast cereals, rice and oat drinks, meat substitutes, or yeast extract. Infants will get sufficient from breast milk or formula. However, a vegetarian breast-feeding mother should ensure she eats foods (or a supplement) containing Vitamin B_{12}; if not, the baby will require a Vitamin B_{12} supplement. A deficiency of Vitamin B_{12} can result in physical and mental developmental delays and poor growth in children.

Vitamin D

Vegans, in particular, may be at risk of Vitamin D deficiency. Useful dietary sources include oily fish (salmon, sardines, mackerel), eggs, fortified margarines and spreads, fortified breakfast cereals, and fortified dairy and soy products. Vitamin D in fortified foods may be of animal origin (cholecalciferol) and the alternative (ergocalciferol) has a lower bioavailability so supplements may be required.[109]

Omega-3 Fatty Acids

Long-chain omega-3 fats (DHA and eicosapentaenoic acid [EPA]) are found mostly in oily fish and eggs. Due to the health benefits of these fatty acids, it may be beneficial for vegetarians to take a supplement (e.g., DHA derived from algae).

Health Benefits

Despite risks of nutrient deficiencies, there are also potential health benefits associated with a vegetarian diet due to it being lower in saturated fat and cholesterol and higher in dietary fiber, some minerals (e.g., potassium, magnesium), some vitamins (e.g., folate), and antioxidants (e.g., Vitamins C and E).[109] This in turn may reduce the risk of overweight and obesity, hypertension, hypercholesterolemia, heart disease, type 2 diabetes, and some cancers (e.g., prostate, colon, breast) and lengthen life expectancy. However, some studies are conflicting largely due to the variable definition of a vegetarian diet and the fact that vegetarians may choose other healthy lifestyle options more frequently, for example, exercise and nonsmoking.

WEIGHT CONTROL

The terms “overweight” and “obesity” refer to body weight that is greater than what is considered healthy for a certain height. It is usually measured as body mass index (BMI) (weight in kg/height in m^2). For children, age and gender are taken into account as body fat changes during growth. BMI-for-age percentile charts are then used to identify overweight or obesity. The International Obesity Task Force (IOTF) [114] gives age- and gender-specific BMI cutoffs that correspond to the adult cutoffs of BMI 25 and 30 for defining overweight and obesity, respectively, based on data from six countries.[115] Two large surveys: the Health Examination Survey (European) and the Health and Nutrition Examination Survey (US) provided the basis for the World Health Organization (WHO) growth references that define overweight as a BMI between the 85th and 95th percentile and obesity >95th percentile.[116,117] In the United Kingdom, a BMI between the 91st and 98th percentile is considered overweight and

>98th percentile is obese.[118]

Overweight and obesity are becoming more prevalent in most affluent countries largely due to a sedentary lifestyle and an abundant supply of energy-dense foods. It may also be associated with genetics, psychological disorders (including eating disorders such as binge eating), stress, social and economic deprivation, and ethnic minorities. In the United States just over, and in the United Kingdom just under, one-third of children are overweight or obese.[119,120] However, there are suggestions that the rate of increase in overweight and obesity in children may be slowing.

Obesity in childhood has been associated with increased risk of cardiovascular disease (due to raised blood lipids, hypertension, and insulin resistance) and some cancers later in life. Type 2 diabetes used to be associated with adults but is increasingly seen in overweight adolescents and children. There is also an association between obesity and incidence of asthma, sleep apnea, and orthopedic problems.

Early introduction of solid foods (before 6 months) has been associated with an increased risk of obesity. Conversely, breast-feeding has been shown to protect against obesity in later life; the longer the duration, the smaller the risk.

In the shorter term, obesity can have a big impact on social and psychological well-being and has been linked with early puberty, low self-esteem, low self-confidence, and depression.

Overweight is essentially an imbalance between energy intake and energy expenditure. There does not appear to be any one dietary or lifestyle factor contributing to the rapid rise we have seen in obesity but rather a combination of many interlinking variables. One of the first steps is to try and identify what factors might be contributing to overweight. This will vary from individual to individual. Below are some of the possible contributing factors and suggestions for intervention.

Goal 1: Family focus

Before any change can happen, both the family and the child must be able to identify obesity as a problem and be willing to attempt lifestyle changes.

Focus on the whole family not just the child when discussing healthy eating and physical activity.

Encourage a long-term healthy lifestyle for the whole family. Children learn by example, if they see their parents and siblings eating healthy they are more likely to follow.

Just like anything we learn, repetition is the key; the more often healthy eating and physical activity is encouraged, the more likely it is to

become habit. And if the whole family is doing it, it is more likely to be maintained.

Parents need to take responsibility for ensuring that healthy foods are purchased and offered and older children need to take responsibility for how much food they choose to eat.

The family should aim to eat together as a family at least five times a week.

Involve the peer group if appropriate. Education in schools can play a big part here.

Goal 2: Eat Regular Planned Meals

Avoid skipping meals as this frequently leads to binge eating on energy-dense snacks.

Always eat breakfast. Studies have shown that breakfast improves concentration and learning, improves the quality of the diet, and reduces the risk of binge eating on energy-dense snack foods.

Try to eat regular, evenly spaced meals and snacks at the same times every day to avoid excessive hunger and the temptation to snack on energy-dense foods.

Planning meals helps to avoid impulse eating. Plan the shopping list in advance to avoid impulse buying and read food labels to choose low-fat, low-sugar, low-energy products.

Goal 3: Variety

Choose from the four main food groups: breads and cereals, vegetables and fruit, meat/protein foods, and dairy foods.

Fruits and Vegetables: these should make up at least one third to one half of every main meal. Fresh, frozen, and canned varieties are all good. Choose canned varieties with no added sugar/salt and juices with no added sugar. Avoid adding butter/margarine, sauces, and dressings.

Breads and Cereals: choose whole grain/wholemeal varieties of breads and cereals as these contain more dietary fiber which will keep children feeling full for longer. Spreads and sauces should be low fat.

Meat Group: recommend lean meat, removing all visible fat and skin from poultry, canned fish in brine/water rather than in oil, and limit fatty meats such as sausages, bacon, and processed sandwich meats.

Milk Group: low-fat or fat-free varieties of milk, yogurt and dairy desserts, and low-fat cheese should be encouraged.

Goal 4: Low Fat, Low Sugar, Low Energy

Reduce intake of energy-dense foods and drinks by reducing their availability.

A range of healthy snacks should be available, for example, fresh fruit, raw vegetables (e.g., carrot, cucumber, peppers, cherry tomato), low-fat yogurt, low-fat/sugar dairy desserts, popcorn, bread/toast.

Limit sugar sweetened drinks to no more than one per day (e.g., soft drinks, fruit juices drinks, sports drinks, flavored milk, squash).

Limit high-fat/sugar snacks that are energy dense but low in other nutrients, for example, crisps, chips, biscuits, pastries, sweets, chocolate.

Choose water as a drink or sugar-free drinks.

Choose low-fat, low-sugar varieties of packaged foods.

Choose low-fat cooking methods such as baking, steaming, boiling, microwave, or stir fry and avoid adding any fats during cooking (butter/margarine, oil).

Choose low-fat or fat-free dressings and sauces.

Skim the fat from soups, stews, and gravies.

Use low-fat or fat-free milk, yogurt, or fromage frais/crème fraiche instead of cream in soups, puddings, sauces, and baked products.

Sugar may also be listed as fructose, glucose, honey, or syrup. If sugar is one of the first few ingredients listed, the product is likely to be high in sugar.

Goal 5: Portion Size

Watch portion sizes. There is evidence that presenting children over the age of 3 years with larger portions of food leads to an increased intake of that food and in food and energy intake in general.[121]

Follow national plans for healthy eating such as “the eatwell plate” in the United Kingdom and “MyPlate” in the United States as a guide to the amount of different food groups that should make up a plate of food at each meal.

Remember that children need less than adults.

Avoid second helpings, particularly of meats, desserts, and other high-fat foods.

Slow down to eat, it should take about 20 minutes to eat a meal. This allows time for the stomach to register that it has had enough. If the child is still hungry at the end of a meal, wait 20 minutes and if still hungry offer low-fat items such as vegetables or fruits.

Goal 6: Eating Out

Limit takeaway food to no more than once a week.

When out and about, take food with you or look for low-energy choices.

Avoid fried foods and choose salads, fruits, and sandwiches with low-fat fillings.

Avoid adding extra sauces, gravies, and dressings or ask for low-fat varieties if available.

Drink water at meal times.

Avoid dishes that are cream or cheese based.

If portion sizes are large, it's okay to leave some, or ask for a container to take the rest home.

Check that the school offers appropriate choices, if not, provide a healthy packed lunch.

Allow a little bit of flexibility for parties and special occasions. Try to encourage healthy choices and avoid overeating; but accept that it is what you eat on most days that matters.

Goal 7: Physical Activity

Exercise is a vital part of any weight control program. It must go hand in hand with dietary changes.

Reduce sedentary behavior and increase lifestyle physical activity.

All children should aim for 60 minutes of moderate intensity physical exercise per day. Twice a week this should include more intense activities that improve bone health, muscle strength, and flexibility such as running, cycling, or swimming.

Limit TV to two hours a day and avoid eating in front of the TV.

Additional Guides

Aiming for weight maintenance (whilst height increases) rather than weight loss is generally recommended for children who are still growing. However, this depends on the severity of the problem and the age of the child. If a child is obese and is experiencing other health problems such as type 2 diabetes or hypertension, then carefully controlled and supervised (by a doctor and/or dietitian) weight loss may be advisable. For obese adolescents, weight loss and/or use of drugs may be considered in addition to lifestyle changes.

Avoid frequent weighing as this can be disheartening (every one to two weeks is more than enough). If a doctor or dietitian is monitoring their

weight, parents may not need to weigh them at all. This can help them to focus more on a healthy lifestyle rather than weight loss. Changing behavior is more important than focusing on one weight measurement.

Avoid using food as a reward or punishment.

Set goals that are specific and achievable, taking into account time, money, family routines, skills, and knowledge base.

Work on one or two changes at a time and use nonfood-based rewards to mark achievements, for example, a trip to the cinema.

Emphasize small gradual changes. If the aim is for weight loss, it should not be more than 1-2 pounds (1/2–1 kg) a week.

Remain positive and accept that there will be setbacks. Focus on what has been achieved rather than on moments of indiscretion.

Nutrition Support Teams

71

Virginie Colomb, MD, PhD and Cécile Lambe, MD

INTRODUCTION

Major insufficiencies in nutrition care have been reported in the hospital setting in developed countries. The reported prevalence of malnutrition in hospitalized children ranges from 15% to 30%, with an impact on growth, morbidity, and mortality. The implementation of nutrition support teams (NSTs) has been suggested to improve nutritional management for hospitalized patients. The main objectives of the NSTs include screening for nutritional risk, identification of patients who require nutritional support, provision of adequate nutritional management, education and training of hospital staff, and audit of practices including cost-effectiveness. The NST should be multidisciplinary, with expertise in all aspects of clinical nutrition care. The funds needed for NSTs should be raised from the health-care system whenever possible. This chapter reviews the disease related-mechanisms causing malnutrition, the consequences of malnutrition, and provides the frame for implementation of NSTs in pediatric units. Further research is needed to evaluate the impact of NSTs in prevention and management of pediatric nutritional disorders, including cost-effectiveness in different settings.

Malnutrition is common among hospitalized children, but hardly recognized and, therefore, not prevented or treated often enough. In spite of major advances in the quality of care in many other areas of pediatric medicine, the prevalence of malnutrition in hospitalized children has not changed apparently over the last three decades, ranging from 15% to 30% of patients, depending on the criteria used to define “malnutrition,” the patient population, and their disease spectrum.[1–10] The detrimental effects of malnutrition on growth, morbidity, and mortality in hospitalized

children are often underestimated. An expert report of the Council of Europe has highlighted major insufficiencies in nutritional care in European hospitals and provided recommendations for improving the situation, including the implementation of nutritional support teams (NSTs) in hospitals.[11] The main goal of NSTs should be to provide optimal nutrition to all the patients,[12] especially in case of need for enteral nutrition (EN) or parenteral nutrition (PN) supplementation.[13,14]

In 2005, the Committee on Nutrition of the European Society of Pediatric Gastroenterology, Hepatology, and Nutrition published a comment which underlined the need for NSTs in pediatric hospital settings.[15]

Mechanisms of Malnutrition in Sick People

Malnutrition starts with inadequate nutrient intake to meet physiological requirements, followed by metabolic and functional alterations, all of which accompanied by impairment of body composition. Regardless of primary disease and age, malnutrition is always the consequence of imbalance between (reduced) nutritional supplies and (increased) protein–energy needs. The primary disease often induces anorexia limiting food intake. In addition, the acute disease (e.g., sepsis, trauma, burn, cancer),[16,17] chronic illness (e.g., inflammatory bowel disease, congenital heart disease, chronic renal failure,[18] cystic fibrosis, severe neuromuscular impairment), or medications increase imbalance between protein and/or energy demands and supply. An increase in resting energy expenditure, protein turnover, and protein breakdown has been shown in children after blunt trauma.[16] Sepsis and fever also induce protein breakdown and increases resting energy expenditure.[19,20] However, in pathologic situations, a decrease in physical activity-related energy expenditure may compensate for the latter.

In children, linear growth depends on a permanent increase in fat and lean body mass, which requires positive energy and nitrogen balance. Therefore, any increase in nutritional demands competes with the specific needs of growth, especially during periods of high-speed growth, like infancy and adolescence or catch-up growth. Consequently, sustained nutritional imbalance induces growth retardation, with a decrease in height-for-age ratio (height divided by the expected height, taken as 50th centile for age and gender).

Assessment of Nutritional Risk and Malnutrition

In clinical practice, nutritional risk and malnutrition are difficult to assess due to lack of simple, sensitive assessment tools and due to the difficulty in separating the impact of malnutrition and of the disease state on some biological markers of malnutrition (e.g., hypoalbuminemia is a marker of both malnutrition and also a marker of severe inflammation or protein-loosing enteropathy) and on outcome.

Nutritional Risk

Children admitted to hospital are at risk for developing malnutrition, even when nutritional status is normal at the time of admission. The size of the so-called "reservoir of malnutrition" among children who are not measurably malnourished but are at risk to become malnourished is hard to determine.[4,10] Several pediatric nutritional risk scores have been proposed over the last 10 years. One of them, specifically designed for children with cancer, takes into account anorexia and gastrointestinal symptoms.[21] Another one, designed for all types of pediatric illnesses, emphasizes the role of severity of the underlying disease, pain, and reduced nutritional intake.[22] Systematic utilization of such scores could help for timely implementation of adequate nutritional support, thus preventing the occurrence or worsening of malnutrition. However, some tools mix criteria of malnutrition and criteria of nutritional risk,[23,24] leading to confusion in the concept of "risk,"[25] and none has been universally accepted and used.[10]

Nutritional Status

The nutritional status is not easier to determine in routine.[26,27] Either subjective[28] or objective, tool-based,[23,24] nutritional screening should lead to quick and reliable triage of children in order to identify those who need more detailed assessment and intervention. The most obvious and earliest clinical sign of malnutrition in children is the absence of linear weight gain, followed by weight loss with visible decrease in fat and muscle mass. The weight-for-height ratio (weight divided by the expected weight taken as 50th centile for height and gender) is widely accepted as a criterion for children malnutrition, but its calculation is a source of errors[26,27,29] and appropriate reference standards for weight-for-height are not available. Apparently, in western countries, not all the expert pediatric societies have developed any policy on the problem of identifying malnutrition in hospitalized children.[10] Whatever the screening method used, careful measurements and use of appropriate growth charts are essential for the

diagnosis of malnutrition in children.[29] One of the factors contributing to the nonrecognition of malnutrition is obviously the failure to measure routinely weight and height in hospitalized children at admission and during hospital stay. Recently, the Nutrition Committee of the French Pediatric Society again recommended weighing and measuring any child when hospitalized or seen in outpatient clinic.[30] These experts recommend to calculate the body mass index (BMI) when growth kinetics cannot be analyzed and state that any child with a BMI below the third centile, or minus 2 standard deviations for age and gender, needs further nutritional assessment.[30]

Consequences of Hospital Malnutrition

Malnutrition is associated with an increase in morbidity and mortality in hospitalized patients. For instance, it was demonstrated that the nutritional status of the children hospitalized in a pediatric intensive care unit with respiratory syncytial virus infection was related significantly to outcomes, such as length of stay, number of days on ventilation, and duration of PN.[31] Data obtained in adult patients have also shown that malnutrition increases length of stay, and therefore hospital costs.[32,33] The increasing prevalence of children with chronic diseases amplifies the problem both during hospital stays and in outpatient care.

The Impact of Hospital Practices on Nutrition Support

In the beginning of 2000s, the Council of Europe provided a review of the current practices in Europe regarding food provision and nutritional care and support of hospitalized patients, focusing mostly on adults.[11] This report highlights major deficiencies related to hospital organization of nutritional care. It states that *«routine nutritional risk screening and nutritional assessment is generally not performed (…);… «the use of energy and protein- dense menu is not widespread, meal times are often inflexible and/or unadapted to patients' food habits, food intake is infrequently recorded, the use of nutritional support for undernourished patients and nutritionally at risk patients is sparse, inconsistent and often performed in special patients or patients who are severely undernourished and that responsibilities and tasks of each personal involved in the food service and the nutritional care of the patient are not clearly assigned…».* The report also pointed out the lack of appropriate education and training of all professionals involved regarding nutrition, as a major cause of malnutrition in hospitalized patients and therefore, advocated the

implementation of NSTs in hospitals. The American Society of Parenteral and Enteral Nutrition also emphasizes that "*organized nutrition support services or teams are associated with improved patient outcomes, decreased length of hospitalization, and improved cost-effectiveness*" and recommends "*if an institution does not have a defined nutrition support services or team, it is recommended that an interdisciplinary team provides specialized nutrition support.*"[34,35]

The Concept of the Nutrition Support Team

The first NSTs were born in the early 1980s.[36–38] The concept of NST was based on the acknowledgement of the fact that most physicians are poorly teached and trained in the domain of nutrition and the idea that the nutrition management of the hospitalized patient would be best addressed through the intervention of a well-organized and coordinated multidisciplinary group, knowledgeable in clinical nutrition, working together as a team.

The Tasks of Nutrition Support Teams

As for any hospital service, the tasks of the NST might be divided into three major categories: patient's care, education/training of physicians and other professionals in the area of nutrition, and research. The main roles of the NST are to implement patient screening for nutritional risk and malnutrition; to identify patients who require further nutritional assessment and nutritional support; to ensure provision of adequate nutritional management to patients; to plan and organize optimal home nutrition after discharge; to educate hospital staff with respect to identification and management of nutritional problems; and to provide standardized protocols and algorithms. The NSTs also have to monitor and evaluate practices, to document and audit its own work, and to provide results to hospital management. The NST members should also participate in training activities by which their own level of practice is raised, and where possible in research.

Composition and Qualification of the Nutrition Support Team

The composition of NSTs varies according to the type of institution, the tasks of the team, and availability of staff and funding. In addition to a senior physician knowledgeable in nutrition, the NST should include a dietician/nutritionist, a nurse, and, if possible, a pharmacist, with some

team members contributing only part of their work time.

In pediatric hospitals, a pediatrician—whose specific competence should be recognized by other physicians and other members of the NST—usually assumes the role of the NST leader. Thus, the leader of the NST has to combine nutrition knowledge, teaching, and management skills enabling successful interactions with all involved disciplines.

Dieticians/nutritionists evaluate the nutritional intakes, advise on improving oral, EN and PN, and may participate in the patient's and family training at the time of planning home EN or PN. Nurses also play a key role in the education and training of hospital staff, especially regarding the techniques of EN and PN, including care for gastrostomies and central venous lines.[39] Nurses also participate in patient's and family training prior to discharge on home nutrition. Depending on the size of the hospital and the amount of tasks covered by the NST, one or more further pediatricians may be necessary, as well as secretarial support and a data coordinator.

Impact of the NST on Patients' Outcome and Cost of Care

Several studies in adults and children in hospitals have shown benefits of the presence of an NST. Patients' outcome is improved by early nutritional support, as assessed by a study in adult patients which showed that a 2-day-earlier nutrition intervention saved 1 day of hospital stay.[32] The NST can improve timing of nutrition intervention through a staff education plan, as shown in 1998 in a pediatric intensive care unit.[40] The implementation of an NST has appeared of particular importance to improve the quality and safety of PN prescription and follow-up, since this form of nutrition is at high risk and high costs.[37,38,41–48] The NST advises physicians on the indication for PN, the optimal composition of PN intakes and thus the choice of standardized or individual PN formulations.[49–51] In hospitals (units) where PN bags should be prepared "on demand," the NST, in cooperation with pharmacists,[51] should ensure that PN compounding and additions (of micronutrients or other components) are performed under sterile conditions according to agreed quality assurance guidelines. Along with the closer supervision of PN, implementation of NSTs has shown to induce a relative increase in the use of enteral feeding and finally helps cost savings.[13,41,53] In 1990, a study conducted in a 500 bed-institution in the United States demonstrated that the NST action, by close supervision of PN indications and procedures, could lead to savings of about 100,000 US $ in 1 year.[41] For all these reasons, the German

Association for Nutritional Medicine, in the Guidelines on Parenteral Nutrition published in 2009, stated that interdisciplinary NSTs should be established in all hospitals.[38]

Obstacles to Establishing a Nutrition Support Team

Although the benefits of NSTs have been confirmed in terms of patients' outcome and cost of care,[54] better recognition of malnutrition issues and initiation of adequate nutritional support as a priority by both physicians and hospital managers are still needed. Therefore, a new NST has often to demonstrate that malnutrition exists at admission and/or appears during hospitalization.

Measuring the Performance of an NST

The NST should show the deleterious medical and financial consequences of malnutrition and should perform audits on its own activity and results, and also to demonstrate the benefits of the intervention of nutrition specialists.[39,41,52,55] A business plan is needed to demonstrate the importance of the NST to the hospital management both medically (diagnosis and intervention) and financially (decreasing hospital costs). NSTs may justify their existence by specifying the most beneficial therapy for the patient at the most cost-effective method for the hospital. For example: the NST will improve the indications for nutrition support so that no patient receives expensive—and sometimes risky treatment unless it is clearly needed; the team will improve the choice of nutrition route so that 100% of the patients who can be fed enterally are fed via this route.[54] In view of the considerably potential for cost savings, the funds needed for running an NST should be raised from the health-care system whenever possible. At the start, it might be advisable to select a small field for a concentrated effort, for example, a pediatric cancer unit or a cystic fibrosis clinic, with a highest chance to demonstrate success.

The Weaknesses and Limitations of NSTs

NSTs still suffer from several weaknesses which limit their impact of the quality of nutritional care of hospitalized patients. Most of them are related to the poor recognition/acceptance of the nutrition therapy by both the health-care professionals and the hospital operating institutions:

- **Lack** of fundings and therefore lack of means devoted to nutrition care. This explains why an European survey showed that very

few of the physicians working in an NST are exclusively devoted to it, when most of the NST managers could spend a mean of 5.5 hours per week only for the NST.[56]

- **Lack** of faculty curriculum and approval of the qualification in Nutrition Medicine by the Health Board.[15,56]
- **Lack** of "decision autonomy" in nutrition care, lack of systematic screening of all patients admitted to the hospital… Due to its consultative function, the impact of the NST on patient's care and outcome is limited by the degree of acceptance/acknowledgment of expertise of the NST by the primary physicians who are in charge of the patients. A study demonstrated 30 years ago, that the incidence of PN complications was greater when the NST was purely consultative than during the period when the NST increased its involvement in patients' care.[37] More recently, an European survey of structure and organization of NSTs showed that none of them were deciding independently on the nutrition therapy and 52% were consulting.[56] Most of the requests to the NSTs were in case of questions or problems while the NSTs were called in less than 30% at admission of the patient.[56]

The Prevalence of NSTs in Pediatric Hospitals in the Twentieth Century

In 1995, nutrition support pharmacists in the United States provided a survey, which showed that >65% of them practiced in hospitals had an NST, but by 2002, this number had dropped to 49.5%.[57,58] In Germany, a survey was conducted in 2000 in the aim to investigate the number, structure, and performance of NSTs in more than 800 acute care hospitals of more than 250 beds. It showed a prevalence of NSTs of 5.6%, out of which the number of specific pediatric NSTs was not specified.[59] The majority of NSTs were informed only when specific questions or problems regarding clinical nutrition were raised and decision making in nutritional support was mainly done by health-care professionals outside the NST. Four years later, a survey screened more than 3000 hospitals in Germany, Austria, and Switzerland, and found NSTs, defined by a minimum one physician plus one staff, in only 3.2% of them. Most NSTs were located in university/academic teaching hospitals with a high number of beds and a large spectrum of specialties with a high requirement for nutrition-therapeutical interventions.[56] Ten years ago, a study described hospital pharmacists' practices in Belgium, France, and Switzerland and reported

that NSTs were present in 32%–45% of the hospitals surveyed.[60]

However, over the last 10 years, few data have been available in scrutinizing the prevalence and structure of NSTs in western countries, particularly in pediatric hospitals.

Key Messages

1. Implementation of NSTs in hospitals is recommended to improve nutritional management of sick children.
2. The main tasks of NSTs include patient screening for nutritional risk, identification of patients who require nutritional support, provision of adequate nutritional management for patients, education and training of hospital staff, and audit of practice.
3. The NST should be independent, multidisciplinary, with expertise in all major aspects of clinical nutrition care.
4. The funds needed for NSTs should be raised from the health-care system.
5. Further research is needed to evaluate the effects of NSTs in prevention and management of pediatric nutritional disorders, including cost effectiveness in different settings.

Statural growth in Williams-Beuren syndrome. *Eur J Pediatr*. 1992;151;751–755.[a] Height-for-age, head-circumference-for-age Pankau R, Partsch CJ, Neblung A, et al. Natural history of body mass index in Williams-Beuren syndrome. *Am J Med Genet*. 1994;52(1):51–54. BMI-for-age, both genders, 0–18 y Martin NDT, Smith WR, Cole TJ, Preece MA. New height, weight, and head circumference charts for British children with Williams syndrome. *Arch Dis Child*. 2007;92(7):598–601. Height-, weight-, head circumference-, and BMI-for-age

[a] A copy of the growth chart is included in this appendix.

TABLE I-11 Clinical Examination in Nutritional Deficiencies and Excesses

	Major Physiologic Status Functions	Deficiency Signs	Excess Signs	Important Food Sources	Potential Causes of Deficiency	Status Assessment
Nutrient						
Carbohydrate	Supplies energy at an average of 4 kcal/g (sparing protein) and is the major energy source for CNS function; unrefined, complex carbohydrates supply fiber that aids in normal bowel function	Ketosis	May cause diarrhea, obesity	Bread, cereals, crackers, potatoes, corn, simple sugar (sugar, honey), fruits and vegetables, milk, breast milk, infant formula	Malabsorption	Blood sugar, OGTT
Fat	Concentrated calorie source at an average of 9 kcal/g; constitutes part of the membrane structure of every cell; supplies essential fatty acids; provides and carries fat-soluble vitamins (A, D, E, K)	Essential fatty acid deficiency (dry, scaly skin, poor weight gain, hair loss); requirements are increased by cell turnover	Atherosclerosis may be affected by excessive intakes of certain dietary fats; altered blood lipid levels	Shortening, oil, butter, margarine, protein-rich foods (meat, dairy, nuts), breast milk, infant formula	Cystic fibrosis, biliary disease, short bowel syndrome, hereditary lipoprotein disorders	Total cholesterol, LDL, HDL
Protein	Supplies energy at an average of 4 kcal/g; regulates body processes as part of enzymes, hormones, body fluids, and antibodies, which increase resistance to infection; provides nitrogen; constitutes part of the membrane structure of every cell	Dry, depigmented, easily pluckable hair; bilateral, dependent edema, cirrhosis, fatty liver, decreased visceral proteins; skin is dry with pellagroid dermatosis in severe cases	Azotemia, acidosis, hyperammonemia	Meat, poultry, fish, legumes, eggs, cheese, milk and other dairy products, nuts, breast milk, infant formula	Protein-losing enteropathy, liver disease, gastrointestinal disease, renal disease	Albumin, retinol-binding protein, prealbumin
Fat-soluble vitamins						
Vitamin A	Formation and maintenance of skin and mucous membranes; necessary for the formation of rhodopsin (the photosensitive pigment of the rods governing vision in dim light); regulation of membrane structure and function; necessary for growth and normal immune function	Night blindness, degeneration of the retina, xerophthalmia, follicular hyperkeratosis, poor growth, keratomalacia, Bitot's spots	Fatigue, malaise, lethargy, abdominal pain, hepatomegaly, alopecia, headache with increased intracranial pressure, vomiting	Carrots, liver, green vegetables, sweet potatoes, butter, margarine, apricots, melons, peaches, broccoli, cod liver oil, breast milk, infant formula	Liver disease, cystic fibrosis, short bowel syndrome, protein deficiency (alters transport)	Plasma retinol (HPLC), plasma retinol-binding protein, relative dose response, dark adaptation test, liver biopsy concentration

Vitamin D	Promotes intestinal absorption of calcium and phosphate and renal conservation of calcium and phosphorus	Rickets, osteomalacia, costochondral beading, epiphyseal enlargement, cranial bossing, bowed legs, persistently open anterior fontanel	Hypercalcemia, vomiting, anorexia, diarrhea, convulsions	Cod liver oil, fish, eggs, liver, butter, fortified milk, sunlight (activation of 7-dehydrocholesterol in the skin), infant formula	Liver disease, cystic fibrosis, short bowel syndrome, renal disease	Plasma 25-hydrooxyvitamin D (HPLC), serum alkaline phosphatase, calcium and phosphate, radiography, bone densitometry
Vitamin E	Acts as an antioxidant and free radical scavenger to prevent peroxidation of polyunsaturated fatty acids in the body; neuromuscular function	Hemolytic anemia in the premature and newborn, enhanced fragility of red blood cells, increased peroxidative hemolysis	In anemia, suppresses the normal hematologic response to iron	Oils high in polyunsaturated fatty acids, milk, eggs, breast milk, infant formula	Cystic fibrosis, short bowel syndrome, liver disease	Plasma tocopherol (HPLC) (corrected for total or LDL cholesterol), hydrogen peroxide hemolysis
Vitamin K	Necessary for prothrombin and the three blood-clotting factors VII, IX, and X; half of the vitamin K in humans is of intestinal origin, synthesized by gut flora; necessary for bone mineralization	Hemorrhagic manifestations (especially in newborns), prolonged clotting	Hemolytic anemia, nerve palsy	Green leafy vegetables, fruits, cereals, dairy products, soybeans, breast milk, infant formula	Liver disease, antibiotic therapy	Prothrombin time (prolonged), plasma phylloquinone, clotting factor levels, proteins induced by vitamin K absence or antagonists-II (PIVKA-II)
Water-soluble vitamins						
Ascorbic acid (vitamin C)	Forms collagen cross-linkage of proline hydroxylase, thus strengthening tissue and improving wound healing and resistance to infection; aids absorption of iron	Joint tenderness, scurvy (capillary hemorrhaging), impaired wound healing, acute periodontal gingivitis, petechiae, purpura, anemia	Documentation of a chronic high intake may result in "rebound" deficiency symptoms	Heat labile; broccoli, papaya, orange, mango, grapefruit, strawberries, tomatoes, potatoes, leafy vegetables, breast milk, infant formula	Stress	Plasma level (enzyme assay/HPLC), leukocyte concentration (longer-term), whole blood concentration, urine concentration
Biotin	Component of several carboxylating enzymes; plays an important role in the metabolism of fat and carbohydrate	Anorexia, nausea, vomiting; glossitis; depression; dry, scaly dermatitis; thin hair; loss of eyebrows	None known	Liver, kidney, egg yolk, breast milk, infant formula	Certain inborn errors of metabolism	Plasma (microbiologic assay), plasma lactate, urine organic acids, lymphocyte carboxylase

Cobalamin (B_{12} intrinsic factor required)	Cobalamin-containing co enzymes function in the degradation of certain odd chain fatty acids and in the recycling of tetrahydrofolate	Megaloblastic anemia, neurologic deterioration	None known	Animal products, breast milk, infant formula	Ileal disease, strict vegetarian, lack of intrinsic factor	Plasma level (RIA or microbiologic), Schilling test, plasma homocysteine, deoxyuridine suppression test
Folacin	Utilized in carbon transfer and nucleotide synthesis	Megaloblastic anemia, stomatitis, glossitis, neural tube defects in pregnancy	None known	Liver, leafy vegetables, fruit, yeast, breast milk, infant formula	Liver disease, alcoholism, celiac disease, inflammatory bowel disease	Plasma level (RIA or microbiologic), red cell level
Niacin	Aids in energy utilization as part of a coenzyme (NAD^+ and $NADP^+$) in fat synthesis, tissue respiration, and carbohydrate utilization; aids digestion and fosters normal appetite; synthesized from the amino acid tryptophan	Pellagra (dermatitis, diarrhea, dementia, death), cheilosis, angular stomatic inflammation of mucous membranes, weakness	Dilation of the capillaries, vasomotor instability, "flushing" (utilization of muscle glycogen, serum lipids, mobilization of fatty acids during exercise)	Liver, meat, fish, poultry, peanuts, fortified cereal products, yeast, breast milk, infant formula	B_6 deficiency (impairs conversion of tryptophan to niacin)	Urine ratio of metabolites (*N*-methyl-nicotinamide: 2-pyridone), tryptophan load, red cell NAD or NAD:NADP ratio
Pantothenic acid	Component of coenzyme A; plays a role in release of energy from carbohydrates and in synthesis and degradation of fatty acids	Infertility, abortion, slow growth, depression, vomiting, malaise, abdominal stress	Diarrhea, water retention	Meat, fish, poultry, whole grains, legumes, breast milk, infant formula	Severe malnutrition	Urine excretion, whole blood level (RIA/ microbiologic)
Pyridoxine (B_6)	Coenzyme component for many of the enzymes of amino acid metabolism; all compounds implicated as neuro-transmitters are synthesized and/or metabolized in B_6-dependent reactions	Convulsions, weight loss, ab-dominal distress, vomiting, hyperir-ritability, depres-sion, confusion, hypochromic and macrocytic anemia	Neuropathy	Fish, poultry, meat, wheat, breast milk, infant formula	Elderly, high protein intake	Red cell amino-transferase activity, plasma pyridoxal phosphate (HPLC), tryptophan load test, urine 4-pyridoxic acid

Riboflavin (B_2)	Functions primarily as the reactive portion of flavoproteins concerned with biologic oxidations (cellular metabolism)	Cheilosis, glossitis, photophobia, angular stomatitis, corneal vascularization, scrotal skin changes, seborrhea, magenta tongue	None known	Dairy products, liver, almonds, lamb, pork, breast milk, infant formula	Alcoholism, starvation, chronic diarrhea, malabsorption	Red cell glutathione reductase activity (EGR), red cell flavin adenine dinucleotide, urine riboflavin: creatinine ratio
Thiamine (B_1)	Aids in energy utilization as part of coenzyme component to promote the utilization of carbohydrate; promotes normal functioning of the nervous system; coenzyme for oxidative carboxylation of 2-keto acids	Beriberi, neuritis, cardiac failure, anorexia, restlessness, confusion, loss of vibration sense and deep tendon reflexes, calf tenderness, edema	None known	Lean pork, nuts, whole grain and fortified cereal products, breast milk, infant formula	Alcoholism, refeeding syndrome, prolonged dialysis	Red cell transketolase activity, whole blood level (HPLC), urine thiamine: creatinine ratio
Minerals						
Calcium	Essential for calcification of bone (matrix formation); assists in blood clotting; functions in normal muscle contraction and relaxation and in normal nerve transmission	Osteomalacia, osteoporosis	Hypercalcemia, vomiting, anorexia, lethargy	Dairy products (milk, cheese), sardines, oysters, salmon, herring, greens, breast milk, infant formula	Renal disease, liver disease	Plasma total calcium, plasma free calcium in altered protein binding (e.g., hypoalbuminemia), acidosis, radiographs, CT, photon densitometry
Magnesium	Essential part of many enzyme systems; important for maintaining electrical potential in nerves and muscle membranes and for energy turnover	Tremor, convulsions, hyperexcitability (hypocalcemia tetany)	Diarrhea, transient hypocalcemia	Widely distributed, especially in food of vegetable origin; breast milk, infant formula	Protein calorie malnutrition, refeeding syndrome	Plasma total or free magnesium, magnesium loading test
Phosphorus	Important intracellular anion; involved in many chemical reactions within the body; necessary for energy turnover (ATP)	Weakness, anorexia, malaise, bone pain, growth arrest	Hypocalcemia (when parathyroid gland not fully functioning)	Dairy products, fish, legumes, pork, breast milk, infant formula	Renal disease, liver disease, refeeding syndrome	Plasma concentration, alkaline phosphatase activity, radiography, densitometry, renal tubular excretion threshold

Trace elements						
Chromium	Maintenance of normal glucose metabolism, cofactor for insulin	Disturbed glucose metabolism (lower glucose tolerance caused by insulin resistance)	None known	Brewer's yeast, meat products, cheeses	Protein calorie malnutrition, elderly	Plasma chromium, glucose tolerance
Copper	Constituent of proteins and enzymes, some of which are essential for the proper utilization of iron; immunity; skeletal development	Anemia (hemolytic), neutropenia, bone disease	Excess accumulation in the liver, brain, kidney, cornea; anemia, diarrhea	Oysters, nuts, liver, kidney, corn oil margarine, dried legumes	Menke's kinky hair syndrome. Excess: Wilson's disease	Plasma copper, plasma ceruloplasmin (ferrochelatase), liver biopsy concentration, superoxide dismutase activity
Fluoride	The main target organs of fluoride in man are the enamel of teeth and bones, where fluoride is incorporated into the crystalline structure of hydroxyapatite and produces increased carie resistance	Poor dentition, caries, osteoporosis	Mottling, brown staining of teeth (in excess of 4 ppm); fluorosis occurs after prolonged (10–20 y) ingestion of 20–80 mg/d	Fluoridated water; depends on the geochemical environment and therefore amount in food varies widely	Unfluoridated water, bottled water	
Iodine	Component of thyroid hormones triiodothyronine and thyroxine; important in regulation of cellular oxidation and growth	Goiter, depressed thyroid function, cretinism	Thyroid suppression (thyrotoxicosis)	Iodized table salt, salt water, fish, shellfish (content of most other foods geographically dependent), breast milk, infant formula	Endemic goiter in low-iodine areas	Thyroid hormones, TSH, urinary iodide/creatinine ratio
Iron	Part of hemoglobin molecule; prevents nutritional anemia and fatigue; increases resistance to infection; functions as part of enzymes involved in tissue respiration	Anemia, malabsorption, irritability, anorexia, pallor, lethargy	Hemosiderosis, hemochromatosis	Red meats, liver, dried beans and peas, enriched farina, breast milk, infant formula, infant cereal	Protein-losing enteropathy, malabsorption, acute or chronic blood loss. Excess: hemochromatosis	Plasma iron and ferritin, total iron-binding capacity, hemoglobin/hematocrit, red cell indices, RBC zinc protoporphyrin: heme ratio, bone marrow aspirate stain

Manganese	Essential part of several enzyme systems involved in protein and energy metabolism and in the formation of mucopolysac charide	Impaired growth, skeletal abnormalities, lowered reproductive function, neonatal ataxia	In extremely high exposure of contamination, severe psychiatric and neurologic disorders	Nuts, whole grains, dried fruits, fruits, leafy vegetables		Plasma level, whole blood level, mitochondrial superoxide dismutase
Molybdenum	Essential for the function of flavin-dependent enzymes involved in the production of uric acid and in the oxidation of aldehydes and sulfites	Not described in man	Acts as an antagonist to the essential element copper; gout-like syndrome associated with elevated levels of molybdenum, uric acid, and xanthine oxidase	Varies considerably, depending on growing environment; main contributions come from meat, legumes		
Selenium	Functions as a part of the enzyme glutathione peroxidase, which protects cellular component from oxidative damage	Cardiomyo-pathy probably secondary to oxidative damage	In animals, blindness, abdominal pain	Seafoods, kidney, liver meat, grains (depending on growing environment)	Cystic fibrosis	Plasma concentration, glutathione peroxidase activity, nail/ hair selenium
Zinc	Constituent of enzymes involved in most major metabolic pathways (specifically nucleic acid synthesis for growth and repair)	Growth failure, skin changes, delayed wound healing, hypogeusia, sexual immaturity, hair loss, diarrhea	Acute gastrointestinal upset, vomiting, sweating, dizziness, copper deficiency	Whole grains, legumes, beef, lamb, pork, poultry, nuts, seeds shellfish, eggs, some cheeses, breast milk, infant formula	Malabsorp-tion, chronic diarrhea, liver disease, sickle cell disease	Plasma concentration, alkaline phosphatase activity, urinary excretion, leukocyte concentration

APPENDIX II

Nutritional Requirements

RDA, recommended dietary allowance; UL, upper intake levels.

Adequate intakes (AIs) are followed by an asterisk (*).

[a]ND = not determinable due to lack of data of adverse effects in this age group and concern with regard to lack of ability to handle excess amounts.

TABLE II-5 Dietary Reference Intakes (DRIs): Estimated Energy Requirements

Category	Estimated Energy Requirements (kilocalories)
Infants and children (0–2 y)	
0–3 mo	(89 × wt [kg] – 100) + 175
4–6 mo	(89 × wt [kg] – 100) + 56
7–12 mo	(89 × wt [kg] – 100) + 22
13–35 mo	(89 × wt [kg] – 100) + 20
Males	
3–8 y	88.5 – 61.9 × age [y] + PA[a] × (26.7 × wt [kg] + 903 × ht [m]) + 20
9–18 y	88.5 – 61.9 × age [y] + PA × (26.7 × wt [kg] + 903 × ht [m]) + 25
>19 y	662 – 9.53 × age [y] + PA × (15.91 × wt [kg] + 539.6 × ht [m])
Females	
3–8 y	135.3 – 30.8 × age [y] + PA × (10.0 × wt [kg] + 934 × ht [m]) + 20
9–18 y	135.3 – 30.8 × age [y] + PA × (10.0 × wt [kg] + 934 × ht [m]) + 25
>19 y	354 – 6.91 × age [y] + PA × (9.36 × wt [kg] + 726 × ht [m])
Pregnancy	
1st trimester	Nonpregnant EER
2nd trimester	Nonpregnant EER + 340
3rd trimester	Nonpregnant EER + 452
Lactation	
1st 6 mo	Nonpregnant EER + 330
2nd 6 mo	Nonpregnant EER + 400

EER, estimated energy requirement

[a]PA = physical activity coefficient based on physical activity level (PAL); PA = 1.00 if PAL is estimated to be 1.0–1.39 (sedentary); PA = 1.12 if PAL is estimated to be 1.4–1.59 (low active); PA = 1.24 if PAL is estimated to be 1.6–1.89 (active); PA = 1.45 if PAL is estimated to be 1.9–2.5 (very active)

Complete report can be accessed at www.nap.edu.

TABLE II-6 Criteria and Dietary Reference Intake Values for Energy by Active Individuals by Life Stage Group*

Life Stage Group	Criterion	Active PAL[a] EER (kcal/d)	
		Male	Female
0–6 mo	Energy expenditure plus energy deposition	570	520 (3 mo)
7–12 mo	Energy expenditure plus energy deposition	743	676 (9 mo)
1–2 y	Energy expenditure plus energy deposition	1046	992 (24 mo)
3–8 y	Energy expenditure plus energy deposition	1742	1642 (6 y)
9–13 y	Energy expenditure plus energy deposition	2279	2071 (11 y)
14–18 y	Energy expenditure plus energy deposition	3152	2368 (16 y)
>18 y	Energy expenditure	3067[b]	2403[b] (19 y)
Pregnancy			
14–18 y	Adolescent female EER plus change in TEE plus pregnancy energy deposition		
1st trimester	2368 (16 y)		
2nd trimester	2708 (16 y)		
3rd trimester	2820 (16 y)		
19–50 y	Adult female EER plus change in TEE plus pregnancy energy deposition		
1st trimester	2403 (19 y)[b]		
2nd trimester	2743 (19 y)[b]		
3rd trimester	2855 (19 y)[b]		
Lactation			
14–18 y	Adolescent female EER plus milk energy output minus weight loss		
1st 6 mo	2698 (16 y)		

2nd 6 mo	2768 (16 y)

[a] EER, estimated energy requirement; PAL, physical activity level; TEE, total energy expenditure, the intake which meets the average energy expenditure of individuals at the reference height, weight, and age.

[b] Subtract 10 kcal/d for males and 7 kcal/d for females for each year above 19 years.

For healthy, active Americans and Canadians.

TABLE II-7 Criteria and Dietary Reference Intake Values for Carbohydrate by Life Stage Group

Life Stage Group	Criterion	EAR (g/kg/d)[a]		RDA (g/kg/d)[b]		AI (g/kg/d)[c]
		Male	Female	Male	Female	
0–6 mo	Average content of human milk					60
7–12 mo	Average intake from human milk plus complementary foods					95
1–3 y	Extrapolation from adult data	100	100	130	130	
4–8 y	Extrapolation from adult data	100	100	130	130	
9–13 y	Extrapolation from adult data	100	100	130	130	
14–18 y	Extrapolation from adult data	100	100	130	130	
> 18 y	Brain glucose use	100	100	0.80	130	
Pregnancy						
14–18 y	Adolescent female EAR plus fetal brain glucose use	135	175			
19–50 y	Adult female EAR plus fetal brain	135	175			
Lactation						
14–18 y	Adolescent female EAR plus average human milk content of carbohydrate	160	210			
19–50 y	Adult female EAR plus average human milk content of carbohydrate	160	210			

[a]EAR, estimated average requirement. The intake that meets the estimated nutrient needs of half of the individuals in a group.

[b]RDA, recommended dietary allowance. The intake that meets the nutrient needs of almost all (97%–98%) the individuals in a group.

[c]AI, adequate intake. The observed average or experimentally determined intake by a defined population or subgroup that appears to sustain a defined nutritional status, such as growth rate, normal circulatory nutrient values, or other functional indicators of health. The AI is used if sufficient scientific evidence is not available to derive an EAR. For healthy infants receiving human milk, the AI is the mean intake. The AI is not equivalent to an RDA.

Guide to Nutrient Requirements. Washington, DC: The National Academies Press; 2006; Reprinted with permission from the National Academies Press, Copyright 2006, National Academy of Sciences. Complete report can be accessed at www.nap.edu.

TABLE II-8 Criteria and Dietary Reference Intake Values for Protein by Life Stage Group

Life Stage Group	Criterion	AI or RDA for Reference Individual (g/d)		EAR (g/kg/d)[a]		RDA (g/kg/d)[b]		AI (g/kg/d)[c]
		Males	Females	Males	Females	Males	Females	
0–6 mo	Average consumption of protein from human milk	9.1 (AI)	9.1 (AI)					1.52
7–12 mo	Nitrogen equilibrium plus protein deposition	13.5	13.5	1.0	1.0	1.2	1.2	
1–3 y	Nitrogen equilibrium plus protein deposition	13	13	0.87	0.87	1.05	1.05	
4–8 y	Nitrogen equilibrium plus protein deposition	19	19	0.76	0.76	0.95	0.95	
9–13 y	Nitrogen equilibrium plus protein deposition	34	34	0.76	0.76	0.95	0.95	
14–18 y	Nitrogen equilibrium plus protein deposition	52	46	0.73	0.71	0.85	0.85	
>18 y	Nitrogen equilibrium	56	46	0.66	0.66	0.80	0.80	
Pregnancy							0.88	1.1
Lactation							1.05	1.3

[a]EAR, estimated average requirement. The intake that meets the estimated nutrient needs of half of the individuals in a group.

[b]RDA, recommended dietary allowance. The intake that meets the nutrient needs of almost all (97%–98%) the individuals in a group.

[c]AI, adequate intake. The observed average or experimentally determined intake by a defined population or subgroup that appears to sustain a defined nutritional status, such as growth rate, normal circulatory nutrient values, or other functional indicators of health. The AI is used if sufficient scientific evidence is not available to derive an EAR. For healthy infants receiving human milk, the AI is the mean intake. The AI is not equivalent to an RDA.

The EAR and RDA for pregnancy are only for the second half of pregnancy. For the first half of pregnancy, the protein requirements are the same as those of the nonpregnant woman.

TABLE II-17 Assessment of Energy Requirements in Hospitalized Pediatric Patients: Step 2. Factors Used in the Calculation of Total Energy Expenditure

Factors	
Activity	
Bedridden	1.20
Ambulatory	1.30
Fever	
Per degree Fahrenheit over normal	1.07
Injury	
Starvation	0.70
Minor surgery	1.00–1.20
Peritonitis	1.20–1.50

Soft tissue trauma	1.14–1.37
Skeletal trauma	1.35
Major sepsis	1.40–1.60
Severe thermal injury	2.00

Enteral Products

Melanie V. Connolly, MSc, RD

TABLE III-1 Enteral Product References: Infant (per 100 mL)

Product (Manufacturer)	kcal/mL	Protein			Fat			Carbohydrate			Na mEq	K mEq	Ca mg	Fe mg	P mg	Water mOsm/kg	General Comments
		g	% kcal	Source	g	% kcal	Source	g	% kcal	Source							
Human milk, term, mature	0.67	1.0	5	Whey and casein	3.90	55	Long chain fatty acids high in palmitic, oleic, linoleic and linolenic	7.2	38	Lactose	0.78	1.35	28	0.04	14	255	Preferred nutrition in human infants
EleCare (Abbott)	0.67	2.0	15	Free L-amino acids	3.2	42	High oleic safflower oil, MCT oil, soy oil	7.2	43	Corn syrup solids	1.3	2.6	78	1.2	57	335	100% Free amino acids 33% fat as MCT oil
Enfamil A.R. (Mead Johnson)	0.67	1.7	10	Nonfat milk	3.4	46	Palm olein, soy oil, coconut oil, high oleic sunflower oil	7.3	44	Lactose, rice starch, malto-dextrin	1.17	1.87	53	1.2	36	240	Thickened with rice cereal
Enfamil Enfacare 22 cal/oz (Mead Johnson)	0.74	2.1	11	Whey protein concentrate and nonfat milk	3.9	46	High oleic vegetable oil, soy oil, MCT oil, coconut oil	7.7	43	Liquid: maltodex-trin, lactosepow-der: lactose, corn syrup solids	1.13	2	89	1.3	49	310	Designed for former premature infants now >2 kg or 40 weeks corrected age. Additional Ca, P, vit A, vit D, folate, Zn
Enfamil Gentlease (Mead Johnson)	0.67	1.53	9	Partially hydrolyzed nonfat milk and whey protein concentrate solids	3.6	48	Palm olein, soy, coconut, and high oleic sunflower oils	7.3	43	Corn syrup solids	1	1.87	55	1.2	31	230	
Enfamil 24 (Mead Johnson)	0.81	1.7	8.5	Reduced minerals whey, nonfat milk	4.3	48	Palm olein, soy, coconut and high oleic sunflower oils, DHA, ARA	8.8	43.5	Lactose	.95	2.25	63	1.46	43	360	
Enfamil Premature (Mead Johnson)	0.67	2.0	12	Whey protein concentrate nonfat milk	3.4	44	MCT, soy and high oleic vegetable oils, single cell oil blend rich in DHA and ARA	7.4	44	Corn syrup solids, lactose	1.69	1.69	112	1.22	56	240	Designed for former premature infants Additional Ca, P, vit A, vit D, folate, Zn, Ca:P ratio of 2:1 High in protein

Enfamil Premature 24 cal/ oz (Mead Johnson)	0.81	2.4	12	Whey protein concentrate nonfat milk	4.1	44	MCT, soy and high oleic vegetable oils, single cell oil blend rich in DHA and ARA	8.9	44	Corn syrup solids, lactose	2.04	2.05	134	1.46	67	300	Designed for former premature infants additional Ca, P, vit A, vit D, folate, Zn, Ca:P ratio of 2:1 High in protein
Enfamil Infant (Mead Johnson)	0.67	1.3	8.5	Whey protein concentrate, nonfat milk	3.5	48	Palm olein oil, soy oil, coconut oil, high oleic sunflower oil	7.5	43	lactose, galactooligo-saccharides, polydextrose	0.78	1.8	52	1.2	29	300	
Enfamil Newborn (Mead Johnson)	0.67	1.4	8.5	Nonfat milk, whey protein concentrate	3.6	48	Palm olein, coconut, soy, and high oleic sunflower oils	7.5	43.5	Lactose, galactooligo-saccharides, polydextrose	0.8	1.9	53	1.22	29	300	Newborn to 3 months Higher in vitamin D (400 IU in 27 oz.)
Enfamil Prosobee (Mead Johnson)	0.67	1.69	10	Soy protein isolate	3.6	48	Palm olein, soy, coconut, and high oleic sunflower oils, single-cell oil blend rich in DHA and ARA	7.2	42	Corn syrup solids	1.05	2.1	70	1.22	46	200	Lactose free
Enfaport (Mead Johnson)	1.01	3.6	14	Calcium caseinate, sodium caseinate	5.5	45	MCT oil, soy oil, DHA and ARA	10.3	41	Corn syrup solids	1.3	3	95	1.83	53	280	Ready to feed 30 cal/oz. formula that can be modified to as low as 20 cal/oz. 84% fat as MCT oil Includes all essential fatty acids
Gerber Good Start Soy (Nestle)	0.67	1.7	10	Soy protein isolate	3.4	46	Palm olein, soy, coconut, high oleic safflower or sunflower oils	7.5	44	Corn maltodex-trin, sucrose	1.1	2.0	70	1.2	42	180	
Gerber Good Start Gentle (Nestle)	0.67	1.5	9	Hydrolyzed whey protein concentrate	3.4	46	Palm olein, soy, coconut and high oleic safflower or sunflower oils	7.8	45	Lactose, corn maltodextrin	0.79	1.9	45	1.0	26	250	100 % whey protein
Monogen (Nutricia)	0.73	2	11	Whey protein concentrate	2	25	Oil blend (including coconut, walnut)	11.9	64	Corn syrup solids	1.52	1.62	48	0.74	35	250	90% fat as MCT oil Contains complete vitamin and mineral profile (including trace elements)
Neocate infant DHA and ARA (Nutricia)	0.67	1.9 pro eq.	12	Free amino acids	4.5	41	High oleic safflower oil, refined vegetable oil (coconut oil and/or palm kernel oil), MCT	11.7	47	Corn syrup solids	1.1	1.9	78	1.0	55	375	33% MCT oil Severe protein allergy Lactose free
Nutramigen with Enflora LGG (Mead Johnson)	0.67	1.89	11	Casein hydrolysate, L-cystine, L-tyrosine, L-tryptophan, taurine, L-carnitine	3.6	48	Palm olein, soy, coconut, and high oleic sunflower oils, DHA, ARA	7	41	Corn syrup solids, modified corn starch	1.39	1.89	64	1.22	43	270	Lactose free
Nutramigen AA (Mead Johnson)	0.67	1.89	11	Amino acids	3.6	48	Palm olein, soy, coconut, and high oleic sunflower oils	7	41	Corn syrup solids, tapioca starch	1.4	1.9	64	1.44	35	350	
Pregestimil 20 (Mead Johnson)	0.67	1.87	11	Casein hydrolysate, L-cystine, L-tyrosine, L-trytophan, taurine, L-carnitine	3.7	48	Liquid: MCT, soy oil, high oleic safflower oils powder: MCT, soy oil, corn oil, high oleic oils	6.8	41	Liquid: corn syrup solids, modified corn starch powder: corn syrup solids, dextrose, modified corn starch	1.4	1.9	63	1.2	35	320	Lactose free
Pregestimil 24 (Mead Johnson)	0.80	2.22	12	Casein hydrolysate L-cystine L-tyrosine L-trytophantaurine L-carnitine	4.5	48	Liquid: MCT, soy oil, high oleic safflower oils	8.1	41	Liquid: corn syrup solids, modified corn starch	1.6	2.3	75	1.4	42	320	Lactose free
PurAmino (Mead Johnson)	0.67	1.88	11	Free amino acid	3.6	48	Palm olein, soy oil and high oleic sunflower oil	6.9	41	Corn syrup solids	1.37	1.2	63	1.89	35	350	Severe protein allergy Lactose free

Similac Advance (Abbott)	0.67	1.4	8	Nonfat milk, whey protein concentrate	3.7	49	High oleic safflower oil, coconut oil, soy oil	7.3	43	Lactose, galactooligo-saccharides (GOS)	0.71	1.8	76	1.22	41	270	Prebiotic
Similac Expert Care Alimentum (Abbott)	0.67	1.86	11	Casein hydrolysate, L-cystine, L-tryptophan, L-tyrosine	3.74	48	Safflower oil, MCT oil, soy oil, DHA, ARA	6.9	41	Corn maltodex-trin, sucrose	1.29	2.04	71	1.22	51	370	33% MCT oil Lactose free
Similac Expert Care 24 with iron (Abbott)	0.80	2.19	11	Nonfat milk	4.25	49	Soy oil, coconut oil	8.5	42	Lactose	1.5	2.6	73	1.45	57	380	
Similac Expert Care Neosure (Abbott)	0.74	2.08	11	Nonfat milk, whey protein concentrate	4.1	49	Soy oil, high-oleic safflower oil, MCT oil, coconut oil	7.5	40	Lactose, corn syrup solids	1.0	2.4	70	1.2	42	250	Designed for former premature infants >2 kg or >40 weeks corrected age Additional Ca, P, vit A, vit D, folate, Zn
Similac PM 60/40 (Abbott)	0.67	1.5	9	Whey protein concentrate, sodium caseinate	3.78	50	High oleic safflower, soy, and coconut oils	6.90	41	Lactose	0.71	1.4	38	0.5	19	280	Low iron Lower in Ca, P, maintaining 2:1 ratio Lower in K
Similac Sensitive (Abbott)	0.64	1.45	9	Milk protein isolate	3.65	49	High oleic safflower, soy, and coconut oil	7.23	43	Corn maltodex-trin, sucrose, galactooligo-saccharides (GOS)	0.88	1.85	57	1.22	38	180	Lactose free
Similac Soy Isomil (Abbott)	0.67	1.65	10	Soy protein isolate, L-methionine	3.69	49	High oleic safflower oil, coconut oil, soy oil, DHA, ARA	6.97	41	Corn syrup, sucrose, fructooligo-saccharides (FOS)	1.29	1.87	71	1.22	51	200	Lactose free
Similac Special Care 20 with iron (Abbott)	0.67	2.03	12	Nonfat milk, whey protein concentrate	3.67	47	MCT oil, soy oil, coconut oil	7.0	41	Corn syrup solids, lactose	1.26	2.2	121	1.22	68	235	Designed for growing low birth weight and premature infants Additional Ca, P, vit A, vit D, folate, Zn, Ca:P ratio of 2:1 High in protein
Similac Special Care 24 with iron (Abbott)	0.81	2.43	12	Nonfat milk, whey protein concentrate	4.41	47	MCT oil, soy oil, coconut oil	8.4	41	Corn syrup solids, lactose	1.51	2.66	145	1.45	81	280	Designed for growing low birth weight and premature infants Additional Ca, P, vit A, vit D, folate, Zn, Ca:P ratio of 2:1 High in protein
Similac Special Care 24 High Protein (Abbott)	0.81	2.7	13	Nonfat milk, whey protein concentrate	4.4	47	MCT oil, soy oil, coconut oil	8.1	40	Corn syrup solids, lactose	1.52	2.7	146	1.46	81	280	
Similac Special Care 30 with iron (Abbott)	1	3	12	Nonfat milk, whey protein concentrate	6.7	57	MCT oil, soy oil, coconut oil	7.8	31	Corn syrup solids, lactose	1.9	3.4	183	1.8	101	325	

Abbreviations: ARA, arachidonic acid, DHA, docosahexaenoic acid; FOS, fructooligosaccharides; GOS, galactooligosaccharides; MCT, medium-chain triglycerides.

At the time of publication, every effort was made to ensure that all product information was accurate. The most current information can always be obtained by referring to the package label.

TABLE III-2 Enteral Products: Non-infant (1000 mL)

Product (Manufacturer)	kcal/mL	Protein			Fat			Carbohydrate			mEq	mg	mEq	mg	mOsm/kg	General Comments
		g	% kcal	Source	g	% kcal	Source	g	% kcal	Source	Na	Ca	K	P	Water	
Boost (Nestle)	1.01	40	17	Milk protein concentrate	16	16	Canola, high oleic sunflower and corn oils	173	67	Corn syrup solids and sugar	28	1390	63	1310	610–670	85 % Free water Gluten and lactose free, low residue, and kosher *Chocolate malt flavor contains gluten
Boost Breeze (Nestle)	1.05	38	14	Whey protein isolate	0			228	86	Sugar, corn syrup	15	0	0	633	900–930	83% Free water Clear liquid, protein containing oral supplement
Boost Kid Essentials (Nestle)	1.0	30	12	Sodium and calcium caseinates, whey protein concentrates	38	34	High-oleic sunflower oil, soybean oil, MCT oil	135	54	Sugar, maltodextrin	24	1260	29	840	550–600	84% free water 20% fat as MCT oil Multiple flavors and fiber containing versions available Lactose and gluten free, low residue, kosher
Boost Kid Essentials 1.5 (Nestle)	1.5	42	11	Sodium and calcium caseinates, whey protein concentrates	75	45	High-oleic sunflower oil, soybean oil, MCT oil	165	44	Sugar, maltodextrin	30	1304	33	992	390	72% free water Fiber-containing versions available Lactose and gluten free, low residue, kosher
Boost Plus (Nestle)	1.52	59	16	Milk protein concentrate, calcium and sodium caseinates	58	34	Canola, high oleic, sunflower and corn oils	200	50	Corn syrup solids, sugar	31	1390	41	1310	720	78% free water Gluten and lactose free, kosher and low residue
EleCare Jr (Abbott)	1.0	30	15	Free L-amino acids	48	42	High oleic safflower oil, medium chain triglycerides, soy oil	109	43	Corn syrup solids	20	1096	39	822	551	100% free amino acid 33% fat as MCT oil Unflavored Gluten, lactose, fructose, galactose, milk and soy protein free
Ensure (Abbott)	1.06	37	14	Calcium caseinates, soy protein isolate, whey protein concentrate	26	22	High-oleic safflower oil, canola oil, corn oil	169	64	Corn syrup, sucrose, maltodextrin	37	1266	40	1055	590	84% free water High protein and high calcium versions available Gluten and lactose free Kosher
Ensure Fiber with FOS (Abbott)	1.06	37	14	Soy protein isolate, sodium and calcium caseinates	26	22	Corn oil, canola oil, high-oleic safflower oil	177	64	Maltodextrin, sucrose, oat fiber, soy fiber, FOS	37	1477	40	1266	500	82% free water Contains fructooligosaccharides 11.8 g fiber/L Gluten and lactose free Kosher
Ensure Plus (Abbott)	1.5	54	17	Sodium and calcium caseinates, soy protein isolates	49	29	Corn oil, canola oil, high-oleic safflower oil	211	56	Corn syrup, malto dextrin, sucrose	44	844	48	844	680	76% free water Gluten and lactose free Kosher
Glucerna (Abbott)	1.0	42	17	Sodium and calcium caseinates	54	49	High-oleic safflower oil, canola oil, soy lecithin	96	34	Corn maltodextrin, fructose, soy fiber	40	705	40	705	355	85% free water Low-carbohydrate content 14 g fiber/L Gluten and lactose free Kosher Comes in 1.2 and 1.5 kcal/mL
Hi-Cal (Abbott)	2.0	84	17	Sodium and calcium caseinates	89	40	Corn oil, soy lecithin	215	43	Corn syrup solids, corn, maltodextrin, sucrose	63	844	62	844	705	70% free water Gluten and lactose free Low residue Kosher
IsoSource HN (Nestle)	1.2	53	18	Soy protein isolate	39	29	Canola oil, MCT oil	160	53	Corn syrup	48	1200	49	1200	490	82% free water 50% fat as MCT oil Higher calorie version available (1.5) Gluten and lactose free
Jevity (Abbott)	1.06	44	17	Sodium and calcium caseinates	35	29	High-oleic safflower oil, canola oil, MCT oil, soy lecithin	154	54	Maltodextrin, corn syrup, soy fiber	40	910	40	760	300	84% free water 20% fat as MCT oil 14.4 g fiber/L Higher calorie versions available (1.2, 1.5) Gluten and lactose free Kosher
Neocate Splash (Nutricia)	1.0	25	10	Free amino acids	35	32	Canola oil, high oleic safflower oil, coconut oil	146	58	Maltodextrin, sucrose, corn syrup solids	8.5	620	24	620	820	3.4 g Gln/L 2.3g Arg/L Flavored version available
Neocate Junior (unflavored) (Nutricia)	1.0	30	13	Free amino acids	50	45	Fractionated coconut oil, MCT oil, canola oil, high oleic safflower oil	104	42	Corn syrup solids	22	790	35	540	590–700	Free amino acid Severe protein allergy Various flavors With or without prebiotics

Nepro with Carb Steady (Abbott)	1.8	70	14	Calcium, magnesium, and sodium caseinates, milk protein isolate	96	43	High-oleic safflower oil, canola oil, soy ecithin	333	43	Corn syrup, sucrose, FOS	37	1370	27	695	665	Gluten and lactose free Kosher
Nutren Junior (Nestle)	1.0	30	12	Whey protein concentrate, milk protein concentrate	49.6	44	Soybean, canola and MCT oil, soy lecithin	110	44	Maltodextrin, sugar	20	1000	33.8	800	350	Fiber-containing version available 25% MCT oil Gluten and lactose free Low residue and kosher
Nutren 1.0 (Nestle)	1.0	40	16	Calcium, potassium caseinates	38	33	Canola, MCT, corn oil and soy lecithin	127	51	Maltodextrin, sucrose	38	1200	32	840	370	Fiber-containing version available 25% MCT oil Kosher, lactose and gluten free, low residue Higher calorie versions available
Nutren 1.5 (Nestle)	1.5	60	16	Calcium, potassium caseinates	68	39	MCT, canola, corn oil, soy lecithin	169	45	Maltodextrin	51	1000	48	1000	430–520	50 % MCT oil
Nutren 2.0 (Nestle)	2.0	80	16	Calcium, potassium caseinates	104	45	MCT and canola oil, soy lecithin, corn oil	196	39	Corn syrup solids, maltodextrin, sucrose	57	1340	49	1340	720	75% of fat as MCT oil Contains taurine, carnitine Kosher, lactose and gluten free, low residue
Nutrihep (Nestle)	1.5	40	11	L-amino acids, whey protein concentrate	21	12	MCT and canola oil, soy lecithin, corn oil	290	77	Maltodextrin	7	956	34	1000	790	66% fat as MCT oil High in BCAA Unflavored Kosher, lactose and gluten free, low residue
Osmolite (Abbott)	1.06	44	17	Sodium and calcium caseinates, soy protein isolate	35	29	Canola oil, MCT oil, soy lecithin, corn oil	144	54	Maltodextrin, corn syrup solids	40	760	40	760	300	84% free water 20% fat as MCT oil Unflavored High-calorie version available (1.2, 1.5 kcal/mL) Kosher, lactose and gluten free, low residue
PediaSure Enteral formula (Abbott)	1.0	30	12	Milk protein concentrate	40	35	High-oleic safflower oil, soy oil, MCT oil	133	53	Corn maltodextrin, sucrose	17	1055	34	845	335	84% free water 20% fat as MCT oil Kosher, lactose and gluten free, low residue
PediaSure with Fiber Enteral formula (Abbott)	1.0	30	12	Milk protein concentrate	38	34	High oleic safflower oil, soy oil, MCT oil	143	54	Corn, maltodextrin, sucrose, dextrose, soy fiber, scFOS	17	1055	34	844	345	85% free water 20% fat as MCT oil 13g fiber/L Kosher, lactose and gluten free
Pediasure 1.5 (Abbott)	1.5	58	16	Milk protein concentrate	67	41	High oleic safflower oil, soy oil, MCT oil	158	43	Corn maltodextrin	16	1458	42	1042	370	Lactose and gluten free Fiber-containing version
Pediasure Peptide (Abbott)	1.0	30	12	Whey protein hydrolysate, hydrolyzed caseinate	40	35	Canola and MCT oils	134	53	Corn maltodextrin	31	1055	34	844	250	
Pepdite Junior (Nutricia)	1.0	31	12	Free amino acids, hydrolyzed protein (pork, soy)	50	46	MCT, coconut oil, canola oil, safflower oil	106	42	Corn syrup solids	17	1130	35	940	430–440	44% Free amino acids 35% Fat as MCT oil Flavored version available
Peptamen (Nestle)	1.0	40	16	Enzymatically hydrolyzed whey protein	39	33	MCT oil, soybean oil, soy lecithin	127	51	Maltodextrin, corn starch	24	800	38	700	270–380	85% Free water Flavored version available 70% of fat from MCT Also in 1.5 kcal/mL
Peptamen Junior (Nestle)	1.0	30	12	Enzymatically hydrolyzed whey protein	38	33	MCT oil, canola oil, soybean oil	138	55	Maltodextrin, corn starch	20	1120	34	840	260–400	85% Free water Flavored version available
Peptamen Junior 1.5 (Nestle)	1.5	45	12	Enzymatically hydrolyzed whey protein	68	33	MCT oil, canola oil, soybean oil	180	55	Maltodextrin, corn starch	30	1652	51	1352	450	77% Free water 60% MCT 5.4 g/L PREBIO
Peptamen 1.5 (Nestle)	1.5	67.6	18	Enzymatically hydrolyzed whey protein	56	33	MCT oil, soybean oil	188	49	Maltodextrin, corn starch	44	1000	48	1000	550	77% Free water Flavored version available
Promote (Abbott)	1.0	62.5	25	Sodium caseinate, soy protein isolate	26	23	Safflower oil, MCT oil, soy oil and soy lecithin	130	52	Corn maltodextrin, sucrose	43	1200	51	1200	340	84% Free water 19% Fat as MCT oil Fiber-containing version available Kosher, lactose and gluten free, low residue
Pulmocare (Abbott)	1.5	63	17	Sodium and calcium caseinates	93	55	Canola oil, MCT oil, corn oil, high-oleic safflower oil, soy lecithin	106	28	Sucrose, corn maltodextrin	57	1060	50	1060	475	79% Free water 20% fat as MCT oil Low-carbohydrate formula Kosher, lactose and gluten free, low residue

Suplena (Abbott)	1.8	30	6	Milk protein isolates, sodium caseinate	96	43	High-oleic safflower oil, canola oil, soy lecithin	196	51	Maltodextrin, sucrose	35	1055	29	717	780	Low protein formula Kosher, lactose and gluten free, low residue Low in phosphorous, K, Ca, Na
Tolerex (Nestle)	1.0	21	8	Free amino acids	1.5	1.0	Safflower oil	230	91	Maltodextrin, modified food starch	22	550	30	551	550	84% Free water Free amino acid, high carbohydrate, low-fat formula Flavor packets available Lactose and gluten free, low residue
TwoCal HN (Abbott)	2.0	84	17	Sodium and calcium caseinates	90	40	High-oleic safflower oil corn oil, MCT oil, canola oil, soy lecithin	218	43	Corn syrup solids, maltodextrin, sucrose, FOS	63	1050	62	1050	725	70% Free water 19% of fat as MCT Multiple flavors available Kosher, lactose and gluten free, low residue, 5 g/L scFOS
Vital HN (Abbott)	1.0	42	17	Partially hydrolyzed protein blend (soy, collagen), whey protein concentrate, whey protein hydrolysate	11	9	Safflower oil, MCT oil	185	74	Corn maltodextrin, sucrose	25	667	36	667	500	Hydrolyzed protein, peptide based, elemental, high carbohydrate, low-fat formula 45% fat as MCT oil Gluten free, low residue
Vivonex TEN (Nestle)	1.0	38	15	Free amino acids	3	3	Safflower oil	210	82	Maltodextrin, modified corn starch	26	500	24	500	630	83% Free water Free amino acids High carbohydrate, low fat formula High protein version available Flavor packets available Lactose free
Vivonex Pediatric (Nestle)	0.8	24	12	Free amino acids	24	25	MCT oil, soybean oil	130	63	Maltodextrin, modified cornstarch	17	1120	31	840	360	89% Free water 68% fat as MCT oil Flavor packets available

Abbreviations: BCAA, branched-chain amino acid; FOS, fructooligosaccharides; MCT, medium-chain triglycerides; scFOS, short-chain fructooligosaccharides.

TABLE III-4 Selected Modular Additives Used in Pediatrics

Product (Manufacturer)	kcal/g or kcal/mL	g/tbsp or mL/tbsp	Energy Source	Comments
Benecalorie (Nestle)	7.3	330 kcal/1.5 oz. serving	Calcium caseinate, high oleic sunflower oil, mono- and diglycerides	High calorie liquid 9% protein (7g/1.5 oz. serving), 91% fat (33g/1.5 oz. serving)
Beneprotein (Nestle)	3.5	1 scoop = 1 ½ tbsp = 7g, 6 g pro/scoop	Whey protein isolate, soy lecithin	Protein powder used to increase protein in formulas/foods 25 kcal/scoop
Canola oil	8.0	15	Canola	
Corn Oil	8.4	15	Corn	Nonemulsified
Cornstarch	3.8	8		30 kcal/tbsp
Corn Syrup (Karo)	3.8	15		60 kcal/tbsp
Duocal (Nutricia)	4.92	8.5	Hydrolyzed cornstarch, blend of refined vegetable oils (corn, coconut), MCT, mono- and diglycerides	59% carbohydrate, 41% fat (35% MCT, 65% LCT) 310 mOsm/kg water Carbohydrate and fat source used to increase caloric density of formula/foods 42 kcal/tbsp
MCT oil	7.7	15	Lipid fraction of coconut oil	Bile salts and lipase not necessary for digestion and absorption Does not contain essential fatty acids Nonemulsified 115 kcal/tbsp
Microlipid (Novartis)	4.5	15	Safflower oil	High in linoleic acid 50% fat emulsion that mixes easily and stays mixed with enteral formulas, beverages, and table food 68 kcal/tbsp
NutriSOURCE Fiber (Nestle)	4	3g fiber per 2 teaspoons, 2 tsp = 3.8g	Partially hydrolyzed guar gum	100% carbohydrate 15 kcal/tbsp
Promod liquid (Abbot)	100kcal/1 oz. 3.3 kcal/mL	10 g protein/ 1 oz.	Glycerine, hydrolyzed beef collagen	Fruit punch-flavored protein liquid that increased protein in formula/foods/beverages 60% carbohydrate, 40% protein
Safflower Oil	8.4	15	Safflower	Nonemulsified
Scandical (Aptalis Pharma)	5.4	6.5	Nonfat milk, corn syrup solids, maltodextrin, vegetable oil, MCT, coconut oil, soy oil	Tasteless powder used to increase calories in hot or cold foods 35 kcal/tbsp

Abbreviations: LCT, long-chain triglycerides; MCT, medium-chain triglycerides.
At the time of publication, every effort was made to ensure that all product information was accurate. The most current information can always be obtained by referring to the package label.

TABLE III-5 Enhancing the Caloric Density of Pumped Breast milk

	Quantity of Additive Needed	Total Volume

kcal/oz. desired by additive	of Breast milk[a] 25 mL	50 mL	100 mL
2 HMF	¼ tsp[b]	1 pkg	2 pkgs
4 HMF	1 pkg	2 pkgs	4 pkgs
2 Infant formula powder	1/8 tsp	¼ tsp	½ tsp
4 Infant formula powder	¼ tsp	½ tsp	1 tsp
6 Infant formula powder	½ tsp	¾ tsp	1 ½ tsp
2 MCT oil	0.2 mL	0.4 mL	0.9 mL
4 MCT oil	0.4 mL	0.9 mL	1.7 mL
2 Corn oil	0.2 mL	0.4 mL	0.8 mL
4 Corn oil	0.4 mL	0.8 mL	1.6 mL
1 Beneprotein powder	1/8 tsp	¼ tsp	½ tsp
2 Beneprotein powder	¼ tsp	½ tsp	1 tsp

Abbreviations: HMF, human milk fortifier; MCT, medium-chain triglycerides.

[a] For calories other than HMF, ingredients should be placed in container and breast milk added to make final volume (to account for displacement).

[b] Level measurements, not heaping, for all teaspoon measurements.

TABLE III-6 Selected Metabolic Disorders for Which Nutritional Therapy is Used

Disorder	Nutritional Therapy	Enteral Products Used
β-Ketothiolase deficiency	Low protein High carbohydrate	Ketonex-1[a]
Biotinidase deficiency	Biotin supplementation	
Galactosemia	Galactose restriction ± calcium supplementation	Soy based (Enfamil ProSobee,[b] Similac Soy Isomil[a])
Glutaricaciduria type 1	Lysine and tryptophan restriction Riboflavin supplementation Carnitine supplementation	XLys XTrp Analog[c] XLys XTrp Maxamaid[c] Glutarex-1,[a] Glutarex-2,[a] GA[b]
Glycogen storage disease types I and III	High carbohydrate (50%–60% of kcal) Low fat (15%–30%) Protein (5%–10% of kcal) Regular feeding regimen	Cornstarch

	Low cholesterol	
Hereditary fructose intolerance	Fructose, sorbitol restriction Vitamin C supplementation	Fructose, sorbitol, sucrose free
Homocystinuria (cystathionine β-synthase deficiency)	Methionine restriction Cystine supplementation ± vitamin B6 supplementation ± betaine supplementation ± folate supplementation	Milupa HOM 2[d], XMET Analog[c] XMET Maxamaid,[c] HCY 1,[b] HCY 2[b] Hominex-1,[a] Hominex-2[a]
Isovaleric acidemia	Leucine restriction Glycine supplementation ± carnitine supplementation	XLeu Analog,[c] XLeu Maxamaid[c] I-Valex-1,[a] I-Valex-2[a]
Long-chain acyl-CoA dehydrogenase deficiency	Low fat MCT acceptable Avoid prolonged fasting ± carnitine supplementation	Portagen[b] ProViMin[a] (add fat and carbohydrate) Tolerex, Vivonex[e] as overnight glucose source
Long-chain hydroxy acyl-CoA dehydrogenase deficiency	Low fat MCT acceptable Avoid prolonged fasting ± carnitine supplementation	ProViMin[a] (add fat and carbohydrate) Tolerex[e], Vivonex[e] as overnight glucose source
Maple syrup urine disease	Valine, isoleucine, and leucine restriction Thiamine supplementation	MSUD Analog[c], MSUD Maxamaid[c] Milupa MSUD 1,[d] MSUD 2[d] BCAD 1[b], BCAD 2[b], Ketonex-1[a]
Medium-chain acyl-CoA dehydrogenase deficiency	Low fat Avoid MCT ± carnitine supplementation Avoid prolonged fasting	
Methylmalonicacidemia	Methionine, valine, threonine, and isoleucine restriction ± vitamin B12 supplementation	XMTVI Analog,[c] XMTVI Maxamaid[c] OA 1,[b] OA 2[b], Milupa OS 2[d] Propimex-1,[a] Propimex-2[a]
Multiple acyl-CoA dehydrogenase deficiency (glutaricaciduria type II)	Fat restriction ± protein restriction Riboflavin supplementation Carnitine supplementation	
Phenylketonuria	Phenylalanine restriction	

	Tyrosine supplementation PKU 3,[d] Phenex-1,[a] Phenex-2[a] ±tyrosine supplementation	XPhe Analog,[c] XPhe Maxamaid[c] Phenyl-Free,[b] Milupa PKU-1[d], PKU 2,[d]
Propionic acidemia	Valine, isoleucine, methionine, and threonine restriction Carnitine supplementation ± biotin supplementation	XMTVI Analog,[c] XMTVI Maxamaid[c] OA 1,[b] OA 2[b], Milupa OS 2[d] Propimex-1,[a] Propimex-2[a]
Pyruvate dehydrogenase deficiency	High fat (>50% of kcal) Low carbohydrate (20%–30% of kcal) Thiamin supplementation	3232A[b] RCF[a]
Tyrosinemia	Phenylalanine and tyrosine restriction Regular feeding regimen	XPhe XTyr Analog,[c] XPTM Analog[c] XPhe XTyr Analog[c] XPhe XTyr Maxamaid[c], tyr 2[d] Tyros 1,[b] Tyros 2[b] Tyrex-1,[a] Tyrex-2[a]
Urea cycle disorders	Protein restriction Essential amino acid supplementation Arginine or citrulline supplementation Sodium benzoate and sodium phenylacetate (or sodium phenylbutyrate)	Cyclinex-1,[a] Cyclinex-2[a], Milupa UCD 2[d]

Abbreviation: MCT, medium-chain triglycerides.

INDEX

Note: Page numbers followed by i or t indicate material in images or tables, respectively.

A

Absorptiometry, dual energy X-ray 12–13, 42
Absorption (*see also* Bioavailability; Digestion)
  development of function in gut 389–381
  gastrointestinal, in HIV 675–676
  laxatives affecting 308
  medications affecting 301–303
  of drugs, in malnutrition 298
  of fats 83–84
  of nutrients, secondary factors in 307
  of trace elements 101, 105, 109, 112, 120, 124
Abuse and neglect
  growth failure secondary to 713, 718t
  starvation as 713
Acanthosis nigrans in axillary skin 620t
Acceptable macronutrient intake level 163, 164
Acetylation, histone, and bioactive food components 355–356
Acidosis, lactic (*see* Lactic acidosis)
Acquired Immune Deficiency Syndrome (*see* HIV *entries*)
Acrodermatitis enteropathica 98
Adaptation, intestinal (*see* Intestinal adaptation)
Adaptive immunity
  breast milk effects on 512
  linked to innate immunity in neonatal gut 505
Adenoma in glycogen storage disease 762
Adenosine triphosphate (ATP)
  chromatin remodeling dependent on 356–357
Adequate intake (AI)
  in dietary reference intakes 164
  of carbohydrates in term and preterm infants 65
Adipose tissue in insulin resistance and MetS 621–622
Adiposity rebound 44 and rapid catch-up growth 691–692
Adolescence

and bone health 1007–22
as critical time for breast carcinogenesis 871–872
as time of bone accretion 1008
changes in bone growth during 47
Adolescent athletes, nutrition in 1091–98
dietary counseling for 1096–97
energy balance in 1095–96
fluids and electrolyte needs in 1094–95
macro- and micronutrients in 1092–94
Adolescent growth, and breast cancer 872–873
Adolescent nutrition
disturbances in, and bone health 1012–1013
U.S. nutritional recommendations for 166, 170, 251–253
Adolescents
diet of (*see* Diet, adolescent)
eating disorders in 1001–06
metabolic syndrome in 613–624
need for iron in 118, 127
with hyperlipidemia and cardiovascular disease 971–976
Adult disease, biological basis of development of 436
Age
and changes in body composition 43i, 46–47, 49i
as factor in measuring RMR and FFM 185i
microbial composition relative to 58i
muscle and organic metabolic rates relative to BMR 186t
Agenesis, pancreatic 839
Aging, impact of DNA methylation on 352–353
Agricultural transformation and child nutrition 649–660
Aids, mechanical, in supplementing lactation 531–532
AIDS (*see* HIV *entries*)
Air displacement plethysmography 13
in infants 44
Albumin 28
Allergens, food 825
labeling regulations 1100
Allergic disease(s)
eosinophilic gastroenteritis as 827
food 825–828
management of 830
novel therapies for 830–831
special diets for 1099–46
potential for probiotics in 175
proctocolitis as 827–828
Allergy

and duration of exclusive breastfeeding 577–578
and failure to grow 718
food (*see also* Food allergies) 823–833
support groups and resources for 1140
to fish 1107
Alpha-tocopherol (*see also* Vitamin E)
laboratory assessment of 32
Amino acid(s)
classified by FAO/WHO/UNU 73t
energy substrates and 196
enzyme disorders of 745t
in physiologic and metabolic function 74t
neonatal implications of supply of 477
nutritional classification of 73t
overview of 71–81
RDA for, relative to age and sex 77–78t
structural formula of 71i, 72–73t
systemic availability in neonatal pigs 80i
umbilical uptake of 472
Amino acid composition of parenteral formulas 1043t
Amino acid metabolism
fetoplacental 471–472
of fetal hindlimb 475
hepatic circulation and, fetal 474–475
Amino acid nutrition, placental function and 465–482
Amino acid profiles 28
Amino acid pools exchanged with body protein 75i
Amino acid requirements
current 80
methods for determining 79–80
Amino acid scoring pattern by age 79t
Amino acid transport
abnormal pregnancy outcome and 475–477
during pregnancy 470–474
placental 466–472
protein chemistry in 467–470
Ammonia metabolism in hepatocytes, enzymes in 751i
Anabolic steroids (*see* Steroids, anabolic)
Anaphylaxis, food-induced 825–826
Anatomy and physiology
in developing fetal and infant gut 387–389
in lactation 517–520
Anemia (*see also* Iron deficiency) 127–128
in glycogen storage disease 762

in pregnancy 425–426
in severe acute malnutrition 211, 221
pernicious, vitamin B_{12} in 157–158
Angioedema resulting from food hypersensitivity 828
Anionic transport system, light-chain placental proteins and 470
Anorexia and cancer treatment 881–882
Anorexia, nervosa (*see also* Eating disorders) 1001–06
and bone status 1014
Anthropometric data on child growth and economic development 654–657
Anthropometric techniques in field studies 40
Anthropometric *z*-scores for age and growth 635i
Anthropometrics
and body composition 7–11
body-mass index in 10–11
correlated with total body densitometry 276–277t
genetic growth potential in 10
ideal body weight percent 11
in children undergoing cancer therapy 882–883
in developmentally disabled children 731–737
in liver disease 854t
percent weight loss in 11
percentiles for age and sex in 10
triceps skinfold thickness and 12
WHO recommended measures for 707
Antibiotics, use of, for diarrhea 918–919
Antidepressant medication during lactation 498
Antihelmintic drugs in preventing morbidity 669
Antimalarial drugs in preventing morbidity 668–669
Antimicrobial activities of oligosaccharides and glycoconjugates 507–508
Antimicrobial proteins and peptides 508
Antioxidants
in adolescent athletes 1093
in HIV 680
Appetite
drugs affecting 316–319
enhancing and suppressing 319
drugs stimulating 683–684
Arm
as proxy for body composition 883
length of, by age 735i
measurement techniques and reference standards for 733–734
mid-upper, circumference of 11, 735
Arterial hypertension in MetS 616
Ascorbic acid (*see also* Vitamin C) 151–152

Aspiration, signs of, in failure to grow 716t
Assessment of nutritional status and body composition
  bioelectric impedance assessing lean body mass 27
  of iron status 134–137
Asthma, comorbid with food allergies 826–827
Atherosclerosis during childhood 971–973
  and lipoprotein level 973
Athletes, young, nutrition in 1091–98
Athletics, strenuous, in female adolescents 1004–05, 1014
Atopic dermatitis 828
Avoidant Restrictive Food Intake Disorder (ARFID) 1001

B

Bacteremia, catheter-related, in IF/SBS 938
Bacteria
  in presence of breast milk
  cellular reactivity to 510–511
  interacting with PPRs 509–510
  intestinal
  nutrient effects on 343
  relative to age 58i
  barrier function, in GI tract 391
Bacterial colonization of the human gut 503–515
Barrier functions, intestinal, development of 391, 505–506
Basal metabolism rate (BMR) (*see also* Metabolism)
  difficulties in measuring 183–187
  related to age and muscle and organic metabolic rates 186t
BCG vaccination rates and real income 659
Behavior, feeding, details of 719t
Behavioral assessment and therapy for child obesity 605–608
Behavioral disorders and feeding problems 702–703
Behavioral feeding problems in liver disease 858
Benign breast disease and adolescent diet 874
Beri-beri 152–155
Beverages, effect of, on drug bioavailability 306
Bifidobacteria, importance of 58
Biliary complications of parenteral nutrition 1065, 1068–69
Binding interactions between feedings and drugs 297
Binge eating disorder (*see also* Eating disorders) 1001–06
Bioactive food components
  DNA methylation and 354
  histone acetylation and 355–356
  possible role of microRNAs in 357–358
Bioactivity, IGH, in malnutrition 373–375

Bioavailability
of drugs, beverage types affecting 306
of iron 119–121
of trace elements 96–97
Biochemical abnormalities in HIV-infected children 678t
Biochemical assessment, variations in factors affecting 26
Biochemical composition of human milk 486–498
Biochemical correlates of trace element deficiency 99, 103, 109
Biochemical indices for measuring iron status 136–137t
Biochemical assessment of iron status 134–137
Biochemical markers of dietary intake 279–281
Bioelectric impedance analysis (BIA) in measuring body water 41
Biofortification in food crops 649
Biotin 158–159
in human milk 496
Biotinylation, histone 356
Birth weight
and later adult cancer 868–870
and risk of breast cancer in premenopausal women 869t
breastfeeding and, in developing economies 690–692
relative to later-life disease 435–443 (*passim*)
pediatric cancer and 866–867
Bisphosphonates, potential benefits and risks of 1917–18
Blood, GH and IGF in 369–370
Blood coagulation cascade, vitamin K in 150
Blood pressure in boys and girls, standard values of 617–619t
Blood stream infections, catheter-related 1069–71
Body cell mass (BCM), estimation of 38–39
Body composition
assessment of 37–54, 275–278
air displacement plethysmography assessment 13
chemical stability in 48–50
developmental changes in, and nutrition 294
effect of celiac disease on 813–815
ethnic and racial differences in 45
in cancer patients 883
in IBD 790, 801–802
in developmentally disabled children 736
metabolic reserves and 963
of HIV-infected children 675–676
of reference infant 567i
Body composition changes
by sex 44t
during growth 43–51, 44t

during malnutrition and disease 50
with age 43i, 44t
Body composition differences at NICU discharge 554–555
Body composition measurement 11, 37, 275–278
air displacement plethysmography in 13
and growth 37–34
characteristics of 278–279
dual-energy X-ray absorptiometry 12
mid-upper arm circumference 11
multicompartment models in 37–40
neutron activation analysis in 38–39
sexual and skeletal maturation in 13
terms used in study of 37t
triceps skinfold thickness in 12
Body composition multi-compartment models 37–40, 38i
atomic 38
cellular 39
equations and methods for determining 38–39
functional 39
molecular 38–39
whole-body 38–40
Body fat
and sports activities 45
as percentage of body composition 44t
changes with growth 43–45
distribution, ethnic and racial differences in 45
Body mass, lean, estimation of 27
Body mass index (BMI) 11
and cardiovascular risk in obesity 622i
correlated with skinfold thickness 278t
in obese children 603
in rural-migrant Indian population 694i
Body temperature
and energy expenditure 189, 194
Body water measurement, methods for 41–43
Body weight 38–39
during first days of life 537–538
percent, ideal, cautions concerning use in assessment 11
in HIV-infected children 677–678
Bolivia, prevention of malnutrition in 237–238
Bone complications in children receiving PN 1065, 1069
Bone density assessment in developmentally disabled children 736–737
Bone diseases 1013–15
in patients with intestinal failure 938

management of 1017–18
novel therapies for 1017–18
prevention of 1018
related to cyctic fibrosis 844–845
Bone health
assessment of 12, 13, 1009–22
exercise and 1009
maximizing 1008–12
nutritional influences on 1009–13
physiology and development of 1007–08
Bone mineral density (BMD), femoral 738i
Bone minerals, equations and methods for measuring 38–40t
Bones in severe acute malnutrition 212
Bowel disease, inflammatory (*See* Inflammatory bowel disease)
Brain development in SAM 212
Brain tumors and *N*-nitroso compounds 868
Breast(s), female
from infancy to lactation 518i
preparation of, for lactation 522–523
Breast cancer
diet and 866–874
carcinogenesis in adolescence and 871–872
risk of, and red meat and soy consumption 873–874
Breast disease, benign 874
Breast-fed infants
allergens affecting 1112
assessment of dietary intake in 274–275
compared to formula-fed infants 568–569
daycare for 529
growth in 484–485
nutritional adequacy in 577
revised estimate of protein intake in 74t
Breastfeeding (*see also* Lactation)
after NICU discharge 561–562
and complementary feeding, preventing malnutrition 232, 644–646
approach to 517–536
avoiding transmission of HIV in 498
discontinuance of 534
education about, desirability of 545
enhancing microbiota in infants 174, 176
exclusive
and real income 658i, 659
duration of 575–576
in low- and mid-income countries 642

strategies to promote 642
WHO recommendations for 666
failure to thrive despite 529–534
in severe acute malnutrition 220–221
initiation of, in low income countries 641
policy recommendations for 484
prenatal considerations in 521
return of interest in 565–566
return to work during 528
stages of 527–529
supplementation during 525
trends in 484
Breast-feeding women
DHA supplied to 89–90
Breast milk (*see also* Human milk)
as innate protection for neonates 391
and gene expression 338–339
in low- and mid-income countries 642–643
Breast pumps and storage of milk 528–529
Brown adipose tissue (BAT), stimulation of 189
Bulimia nervosa (*see also* Eating disorders) 1001–06

C

Cachexia
in cancer patients 878
in HIV-infected children 877–878
Calcium
and bone health 1011–12
dietary sources of 1018t, 1130, 1132–33
during peak bone growth 47
in human milk 497
in vegetarian diets 1137
in young athletes 1093
lactose-free sources of 1111t
RDA for 1012t
requirements during pregnancy 427–428
Calculations of REE/BMR to measure against critically ill children 1039t
Caloric deficiency in IBD 790
Calorie counts in assessing dietary intake 6, 7
Calorimetry, indirect, and REE 15
Canada
community nutrition in 244, 247, 248t (*see also* Community nutrition)
existing programs in 262, 263t, 264t
current nutrition guidelines in 265t

nutritional needs of special-needs children in 255, 256t
nutritional status of infants and youth in 255–256, 254t
resources for 265t, 266t
Cancer (*see also* specific type)
adolescent diet in 872–873
body composition measures in 883
connected to growth 865–866
in-utero diet/exposure and 866–868
laboratory evaluation in patients with 883–884
later-adult, and previous breastfeeding 870–871
malnutrition in 877–878
metabolic effects of 878–879
in treatment 879–881
nutritional assessment in 882–884
nutritional intervention in 884–886
pediatric, treatment of 877–889
Cancer prevention in childhood 865–876
Cancer survivors, nutritional concerns of
Cancer treatment in childhood 877–889, 879–881
food aversion in 881–882
side effects of 879–881
Carbohydrate balance in obesity 591–593
Carbohydrate component of human milk 486–488
Carbohydrate counting in diabetes 904–905
Carbohydrate disorders 66–68
Carbohydrate intake, recommendations for 64–66
Carbohydrate intolerance 1117–19
Carbohydrate metabolism
enzyme disorders of 745t
in critically ill children 961
in the fetus 445–456
in liver disease 851–852
Carbohydrate requirements in parenteral nutrition 149–151
Carbohydrate substrates, alternative, for fetal oxidation 451
Carbohydrates (CHO) 55–69
and sources, classification of 57t
as sources of glucose for placenta and fetus 446–456
composition of, during childhood 64
dietary, in diabetes mellitus 897–898
digestible, recommendations based on 64–65, 66t
digestion and absorption of 390
impact of, on drug kinetics 303
in cancer 878
in formula 570

in GI tract, overview of 55–69
in intestinal microbiota 56–57
in young athetes 1092
local and systemic effects of 57i
malabsorption of 66–67
recommended dietary intake of 64–66
required in preterm infants 543
Carbonated beverages and adolescent bone health 1013
Cardiac system in SAM 210
Cardiometabolic health, in post-discharge preterm infants 557–558
Cardiovascular disease
cholesterol-lowering diet in 1128–1130
in children and adolescents 971–986
Cardiovascular risk factors in obesity 622i
Carnitine
deficiency in 30
in formula 571
supplementation in lipid-based parenteral formulas 1048
Carotenoids (*see also* Vitamin A)
in human milk 493
Case-control studies of vitamin supplements in NTDs 286–287
Casein in human milk 491–492
Catabolic diseases
anabolic steroids in 379
of liver 751–752
Catabolic responses in critically ill children 957
Catch-up growth 364–366
nutritional needs for 720
rapid, and adiposity rebound 691–692
Catheter(s) in parenteral nutrition 1062–64
Catheter line infection in IF/SBS 938
Catheter-related blood stream infections (CRBSIs) 1069–71
prophylaxis of 1070–71
Catheter-related occlusion and thrombosis 1071–72
prophylaxis of 1071–1072
Caveats in use of nutraceuticals 178–180
Celiac disease 809–822
and bone disorders 1015
and duration of exclusive breastfeeding 577–578
and type 1 diabetes mellitus 905, 1117
catch-up growth in 365
classic presentation of 815i, 816i
clinical presentation of 811–812
diagnosis of 812–813

diet and 271–272
diets for 1115–17
effects on growth and body composition of 813–815
extra-intestinal manifestations of 816
natural history of 816–817
nutritional deficiencies in 815–816
prevalence and pathogenesis of 809–811
probiotics in 175
reaction to gluten protein in 828
treatment of 817
web information on 1117
Cell growth and nutrition 362
Cell signaling from intestinal lumen to mucosal immune system 339–345
Cellular reactivity to bacteria in presence of breast milk 510–511
Cellular regulation of growth, hormones in 362t
Cereal products as complementary foods 648
Cerebral palsy
and feeding difficulties 701–702
nutrition and feeding in 729–731
Chamomile 179
Chelation in sickle cell disease 134
Chemical analyses (*see also specific element*)
in vivo, for measuring body composition 42
Chemical composition
of body 38
of carbohydrates 48–50
Chemical stability of body weight 50–52
Chemokines and intestinal immune system 340–341
Chemotherapy, side effects of 879–881
Child abuse and neglect (*see also* Abuse)
Child development
conceptual, relative to malnutrition 230i
early, affecting later-life diseases 435–437
linked with nutrition and economics 653–661
Child health, global
and the nutrition transition 631–640
interventions for 663–672
Child Health Days, aiding at-risk children 670
Child nutrition (*see also* Nutrition, child)
and cancer prevention 865–876
and economic development 653–661
structural changes affecting 659–660
Childhood illnesses, integrated management of 669–670
Childhood obesity

behavioral assessment and therapy for 605–608
causes of 692–694
co-morbidities in 604
epidemiology and pathophysiology of 599–602
evaluation and management of 599–612
in developing economies 689–697
nutritional assessment of 604–605
prevention of 625–630
gaps in evidence on 628–629
recent trials of 628t
risk factors for 625–626
treatment of 606–610
weight-loss drugs and surgery for 608–609
Children
at risk for cardiovascular disease 972
at-risk, early interventions for 261–262
critically ill 957–970
injured, protein requirements for 959t
school-age, in U.S., nutritional recommendations for 250–252, 252t
with special needs (*see* Special-needs children)
Chile
interventions to prevent obesity in 694–695
prevention of malnutrition in 237–238
Chinese herbal medicine during pregnancy 430–431
Chloride in human milk 497
Cholera, treatment of 920
Cholestasis
and hepatobiliary disease 749
in intestinal failure 934–938
Cholesterol, and nutrition 977
Cholesterol-lowering diet in cardiovascular disease 1128–30
Cholesterol metabolism and transfer in placenta 467–458
Cholesterol screening, universal vs. selective 976–977
Choline requirements in parenteral nutrition 1057
Chromatin remodeling, ATP-dependent 356–357
Chromium 108–110
possible toxicity in parenteral solutions 1061
Cirrhosis
North American Indian 751
Clostridium difficile infections in diarrheal diseases 918
Cobalamin (*see also* Vitamin B_{12}) 157–158
Coenzyme A, conversion from pantothenic acid 159i
Coenzyme Q10 in human milk 494
Colitis

Crohn's, enteral nutrition in 796
ulcerative, nutritional therapy for 792–793
Colonization, neonatal intestinal 503–515
immune education in 509–512
Colostrum
energy composition of 487t
fatty acids in 489–490
Community nutrition
defined 245
effectiveness of 670
for malnutrition 213, 235–236
in Canada 244, 247, 248t, 253–254. 255, 256t, 263t, 264t, 266t
in industrialized countries 243–269
U.S. governmental programs for 243–262
web-based resources for 262–265
Complementary feeding
and content of diet 578–579
and health outcomes 575–582
during weaning 571–572
in low-income countries 644–646
interventions in practice of 649–650, 666–667
timing of introduction to 644i
Complementary foods
energy and density requirements of 644–645
nutrient requirements of 646–647
processed 648–649
safety in preparation of 649
Congenital disorders of glycosylation 747t
Congenital enteropeptidase deficiency 839
Congenital heart disease
and feeding difficulties 702
and hyperlipidemia, dietary restrictions in 1127–28
Congenital lipase/colipase deficiency 839
Contaminants, environmental, in human milk 498
Cooking methods influencing dietary metabolism 305
Copper
in human milk 497
in parenteral solutions, cautions about 1061
Copper deficiency 102–105
Copper metabolism, diseases involving 751
Cori disease 764–765
Coronary heart disease (CHD),
later-life mortality from related to birth weight 435i, 437–438
Cortisol and sex steroids 378–379

Costs of food and nutritional assistance in U.S. (FY2010) 257t
Counseling, dietary, for young athletes 1097–98
Cow’s milk
  and immune response in diabetes 894
  as percentage of infants fed 567
  as source of iron 579
  substitutions for 1112
  undesirability of, in early infancy 572
Cow’s milk allergens in breast milk 827–828, 1112
Cow’s milk allergy, challenges to 1115
Cow’s milk–free infant formulas 1112t
Cow’s milk protein-free diet 1110–15
Creatinine, urinary, assessing muscle mass 27
Critically ill children 957–970
  enteral nutrition in 1029
Crohn’s disease
  and protein metabolism 193
  dietary treatment in 1119
  elemental diet in 794
  enteral nutrition in 793, 796–797, 1029
  mechanisms of 799–801
  nutrient-gene interactions in 344–345
  nutritional compromise in, key factors in 789t
  nutritional therapy in 787–788, 794–796
  polymeric diet in 795
  responding to inaction in malnutrition 207–208
Cutaneous food hypersensitivity reactions 826
Cystic fibrosis 835–837, 841–846
  and bone disorders 1015–16
  and feeding difficulties 702
  bone disease in 844
  clinical manifestations of 837t
  enteral tube feeding in 847
  malnutrition in 842–844
Cytokines
  affecting energy expenditure 184
  and intestinal immunity 340–341
  in cancer 878–879
  in HIV-infected children 676

D

Dairy intake and bone health 1013
Daycare for breastfeeding infant 529
Daycare centers and treatment for malnutrition 235–236

Debranching enzyme deficiency 764–765
Decosahexaenoic acid (DHA), benefits of 177–178
Dehydration
  degree of, and gastroenteritis 916
  dietary therapy for 917–918
  hypernatremic 918–919
  in SAM 216–217
  severe
  hospital and outpatient therapy for 917
  signs of 915t
  treatment plans for 916t
Dehydroepiandosterone (DHEA), caveats concerning 1014
Demographic transition and structural changes affecting nutrition 659–660
Densitometry
  correlated with anthropomorphic measurements 276–277t
  in estimating body water 42
Dental benefits of fluorides 994–997
Dental caries
  etiology of 989–982
  fluoride preventing 111
  polyols reducing 991–992
  treatment of lesions in 997–998
Dental disease
  and diet 987–1000
  and sugar-containing food 990–991
Dentin, structure of 988
Depression, maternal, as factor in growth failure 711
Dermatitis, atopic, as food reaction 826
Developing countries and economies
  and the nutrition transition 637–639
  obesity and overweight in 689–697
  targeting interventions to achieve health goals 665–669
Development, economic (*see* Economic development)
Developmental disabilities, monitoring growth and nutrition in 729–741
Developmental origins of later-life disease 435–437
  hypothesis for 436–437
DHA-free formula feeding 177
Diabetes 891–910
  after kidney transplant 781
  and dyslipidemia 972
  as carbohydrate disorder 67
  carbohydrates in 897–898
  celiac disease and 1117
  dietary fiber in 898

dietary sweeteners in 900–901
energy, dietary intake in 896–897
fat, dietary, in 899–900
goals of medical nutrition therapy for 895
hypoglycemia in 906–907
lab assessment of 605t
macronutrients in 897
meal planning in 902–905, 906–908
nutritional management of 896
outpatient 905
prevalence, definition, and clinical description of 891–893
protein in 898
type 1
and eating disorders 702
celiac disease and 905
dietary factors in pathogenesis of 893–894
meal plan for 902–903
type 2
in later life, birth weight and 438–439
meal plan for 903–904
metabolic syndrome and 972
Dialysis, maintenance, energy requirements for 776–777
Diarrhea
acute bloody 920
home management of 913–914
chronic, hepatic and GI dysfunction in 648t
functional foods in 919
in SAM 216–217
persistent 920–921
sanitary measures to alleviate 657–659
treatment of, relative to income 657–659
with severe malnutrition 921–922
Diarrheal diseases 911–924
clinical assessment of 914–915
historical background to 911–912
pharmacologic therapy for 918–919
Diet(s)
adolescent
and benign breast disease 874
and breast cancer 873
red meat and soy consumption, risk of breast cancer and 873–875
affecting microbial composition of gut 57
and genetics in analysis of 284–286
balanced, plate method of 983i

childhood and age at menarche 874
cholesterol-lowering 1128–30
complementary feeding and 578–579
modification and diversity in 646
cow’s milk-protein-free 1110–1115
dental disease and 987–1000
egg-free 1100–02
elemental, in IBD 794
fluid-restricted 1127–28
for childhood obesity 607
for hereditary fructose intolerance 1122, 1123–24t
for GI disease 1115
for long-chain fatty acid disorders 1122
gluten-free diet in celiac disease 817–81, 115–178
gut microbiota in metagenomics era 399–409
high-calcium 1130–1133
high-energy, in growth failure 1126–27
high-fiber 1133, 1135–37
GI absorption in 305
immunity enhancing, for critically ill children 965–966
in etiology of IBD 787–788
interacting with microbiota and intestinal immune system 174i
iron-rich 1133, 1134–35t
lactose-free 1107–10
low-fat, to prevent CHD 978–979
low-phenylalanine 1119–21
maternal, and essential fatty acid supply to fetus 459
oral, in cancer paatients, 885
peanut-free 1103, 1105–06
polymeric, in Crohn’s disease 795
quality of, and food availability 657
rice-milk 219t
shellfish-free 1106–07
soy-free 1102–03
special (*see also* Special diets) 1095, 1099–46
tree-nut-free 1106
variations in, affecting response to drugs 293–322
vegan, as result of low food availability 657
vegetarian
health benefits of 1138
in infants 579
very-low-calorie, and drug metabolism 306
very-low-fat 1125t
very-low-fructose 1132, 1123–24t

Dietary adherence in diabetes 907–908
Dietary allowance, recommended (*see also* RDA)
  for amino acids by age and gender 77–78t
Dietary analysis
  compensating for missing data in 282–283
  genetics in 284–286
Dietary changes affecting drug kinetics 301–307
Dietary counseling for young athletes 1096–97
Dietary factors
  altering class II MHC 342
  in pathogenesis of diabetes 893–894
Dietary fats, and drug kinetics 304
Dietary fiber(s) (DFs)
  food sources for 1136t
  in IBD 788
  in vegetarian diets 1137
  intake recommendations based on 65, 66t
Dietary guidelines for Americans 167–169, 899
Dietary intake(s) (*see also* Dietary reference intakes and Appendix II on pp. 1201–15 for detailed information)
  assessment methods in 272–275
  in breast-fed babies 274–275
  biochemical markers of 277–282
  driving obesity in developing countries 692–694
  history of 5–6, 274
  in breast-fed infants
  adding solid foods in 527
  assessment of 6, 275
  in children with CP 730
  in hypercholesterolemia 1128

  of fats 337
  in infants and children 85–86
  tracking 281
Dietary management
  in chronic kidney disease 774
  in SAM 218–220
Dietary nutrients
  absorption in the gut 173–175
  affecting gene expression 335i
Dietary patterns, effects of urbanization on 637–638
Dietary recommendations to reduce triglyceride and HDL levels 977–980
Dietary records for assessing nutrient intake 274t
Dietary reference intakes (DRIs)

accepted macronutrient distribution range 164
adequate intake in 164
data used to formulate 166
establishing values for 171–172
for macronutrients 167–168
in the U.S. 6, 14, 163–171
life-stage groups in pediatric population in 165–166
macronutrient recommendations 166–168
practical aspects of 168
RDAs in 164
tolerable upper limit in 164–165
Dietary regulation and enterocyte gene expression 334i, 334t
Dietary requirements
for bone health 1009–12
for iron 117–119, 128–129
for trace elements 97, 101–102, 105, 108, 110, 113
Dietary restrictions affecting drug metabolism 306
Dietary sources (*see also* Food sources)
of calcium 1018t
of folate 156
of iodine 113
of niacin 154
of riboflavin 153
of vitamin B_{12} 158
Dietary supplements (*see also specific supplement*)
fish oil, benefits of 177–178
in SAM 221
potential risk of 177–180
toxic side effects of 179–180
widespread use of 177
Dietary therapy for dehydration 917–918
Digestion (*see also* Absorption)
fatty acid
comparison of chain length in 390t
in premature infants 389–390
of fats 83–84
in exocrine pancreatic disorders 840, 846
Digestive absorptive function, development of 389–391
Disabilities, developmental (*see* Developmental disabilities)
Disaccharides 55–56
Disease(s)
adult, and early pre- and postnatal growth 635–636
and food association 271–272
changes in body composition during 50

communicable, and undernutrition 636
effects on energy expenditure during 192–198
hepatobiliary 749
involving inborn errors of metabolism 743–756
later-life
developmental hypothesis for,
origins in early nutrition and growth 435–443
role of genes and environment in 441–442
role of placenta in 440
metabolic, featuring hepatic and GI dysfunction 745–748t
occurring during economic development, treatment of 657–659
of iron metabolism 133t
protein metabolism in 192–194
renal, acute and chronic 769–786
Disease burden, global trends in 631–632
Disease prevention
by food fortification 287–288
interventions for 667–668
Disease-specific growth charts 1192–93
Disease states, GH in 372–373
DNA methylation 351–354
bioactive food components and 354
during lifetime 352–353
embryonic development and 352
folate deficiency and 353
nutritional influence on 353–354
Docasahexaenoic acid (DHA)
supplied to pregnant and breastfeeding women 89–90
Doping agents in young athletes 1094–95
DPT vaccination rates and real income 659i
Drivers of overweight and obesity in developing economies 692–694
Drug absorption in malnutrition 298
Drug bioavailability, affected by beverages 306
Drug clearance, hepatic, in malnutrition 299
Drug distribution in malnutrition 298–299
Drug kinetics
affected by nutritional status 293–327
effects of malnutrition on 298–301
effects of diet on 301–307
factors having an impact on 293–299
Drug metabolism, factors affecting 305–306
Drug-nutrient interactions 5t, 293–327
examples of 309–311t
Drug therapy and the role of nutrition 293–327

Drugs
affecting absorption 301–303
affecting nutrient transport 309–316
altering glucose metabolism 312–314
and appetite 316–319
antihelmintic and antimalarial, in preventing morbidity 668–669
causing weight gain in obese children 604t
chemotherapeutic, in cancer 880–881t
effects of, on nutrient status 309
in human milk 11, 13, 498
in hyperlipidemia 981t
in kwashiorkor 299
in marasmus 299–300
inducing fluid and electrolyte imbalance 309–312
interacting with grapefruit juice 305
interacting with vitamins 320–321t
lipid-lowering 980
rectal administration of 295–296
weight-loss 608–609
Dual energy X-ray absorptiometry (DXA) 12
in estimating body water 42
in evaluating bone mineral density 1016
Dust Bowl, nutritional problems in 2
Dysentery, treatment of 920
Dyslipidemia
after renal transplant 781
drugs associated with 315–316t
in metabolic syndrome 616
major, diagnosis of 974–976
pediatric, and CVD 971–972
treatment for 978–979

E

Eating disorders
adolescent 1001–06
clinical assessment of 1002
feeding problems with 702–704
long-term consequences of 1004–05
precursors to 721–722
refeeding syndrome in 1003
treatment of 1004
Eating patterns, healthy 169–170
Echinacea 178
Economic development and child nutrition 653–661

Ecosystem, intestinal, and microbiota 393–394
Education
  nutritional, in fighting malnutrition 234
  of mucosal immune system by factors in breast milk 509–512
  women's, improving health environment via 232
Egg-free diet 1100–02
  substitutions for egg in 1102
Eicosapentaenoic acid, benefits of 177–178
Electrolyte imbalance
  drug-induced 309–312
  in SAM 216–217
Electrolyte homeostasis in acute kidney injury 772
Electrolyte metabolism in critically ill children 962–963
Electrolyte requirements in parenteral nutrition 1051–54
  in VLBW infants 1054–55
Electrolytes
  changing during malnutrition 206
  disturbances in, in chronic kidney disease 779–780
  needed in young athletes 1094
  required in preterm and VLBW infants 544, 1051–55
Elemental diet in IBD 794
Embryonic development, DNA methylation in 352
Emergency treatment for SAM 213–222
Emotional deprivation and growth retardation 376–377
Emotional stimulation in SAM 222
Enamel
  dental, structure of 988
  mottled 992–994
Endocrine system
  and growth 361–385
  changes in, in severe acute malnutrition 208
Energy
  and substrate regulation in obesity 583–597
  dietary fiber and 1137
  resting (*see* Resting Energy expenditure)
Energy balance
  in cancer 879
  in young athletes 1095–96
Energy content
  enriching formula after NICU discharge 558
  of human milk 486
Energy deficits, after time in NICU 554–555
Energy expenditure 189
  and disease states 192–198

and malnutrition 191–192
and utilization of energy substrate 194
cost of, in protein synthesis 188
in critically ill children 960–961
in Crohn's disease 801–802
in cystic fibrosis 843–844
in disabled children 730
in growth, estimation of 187
in liver disease 853
in obesity 589–593
imbalance of 625
in parenteral nutrition 1037–41
physiologic determinants of 183–190
twenty-four-hour 190
Energy intakes
and food availability 657
in breast-fed vs. formula-fed infants 569
in cystic fibrosis 842–843
in diabetes mellitus 896–897
in disabled children 737–739
in GH-treated patients 373i
in HIV-infected children 674–675
in obesity 589, 593
in severe acute malnutrition 295–206
statistical models for assessing 283–284
total, in epidemiologic studies 283–284
energy metabolism in critically ill children 960–961
Energy regulation in obesity 588–589
Energy requirements 28–31
complementary feeding and 578–579, 644–645
estimated average 592i
in acute kidney injury 779–771
in developmentally delayed children 711t
in chronic kidney disease 776–777
in health and disease 183–200
in parenteral nutrition 1037–41
in preterm and VLBW infants 1040–41
in term infants 568
normal 738–739i
Energy-protein requirements in preterm infants 541
Energy substrate
and amino acids 196
balance of, in obesity 591–593
effects of disease on 194–195

Enrichment of formula and human milk in preterm infants 558–559
Enteral feeding
and drug interactions 297
devices used for 941t
drug-nutrient interactions in 1031
in cancer patients 885
in cystic fibrosis 847
interventional approaches to 394–395
in LBW and VLBW infants 389–396, 542–543t, 546t
methods for advancement in 942
minimal 394–395
optimization of 546t
Enteral formulas 885, 1023–34
composition of 1025–27
disease-specific 1026–27
for infants 1025–26
Enteral intake as proportion of human milk in preterm infants 556i
Enteral nutrition (*see also* Tube feeding) 1023–1034
access to
complications in 1030–1031
management of 1029
as maintenance therapy in IBD 796–797
at home 1031
contraindications to 1024–25
gastrointestinal complications of 1030
in critically ill children 964–965
in Crohn’s disease 792–794, 796–797
in growth failure 798–799
in HIV-infected children 683
in intestinal failure and SBS 929–931, 940–941
in IBD 794
mechanism of 799–801
in preterm infants 394–398, 544–547
in specific disease states 1029
in VLBW infants, challenges for 387–398
infectious complications of 1030
initiation and advancement of 545–547
mechanical complications of 1030–31
modes of delivery of 1028
role in growth and development 798–799
pulmonary complications of 1030
routes of administration for 1027–28
steroids vs., 795–798
Enteral products, infant and noninfant [see Appendix III on pp. 1217–1231 for

detailed tables]
Enterocolitis, food protein-induced 828
Enterocytes (*see also* Intestinal epithelial cells)
and diet 57
adapting to nutritional cycle 336–339
genetic expression in 336i
in fatty acid uptake 338
in hormonal regulation of iron 123i
Enterokinase deficiency affecting the pancreas 839, 841
Enteropeptidase deficiency, congenital 839
Enteroplasty, serial transverse, technique for 943i
Environment
role of, in later-life diseases 441–442
shaping gut microbiota 402–403
Environmental contaminants in human milk 498
Environmental vs. genetic factors in obesity 586
Enzyme deficiency disease, debranching 764
Enzyme disorders of liver and GI tract 745–748t, 751–752
Enzymes
in human milk 492–493
in HMO metabolism 59t
Eosinophilic esophagitis (EoE) in food reaction 827
Ephedra 178
Epidemic, HIV and pediatric AIDS 673
Epidemiologic studies (*see also* Anthropometrics; Field studies)
models accounting to total energy input in 283–284
types of 286–288
Epidemiologic variables, preservation of data in 285–286
Epidemiology
nutritional 271–291
of childhood obesity 599–600
of feeding disorders 699
of growth failure 798–799
of iron deficiency 126
of pediatric growth failure 707–708
Epidermal growth factor in intestinal adaptation 933
Epigenetic modification in nutrition 329
Epigenetics and nutrition 351–360
Epithelial cells (*see also* Enterocytes; Intestinal epithelial cells)
polarity of 334
role in absorption and in immune system 173, 329–349
Equations for measuring body composition 38–39t
Erythropoietic regulation of iron 124
Esophagitis, eosinophilic 827

Essential fatty acids (EFAs; *see also* Fatty acids) 30
  availability of, to fetus 458–460
  deficiency in 30
  intravenous lipid emulsions for 1046–48
  maternal diet and 459
Estimated average requirements (EAR) 163–164
  for amino acids by age and gender 77–78t
Ethnic differences
  in body composition 45
  in stature 50
Etiologic features of trace element deficiencies 99–100, 104, 106–107
Etiology
  of anorexia in cancer patients 881–882
  of dental caries 989–992
  of feeding disorders 701–703
  of growth failure 710t
  in IBD 798–799
  of IBD 787–788
Evidence-based results of health interventions 669
Exclusive Liquid Diet therapy in children with Crohn's disease 1119, 1120t
Exercise (*see also* Physical activity)
  affecting bone health 1009
  and body fat 45
  in diabetes mellitus 906
Exocrine pancreatic disorders 835–849
  absorption and digestion of fats in 840, 846
  nutrition in 841–847
  protein absorption and digestion in 841–844
Extracellular fluid (ECF), estimation of 39
Extrauterine growth restriction 538
  during NICU hospitalization 553i
Extremely-low-birth-weight (*see* Low-birth-weight; Very-low-birth-weight)
Eye care in SAM 222

F

Factorial approach in determining protein or amino acid requirements 79
Failure to let down milk 533–534
Failure to thrive (*see also* Growth failure)
  in outpatient setting 707–727
  maternal causes of 533–534
  risk factors for 708–713
  while breastfeeding 529–534
Failure to wean 700
FAO/WHO/UNU, assessment of energy needs by 190

Familial dyslipidemias 974–976
Famine
as political weapon 2
effects of, on human health 871–872
Fasting
and energy substrate 192
effects of
on GH release 371–372
on somatomedin and nitrogen balance 375i
growth hormone release in 372t
Fasting adaptation, inborn errors of 757–768
Fat(s),
absorption in, biochemistry of 84
balance of, in obesity 591–593
contents of milk, considerations in reducing 578–579
dietary intake of 337
and drug kinetics 304
in diabetes 899–900
digestion of 83–84
in breast-fed infants 83
in cystic fibrosis 839–841
ectopic, stored in muscle and liver 622–623
in breast-fed vs. formula-fed infants 570
in human milk 488–489
malabsorption of in CF 846–847
needed in young athletes 1092
Fat distribution
ethnic and racial differences in 45
relative to gender during adolescence 45
Fat-free mass (FFM)
and resting metabolic rate 184i, 185i
changes during lifespan 49i
changes relative to growth 48
fat metabolism in liver disease 852
Fat-soluble vitamins 31–32
deficient, in liver disease 853, 854
Fatty acid(s) (*see also* Essential fatty acids)
biochemistry of 86–87
chain length of 389–390
conversion in premature infants 389–390
essential 87–89
in human milk and colostrum 489–490
long-chain polyunsaturated, in liver disease 852–853
macronutrient assessment of 30–31, 83–93

mitochondrial, oxidation of 754i
omega-3, in VLBW infants 396
oxidation defects in 746–747t
relative to maternal plasma 89i
required in preterm infants 544t
structural formulas of 87i
uptake, metabolism, and transport in placenta 456–457
Fatty acid deficiency 88t
Fatty acid metabolism
genetic variation in 88–89
Fatty acid transfer, placental 89
Fatty acid uptake
adaptation of enterocytes in 338
comparison of chain length in 390t
trophoblast 90i
Feeding
complementary (*see also* Complementary feeding)
health outcomes and 575–582
in countering malnutrition 232
in low-income countries 641–652
difficulties in 699–704
enteral, in LBW and VLBW infants 389–396, 543–547
infant
gastrodevelopment and 387–398
trends in 565–566
methods of, during complementary food period 580
oral, development of mechanical function for 388–389
parenteral, in preterm infants 547–549
physiology of 699–700
school programs for, effectiveness of 670
thermic effect of 187–188
tube, administration and tolerance for 547
Feeding behavior, observation of 719t
Feeding devices
mechanical difficulties in 1030–1031
postpyloric 1028
Feeding difficulties in disabled children 729–730
Feeding disorders 699–705, 711–712, 719t
assessment and management of 703–704
classification of 712–713t
post-traumatic 702–703
Feeding problems, behavioral, in liver disease 858
Feeding skills
interrupted by cancer treatment 882

normal development of 700
Feeding tubes, gastric access to 1027–1028
Female athlete triad
energy balance and 1096
of eating disorders 1004
Ferritin in assessing iron status 134–138
Fetal fat content 43 (*See also items under* Gestation *or* Gestational)
Fetal glucose and lipid metabolism 445–460
Fetal growth, and risk of adult disease 635–636
Fetal growth restriction (FGR), amino acid transport in 475–477
Fetal hepatic circulation, amino acid metabolism and 474–475
Fetal iron needs 117–118
Fetal nutrition
amino acids supplying 465–482
later-life disease and 439
Fetal oxidation, amino acids and 472–474
Fetal-placental interrelationship 445–460 (*passim*)
Fetus
carbohydrate and lipid metabolism in 445–463
essential fatty acid accumulation in 459–460
glucose in 446–456
hyper- and hypoglycemia in 453–456
lipid uptake, metabolism, and transfer to 456–460
Fever, effects of, on energy substrate 194
Fibers, dietary
in diabetes 898
in vegetarian diets 1137
GI absorption in 305
recommendations based on 65
sources of 1136–37t
to modify lipid profiles in dyslipidemia 979
Field studies, anthropometric techniques in 40
Fish allergy 1107
Fish oil supplements
benefits of 177–178
during pregnancy 431
Flavor of breast milk vs. formula 569
Fluid(s) and electrolytes
needed in young athletes 1094
required in preterm infants 544, 1055–1951
Fluid imbalance, drug-induced 309–312
Fluid-restricted diet 1127–28
Fluoridation of water supply, benefits of 995–996
Fluoride(s) 11–112

excess, toxicity of 992–994
human health and 992–998
in human milk 497
in preventing dental caries 111
in tablets, toothpaste, and oral rinses 996–997
intake by infants 111
mechanisms of action of 997
naturally available 994–995
Fluorosis 111
Folic acid 156–157
dietary sources of 156
DNA methylation in deficiency 353–354
in HIV-infected children 680
in human milk 495–496
metabolism of 156–157
status in pregnancy 426–427
Folic acid deficiency
and neural tube defects 286–288
DNA methylation and 353–354
laboratory assessment of 33
use of vitamin supplements in 287–288
Folic acid requirements in pregnancy 287–290, 426–427
Food (*see al*so Complementary food; Drug-nutrient interactions)
and nutritional assistance plans, in U.S. 253–262
as political weapon 2–3
availability of, and per-capita income 657
complementary (*see also* Complementary feeding; Complementary foods)
insecurity about availability of 670
interacting with drugs 296
functional, in diarrheal disease 919
reintroduction of, after exclusive enteral feeding 796
safe preparation of 649
solid, added in breast-fed infants 527, 571–572
Food allergies (*see also* Celiac disease *and* Allergy *entries*) 823–833
clinical disorders of 825–828
management of 830, 1099–11
novel therapies for 830
pathophysiology of 824
reaction mechanisms in 825
Food aversion 702–703
in cancer patients 881–882
Food crops, biofortification in 649
Food hypersensitivity reactions 826–828
Food information laws 1100

Food ingredients, functional, overview of 173–181
Food intake
  and drug-nutrient interactions 297
  questionnaire in assessing dietary intake 6, 273–274
  reduction in, and rate of metabolism 183
  24-hour recall of 272–273
Food record (*see also* Dietary records) 273
Food safety in patients receiving HSCs 884–885

Food sources (*see also* Dietary sources)
  of chromium 110
  of copper 195
  of iodine 113
  of riboflavin 153
  of selenium 108
  of vitamin D 146
  of zinc 102
Food supply, fortifying
  to prevent iron deficiency 129–130
  to prevent NTDs 287–288
Forbes disease 764–765
Formula(s)
  as risk factor for childhood obesity 626
  benefits in preterm infants 555
  composition of 566, 570–571
  cow’s milk-based, contraindications for 1108
  cow’s milk–free 1112t
  DHA-free, deficits of 177
  disease-specific 1026–27
  enteral (*see* Enteral formulas)
  in glycogen storage disease 760–761
  for children with liver disease 856t
  for parenteral nutrition, amino acid composition of 1043t
  for preterm infants 546
  after NICU discharge 560t
  isocaloric nutrient enrichment of 558–559
  in diarrheal diseases 917–918
  in intestinal failure/SBS 940
  kidney-specific 773t
  MCT-based 1126
  substances added to 571
Formula-fed vs. infants at term 566–571
Fortification of food supply
  to prevent NTDs 287–288

iron 129–130
of human milk after NICU discharge 559–560
Frankfort plane
in assessing length 7i, 732i
Free radicals in severe acute malnutrition 208–209
Frontal occipital circumference (*see* Head circumference)
Fructose
controversial opinions concerning 63
dietary, in diabetes 900
metabolic aspects of 62
sources to be avoided 1122t
Fructose intake, high, potential risks in 62
Fructose intolerance 67
hereditary 750, 1122
Fructose load, metabolic fate of 61i
Fruits, sucrose content of 1118t
Fungemia, catheter-related, in IF/SBS 938

G

Galactosemia 1107
acute manifestations of, in infant 750
as carbohydrate diease 67
low-lactose cheese allowed in 1108
Garlic 178–179
Gastric access feeding devices 1027–1028
Gastric acids and innate defense mechanisms 391
Gastric bypass surgery for obesity 300, 609
Gastric emptying and intestinal transit 294–295, 388–389
Gastric lipase (*see* Lipase, gastric)
Gastroenteritis
allergic eosinophilic 827
bacterial, and intestinal epithelium 335–336
therapy of, based on degree of dehydration 916
Gastrointestinal development
implications for infant feeding and 387–398
microbiota and 399–409
Gastrointestinal diseases
diets for 1115–1119
enteral nutrition in 1029
complications in 1030
Gastrointestinal food hypersensitivity disorders 827–828
Gastrointestinal sphincter tone, development of 388
Gastrointestinal tract
absorption, in HIV-infected children 675–676

adverse effect of medications on 307–312
development of defense and barrier function in 391–393
in SAM 210–211
inborn errors of metabolism in 744–749
influenced by milk oligosaccharides and prebiotics 63i
pediatric, role of carbohydrates in development of 55
side effects of medication for HIV in 675t
Gene expression
and breast milk 338–339
and nutritional regulation 329–349
Gene-diet interactions 284–286
signal transduction mediating 335i and growth hormones 367–368
therapeutic implications of 344–345
Genes
and growth hormones 367–368
role in later-life diseases 441–442
Genetic disorders
exocrine pancreatic 835–837
hepatic 749–755
of iron overload 132–134
Genetic growth potential
calculation of 714t
midparental length in 10

Hemochromatosis, perinatal and juvenile 750
Hemoglobin in assessing iron status 134
Hepatic circulation, fetal, amino acid metabolism and 474–475
Hepatic complications in parenteral nutrition 1065
Hepatic diseases and inborn errors of metabolism 743–756
Hepatic glycogen synthase deficiency 757–759
Hepatic injury and pathophysiology 749
Hepatic involvement in celiac disease 816
Hepatic metabolism and nutrient-drug interactions 295
Hepatic pathology from peroxisomal disease 752–753
Hepatocellular necrosis 749
Hepatomegaly 752–753
Hepcidin in iron regulation 123i
Herbal supplements (*see also* Chinese herbal medicine *and specific supplement*) 178–179
in pregnancy 430–431
Herbal teas during lactation 526–527
Hereditary exocrine pancreatic disorders 835–839
Hereditary fructose intolerance 750
very-low-fructose diet for 1122, 1123–24t
Heritability
of childhood obesity 600–601
of individual components of MetS 621t

Hers disease 765–766
High-energy diet in growth failure 1126–27
High-fiber diet 1133, 1135–37
Histones
  acetylation of 355–356
  biotinylation of 356
  DNA methylation modifying 354–356
History, medical, in assessing growth failure 714–716
HIV in human milk, precluding breastfeeding 498
HIV-associated metabolic disturbances 678–679
HIV-infected children
  diagnostic evaluation in 680–681
  wasting in 674–677
HIV infection 772
  avoiding transmission of, by breastfeeding 498
  in severe acute malnutrition 212, 218
  pediatric 673–687
Home-based devices for nutritional feeding 1073–75
  complications and infections in 1073
  enteral, 1031
  long-term monitoring of 1074
  parenteral 1073–75
Home management of acute diarrhea 913–914
Homeostasis
  electrolyte, after acute kidney injury,
  intestinal, restored by probiotics 175–176
  iron 121–124
Hormonal preparation post partum for lactation 519i
Hormonal regulation of iron efflux 123
Hormonal status affecting bone health 1009
Hormone secretion, nutrient stimulation of 332–334
Hormones (*see also* Growth hormones; Insulin-like growth factors *and specific hormones*)
  acting on body compartments 363t
  affecting intestinal adaptation after resection 935t
  and growth factor and nutrients 361–362
  in human milk 492
  thyroid 377–378
Hospital treatment
  monitoring 1064–65, 1074
  of dehydration 917
  of malnutrition 213–216, 234–235
Hospitalized child, assessing nutritional needs of 5–17, 1147–51
Human capital, investing in, by lessening malnutrition 233

Human immunodeficiency virus (*see* HIV *entries*)
Human milk (*see also* Breast milk)
  adequacy after 6 months 578
  affording immune protection 176
  biochemical composition of 486–498
  and maternal nutrition 642–643
  cellular reactivity to bacteria in presence of 510–511
  compared with formula 560t
  composition in preterm and term infants 456t
  deficits in, in preterm infants 555
  donor's vs. mother's 545
  education mucosal immune system 509–510
  enriched after NICU discharge 559–560
  factors modulating response to bacteria 510t
  in at-term infants 565–573
  breast-feeding vs. formula–feeding 566–572
  in preterm infants 545
  initiation of secretion of 520–251
  macro- and microminerals in 496–498
  macronutrients in 58t
  microbiome in 511
  nutritional properties of 483–502
  production of 485–486
  protective properties of, in neonatal gut 503–515
  protein and micronutrient content of 643t
  PPR-bacteria interactions in presence of 509–510
  pumping and storage of 528–529
  shaping intestinal microbiota 507
  supplementation of, during breastfeeding 525
  synthesis and secretion of 519–521
  TGF-β in immune education 511–512
Human milk oligosaccharides (HMOs) 487–488
  antimicrobial and prebiotic activities of 507–508
  metabolized by bifidobacteria 59t, 59–61
  monosaccharide composition of 61t
Human population, microbiome variation, in 403–405
Humoral regulation of growth, and nutrition 361–385
Hydration in young athletes 1094
Hydrolysis of fatty acids 84i
Hypercholesterolemia
  dietary therapy for 1128–30
  severe, other therapies for 980
Hyperglycemia
  affected by medications 313–314t

maternal, and placenta and fetus 455–456
in critical illness 961–962
Hyperinsulinism 67
Hyperlactatemia in GSD type Ia 761
Hyperlipidemia
and cardiovascular disease 971–986
diet for 1131t
dietary restrictions in 1127–28
medications treating 981t
secondary, causes of 975
Hypernatremic dehydration 918–919
Hypersensitivity to food, diagnostic methods for 829–830
Hypertension
arterial, in MetS 616
classification of, in children and adolescents 629t
later-life, relative to birth weight 438–439
potential link of fructose to 62i
Hypervitaminosis 319–322
Hypoalbuminemia 28
Hypoglycemia
affected by medications 313–314t
in diabetes 906–907
placenta and fetus and 453–454
in SAM 213–214, 216
Hypothermia in SAM 216
Hypothyroidism, catch-up potential in 365i

I

Identification of children at risk of obesity 627
Illness, chronic, affecting bone health 1009
Imaging techniques in measuring body water 42
Immune defense mechanisms, micronutrients involved in 34
Immune responses
adaptive and innate, in celiac disease 810i
and bovine insulin 894
in SAM 208–209
innate mucosal, in mature gut 503–506
Immune system
influenced by milk oligosaccharides and prebiotics 63i
interacting with microbiota and diet 174i
intestinal 173–175
prenatal 504i
Immune system, mucosal
educated by factors in breast milk 509, 511

TGF-β in 511–512
signaling from intestinal lumen to 339–345
Immunity
adaptive, breast milk effects on 512
cell-mediated, in SAM 209–210
diets to enhance, in critical illness 965–966
humoral, in SAM 210
Immunization, campaign for, in developing countries 659
Immunoglobulin E (IgE)
diagnostic methods for 828–830
mediating reactions to food 825
Immunoglobulins in neonatal gut 510–511
Immunological tests for nutritional status 34
Inborn errors
of fasting adaptation 757–768
of metabolism
and diseases of the liver and GI tract 743–756, 859
dietary treatment for 1119
of trace element metabolism (*see also specific disease*) 96
Income
food and water availability and sanitation, relative to 657–659
household, related to CHD 437t
low to middle, in nonwestern countries, and childhood obesity 628–629, 689–697
real, and child nutrition 653–661
India, BMI related to rural/urban status 694t
Industrialized countries, community nutrition in 243–269
Inequity of food availability in undernutrition 670
Infancy, nutrition during, later-life disease and 435–443 (*passim*)
Infant feeding
breastfeeding vs. formula-feeding 566–573
in low- and mid-income countries 641–652
initiation of solid food in 527
GI development and 387–389
preterm and neonatal 387–398
Infants
air-displacement plethysmography in 42
breast-fed
assessing growth of 484
development of gut microbiota in 406
dietary assessment in 274–275
iron levels in 130
role in initiating lactation 523–524
vs. formula-fed 568–572
enteral formulas for 1025–26

failure to thrive in, interventions for 720–721
fluoride intake by 111
growth in, later-life development of disease and 437–438
health benefits of breastfeeding in 483–485
in malaria-endemic areas 131
in U.S.
community nutrition concerns for 249–250
nutritional recommendations for 166, 250t, 251t
LC-PUFA supply to 90–91, 389–390
need for iron in 117–118
nutrient requirements of 566–568
in cystic fibrosis 846–847
preterm or LBW (*see also* Preterm infants)
energy requirements for 1040–41
enteral nutrition in 387–398
fat absorption in 84
iron deficiency in 126–127
parenteral nutrition in 1036–37
trace element deficiency in 96
reference, body composition and weight gain in 567i
suckling disorders in 530–531
term 565–573
very-low-birth-weight (VLBW)
enteral and parenteral nutrition in 387–398
vitamin K deficiency bleeding in 151
Infection(s)
and iron, interaction between 131
and nutrition, relation of 206–207
as complication of enteral feeding 1030
breastfeeding and 576–577
catheter-related 1069–72
effects of, on energy expenditure 194–195
in SAM 218
pediatric HIV 673–687
with *Clostridium difficile,* in diarrhea 918
Infectious diseases
and undernutrition 636
sanitary interventions to prevent 657–659
Inflammation, systemic, affecting bone health 1009
Inflammatory bowel disease (IFB) 787–808
and gut microbiota 175, 788
bone disorders and 1015
in glycogen storage disease type Ib 763
role of pre- and probiotics in 173–175

Inflammatory syndrome, pharmacologic approach to 196–197
Injury, acute kidney 769–772
Innate immunity linked to adaptive immunity in neonatal gut 505
Innate mucosal immune response in mature gut 503–506
Insulin 370–371
  bovine and immune response 894
  in malnutrition 375–376
  nutrient stimulation of 332
  parenteral, and intestinal adaptation 933–934
  pharmacodynamics, profiles of 892t
Insulin level
  fetal, 451
  in elderly, relative to birth weight and genes 441t
Insulin-like growth factors (IGFs) 366–375
  and intestinal adaptation 932
  and somatomedin hypothesis 366–367
  in malnutrition 373–375
  nutrient stimulation of 332–334
  regulation by 375
Insulin-like growth factor-binding proteins (IGFBPs) 367–368, 367–368
  and genes 367–368
  and immune system 342
  in malnutrition 373–375
Insulin-mediated signal transmission in glycogen synthesis 621i
Insulin resistance
  and glucose regulation disorder 616
  as pathomechanism of MetS 619
  molecular basis of 619–621
  potential link of fructose to 62t
  role of adipose tissue in 621–622
Insulin secretion, fetal 452–453
Interleukins, effect of, on energy expenditure 184
Interventions
  global health, evidence-based results of 669
  nutritional, for growth failure 720–722
  in HIV-infected children 682–684
  targeted towards women and children 665–669
  to prevent malnutrition in Canada and U.S. 247–267
  to support growth after NICU discharge 558–561
Intestinal adaptation 927–929
  after resection 935t
  nutritive and non-nutritive factors in 929–934
Intestinal barrier, neonatal, components of 505–506
Intestinal damage in celiac disease 813i

Intestinal environment
in infants 387–398
microbiota and 393–394
Intestinal epithelial cells (IECs) 329–349 *passim*
nutritional factors and gene expression in 333–334

Menarche, age at, and childhood diet 874
Menkes' syndrome 96, 102–104
Metabolic abnormalities after HIV treatment 678–679
Metabolic aspects of fructose 62
Metabolic cost of protein synthesis 188
Metabolic complications
  of enteral nutrition 1031
  of parenteral nutrition 1065–1069
  IFAD and 1066–1068
  of biliary tract, liver, bone, and kidney 1068–69
  short-term 1066t
Metabolic disorders
  enteral products for 1230–1231
  featuring liver and GI dysfunction 745–748t
Metabolic disease, gut microbiota in 406–407
Metabolic effects of cancer and its treatment 878–881
Metabolic fate of oral fructose load 61i
Metabolic function, amino acids in 74t
Metabolic programming in obesity 586–588, 600–601
Metabolic reserves, and body composition 963
Metabolic response
  mechanisms and pathways of 958
  to critical illness 957
Metabolic stress and plasma concentrations of micronutrients 31t
Metabolic syndrome (MetS) 613–624
  and risk of CVD 972
  etiology and pathogenesis in 616–622
  heritability of individual components of 621i
  prevalence, prevention, and therapy for 623–624
  role of adipose tissue in 621–622
Metabolism
  and amino acid nutrition in utero 465–482
  carbohydrate
  in liver disease 851–852
  and lipid, in fetus and placenta 445–460

cooking methods influencing 305
effect of drugs on 308–309
glucose
drugs altering 312–314
in fetus and placenta 445–456
normal 757
hepatic, and nutrient-drug interactions 295
histone methylation, one-carbon metabolism of 356
in critically ill children 958– 963
in HIV-infected children 676
in malnutrition 299
inborn errors of, in liver disease 859
lipid
and fatty acid 456–460
and transfer to placenta and fetus 456–460
of fatty acids 88–89
of fluorides 996
of HMOs by bifidobacteria 59–61
of iron 133t
of protein 74–75
disease states affecting 192–194
of trace elements 101, 105, 107, 109, 112
one-carbon, and histone methylation 356
Metabolomics
in assessing nutritional status 35
in studying gut microbiota 401
Metagenomics describing human microbiota 399–409
Metal metabolism disorders 748t
Methylation
DNA (*see* DNA methylation)
histone, one-carbon metabolism and 356
Microbes (*see also* Microbiome; Microbiota)
in human milk, educating neonatal immune system 511
modulated by breast milk 507
Microbial composition of gut, and age 58i
Microbiome, core, in studying gut organisms 402
Microbiota
characterization of 57
gut (*see* Gut microbiota)
interacting with diet and immune system 174i
intestinal 173–175, 334–335, 393–394, 399–409
and carbohydrates 56–57
development of 506–507
Microminerals in human milk 497–498

Micronutrient composition of human milk 643t
Micronutrient deficiency
  in IBD 791–792
  underlying causes of 717–718t
Micronutrient supplements
  maternal 665, 667
  to complementary foods 649
Micronutrients
  and immune defense mechanisms 34 t
  and major minerals, assessment of 31–33
  and malnutrition 636–637
  in acute kidney injury 771–772
  in HIV-infected children 679–680
  needed in young athletes 1092–1094
  plasma concentrations of, and metabolic stress 31t
Microorganisms contributing to dental caries 989–992
MicroRNAs, DNA methylation and 357–358
Middle-income countries, early feeding in 641–642
Migrants, rural to urban, and obesity 694
Migration and shift of disease risk 872
Milk (*see also* Cow's milk; Human milk)
  macronutrients in 58t
  supplementing breast milk 525
  undesirability of, in early infancy 572
Milk oligosaccharides (*See also* Human milk oligosaccharides)
  and gut microbiota 58–59
  influencing the intestinal immune system 63i
  monosaccharide composition of 61t
  milk proteins, functional role of 492–493
Millennium Development Goals (MDGs) to promote child health 663
Mineral mix solution in SAM 219t
Mineral supplementation 319–322
  in children on special diets 1130
  in children with allergies to milk 1108
  in pregnancy 429–430
Mineralized tissues 988–989
Minerals
  deficits in, after discharge from NICU 555
  drug kinetics and 304
  equations measuring amounts in body 38–40t
  reference intervals for 20–25t
  required in preterm infants 543
Mitochondrial dysfunction in hepatic disease 753–755
Mitochondrial energy production dysfunction 747t

Models
multicompartmental, of growth 37–40
of child development, conceptual 230i
Molecular basis of insulin resistance in MetS 619–621
Molybdenum in parenteral nutrition, cautions about 1061–62
Monitoring food intake, necessity for 167
Monitoring PN at home or hospital 1064–1065, 1074
Monogenic causes of obesity 601–602
Monosaccharide linkages in prebiotics 62t
Monosaccharides 55–56
in HMOs and PBOs 61–62
Morbidity, malarial, interventions to prevent 668–669
Mortality, child, global trends in 632
Mother's vs. donor's milk 546
Motor impairment, oral, and feeding difficulties 701
Mottled tooth enamel, classification system for 994
Mucosal barrier, intestinal 173t
Mucosal healing in IBD 801
Mucosal immune system (*see also* Immune system, mucosal)
education of by factors in breast milk 509
innate response in 503–506
Multivitamin formulations for parenteral nutrition 1059t
Multivitamin supplements during pregnancy 429–430
and risk of childhood cancer 868
Muscle, storage of ectopic fat in 622
Muscle mass
creatinine levels in 27
skeletal, changes during growth 47
Muscle metabolic rates relative to age and BMR 186t
Muscle protein, status of 27

N

Nasogastric tube feeding in cancer patients 885
Necrosis, hepatocellular 749
Necrotizing enterocolitis, probiotics in 175
Neglect, child (*see* Abuse and neglect)
Neonatal gut
bacterial colonization of 509–512
immunoglobulins in 510–511
innate and adaptive immunity linked in 507
Neonatal immune system, educated by microbes in human milk 511
Neonatal Intensive Care Unit (NICU)
growth and nutritional deficits after discharge 553–556
nutritional management after discharge 553–563

Neonatal intestinal barrier, components of 505–506
Neonates
  drug clearance rates in 293i
  implications of fetal amino acids in 477–478
  recommendations for breastfeeding of 168
Neural tube defects (NTDs)
  and folate deficiency 286–288
  DNA methylation and 353–354
  epigenetic role of DNA methylation and 353–354
Neurodevelopmental disorders and feeding difficulties 702, 729–731
Neurological development after discharge from NICU 557
Neurological impairment, nutrition in children with 256t
Neurological involvement in celiac disease 816
Neutron activation analysis in measuring body composition 38–39
Niacin 154–155
  in human milk 495
  laboratory assessment of 33
NICU (*see* Neonatal Intensive Care Unit)
Nipple, normal 521i, 522i, 523i 524i, 532i, 534i
Nitrogen, non-protein, in human milk 491, 493
Nitrogen balance
  effects of fasting on 375i
  laboratory assessment of 27
  to determine protein or amino acid requirements 79
Nitrogen loss, calculating 27
N-nitroso compounds and brain tumors 868
Non-cystic fibrosis pancreatic diseases 837–839
Nongovernmental organizations (NGOs) in preventing malnutrition 233
Non-nutritive factors in intestinal adaptation 931–934
Nonprotein nitrogen (NPN) in human milk 491, 493
North American Indian cirrhosis 751
Nucleotides in breast milk vs. formula 571
Nursing (*see* Breastfeeding *and* Lactation)
Nutraceuticals, overview of 173–181
  cautions about 178–180
  nonphytochemical 177–178
  pediatric considerations in 177–180
  phytochemical 178–181
Nutrient balance in obesity 591–593
Nutrient densities in complementary foods, recommended 648t
Nutrient-drug interactions (*see also* Drug-nutrient interactions) 5t, 293–327, 309–311t
Nutrient effects on intestinal bacteria 343–344
Nutrient-enriched formula after NICU discharge 558–559

Nutrient functions, dietary references intakes for 167–168
Nutrient-gene interactions
signal transduction mediating 335i
therapeutic implications of 344–345
Nutrient-nutrient interactions 320t
Nutrient recognition and signal transduction 342–343
Nutrient requirements
by age, based on UNICEF report and DRI 647t
from complementary foods 646
in pancreatic insufficiency 845t
of infants and young children 646
Nutrient transition
and global child health 631–640
in developing countries 637–639
Nutrient transport
and drug absorption 296–297t, 309–316
in the gut 337
Nutrients
absorption of, secondary mechanisms in 307
and cell and tissue growth 362–363
and drug kinetics 309–305
and hormones and growth 361–371
changing view of 3
IGF regulation by 375
metabolism of 308–309
problem, in complementary foods 646
required in term infants 566–568
stimulating hormone secretion 332–334
storage of 188
genes regulating 331–332
Nutrition (*see also* Child nutrition)
amino acid in utero 465–482
and anthropomorphic data in developing countries 654–657
and cholesterol in children 977
child, linked with economic development, 653–661
structural changes affecting 659–660
community 243–269 (*see also* Community *entries*)
drug therapy interacting with 293–327
enteral (*see* Enteral nutrition) 1023–1034
epigenetics and 351–360
feeding difficulties and 699
fetal, carbohydrate and lipid metabolism in 445–463
gene expression and 329–349
historic overview of 1–4

humoral regulation of growth and 361–385
in cancer survivors 886–887
in cystic fibrosis 841–847
in disabled children 729–741
in exocrine pancreatic disorders 841–844
in low-birth-weight infants 394–398
in renal disease 769–786
in young athletes 1091–1098
inadequate, in growth retardation 538–539
individual, meal plans for 904–905
influencing DNA methylation 353–354
interacting with infection 206–207
maternal
and pregnancy outcome 425–433
and volume and composition of breast milk 642–643
in lactating women 525–527
later-life disease and 439–441
parenteral (*see* Parenteral nutrition) 3, 547–549, 1035–40
Nutrition programs, community, in Canada 262, 263t, 264t, 265t, 266t
Nutrition Support Teams (NSTs) 1147–1151
in assessing risk of malnutrition in hospitalized children 1148
Nutritional adequacy of breast milk 577
Nutritional assessment 5–17 (*see also* Appendix I on pp. 1153–1199 for pertinent charts and tables)
in childhood obesity 604–605
in children at risk for HIV infection 680–681
in disabled children 731
in exocrine pancreatic disorders 844–847
in liver disease 854–855
in pediatric cancer 882–884
in severe acute malnutrition 205–207
in weight-loss surgery 610
Nutritional complications of IBD 789–792
Nutritional deficiencies (*see specific nutrient or condition*)
Nutritional disease states and impaired bone health 1014–15
Nutritional disturbances, and adolescent bone health 1012–13
Nutritional epidemiology 271–291
Nutritional influences on bone health 1009–12
Nutritional interventions
for growth failure 720–722
in HIV-infected children 682–684
to mitigate dyslipidemia 929–930
Nutritional management
after discharge from NICU 553–563

after renal transplant 780, 781–782
in diabetes 896–901, 905
in glycogen storage diseases 758–759, 760–761, 763–764, 766
Nutritional needs of a hospitalized child 5–17
Nutritional properties of human milk 483–502
Nutritional provision in critically ill children 964–965
Nutritional recommendations
in infants, children, and adolescents in U.S. 250–253
Nutritional regulation of gene expression 329–343
Nutritional requirements (see Appendix II on pp. 1201–1214 for pertinent charts and tables)
for trace elements 96–97
in preterm infants 541–544
Nutritional screening
brief
dietary history in 5–6
medical history in 5–6
physical examination in 5–6
in community nutrition 247t, 247–248
Nutritional status (*See also* Macronutrient assessment; Micronutrient and Major mineral assessment)
clinical assessment of 5–17, 19t
during economic development 657–659
effect of drugs on 307
effect of liver transplantation on 859–860
emerging technologies in assessment of 34–35
hematological tests of 33–34
immunological tests of 34
laboratory assessment of 19–36
confounders in 19, 25–26
in critically ill children 964
maternal, and volume and composition of breast milk 642–643
serum IGF as index of 374
specific tests of 26–35
Nutritional studies of oral tissues and structures 988–989
Nutritional support
in intestinal failure/SBS 940–943
in liver disease 855–856
perioperative, in IBD 793
Nutritional treatment
for diabetes 896–907
for IBD 792–793, 794–796
for ulcerative colitis 792–793
Nutritive factors in intestinal adaptation 929–931

O

Obesity (*see also* Overweight) 3–4
affecting body composition 50, 51
alternative therapies for, information about 611
and drug availability 300–301
and iron deficiency 121
and risk of CVD 972
and therapy for malnutrition 239
as carbohydrate disorder 67–68
childhood (*see* Childhood obesity)
dietary prevention of 1138–40
drivers of, in developing economies 692–694
energy and substrate regulation in 583–597
evaluation of 602–606
genetic vs. environmental factors in 586
in children and adolescents (*see also* Childhood obesity) 588–612, 625–630
in developing economies 689–697
in glycogen storage diseases 762–763
in young athletes 1095–96
metabolic programming in 586–588, 600–601
monogenic causes of 601t
offset by nonexercise physical activity 191
pathophysiology of 600–601
potential link of fructose to 62t
risks of 584–586
in children 625–626
role of gut microbiota in 406–407
rural-to-urban migration in 694
substrate balance in 591–593
treatment of 593, 606–610
visceral, in MetS 615–616
oil-based emulsions in parenteral nutrition 1044–1046
Occlusion, catheter, in parenteral nutrition 1071–1072
25-OH-cholecalciferol, lab assessment of 32
Oligosaccharides 56, 59–61
in breast milk 569
lactose-derived, monosaccharide linkages in 61t
milk (*see also* Milk oligosaccharides) 58–59, 487–488
prebiotic
affecting the gut 59–61
linkage specificity of 61t
monosaccharide composition of 61t
Omega-3 fatty acids (*see also* Fatty acids, omega–3)

in critically ill children 966
in vegetarian diets 1138
to modify lipid profiles 979–980
Oral cavity
diseases of 989–992
soft tissues in 988
Oral feeding, mechanical functional development in 388–389
Oral-motor impairment in feeding difficulties 701, 729–730
Oral rehydration solutions (ORS)
choice of 920–921
composition of commercial preparations 913t
in severe malnutrition 921t
physiologic basis for 912–913
Oral rehydration therapy (ORT)
limitations of 918
obstacles to good practice of 922
Oral rinses, fluoride, dental benefits of 997
Oral tolerance in food allergies 824
Organs
genes controlling nutritional requirements of 330–331
metabolic rate in, relative to age and BMR 186t
protein synthesis rate in 75i
osteomalacia, factors contributing to 1013
outliers, statistical, in dietary analysis 282–283
relative contribution of, to body weight 49t
Osteoporosis 1013
in glycogen storage diseases 762
in IBD 790–791
predisposing conditions for 1010t
Overfeeding syndrome and RQ 29
Overnutrition 3–4
Overweight
dietary prevention of 1138–40
energy and substrate regulation in 583–597
in developing economies 689–697
prognostication for 45
Oxidation, fetal and placental 472–474
Oxygen consumption, fetal, glucose and carbon substrates in 451
Oxytocin release in lactation 521

Paneth cells in developing intestine 392
Pantothenic acid 159–160
  in human milk 496
Parasites in SAM 218
Parental behavior in feeding disorders 703
Parental factors in early feeding of infant 580
Parental stress as risk factor for failure to thrive 711
Parenteral nutrition 3, 547–549, 1035–1090
  as proxy for prevalence of IF/SBS 926
  catheter-related complications of 1069–72
  choline requirements for 1057
  chronic, and quality of life 944
  cyclic vs. continuous infusion in 1072–73
  drug metabolism and 306–307
  energy requirements in 1037–41, 1040t
  in preterm and VLBW infants 1040–41
  essential fatty acids needed in 1046–1048
  home-based 1073–75
  long-term monitoring of 1074, 1075t
  survival and mortality in 1074
  immediate establishment of 547
  in active Crohn’s disease 794
  in critically injured children 965
  in essential fatty acid deficiency 1046–1048
  in HIV-infected children 683
  in hospital setting, initiation and monitoring of 1064–65
  in liver disease 857–858
  in pediatric intensive care unit 1039–40
  in preterm infants 547–549, 1036–37
  initiating and monitoring in hospital and home 1064–65, 1073–75
  intravenous lipid emulsions in 1044–1949
  maintenance of trace elements during 97t, 394
  metabolic complications of 1065–1069
  biliary 1065, 1068–69
  bone 1065, 1069
  renal 1065, 1069
  peripheral 1075–76
  potentially detrimental in VLBW infants 394
  protein requirements in 1041–44
  -related side effects of chemotherapy 880–881t, 882i
  relative to MDGs 663
  risk of IFALD in 1973
  role of education in 233–234, 267

role of placenta in 440–441
routes of, in acute kidney injury 772
social development and 229–230
tracking 281
weaning from 1074
Parenteral nutrition solutions
carbohydrate requirements in 1049–51
delivery bags for 1078–79
fluid, electrolyte, and mineral requirements in 1051, 1052t
in VLBW infants 1054–1055
individually tailored vs. standard 1078–80
lipid requirements in 1044–1049
molybdenum in, cautions concerning 1061–62
multivitamin formulations in 1059t
safety of 1078
trace elements in 1058–62
cautions concerning 1059–62
unbalanced, and risk of IFALD 1067–68
vitamin requirements for 1055–58
Pathophysiology, hepatic 749
Pattern recognition receptors (PRRs) 174
and their ligands 174t
interacting with bacteria in presence of breast milk 509–510
Peanut-free diet 1103, 1105–06

enteral nutrition in 543t, 544–547
formula for 546
inpatient care of 537–551
mothers' and donors' milk in 545
nutritional management of 553–563
optimizing feeding practices in 546
patterns of growth after NICU discharge 556–557
tube feeding in 547
Prevalence estimates of obesity and overweight based on income group 691i
Prevention
of childhood obesity 625–630
recent trials in 628t
of severe acute malnutrition 223–224
Probiotics
in diarrheal diseases 919
in restoring intestinal hemostasis 175–176
modulating gut microbiota 407
overview of 173–181
safety concerns in infants 396
Processed complementary foods 648–649
Prognostic significance of overweight 4
Progressive familial intrahepatic cholestasis syndromes 748t, 749
Prolactin levels in let-down failure 533–534
Prolactin release in lactation 521
Protein(s)

acute phase, in SAM 207–208
airborne, in food allergies 827
amino acids and 469–470
and drug kinetics 303–304
antimicrobial in breast milk 508
dietary recommendations for 75–80
digestion and absorption of 75
distribution of, in various organs 75
immunologically active, in gut 340–342
in developing gut 395
in formula 570
in human milk 491–493
in vegetarian diets 1137
macronutrient assessment of 27–28
metabolism and distribution in 74–75
overview of 71–81
requirements of, for deposition 76t
Protein deficits in preterm infants 554–555
Protein deposition rates by age and sex, mean protein requirements for 76t
Protein digestion and absorption in exocrine pancreatic disorders 841
Protein-energy malnutrition
and community and government networks 233i
in preterm infants, irreversible effects of 541
Protein-energy supplementation to counter poor maternal health 666
Protein exchange with amino acid pools 751
Protein gain in last trimester of pregnancy 538I
Protein intake
during complementary food period 579
high, and risk of IBD 788
in breast-fed infants 74t, 569
in children with chronic kidney disease 777t
in liver disease 856–857
in severe acute malnutrition 205–206
Protein maldigestion in exocrine pancreatic disorders 839–841
Protein metabolism
and disease states 192–194
Crohn’s disease and 193
in critically ill children 958–960
in inflammatory bowel disease 801–802
in cancer 878
in liver disease 852
in rheumatoid arthritis 193
Protein needs in children by age 76t
Protein requirements

current 80
for term infants 568
in acute kidney injury 771
in chronic kidney disease 777–779
in critically injured children 959t
in diabetes 898–899
in preterm infants 541–542
in VLBW infants 1044
in young athletes 1092
methods for determining 79–80
Protein synthesis rate in organs 75i
Proteomics in assessing nutritional status 34–35
Psychosocial factors
in growth failure 710–713
in HIV-infected children 676–677
Psychosocial growth failure 376–377
Puberty
changes in bone growth during 49
changes in stature during 52
delayed, effects of malnutrition on 379
Public health programs
interventions to prevent obesity in developing economies 694–695
malnutrition as global problem in 232–240, 245
programs to improve nutrition in industrialized countries 262–267
Pulmonary complications of enteral feeding 1030
Pumping and storing milk during breastfeeding period 528–529

Q

Quality of life in patients with chronic parenteral nutrition 944, 1075
Questionnaire to assess eating disorder 1002t

R

Race, changes in stature relative to 50
Racial differences in body composition 45
Rapid early growth in utero as risk factor for obesity 626
Reaction mechanisms in food allergies 825
Ready-to-use therapeutic food (RUTF)
in SAM 213, 218–220
Recommended dietary allowances (RDAs) (*see also* Appendix II, pp. 1201–14)
in neonates 168
of iron 129–130
reference intakes 163, 164
Recommended dietary intake (RDI) (*see also* Appendix II, pp. 1201–14)

of carbohydrates 64–66
Rectal administration of drugs 295–296
Refeeding syndrome
in anorexic or starved children 1003
in SAM 221–222
Reference nutrient intakes (*see* Appendix II for detailed tables)
daily RDIs (U.S.) 1142t
daily RNIs (U.K.) 1141t
daily reference intakes (E.U.) 1143
Reference standards in disabled children 732, 733, 734
Rehabilitation in severe acute malnutrition
hospital vs. community 213–223
national guidelines for 229–242
Rehydration solutions, oral (*see* Oral rehydration solutions)
Rehydration therapy, oral (*see* Oral rehydration therapy)
Renal calculi in short bowel syndrome 939
Renal complications in parenteral nutrition 1065, 1069
Renal disease, nutrition in 769–786
Respiratory quotient (RQ) 15, 28
and overfeeding syndrome 28
clinical utility of 29
Respiratory reactions in food hypersensitivity 828
Respiratory system in SAM 210
Resting energy expenditure (REE) 14
and indirect calorimetry 15
predicting from body weight 739t
Resting metabolic rate (RMR), relative to fat-free mass 183, 184i, 185i
Resveratrol 356
Retinoids (*see also* Vitamin A) 144
in human milk 493
Retinol-binding protein (RBP), laboratory assessment of 28
Rheumatoid arthritis (RA), and protein metabolism 193
Riboflavin (*see also* Vitamin B_2) 153–154
in human milk 495
interconversion of co-factors and 153i
laboratory assessment of 33
Risk factors
for childhood obesity 625–627
for growth failure 708–713
Risk(s)
of adult disease, and fetal and early postpartum growth 635–636
potential, of high fructose intake 62, 62i
RNAs (*see* MicroRNAs)

S

Safety in preparation of complementary foods 649
Saint John's wort 178
Sample collection, variable factors in 26
Salt intake during complementary food period 579
Sanitation
  changing during economic development 657–659
  in global initiative to prevent morbidity 667–668
Schofield prediction equations 14, 15
School-based programs to promote health 267
School-based strategies to counter obesity in developing world 695–696
School feeding programs, effectiveness of 670
Screen time as risk for obesity 626
Screening (*see also* Nutritional screening)
  and diagnosis in growth failure 713–714
  cholesterol, in pediatric patients at risk for CVD 976–977
Scurvey and diet 151, 271–272
Sedentary behavior as risk factor for obesity 626
Selenium 105–108
Serum markers of bone turnover 1017
Severe acute malnutrition (SAM) (*see also* Malnutrition) 203–228
  clinical management of 212–224
  complications of 213–218
  criteria for diagnosis 203–204
  kwashiorkor in 204–205, 208, 209, 211, 222
  marasmus in 204
  oral rehydration for 921t
  pathophysiology of 205–212
  WHO-supported guidelines for 213–233
Sex
  relative to body composition by age and 46t
Sex steroids and cortisol 378–379
Sexual maturation in assessing body composition 13
Shellfish-free diet 1106–07
Short bowel syndrome (*see also* Intestinal failure)
  and intestinal failure and transplantation 925–956
  enteral nutrition in 1029
  management of and outcomes in 939–935
  medical support in 940–943
  renal calculi in 939
  surgical support in 943–944
  transplantation for 945–949
Shwachman-Diamond syndrome 835, 837, 838t

Sickle cell disease (SCD)
  chelation in 134
Signal transduction in nutritional gene expression 330i, 342–343
Singapore, interventions to prevent child obesity in 694–695
Skeletal maturation in assessing body composition 13
Skeletal muscle mass, changes during growth 47
Skin, hair, and teeth in SAM 211–212, 222
Skinfold thickness measurement
  correlated with BMI 277–278t
  in disabled children 736
  in measuring subcutaneous fat 40
Sleep, poor, as risk factor for obesity 626
Snacking in dental disease 991–992
Social class relative to hypertension and birth weight 441t
Social development, nutrition as key in 229–230
Socioeconomic development and nutrition transition 637–638
Sodium
  in diabetic diets 900
  in human milk 497
Sodium-restricted diet 1128, 1129t
Solid food(s) (*see also* Complementary foods)
  added to diet in breast-fed infants 527
Solutions for oral rehydration therapy 913, 921–922
Somatic proteins 27
Somatomedin(s)
  axis with GH 368i
  effects of fasting on 375i, 901
Somatomedin hypothesis 366–377
Sorbitol in diabetic diets 901
Soy-free diet 1102–03
Soy intake, adolescent, and breast cancer 873–874
Special diets (*see also specific diets*)
  cow’s milk-protein free 1110–1115
  egg-free 1100–02
  in young athletes 1095, 1099–1046
  lactose-free 1107–10
  low-phenylalanine 1119–21
  peanut-free, 1103, 1105–06
  shellfish-free 1106–07
  soy-free 1102–03
  tree-nut-free 1106
Special-needs children
  Head Start programs for 261
  nutrition for 254–255

Sphingolipids in human milk 491
Sports activities and body fat 45
Sports drinks vs. energy drinks 1094
Standardization of laboratory tests 26
Standardized BMI curves 40
Stanols in interventions for CVD 979–980
Starch 56, 901
  resistance to, in diabetic diets 901
Starvation as child abuse 713
Statistical models for assessing energy intake 283–284
Stature
  in disabled children 732–733
  in linear growth 50
  in measuring nutritional status 7–8
Steatosis, 752
Steroids
  anabolic
  in catabolic disease 379
  in young athletes 1094–95
  vs. enteral nutrition in Crohn’s disease 795–796
Sterols
  defects in synthesis of 748t
  in human milk 491
Stimulants, appetite, in HIV-infected children 683–684
Storage
  intracellular, of iron 122–124
  of pumped milk 528–529
Storage disorders, hepatic disease due to 747t, 754–755
Strategies
  for delivering targeted interventions 669–670
  school-based, to prevent obesity in developing countries 695–696
  to promote exclusive breastfeeding 642
Streptococcus mutans in dental disease 989–992
Stress, parental, as risk factor for growth failure 711
Stress response, metabolic, in critically ill children 957
Structural changes affecting child nutrition 659–660
Stunting
  and obesity, economic relationship between 692
  anthropometric data on, and income 654–657
  as side effect of cancer therapy 887
  prevalence of 664i
Substrate, energy
  effects of fasting on 192
  regulation in obesity 583–597

Suck-swallow coordination, development of 383
Suckling disorders in infants 530–531
Sucrase isomaltase deficiency 1118
Sucrose diets
  in diabetes 900
  in sucrase isomaltase deficiency 1118
Sucrose intake, adaptation of enterocytes to 336
Sugar(s) (*see also specific sugar*) 56
  during complementary food period 577
Sugar alcohols in diabetic diets 900–901
Sugar-containing food and dental disease 990–991
Sugar-sweetened drinks as risk factor for obesity 626
Sulfur dioxide and sulfites as allergens, sources of 1107
Supplemental feedings in chronic kidney disease 775–776
Supplemental nutrients, amino acid, caveats concerning 80–81
Supplements
  DHEA, cautions against 1014
  fluoride, to prevent caries 996–997
  formula, kidney-specific 773t
  herbal, during pregnancy 430–431
  micronutrient 649, 665, 667
  multivitamin, and childhood cancer 868
  oral, enteral, and parenteral, in HIV-infected children 682–683
  protein-energy, to counter poor maternal health 666
  vitamin and mineral 319–322
  during breastfeeding 525
  during pregnancy 428–430
  in chronic kidney disease 778–779
  in liver disease 857
  in SAM 221
  with vaccination 659–660
  zinc, in diarrheal diseases 920
Suppressants, appetite 319
Surgery
  in children with IF/SBS 943–944
  weight-loss 609–610
Survivors of pediatric cancer, nutrition in 886–887
Sweeteners in diabetic diet 900–901
Sympathetic nervous system (SNS) and energy expenditure 188

T

Tanner staging
  in assessing body composition 13
Taurine in formula 571

Teeth
hypoplasia in 988–989
in SAM 211–212
Temperature, body (*see* Body temperature)
Temporal difference in interpreting laboratory values 25
Term infant 565–573
Thermic effect of feeding (TEF) 187–188
Thermogenesis 189–190
Thiamine (*see also* Vitamin B_1) 152–153
in human milk 495
laboratory assessment of 32
Thrombosis, catheter-related 1071–73
Thyroid hormones 377–378
and nutrients 362–363
critical periods in 363–364
Tissue(s)
major, contributing to body weight 48t
oral cavity
mineralized 988–989
soft 988
Tissue growth
and nutrients 362–363
critical periods in 363–364
Tobacco, and adolescent bone health 1013
Tolerable upper intake levels 163t, 167
Tolerance, oral, in food allergies 824
Tomography, quantitative computed, to assess BMD 1016–17
Toothpaste, fluoride, benefits/cautions in using 996–997
Total body water, estimation of 38–39
Total energy expenditure (TEE) 14
Toxic side effects of dietary supplements 179
Toxicity
amino acid 70–71
chromium 108
copper 104–105
iodine 113
iron 131–132
manganese 857–858
mineral, in liver disease 857–858
of excess fluoride 992–994
selenium 107
zinc 101
Trace elements (*see also individual element*) 95–116
biologic roles of 95

chromium 108–110
copper 102–105
deficiencies in 96–97
clinical features of 98–99, 103, 106–107, 108–109
lab analyses to detect 97–98
dose-response of 95–96
fluoride 111–112
iodine 112–113
in common foods 102t
in HIV-infected children 680
in human milk 497
in parenteral nutrition 1058–62
interacting with nutrients 312
manganese 110–111
metabolism of, inborn errors of 96
nutritional requirements for 97
selenium 105–108
supplemental 319–322
Trace element requirements for solutions 1060t
Trace mineral metabolism in critically ill children 963
Transferrin
laboratory assessment of 28
receptor, in screening for iron deficiency 137–138
Transforming growth factor-beta (TGF-β)
immune education by 511–512
Transplantation
for intestinal failure and short bowel syndrome 945–949
graft types used 946–947
indications for 946t
nutritional care afterward 947–948
outcomes in 948–949
hematopoietic stem cell, in cancer 881t
kidney, management after 780–782
liver, affecting nutritional status 859–860
Transport, iron 125
Transport mechanisms of carbohydrates and lipids in placenta and fetus 445–460
Transport systems, amino acid, and abnormal pregnancy outcomes 475–477
Tree-nut-free diet 1106
Triage for rehabilitation in SAM 213
Triceps skinfold thickness 12, 40
Triglycerides
medium-chain
and fat absorption 84–85
energy content of 85i

Tube feeding (*see also* Enteral nutrition)
in cancer patients 885
in cystic fibrosis 847
in preterm infants, administration and tolerance of 547
mechanical complications of 1030–31
nasogastric, in cancer 885
Tube placement in, bedside evaluation of 1030t
Tumors (*see also specific locus*)
Twenty-four-hour energy expenditure (24hEE), assessment of 190
Twenty-four-hour recall in dietary assessment 272–273
Tyrosinemia in early infancy 752

U

Ulcerative colitis, nutritional therapy for 792–793
Umbilical uptake of amino acids 472
Underfeeding affecting energy expenditure 191
Undernutrition (*see also* Malnutrition)
and economic development 654–657
and mortality risk 632–634
and susceptibility to communicable diseases 636
effects of, on GH-IGF axis 374t
food insecurity and 670
global interventions to prevent 665–669
in IBD 799
prevalence by age 709t
protein-energy, irreversible effects of 541
Underweight, prevalence of 664i
United States
community nutrition and programs in 243–267
dietary references intake for 163–171
Urbanization
affecting dietary patterns 637–638
as factor in child obesity 694
Urea cycle and related diseases 745–746t, 751
Urticaria as hypersensitivity reaction to food 826

V

Vaccination
against measles, relative to income 660i
in developing economies 659, 669
Valerian root 179
Variables, uncontrolled, in determining nutritional intake 25
Variation, intraindividual and analytical, in interpreting lab results 25–26

Vascular access to parenteral nutrition solutions 1062–1063
Vegan diet, default, as result of poverty 657
Vegetables
  and drug kinetics 304–305
  sucrose contents of 1118t
Vegetarian diets
  health benefits of 1138
  in infants 579
Vegetarianism 1135, 1137
  and drug metabolism 305
Very-low-birth weight (VLBW) infants (*see also* Low-birth-weight infants; Preterm infants)
  energy requirements in 1040–1041
  fluid, electrolytes, and minerals required for 1054–1055
  intravenous lipid emulsions in 1048–49
  protein requirements in 1044
Very-low-fat diet 1125
Very-low-fructose diet for hereditary fructose intolerance 1122–23
Virus, human immunodeficiency (*see* HIV entries)
Visceral mass, changes during growth 47–48
Visceral obesity in the MetS syndrome 615–616
Vitamin A (*see also* Retinoids) 143–146
  in HIV-infected children 679–680
  laboratory assessment of 31, 32
  supplementing measles vaccine 659–660
  visual cycle 145i
Vitamin B_1 (*see also* Thiamine) 152–153
  laboratory assessment of 33
Vitamin B_2 (*see also* Riboflavin) 153–154
  laboratory assessment of 33
Vitamin B_3 (*see also* Niacin)
  laboratory assessment of 33
Vitamin B_5 (*see* Pantothenic acid)
Vitamin B_6, 155–156
  -dependent enzymes in carbon metabolism 155i
  in human milk 495
  laboratory assessment of 33
Vitamin B_{12}
  fortifying food with 287–288
  in HIV-infected children 680
  in human milk 495
  laboratory assessment of 33
Vitamin C

in human milk 495
laboratory assessment of 33
Vitamin D 146–148
and adolescent bone health 1011–1012
DRI/RDA for 1012t
in human milk 493–494
in severe acute malnutrition 212
laboratory assessment of 32
metabolism of 147i
supplementation
during pregnancy 428
in chronic kidney disease 778–779
Vitamin deficiency 30
epigenetic role of SNA methylation in 354
in CF-related bone disease 844
Vitamin E
in human milk 494
laboratory assessment of 32
Vitamin K
in blood coagulation cascade 150i
in human milk 496–497
laboratory assessment of 32
Vitamin K deficiency bleeding (VKDB) 151
Vitamin malabsorption disorders 748t
Vitamin metabolism in critically ill children 963
Vitamin requirements in parenteral nutrition 1055–1059
Vitamins 143–162
drug interactions with 307–309, 320–321t
fat-soluble 31–32
food sources for 167–168
in HIV-infected children 679–680
in human milk 493–496
needed in young athletes 1093
reference ranges for 20–25t
supplementation with 319–322
during pregnancy 428–430
in SAM 221
to prevent NTDs 286–287
in vegetarian diets 1138
Vitamin and mineral supplementation
in children with allergies to milk 1108
in liver disease 857
von Gierke disease 759–763

W

Waist circumference relative to ethnicity and gender 614–615t
Wasting
  in childhood cancer 878
  in HIV-infected children 674–677
  related to income 654–657
Water
  as percentage of body composition by age and sex 44t
  fluoridation of, dental benefits of 995–996
  in preventing disease in at-risk children 667
Water loss, insensible, in preterm infants 541t
Water-soluble vitamins, laboratory assessment of 32–33
Water supply
  access to, relative to income 657–659
  sanitary, in preventing infectious diseases 657
Waterlow criteria for categorizing malnutrition 708t
Weaning
  from breastfeeding 527–528
  complementary foods in 571–572
  failure of 700
  premature 534
  from parenteral nutrition 1074
Web-based resources
  for community nutrition 262–265
  for treatment of obesity 610–611
Weight
  birth, affecting health in developing countries 690–692
  body (*see* Body weight)
  for height and length 10–11
  in disabled children 732–34
  in measuring nutritional status 7
  loss or gain, during development 52
Weight control to prevent obesity 1138–1140
Weight gain
  as risk factor for diabetes 895
  drugs causing, in obese children 604t
  in reference infant 567
  poor, in infants 530–531
Weight loss, therapy for 608–611
Weight-related behavior in young athletes 1094–96
Whey in human milk 492
Women, status of, and alleviation of malnutrition 232
World Health Organization (WHO)

criteria for assessing SAM 205–206, 222
guidelines for oral rehydration 912
guidelines undergirding protocols for treating SAM 213–233
manual for aids in physical and emotional stimulation 222
Worms, screening for, to target intervention 668

X

Xylitol
in dental disease 997–998
in diabetic diets 901

Z

Zellweger disease 752–753
Zinc (*see also* Trace elements)
in human milk 497
interacting with nutrients 312
requirements during complementary food period 579
supplementation
in at-risk children 667
in diarrheal diseases 920
Zinc deficiency 98–102
neuropsychological consequences of 420

Preface 26
Part I: General Concepts 28
Chapter 1: Nutrition: The Driving Force for Health, Disease Prevention, and Development 28
Chapter 2: Clinical Assessment of Nutritional Status 38
Chapter 3: Laboratory Assessment of Nutritional Status 71
Chapter 4: Body Composition and Growth 110
Chapter 5: Carbohydrates 153
Chapter 6: Proteins and Amino Acids 187
Chapter 7: Macronutrient Requirements for Growth: Fats and Fatty Acids 211
Chapter 8: Trace Elements 238
Chapter 9: Iron 294
Chapter 10: Vitamins 353
Chapter 11: Dietary Reference Intakes in the United States 403
Chapter 12: Functional Food Ingredients: Probiotics, Prebiotics, Nutraceuticals, and Phytochemicals 424
Part II: Physiology and Pathophysiology 447
Chapter 13: Energy Requirements in Health and Disease 447
Chapter 14: Severe Acute Malnutrition: Pathophysiology, Clinical Consequences, and Treatment 496
Chapter 15: Childhood Malnutrition: Prevention and Control at the National Level 558
Chapter 16: Community Nutrition and Its Impact on Children: 591

Highly Industrialized Countries 591

Chapter 17: Nutritional Epidemiology 653
Chapter 18: Drug Therapy and the Role of Nutrition 702
Part III: Perinatal Nutrition 777
Chapter 19: Nutrition and Gene Expression 777
Chapter 20: Nutrition and Epigenetics 830
Chapter 21: Nutrition and the Humoral Regulation of Growth 855
Chapter 22: Gastrointestinal Development: Implications for Infant Feeding 915
Chapter 23: Diet, Environment, and Gut Microbiota in the Metagenomic Era 945
Chapter 24: Nutrition and Neuropsychological Development 970
Chapter 25: Maternal Nutrition and Pregnancy Outcome 1003
Chapter 26: Human Growth and Disease in Later Life 1026
Chapter 27: Nutrition and Development of the Fetus: Carbohydrate and Lipid Metabolism 1047
Chapter 28: Amino Acid Nutrition in Utero: Placental Function and Metabolism 1092
Chapter 29: Human Milk: Nutritional Properties 1137
Chapter 30: Protective Properties of Human Milk and Bacterial Colonization of the Neonatal Gut 1184
Chapter 31: Approach to Breastfeeding 1218
Chapter 32: The Low-Birthweight Infant: Inpatient Care 1263
Chapter 33: Nutritional Management of Preterm Infants Post-Discharge 1293
Chapter 34: The Term Infant 1317
Chapter 35: Complementary Feeding and Health Outcomes 1337
Part IV: Obesity 1356
Chapter 36: Energy and Substrate Regulation in Obesity 1356
Chapter 37: Evaluation and Management of Childhood Obesity 1391
Chapter 38: The Metabolic Syndrome in Children and Adolescents 1423
Chapter 39: Childhood Obesity Prevention 1448
Part V: Nutrition in Low- and Middle-Income Countries 1461

Chapter 40: The Nutrition Transition and Global Child Health 1461
Chapter 41: Infant and Young Child Feeding in Low- and Middle-Income Countries 1483
Chapter 42: Child Nutrition and Economic Development 1511
Chapter 43: Global Interventions in Child Health 1530
Chapter 44: Pediatric HIV Infection 1552
Chapter 45: Obesity in Developing Economies 1588
Part VI: Nutritional Aspects of Specific Disease States 1608
Chapter 46: Feeding Difficulties 1608
Chapter 47: Failure-to-Thrive: Growth Failure in the Outpatient Setting 1626
Chapter 48: Developmental Disabilities 1672
Chapter 49: Inborn Errors of Metabolism and the Liver 1706
Chapter 50: Inborn Errors of Fasting Adaptation—Glycogen Storage Disease 1734
Chapter 51: Acute and Chronic Kidney Disease: Nutrition in Renal Disease 1762
Chapter 52: Inflammatory Bowel Disease 1807
Chapter 53: Celiac Disease 1861
Chapter 54: Food Allergies 1892
Chapter 55: Exocrine Pancreas 1919
Chapter 56 Acute and Chronic Liver Disease 1956
Chapter 57 Cancer Prevention 1987
Chapter 58 Cancer Treatment 2017
Chapter 59 Diabetes Mellitus 2049
Chapter 60 Diarrheal Diseases 2099
Chapter 61 Intestinal Failure, Short Bowel Syndrome, and Intestinal Transplantation 2132
Chapter 62 The Critically Ill Child 2208
Chapter 63 Hyperlipidemia and Cardiovascular Disease 2239
Chapter 64 Diet and Dental Disease 2275
Chapter 65 Adolescent Eating Disorders 2307
Chapter 66 Adolescence: Advancing Bone Health 2320
Part VII: Approach to Nutritional Support 2360
Chapter 67 Enteral Nutrition and Formulas 2360

Chapter 68 Parenteral Nutrition 2389
Chapter 69 Nutrition in the Athlete 2527
Chapter 70 Special Diets 2548
Chapter 71 Nutrition Support Teams 2642
Appendices 2654
Appendix i: Nutritional Assessment 2654
Appendix ii: Nutritional Requirements 2706
Appendix iii: Enteral Products 2720
Index 2730
