5th Edition

Nutrition in Pediatrics

Basic Science • Clinical Applications

Duggan • Watkins • Koletzko • Walker

NUTRITION
IN PEDIATRICS

BASIC SCIENCE • CLINICAL APPLICATIONS

FIFTH EDITION

Christopher Duggan, MD, MPH
Editor in Chief
Professor of Pediatrics
Harvard Medical School
Director, Center for Nutrition
Division of Gastroenterology, Hepatology, and Nutrition
Boston Children's Hospital
Professor in the Department of Nutrition
Harvard T.H. Chan School of Public Health
Boston, Massachusetts

John B. Watkins, MD
Emeritus Associate Professor of Pediatrics
Harvard Medical School
Division of Gastroenterology, Hepatology and Nutrition
Boston Children's Hospital
Boston, Massachusetts

Berthold Koletzko, MD, PhD
Head, Division of Metabolic and Nutritional Medicine
Dr. Von Hauner Children's Hospital
University of Munich Medical Centre
München, Germany

W. Allan Walker, MD
Conrad Taff Professor of Nutrition
Director, Division of Nutrition
Harvard Medical School
Boston, Massachusetts
Member, Mucosal Immunology and Biology Research Center
Massachusetts General Hospital
Charlestown, Massachusetts

Notice: The authors and publisher have made every effort to ensure that the patient care recommended herein, including choice of drugs and drug dosages, is in accord with the accepted standard and practice at the time of publication. However, since research and regulation constantly change clinical standards, the reader is urged to check the product information sheet included in the package of each drug, which includes recommended doses, warnings, and contraindications. This is particularly important with new or infrequently used drugs. Any treatment regimen, particularly one involving medication, involves inherent risk that must be weighed on a case-by-case basis against the benefits anticipated. The reader is cautioned that the purpose of this book is to inform and enlighten; the information contained herein is not intended as, and should not be employed as, a substitute for individual diagnosis and treatment.

DEDICATIONS

To the continued successful growth and nourishment of Michael, Brendan, and Emily Duggan and in gratitude for many teachers and students in the field of pediatric nutrition.

—Christopher Duggan, MD, MPH

To the children, parents, and staff of the growth and nutrition program whose shared knowledge, caring, and expertise enriches us all and to our grandchildren: Mariposa, Charlotte, Lillie, Gwen, and their “Pinkhouse” partners in “Friendship.”

—John B. Watkins, MD

To a wonderful group of teachers, colleagues, and friends that I have been privileged to work with and to learn from, and to my family, especially my wife Sibylle, for all their patience and support.

—Berthold Koletzko, MD, PhD

To my youngest grandchild William McDonald Walker (Mac), the paradigm of healthy nutrition in children.

—W. Allan Walker, MD

CONTENTS

CONTRIBUTORS
PREFACE

PART I: GENERAL CONCEPTS

CHAPTER 1 Nutrition: The Driving Force for Health, Disease Prevention, and Development
Robert D. Baker and Susan S. Baker

CHAPTER 2 Clinical Assessment of Nutritional Status
Babette S. Zemel, Asim Maqbool, and Irene E. Olsen

CHAPTER 3 Laboratory Assessment of Nutritional Status
Clodagh M. Loughrey and Ian S. Young

CHAPTER 4 Body Composition and Growth
Kenneth J. Ellis

CHAPTER 5 Carbohydrates
Clemens Kunz, Lena Geiger, and Christoph Fusch

CHAPTER 6 Proteins and Amino Acids
Johannes B. van Goudoever

CHAPTER 7 Macronutrient Requirements for Growth: Fats and Fatty Acids
Kathrin Krohn, Hans Demmelmair, and Berthold Koletzko

CHAPTER 8 Trace Elements
Nancy F. Krebs and K. Michael Hambidge

CHAPTER 9 Iron
Amina Khambalia, Ashley Aimone, and Stanley H. Zlotkin

CHAPTER 10 Vitamins
Roland Kupka and Eduardo Villamor

CHAPTER 11 Dietary Reference Intakes in the United States
Alice H. Lichtenstein and Stephen R. Daniels

CHAPTER 12 Functional Food Ingredients: Probiotics, Prebiotics, Nutraceuticals, and Phytochemicals
Mandana Amir Shaghaghi, Peter J.H. Jones, and Philip M. Sherman

PART II: PHYSIOLOGY AND PATHOPHYSIOLOGY

CHAPTER 13 Energy Requirements in Health and Disease
Jean Louis Bresson

CHAPTER 14 Severe Acute Malnutrition: Pathophysiology, Clinical Consequences, and Treatment
Mary E. Penny

CHAPTER 15 Childhood Malnutrition: Prevention and Control at the National Level
Gerardo Weisstaub, Ana María Aguilar, Magdalena Araya, Ann Hill, and Ricardo Uauy

CHAPTER 16 Community Nutrition and Its Impact on Children: Highly Industrialized Countries
Johanna Dwyer, Kristy Hendricks, Janice H.Y. Chow, and Melanie Reyes

CHAPTER 17 Nutritional Epidemiology
Carine M. Lenders, Emily Keefe, and Walter C. Willett

CHAPTER 18 Drug Therapy and the Role of Nutrition
Kathleen M. Gura and Lingtak-Neander Chan

PART III: PERINATAL NUTRITION

CHAPTER 19 Nutrition and Gene Expression
Mona Bajaj-Elliott and Ian R. Sanderson

CHAPTER 20 Nutrition and Epigenetics
Sang-Woon Choi and Simonetta Friso

CHAPTER 21 Nutrition and the Humoral Regulation of Growth
William E. Russell and J. Marc Rhoads

CHAPTER 22 Gastrointestinal Development: Implications for Infant Feeding
Josef Neu, Martha Douglas-Escobar, and Sandra Fucile

CHAPTER 23 Diet, Environment, and Gut Microbiota in the Metagenomic Era
Carlotta De Filippo and Paolo Lionetti

CHAPTER 24 Nutrition and Neuropsychological Development
Maureen M. Black and Kristen M. Hurley

CHAPTER 25 Maternal Nutrition and Pregnancy Outcome

Theresa O. Scholl and Xinhua Chen

CHAPTER 26 Human Growth and Disease in Later Life
David J.P. Barker

CHAPTER 27 Nutrition and Development of the Fetus: Carbohydrate and Lipid Metabolism
William W. Hay, Jr., Laura D. Brown, Stephanie R. Wesolowski, and Paul J. Rozance

CHAPTER 28 Amino Acid Nutrition in Utero: Placental Function and Metabolism
Timothy R.H. Regnault and Frederick C. Battaglia

CHAPTER 29 Human Milk: Nutritional Properties
Marcia H. Monaco and Sharon M. Donovan

CHAPTER 30 Protective Properties of Human Milk and Bacterial Colonization of the Neonatal Gut
Anne Donnet-Hughes, Eduardo J. Schiffrin, and W. Allan Walker

CHAPTER 31 Approach to Breastfeeding
Robert M. Lawrence and Ruth A. Lawrence

CHAPTER 32 The Low-Birthweight Infant: Inpatient Care
Thibault Senterre and Alexandre Lapillonne

CHAPTER 33 Nutritional Management of Preterm Infants Post-Discharge
Mandy Brown Belfort

CHAPTER 34 The Term Infant
Ekhard E. Ziegler and Susan J. Carlson

CHAPTER 35 Complementary Feeding and Health Outcomes
Mary S. Fewtrell

PART IV: OBESITY

CHAPTER 36 Energy and Substrate Regulation in Obesity
Daniel J. Hoffman and Susan B. Roberts

CHAPTER 37 Evaluation and Management of Childhood Obesity
Alison G. Hoppin and Janey S. Pratt

CHAPTER 38 The Metabolic Syndrome in Children and Adolescents
Martin Wabitsch

CHAPTER 39 Childhood Obesity Prevention
John J. Reilly and Adrienne H. Hughes

PART V: NUTRITION IN LOW- AND MIDDLE-INCOME COUNTRIES

CHAPTER 40 The Nutrition Transition and Global Child Health
Benjamin Caballero

CHAPTER 41 Infant and Young Child Feeding in Low- and Middle-Income Countries
Souheila Abbeddou and Kenneth H. Brown

CHAPTER 42 Child Nutrition and Economic Development
William A. Masters

CHAPTER 43 Global Interventions in Child Health
Zulfiqar Ahmed Bhutta and Jai K. Das

CHAPTER 44 Pediatric HIV Infection
Colleen Hadigan and Anna Coutsoudis

CHAPTER 45 Obesity in Developing Economies
Sumathi Swaminathan and Anura Kurpad

PART VI: NUTRITIONAL ASPECTS OF SPECIFIC DISEASE STATES

CHAPTER 46 Feeding Difficulties
Peter B. Sullivan

CHAPTER 47 Failure-to-Thrive: Growth Failure in the Outpatient Setting
Jennifer A. Woo Baidal and Susanna Y. Huh

CHAPTER 48 Developmental Disabilities
Kelly A. Dougherty and Babette S. Zemel

CHAPTER 49 Inborn Errors of Metabolism and the Liver
Charles P. Venditti and Gerard T. Berry

CHAPTER 50 Inborn Errors of Fasting Adaptation—Glycogen Storage Disease
David A. Weinstein and Katalin M. Ross

CHAPTER 51 Acute and Chronic Kidney Disease: Nutrition in Renal Disease
Nancy M. Rodig

CHAPTER 52 Inflammatory Bowel Disease
Francesca Penagini and Rob Heuschkel

CHAPTER 53 Celiac Disease
Dascha C. Weir and Ciaran P. Kelly

CHAPTER 54 Food Allergies
Julie Wang, Jennifer M. Maloney, and Hugh A. Sampson

CHAPTER 55 Exocrine Pancreas
Kevin Gaskin and Karen Blumenthal

CHAPTER 56 Acute and Chronic Liver Disease
Deirdre A. Kelly, Susan Protheroe, and Sara Clarke

CHAPTER 57 Cancer Prevention
A. Lindsay Frazier

CHAPTER 58 Cancer Treatment
Lori J. Bechard and Christopher Duggan

CHAPTER 59 Diabetes Mellitus
Joseph I. Wolfsdorf, Sanjeev Mehta, Maryanne Quinn, and Karen Y. Warman

CHAPTER 60 Diarrheal Diseases
Kerri Gosselin and Christopher Duggan

CHAPTER 61 Intestinal Failure, Short Bowel Syndrome, and Intestinal Transplantation
Daniel Kamin

CHAPTER 62 The Critically Ill Child
Eric A. Sparks, Jeremy G. Fisher, Faraz A. Khan, Nilesh M. Mehta, and Tom Jaksic

CHAPTER 63 Hyperlipidemia and Cardiovascular Disease
Sarah D. de Ferranti

CHAPTER 64 Diet and Dental Disease
Rosalyn Sulyanto and James H. Shaw

CHAPTER 65 Adolescent Eating Disorders
Kendrin R. Sonneville and Alison E. Field

CHAPTER 66 Adolescence: Advancing Bone Health
Keith J. Loud and Catherine M. Gordon

PART VII: APPROACH TO NUTRITIONAL SUPPORT

CHAPTER 67 Enteral Nutrition and Formulas
Zoë McCallum and Julie E. Bines

CHAPTER 68 Parenteral Nutrition
Corina Hartman, Arie Riskin, and Raanan Shamir

CHAPTER 69 Nutrition in the Athlete
Kathryn E. Ackerman and Madhusmita Misra

CHAPTER 70 Special Diets
Sharon Evans, Tracey Johnson, Katharina Dokoupil, and Anita MacDonald

CHAPTER 71 Nutrition Support Teams
Virginie Colomb and Cécile Lambe

APPENDICES

APPENDIX I Nutritional Assessment
Melanie V. Connolly

APPENDIX II Nutritional Requirements
Melanie V. Connolly

APPENDIX III Enteral Products
Melanie V. Connolly

INDEX

CONTRIBUTORS

Souheila Abbeddou, MSc, PhD
Postdoctoral Scholar, Department of Nutrition
University of California, Davis
Davis, California
Infant and Young Child Feeding in Low- and Middle-Income Countries (41)

Kathryn E. Ackerman, MD, MPH
Division of Sports Medicine
Boston Children's Hospital
Harvard Medical School Neuroendocrine Unit
Massachusetts General Hospital
Boston, Massachusetts
Nutrition in the Athlete (69)

Anna María Aguilar, MD, MSc
Universidad Mayor de San Andrés
La Paz, Bolivia
Childhood Malnutrition: Prevention and Control at the National Level (15)

Ashley Aimone, MSc, RD
Registered Dietitian
University of Toronto
Toronto, Ontario, Canada
Iron (9)

Magdalena Araya, MD, PhD
Instituto de Nutrición y Tecnología de los Alimentos (INTA)
University of Chile
Santiago, Chile
Childhood Malnutrition: Prevention and Control at the National Level (15)

Jennifer A. Woo Baidal, MD, MPH
Assistant Professor of Pediatrics at CUMC
Director of Pediatric Weight Management,
Division of Pediatric Gastroenterology, Hepatology, and Nutrition
New York–Presbyterian Morgan Stanley Children's Hospital
New York, New York
Failure-to-Thrive: Growth Failure in the Outpatient Setting (47)

Mona Bajaj-Elliott, PhD
University College London
Institute of Child Health
London, United Kingdom
Nutrition and Gene Expression (19)

Robert Baker, MD, PhD
Professor of Pediatrics
University at Buffalo
Buffalo, New York
Nutrition: The Driving Force for Health, Disease Prevention, and Development (1)

Susan S. Baker, MD, PhD
Professor of Pediatrics
University at Buffalo
Buffalo, New York
Nutrition: The Driving Force for Health, Disease Prevention, and Development (1)

David J. P. Barker, MD, PhD, FAC*
MRC Lifecourse Epidemiology Unit
University of Southampton
Southampton, United Kingdom
Knight Cardiovascular Institute and Moore Institute
Oregon Health and Science University
Portland, Oregon
Human Growth and Disease in Later Life (26)
**Deceased*

Frederick C. Battaglia, MD
Professor Emeritus
University of Colorado School of Medicine
Aurora, Colorado

Nutrition and Development of the Fetus: Carbohydrate and Lipid Metabolism (27)

Lori J. Bechard, PhD, Med, RD, LDN
Instructor in Pediatrics
Center for Nutrition
Division of Gastroenterology, Hepatology and Nutrition
Boston Children's Hospital
Harvard Medical School
Boston, Massachusetts
Cancer Treatment (58)

Mandy Brown Belfort, MD, MPH
Assistant in Medicine
Assistant Professor of Pediatrics
Boston Children's Hospital
Harvard Medical School
Boston, Massachusetts
Nutritional Management of Preterm Infants Post-Discharge (33)

Gerard T. Berry, MD
Director, Metabolism Program
Professor of Pediatrics
Harvard Medical School
Boston Children's Hospital
Division of Genetics
Boston, Massachusetts
Inborn Errors of Metabolism and the Liver (49)

Zulfiqar Ahmed Bhutta, MBBS, PhD, FRCP, FRCPCH, FCPS
Husein Lalji Dewraj Professor and Head Division of Women & Child Health
The Aga Khan University
Karachi, Pakistan
Global Interventions in Child Health (43)

Julie Bines, MBBS, MD, FRACP
Professor of Paediatrics
Department of Paediatrics
University of Melbourne
Victoria, Australia
Enteral Nutrition and Formulas (67)

Maureen M. Black, PhD
Professor of Pediatrics
Department of Pediatrics
University of Maryland School of Medicine
Baltimore, Maryland
Nutrition and Neuropsychological Development (24)

Jean Luis Bresson, MD, PhD
Physiologie
Hôpital Necker-Enfants Malades
Paris, France
Energy Requirements in Health and Disease (13)

Kenneth H. Brown, MD
Distinguished Professor Emeritus
Department of Nutrition
University of California
Davis, California
Infant and Young Child Feeding in Low- and Middle-Income Countries (41)

Laura D. Brown, MD
Department of Pediatrics
Perinatal Research Center
University of Colorado School of Medicine
Aurora, Colorado
Nutrition and Development of the Fetus: Carbohydrate and Lipid Metabolism (27)

Benjamin Caballero, MD, PhD
Professor of Pediatrics and International Health
Johns Hopkins Bloomberg School of Public Health
Johns Hopkins University School of Medicine
Baltimore, Maryland
The Nutrition Transition and Global Child Health (40)

Susan J. Carlson, MMSc, RD
Department of Food and Nutrition Services
University of Iowa Hospital
Iowa City, Iowa

The Term Infant (34)

Lingtak-Neander Chan, PharmD, BCNSP
Associate Professor of Pharmacy
School of Pharmacy
University of Washington
Seattle, Washington
Drug Therapy and the Role of Nutrition (18)

Xinhua Chen, MD
Assistant Professor of Medicine
Beth Israel Deaconess Medical Center
Harvard Medical School
Boston, Massachusetts
Maternal Nutrition and Pregnancy Outcome (25)

Sang Woon Choi, MD, PhD
Adjunct Scientist
Vitamins and Carcinogenesis Laboratory
Jean Mayer USDA Human Nutrition Research Center on Aging
Tufts University
Boston, Massachusetts
Nutrition and Epigenetics (20)

Janice H. Y. Chow, MS, RD
Clinical Dietitian
San Mateo Medical Center
San Mateo, California
Community Nutrition and Its Impact on Children: Highly Industrialized Countries (16)

Sara Clarke, BSc (Hons)
The Liver Unit
The Department of Gastroenterology and Nutrition
Birmingham Children's Hospital
Birmingham, United Kingdom
Acute and Chronic Liver Disease: Nutrition in Renal Disease (56)

Virginie Colomb, MD, PhD
Department of Pediatric Gastroenterology Nutrition Hôpital Necker-Enfants Malades
Paris, France
Nutrition Support Teams (71)

Melanie Connolly, MSc, RD, CNSC
Adjunct Professor, Nutrition
Northeastern University
Boston, Massachusetts
Regis College
Weston, Massachusetts
Framingham State University
Framingham, Massachusetts
Appendix I: Nutritional Assessment
Appendix II: Nutritional Requirements
Appendis III: Enteral Products

Anna Coutsoudis, PhD
Department of Pediatric and Child Health
School of Clinical Medicine
University of KwaZulu-Natal
Glenwood, Durban, South Africa
Pediatric HIV Infection (44)

Stephen R. Daniels, MD, PhD
Professor and Chairman, Department of Pediatrics,
University of Colorado School of Medicine
Pediatrician-in-Chief
L. Joseph Butterfield Chair in Pediatrics
Children's Hospital Colorado
Aurora, Colorado
Dietary Reference Intakes in the United States (11)

Jai Das, MD, MBA
Division of Woman and Child Health
Aga Khan University
Karachi, Parkistan
Global Interventions in Child Health (43)

Sarah D. de Ferranti, MD, MPH
Director, Preventive Cardiology
Department of Cardiology

Boston Children's Hospital
Harvard Medical School
Boston, Massachusetts
Hyperlipidemia and Cardiovascular Disease (63)

Carlotta De Filippo, DSc, PhD
Department of Food Quality and Nutrition
Fondazione Edmund Mach-Research and Innovation Centre
San Michele All'adige TN, Italy
Diet, Environment, and Gut Microbiota in the Metagenomic Era (23)

Hans Demmelmair, PhD
Division of Metabolic Diseases and Nutritional Medicine
Dr. von Hauner Children's Hospital
University of Munich Medical Centre
München, Germany
Macronutrient Requirements for Growth: Fats and Fatty Acids (7)

Katharina Dokoupil, MSc
Department of Metabolism and Nutrition
Dr. von Hauner Children's Hospital
University of Munich
Munich, Germany
Special Diets (70)

Anne Donnet-Hughes, PhD
Nestlé Research Center
Lausanne, Switzerland
Protective Properties of Human Milk and Bacterial Colonization of the Neonatal Gut (30)

Sharon M. Donovan, PhD, RD
Professor and Melissa M. Noel Endowed Chair in Nutrition and Health
Departments of Food Science and Human Nutrition
University of Illinois
Urbana, Illinois
Human Milk: Nutritional Properties (29)

Kelly A. Dougherty, PhD
Division of Gastroenterology, Hepatology and Nutrition
Department of Pediatrics
The Children's Hospital of Philadelphia
University of Pennsylvania
Philadelphia, Pennsylvania
Developmental Disabilities (48)

Martha Douglas-Escobar, MD, FAAP
Assistant Professor
Department of Pediatrics
University of California San Francisco
San Francisco, California
Gastrointestinal Development: Implications for Infant Feeding (22)

Christopher Duggan, MD, MPH
Professor of Pediatrics
Harvard Medical School
Professor in the Department of Nutrition
Harvard TH Chan School of Public Health
Director, Center for Nutrition
Division of Gastroenterology and Nutrition
Boston Children's Hospital
Boston, Massachusetts
Cancer Treatment (58)
Diarrheal Diseases (60)

Johanna Dwyer, DSc, RD
Frances Stern Nutrition Center
Tufts Medical Center
Department of Medicine and Community Health
Tufts University School of Medicine
USDA HNRC on Aging at Tufts University
Medford, Massachusetts
Community Nutrition and Its Impact on Children: Highly Industrialized Countries (16)

Kenneth J. Ellis, PhD
Professor of Pediatrics and Nutrition
Baylor College of Medicine
Houston, Texas
Body Composition and Growth (4)

Sharon Evans, MSc, RD
Research Dietitian
Dietetic Department
Birmingham Children's Hospital
Birmingham, United Kingdom
Special Diets (70)

PREFACE

This fifth edition of *Nutrition in Pediatrics: Basic Science and Clinical Applications* is our continuing effort to establish a comprehensive and accessible approach to pediatric nutrition for a wide range of clinicians, scientists, and—most importantly—trainees. An important addition to the textbook has been the inclusion of Professor Berthold Koletzko to our Editorial Board. As Professor of Pediatrics at the University of Munich and Head of the Division of Metabolic and Nutritional Medicine at Hauner Children's Hospital, Dr. Koletzko brings a wealth of clinical and research expertise to this text. In addition, his global collaborations have allowed us to substantially broaden our team of authors, making this version of the text a truly international one.

The fifth edition builds on the foundations of the several previous versions, with updated chapters on the broad themes of General Concepts, Physiology and Pathophysiology, Perinatal Nutrition, Obesity, Nutritional Aspects of Specific Disease States, and Approach to Nutritional Support. Owing to the recognition that nutritional issues overwhelmingly affect children living in resource-poor countries, we have also added a new section entitled "Nutrition in Low- and Middle-Income Populations." Expert authors in this field have contributed reviews on the topics of the nutrition transition, complementary feeding, economic development, HIV disease, and the occurrence of obesity in developing economies.

Although all of our contributions are excellent, notable additions to this 5th edition include an outstanding leadoff chapter on the role of nutrition for health, disease prevention, and development; new contributions on macronutrients, epigenetics, and the microbiome; and several significantly revised and updated classic chapters. As in past editions, comprehensive appendices are included that serve the reader by collating important tools for nutritional assessment, nutritional requirements, and enteral products.

The editors are grateful to Ms. Linda Mehta for her many efforts in the publication of this textbook.

Finally, we sincerely thank the dozens of authors who contributed countless hours of writing and research for the completion of this text. Their expertise and labors constitute the heart of this book.

—Christopher Duggan,

Nutrition: The Driving Force for Health, Disease Prevention, and Development

1

Robert D. Baker, MD, PhD and Susan S. Baker, MD, PhD

A SWEEPING LOOK AT NUTRITION

Nutrition is the underpinning of life itself. Good nutrition has consequences for health, societal well-being, economic stability, and advancements. Poor nutrition has a direct and measurable impact on all aspects of human functioning. Nutrition is the driving force for much of human and societal evolution. This fundamental role of nutrition has been recognized since ancient times. More recently, evolutionary biologists have recorded the importance of nutrition on evolution, and the basic requirements for the human organism have been identified.

This book deals with the scientific and clinical practice of pediatric nutrition. That it is now into its fifth edition implies that readers and users of this book are convinced of the importance of nutrition to the growing and developing child. In this first chapter, we invite “devotees” of pediatric nutrition to take a very broad look at the importance of food and to consider food as a driving force for the evolution of the human race, as a major part of our culture, as an economic force, and as a means toward future change.

From prehistory forward, food and the search for food have been

central to human evolution. In examining the expansion of humans from their African origins throughout the Middle East, Europe, Asia, the Far East including the Pacific Islands, across the bridge to North America, and south through Central America to include all of South America, one of the most striking aspects of this amazing migration is the rapidity with which it took place. After existing in Africa for 5–6 million years, the great migration started about 1 million years ago and was essentially complete about 20,000 years ago.[1] The migration was not a single sweep, but occurred in waves and fits and starts. The reasons for man's moving were undoubtedly multifactorial, but prominent among these factors had to be food availability. The move from "gathers" to "hunter-gathers" required the acquisition of tools, weapons, and necessitated cooperation, but also ushered in conflict. The beginning of agriculture, in the fertile crescent, not only provided a more stable source of nutrition but also allowed humans to establish settlements, which required rules and patterns of behavior far different from the behavior of hunter-gathers. Among many other results of "settlements" was the possibility of specialization; most would be farmers but there were also warriors, carpenters, builders, teachers, and eventually philosophers and scientists.[1] The move toward agriculture was gradual. Man first learned that by tending plants that bore fruit, the yield could be increased. Some tribes in New Guinea still practice this early form of agriculture. They clear completing plants from food-bearing plants and then leave returning months later to harvest the enhanced fruit production.[1] Wheat and other grains were the first food plants to be domesticated. The cultivation of pulses in addition to grains allowed both protein and carbohydrate needs to be largely supplied through plants. Domesticated animals became a readily available and dependable source of protein. Initially in the Middle East but then spreading, communities began domesticating animals; first sheep and then goats and finally cattle.

LACTOSE INTOLERANCE

About 7000–8000 years ago, these Middle Eastern farmers began consuming milk.[2] This created a genetic dilemma for humans. Lactose is the disaccharide in most mammalian milk, including human milk.[3] Human infants, to survive, must be able to digest and use lactose. Before the introduction of dairy products into the human food chain, there was no advantage of being able to digest lactose beyond the age of weaning. So, for most of the human race, the gene that codes for lactase becomes progressively less active during childhood. However, with the introduction

of milk into the human diet, an evolutionary pressure for persistent lactase activity was created. Humans dealt with this dilemma in two ways. The lifelong use of dairy products spread from the Middle East north to Europe and Scandinavia where the persistence of the lactase gene was common. An added advantage for human at northern latitudes was lactose's positive effect on calcium absorption, partially making up for decreased vitamin D due to lack of exposure to sunlight. Dairy as a food source also spread from the Middle East into Eastern Europe and Asia. Here, the gene of persistence of lactase was less common, but man developed a system to decrease the lactose by fermenting milk to make yogurts and cheeses.[2]

THE POTATO FAMINE

The results of agriculture have not always been beneficial. The potato was first domesticated 7000 years ago in the Andes, where thousands of varieties are still grown.[4] Potatoes were introduced to Europe after the Spanish conquest of South America in the 1500s. After an initial slow start in Europe, it became a staple food and is estimated to be responsible for 25% of the European population growth between 1700 and 1900. The limited varieties of potatoes grown in Europe created a setup for disease. The Great Irish Potato Famine began in 1845 when a fungus, *Phytophthora infestans,* caused potato harvest failure.[5] In Ireland, where a third of the population was entirely dependent on potatoes for food, over a million people died and a million emigrated.[6] This diaspora forever changed the history of Ireland, Great Britain, and the United States. In Ireland, so great was the suffering and death that the famine has entered in the folk psyche of the people. It triggered the growth of Irish nationalism and soured the Irish–English relationship. It furthered the split between the Catholic and Protestant islanders. Great Britain is still dealing with the aftermath of the famine and the sense among the Irish that they were abandoned. In the United States, one need only look at surnames on the ballot in any election to verify to what extent the Irish have entered into our national heritage.

THE DUST BOWL

The Great Plains were originally known as the "Great American Desert," because this region received an average of less than 10 inches of precipitation a year and was considered unacceptable for agriculture. However, a combination of huge pressure to settle in the West and a string

of unusually wet years induced farmers, mostly immigrants, into this area.[7] Poor farming techniques such as deep plowing of virgin top soil, no cover crops, no crop rotation, and lack of wind breaks created a few very profitable years followed by a collapse of the agriculture when the wet years gave way to more normal rainfall. The result was soil erosion on a vast scale leading to huge dust storms called “black rollers.”Dust from the Great Plains reached East Coast cities. Hundreds of thousands of people were displaced. Hunger became so severe that tumble weed (an invasive species inadvertently introduced from the Ukrainian steppes) was used for feeding cattle and even for human consumption.[7]

THE GREEN REVOLUTION

The green revolution refers to the widespread application of modern farming techniques, improved seeds, fertilizers, and pesticides, to areas where traditional, small-scale farming was practiced. This movement began in the 1940s in Mexico, but became vitally important in the 1960s in India. In 1961, India faced a huge food shortage. The prospect of massive food shortages and famine frightened the Indian government and the world. The Indian government adopted the green revolution methods, in particular, use of a variety of rice developed at the International Rice Research Institute along with fertilizers and pesticides. Yields were up to 10 times that of traditionally grown rice crops. Some say that over a billion people, worldwide, have been saved from starvation because of the green revolution.[8] Green revolution techniques have gained widespread use. Famine, suffering, and death have been avoided. But the green revolution is not without its critics. The green revolution is heavily dependent on herbicides, pesticides, fertilizers, and monoculture. Hence, reliance on petrochemical products necessarily increased. While the crop yield dramatically increased so did the energy input needed to produce crops. In addition, the world population continues to increase, leading some to propose the Malthusian argument that we have merely postponed starvation and famine that will surely come. The green revolution has led to widespread deforestation and dramatic loss of biodiversity. So the verdict on the green revolution is not yet in.[9]

GENETICALLY MODIFIED FOODS

Genetically modified (GM) foods have been genetically engineered via DNA modification. Currently, there are many examples of GM foods on

the market. There is a general consensus that GM foods do not add risk to the consumer. The DNA of GM foods is largely broken down and inactivated in the gastrointestinal (GI) tract. To date, there have been no reports of allergy induced by conformational changes within the structure of GM foods. Likewise, there have been no reports of toxicity. However, there are concerns. Could GM crops become locally invasive? The evidence is against this as almost always the GM crop is less "fit" than its non-GM counterpart, so although it can escape the field, it rarely survives in the wild. To date, the major aim of developing a GM crop is to increase the yield. Examples of this are Bt. In this case, a gene from the bacteria, *Bacillus thuringiensis*, is introduced into the plant genome. This gene codes for a toxin that attacks the Lepidoptera larvae, allowing for naturally occurring bacteria to infect and kill the larva. In the case of corn, the initial target was the European Corn Borer.[10] Since first introduced, Bt crops have been further modified to include other insect pests. The modified varieties have become significantly more sophisticated than the original Bt varieties. Another aim of GM technology has been to improve the quality of the crop. An example of this is "golden rice," a variety of rice genetically modified to contain beta-carotene and thus serves as a tool to fight vitamin A deficiency.[11] As with the Green revolution, there has been substantial opposition to genetically altering the food chain. The opposition mainly centers around fears of unintended environmental consequences and fear that a few large multinational corporation will control all access to seeds.

FOOD USED FOR GOOD AND EVIL

In writing about Ethiopian refugees in 1986, Nevin Scrimshaw wrote: "In Ethiopia today as in Biafra in 1969 and frequently throughout history, enforced hunger has been a weapon to crush political resistance."[12] A US policy of using food as political weapon could not have been more clearly stated than it was by Henry Kissinger in a memo written in 1974, where he stated that food aid could be withheld from third world countries that did not implement birth control as demanded by the US government.[13] Recently, we have witnessed an example of food as a political weapon when the Obama administration stopped food shipments to North Korea in response to the launch of a missile into space by North Korea.[14] One can argue the propriety of such a use of food; one can question the effectiveness in achieving the desired results, but it is clear that food is a weapon in world politics.

Food is also a means to achieve laudable ends. Treating vitamin A deficiency with “golden rice” is a desirable goal. Fortifying fish sauce with iron in Vietnam has greatly reduced the prevalence of iron-deficiency anemia.[15] Salt in the United States has been fortified with iodine since 1924. Adding iodine to salt virtually eliminated goiter resulting from iodine deficiency in the United States.[16] The addition of folate to wheat has reduced the occurrence of neural tube defects.[17]

The wide distribution and relative lack of safety measures (most of the regulations are adhered to and monitored by the producer and thus largely voluntary) in our food supply have opened the way to accidental contamination, but also to allow an opening to those who would like to harm large numbers of people. A challenge for the future is to devise safety measure that will ensure that health-promoting, uncontaminated food is delivered from the point of origin to the table.

FOOD BECOMES A SCIENCE

As discussed earlier, knowledge of food and how it relates to mammalian health was accumulating throughout history and was a driving force for health and development. However, nutritional sciences as currently understood probably began with the advances made during the mid-18th century in France.[18] Studies conducted during this time focused on understanding macronutrients and how they were incorporated into human tissue, that is, how ingested plant or animal products, or air, as it was known to contain nitrogen, were transformed into body parts. The first observations that dietary carbohydrate could be converted to fat were made, and it was established that animals generated heat and that this heat could be quantified. During the early 1900s, proteins were observed to hydrolyze into amino acids and short-order proteolytic enzymes were discovered, setting the stage for understanding the essentiality of specific amino acids.

Atwater, known as the father of nutritional sciences, initially focused on protein nutrition and also built the first calorimeter and was able to show that the heat produced by an individual is the same as that produced by the combustion of the same quantities of nutrients. He also established the estimates of metabolizable energy from protein, carbohydrate, and fat in mixed diets as 4, 4, and 9 kcal/g, respectively. These values retain their validity today.

For several decades, the focus of nutritional sciences was on the requirements for protein and energy, how they were related, and how

disease or trauma would alter them.[19,20] The essentiality of specific nutrients and deficiency states caused due to their absence from the diet were established. The list of essential nutrients is long, but vitamins, minerals, lipids, and specific amino acids were identified and synthesized. Products were developed that could be consumed to prevent or treat deficiency states.

During the late 20th century, the life-saving option of parenteral nutrition, delivery of nutrients that bypassed an absent or nonfunctional GI tract to sustain life and promote growth and development, was discovered and used clinically.[21–23] However, as the dangers of this option became apparent and the importance of directly nourishing the GI epithelial cells was discovered, parenteral nutrition as a common therapy for moderately ill patients or as a preparation for surgery in patients with an intact GI tract lost favor. Currently, parenteral nutrition is used only when the GI tract cannot deliver the required nutrition. Technical strides permitted the development of appliances, formulas, and experience, so enteral nutrition became the preferred route to deliver nutrients, even when the GI tract was compromised, to support ill children and promote health. The enteral route of nutrition support acknowledged the importance of the GI tract as a modulator of nutrition and immune function. Most recently, the complicated and dynamic interaction of nutrients, metabolism, and the GI microbiome has received attention.[24,25]

CHANGING VIEW OF NUTRIENTS

As these concepts were incorporated into the practice of nutrition, additional observations suggested that diets could provide therapeutic options and nutrients might play a role in treating disease. For example, the relative content of dietary fat and carbohydrate can have a desirable effect on the respiratory quotient and assist those with pulmonary disease.[26,27] Some nutrients, specifically, omega-3 polyunsaturated fatty acids, nucleotides, vitamin D, and specific amino acids singly or in combination have been shown to modulate the immune system within defined disease states or specific situations.[18,28–34] This has led to the concept of nutrients as pharmacological agents. Indeed, enteral nutrition support can have a positive effect on the induction and maintenance of remission in inflammatory bowel disease; however, no specific nutrient or combination of nutrients that can treat inflammatory bowel disease has been identified. To date, except for deficiency states, no single nutrient has withstood the scrutiny demanded of pharmaceutical agents to demonstrate

the efficacy for treatment of a specific condition or disease.

OVERNUTRITION

Although nutrition prescribed "correctly" can have a positive effect on health, it can also cause harm. Recent observations have brought to light the concept of overnutrition as a disease state.

According to the Centers for Disease Control, overweight and obesity are labels for ranges of weight that are greater than what is generally considered healthy for a given height. The terms also identify ranges of weight that have been shown to increase the likelihood of certain diseases and other health problems.

Growth charts for children and adolescents aged 2–19 years are used to determine the body mass index (BMI), weight/height^2, for age and sex percentile. Overweight is defined as a BMI at or above the 85th percentile and lower than the 95th percentile for children of the same age and sex.[35] Obesity is defined as a BMI at or above the 95th percentile for children of the same age and sex.[35]

The concern for obese and overweight children and the focus of resources on this disease state by health and government agencies developed because of observations that childhood obesity is associated with risk factors for chronic diseases that include cardiovascular disease, insulin resistance and type 2 diabetes, sleep apnea, fatty liver disease, joint and musculoskeletal problems, and a greater risk of social and psychological problems than nonobese children. These observations are magnified by the fact that obese children are likely to become obese adults and adult obesity is associated with serious, chronic health conditions.[36]

OVERVIEW OF THIS BOOK

The next chapters in this book address the current body of knowledge in nutrition for children. The basic biochemistry and metabolism of the science of nutrition is presented in a manner that makes this information clinically useful. Specifically, the book addresses nutritional strategies to support the sickest of children, to provide for normal growth and development for normal infants and children and those born with metabolic errors, to prevent diseases, both in childhood and later in adulthood, and to support normal growth and development for children who have specific disease states. The knowledge contained in this volume will be directly applicable to the practice of medicine to the primary care

physician, those who work in intensive care units and serve nutrition support services.

Clinical Assessment of Nutritional Status

2

Babette S. Zemel, PhD, Asim Maqbool, MD, and Irene E. Olsen, PhD, RD

The clinical assessment of nutritional status is an integral part of patient care because nutritional status affects the body's response to illness. Attention to this is especially important in pediatric patients because the nutritional requirements to support normal growth and maturation are combined with those of coexisting medical illness. This combination creates for clinicians the unique challenge of estimating and meeting the nutritional needs of pediatric patients in the clinical setting as discussed throughout this chapter and book.

The assessment should allow for the early detection of both nutrient deficiencies and excesses. There is no single nutrition measurement that is optimal; therefore, a combination of different measures is required. Growth is an important indicator of health and nutritional status of a child and requires a growth chart for interpretation; a variety of growth charts are currently available and will be reviewed in this chapter. Each growth measurement performed needs to be accurate and obtained at age-appropriate intervals in order to identify at-risk patients or monitor a patient's clinical response to nutritional therapy.

During infancy, childhood, and adolescence, profound changes in growth and body composition occur. Therefore, clinicians must understand normal growth to recognize abnormal patterns and the nutritional changes that occur with acute and chronic disease. With the epidemic of pediatric

obesity, the proper identification of the overweight or obese patient is also important. A brief nutritional screening assessment may be used to identify patients in need of an in-depth assessment. A typical nutritional screening includes a brief medical and dietary history (including feeding ability), anthropometric measurements (e.g., weight, stature), and possibly laboratory data. A full nutritional assessment includes more detailed medical and dietary histories (including a measure of dietary intake), a complete physical examination, further anthropometric and body composition measurements, sexual and skeletal maturation, laboratory data, and the estimation of nutritional requirements. In addition to the clinician's global assessment of the child based on these objective data, his/her clinical judgment is important in determining the nutritional status.[1]

MEDICAL HISTORY

Medical history is a central component of the nutritional assessment. Past and present medical information, including the duration of the current illness, relevant symptoms, diagnostic tests and therapies (e.g., chemotherapy, radiation), and medications, is documented. Because nutritional abnormalities are often associated with certain disease states, it is essential to identify underlying medical conditions and the concomitant medication history. Medications can cause nutritional deficiencies (e.g., methotrexate as a competitive antagonist of folic acid metabolism) and drug–nutrient interactions (e.g., phenytoin and tube feedings; Table 2-1). Drug–nutrient interactions may occur between drugs (prescription and nonprescription) and foods, beverages, and dietary and vitamin/mineral supplements. Alterations in drug metabolism and absorption by food or pharmacologic interactions may be clinically significant.[2] Past medical history includes previous acute and chronic illness, hospitalizations, and surgical procedures. The history of past growth patterns (with previous growth charts, as possible), onset of puberty (for the child and other family members), and a developmental history (including feeding abilities) may also be included. Family history should include a medical history and the family's social and cultural background, especially as related to diet therapy and the use of alternative and complementary medicine. The review of systems includes oral motor function, dental development, and gastrointestinal symptoms such as vomiting, gastroesophageal reflux, diarrhea, and constipation.

TABLE 2-1 Examples of Some Common Drug–Nutrient Interactions

Drug	Nutrient
Amphotericin B	Hypokalemia, hypomagnesemia
Antacids	Vitamin D and iron deficiency, hypophosphatemia
Phenobarbital	Vitamin D deficiency
Cholestyramine	Vitamin A, D, E, and K malabsorption
Cyclosporin	Elevated triglycerides, hypokalemia, hypomagnesemia
H2 blockers	Iron deficiency
Methotrexate	Folate deficiency
Phenytoin	Folate deficiency
Corticosteroids	Hyperglycemia, hypophosphatemia
Sucralfate	Hypophosphatemia
Sulfasalazine	Folate deficiency
Trimethoprim	Folate deficiency
6-Mercaptopurine	Purine metabolism (DNA synthesis/repair)

PHYSICAL EXAMINATION

Physical examination includes anthropometrics (see later), including weight, length or stature, head circumference, and upper arm measures. The frequency of measurements of well children follows the recommendations of the American Academy of Pediatrics (AAP).[3] For the preterm infant, weight should be measured daily, and length and head circumference weekly. For newborns, weight, length, and head circumference should be measured at birth and again at 3–5 days of age. For healthy children up to 2 months of age, all three measures should be obtained monthly, then every two months from 2–6 months of age, and every 3 months from 6–24 months of age. For children aged 24–36 months, weight and length/height should be assessed every 6 months and annually thereafter. The pattern of measurement for hospitalized patients depends on the age of the patient, illness, and the degree of nutritional intervention. Nutritional assessments for patients with complex chronic disease states should be conducted every one to two months and less often in those with milder disease (every 6–12 months). The general physical examination includes an assessment of the patient's general condition and close examination of skin, hair, and teeth (see Appendix Table I-8). This includes an assessment for pallor, clinical assessment of body fat stores,

wasting of muscle mass, edema, rash, thinning of hair, and evidence of specific nutritional deficiencies. Examples of specific signs include the flag sign or the loss of hair color associated with a period of malnutrition followed by recovery with a return of normal hair color and texture. Examination of specific organ systems and obtaining medical record information is helpful in assessing the severity of the underlying disease process. It is also important to consider the clinician's clinical judgment in the assessment of nutritional status.[1] Documenting sexual development by Tanner staging (Appendix I) is a routine part of the nutritional assessment of adolescents (see later). For a summary of signs and symptoms of specific nutritional abnormalities, see Appendix Table I-8.

DIETARY HISTORY

The dietary history is an essential component of the nutritional assessment. The dietary history provides information not only on the amount and quality of the food consumed but also on the eating patterns and behaviors of the family. This part of the nutritional assessment should detail the number of meals, snacks, and beverages consumed; special foods eaten by the child and family; vitamin and mineral supplements ingested regularly; food allergies; intolerances; and unusual feeding behaviors. The child and family are asked about psychosocial factors that impact on food selection and intake, including family history, socioeconomic status, and use of the Special Supplemental Nutrition Program for Women, Infants, and Children and supplemental food programs, parent/caretaker's perception of the child's nutritional status, and religious and cultural considerations. Food-related factors may affect dietary intake and include food allergies, intolerances, self-imposed and prescribed diets, and feeding skills. These factors are also noted in the assessment.

The assessment of dietary intake of breastfed infants is more difficult because the volume of milk consumed cannot be directly measured. An estimate is obtained by weighing the infant before and after feeds and using a conversion factor of 1 mL volume of breast milk consumed for each gram of weight gained. In formula-fed infants, the clinician should inquire about both the amount and type of formula consumed and the details of the method of preparation (concentrates, powders, modular additives).

The quantity and quality of dietary intake are assessed by prospective food records (with weighed or estimated food portions), retrospective 24-hour recalls (previous 24 hours or of a "typical" 24-hour period), or food

frequency questionnaires.[3] The prospective food records are usually carried out for three to seven days (including a combination of weekend and weekdays) and provide the most accurate assessment of actual intake. However, food records are used most often in the research setting because they are labor intensive and time consuming. As available, these records are analyzed and compared to the dietary reference intakes (DRIs) (see later) using a computerized nutrient analysis program. A limitation of food records is that parents tend to forget to record all foods eaten or modify feeding practices to be more healthy, which may lead to incorrect estimates of intake.[4] The retrospective 24-hour diet recall provides a quicker assessment of dietary intake. For a 24-hour recall, the child/parent is asked to recall what and how much the child ate and drank over the past 24 hours. Recall accuracy depends on the child/parent's memory and their ability to estimate portion sizes. Also, because this is only one day of intake, it may not be representative of the usual intake. When the child's intake is affected by acute illness, a 24-hour recall of a "typical day" is more useful to estimate usual intake. The 24-hour recall tends to underestimate usual energy intake yet may overreport the intake of infants and toddlers.[5]

Another way of assessing dietary intake is the food frequency questionnaire method. These questionnaires collect information on both the frequency and the amount consumed of specific foods and are useful in the clinical setting to identify usual eating patterns. A limitation of the food frequency questionnaires is that the amounts of food and thus intake of energy and some nutrients are often overreported.[5] All of these methods of dietary assessment are somewhat limited owing to gaps in the nutrient databases, which lack information about bioavailability, presence of inhibitors and enhancers of absorption, and nutrient availability of specific nutrients of interest.[6]

The most commonly used method of dietary assessment in hospitalized patients is the calorie count. This is a variation of the prospective food records as the amount of food consumed from a known quantity of food (as specified by a menu or list) is recorded. The accuracy of the calorie count assessments is limited by the number of individuals required for the completion of these forms throughout a 24-hour period (e.g., the dietitian, the nurse for each shift, the child's family, the child). However, calorie counts are a useful part of nutritional assessment follow-up because these provide a rough assessment of the patient's appetite, intake, and compliance with nutrition recommendations.

ANTHROPOMETRICS AND BODY COMPOSITION

At a minimum, nutritional assessment of a child includes a measured weight, length or height, and head circumference (birth to 3 years of age), and these measurements are followed up over time to assess short- and long-term growth and nutritional status. For children with chronic disease, a mid-upper arm circumference (MUAC) and triceps skinfold (TSF) thickness are also part of the assessment to determine body fat and protein stores. In addition, a dual energy x-ray absorptiometry (DXA) scan may be added to more thoroughly assess body composition (percent fat, lean body, and fat mass) and bone mineral density (BMD) (see Chapter 4).

Accurate and reliable anthropometric and body composition measurements require proper equipment and techniques. Training and practice in anthropometric technique cannot be overemphasized. For all growth measures, three independent measures should be obtained. The current convention is to use the average of three measurements. The clinician's assessment for a child depends on the quality of these data. Equipment requirements for each measure are discussed below.

Weight

Weight is a measure of overall nutritional status. Optimal interpretation requires additional information regarding the age, sex, and height/length of the child. Weight is determined using a digital or beam balance scale. Until the child is approximately 24 months or can cooperate and stand independently, a pan version of the scale is used. Weight should be measured in light or no clothing and without a diaper for infants. It is important that the scale is zeroed prior to each measurement and is calibrated using known weights at least monthly or on movement of the scale.[3] Weights are recorded to the nearest 0.01 kg in infants and 0.1 kg in older children.

Stature: Length or Height

A measure of stature is important for monitoring long-term nutritional status. Recumbent length is measured using a length board for children from birth to 2 years. The measurement of length requires two individuals. The first person positions the infant straight on the board so that the infant's head is against the headboard and positioned with the Frankfort plane parallel to the headboard.[3] The Frankfort plane is the alignment from the lower margin of the orbit to the upper margin of the auditory meatus as

shown in Figure 2-1. The second person extends the infant's legs with the knees flattened and adjusts the moveable footboard such that the heels lie flat against the movable footboard.[3] For children aged 2 years and older who are able to stand independently and cooperate, height is measured using a stadiometer, with a moveable headboard at a fixed 90-degree angle to the back of the stadiometer. The child is measured barefoot or in thin socks and in minimal clothing to allow the observer to check for correct positioning. For the measurement, the child stands erect, with feet close together, heels, buttocks, and back of head touching the stadiometer, and looking ahead with the Frankfort plane parallel to the floor.[3] Asking the child to inhale deeply just prior to obtaining the measurement assists in attaining fully erect posture. Because length overestimates the height by 0.7 cm,[7] it is essential to record the method of measurement during the transition from recumbent length to standing height. The change to standing height is also accompanied by the transition to pediatric (2–18 years) growth charts (see later). Both length and height measurements are recorded to the nearest 0.1 cm.

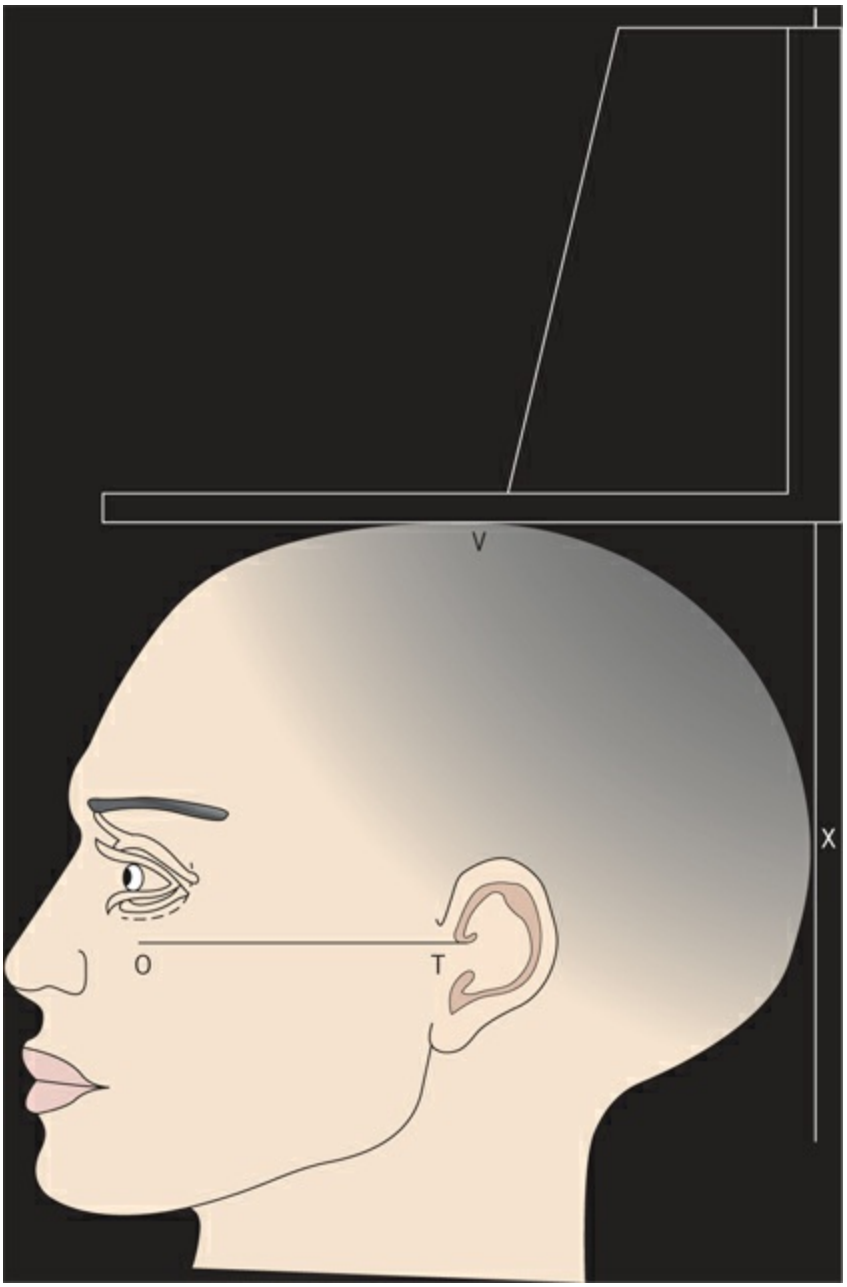

Figure 2-1 The Frankfort plane is the horizontal line extending from the auditory meatus (T) to the lower margin of the orbit (O). Reprinted with permission from Anthropometry Illustrated, Roww WD, Carr RV, and Carter JEL, Turnpike Electronic Publications, Inc.

Among children for whom the stature measurements are not possible owing to physical constraints (e.g., contractures, nonambulatory), alternative measures are available. Upper arm and lower leg lengths provide reliable and valid indexes of stature in children.[8,9] These

measurements are conducted using sliding calipers. All measurements are recorded to the nearest 0.1 cm.

The shoulder to elbow length is used for the upper arm measurement in infants and young children (birth to 24 months).[8,9] This measurement is obtained with the arm bent to a 90-degree angle, and the measurement is taken from the superior lateral surface of the acromion to the inferior surface of the elbow. For older children (2–18 years), the arm should hang in a relaxed position at the side, and the distance between the superior lateral surface of the acromion and the proximal tip of the radius is measured. The lower leg length is measured as the knee-to-heel length for infants and young children (0–24 months) and as a tibia length in older children (2–18 years). For infants and young children, the superior surface of the knee to the heel is measured while the leg is bent at a right angle at the hip, knee, and ankle. In older children, the tibia length is measured from the proximal medial border of the tibia plateau to the medial malleolus; ideally, the leg being measured is crossed over the opposite knee.[3] Alternatively, knee-to-heel length can be measured in older children and used to predict stature.[10,11] The right-side extremity should be measured for these alternative stature estimates.[3] If there are asymmetric extremity abnormalities, the measurement should be taken on the least affected side and the side of measurement noted in the chart.

Head Circumference

Head growth, primarily owing to brain development, is most rapid during the first 3 years of life. Routine measurement of head circumference (the frontal occipital circumference) is a component of the nutritional assessment in children up to age 3 and longer in children who are at high nutritional risk. Head circumference is a less-sensitive indicator of short-term nutritional status than weight and height because brain growth is generally preserved in cases of nutritional stress. Head circumference is not a helpful nutritional status measure in children with hydrocephalus, microcephaly, or macrocephaly.

Head circumference is measured using a flexible, nonstretch tape measure. The circumference should be taken at the maximum distance around the head, which is found by placing the measuring tape above the supraorbital ridge and extending around the occiput.[3] Care should be taken to keep the tape measure flat against the head and parallel on both sides. The measurements should be recorded to the nearest 0.1 cm.

GROWTH CHARTS AND TABLES

Serial measurements are essential for the optimal assessment of short- and long-term growth and nutritional status. A number of growth charts and tables are available for the comparison of weight, stature, and head circumference with reference populations by age and sex. Weight is also assessed relative to a child's stature using growth charts that evaluate weight for length/height, weight/height[2] (body mass index [BMI]) for age, or weight/length[3] (ponderal index) for age; these measures assess "relative weight" or weight independent of stature. The types of charts and tables available for clinical assessment in infants and children are reviewed. Several of these charts are included in Appendix I.

Premature Infant Growth Charts

Several types of charts are available for growth assessment of premature infants in the neonatal intensive care unit (NICU). Intrauterine growth charts[12–15] are preferred over postnatal growth charts[16–19] as the pattern and rate of normal intrauterine growth are the standard for growth of premature infants.[20] Postnatal growth charts are based on actual, not ideal, growth of premature infants over time so that these can serve as a useful adjunct curve in a nutritional assessment. Growth measurements are plotted using corrected gestational age of 12–36 months, depending on the child's size and growth.

The three most widely used intrauterine growth charts in US NICUs include the Lubchenco,[12,13] Fenton,[15] and Olsen[14] charts. All include weight-, length-, and head circumference-for-age curves. The newest and first gender-specific set of charts from Olsen et al.[14] are becoming a clinical standard of care as these were based on more recent data (1998–2006) and a large sample of birth data that represents the racial distribution of US births. The Fenton unisex growth charts[15] have a popular "hybrid" curve presentation that joined intrauterine data with postnatal data and span from 22–50 weeks gestational age. However, the intrauterine portions of these curves were created from mixed sources of non-US data: Canadian data[21] were used for weight-for-age, and a combination of Swedish data[22] and Australian data[23] were used for the length- and head circumference-for-age curves. The postnatal portion of the Fenton curves used the Centers for Disease Control and Prevention (CDC) 2000 data[24] and later the World Health Organization (WHO) data.[25] Finally, the Lubchenco growth charts,[12,13] while historically a NICU standard of care,

are now less representative of the growth of infants in the US NICUs. However, this set of charts has the advantage of including a measure of relative weight (ponderal index-for-age) that may be helpful in the growth assessment of premature infants (see "Weight-for-Length/Height" section).

The Olsen curves define new cutoffs for the classification of infants as small-for-gestational age (or <10th percentile) or large-for-gestational age (>90th percentile), and the cutoffs vary from existing curves used in NICUs. For example, the Olsen curves tend to have a lower average size than the Lubchenco curves at younger gestational ages and a higher average size at the older gestational ages; differences from the Fenton curves vary based on age, gender, and growth measurement.[14] The relationship between these newly defined high-risk groups and health outcomes is under investigation.

Once a preterm infant reaches 40 weeks corrected gestational age, their growth should be monitored on the WHO growth charts[25] until 2 years of age and then switched to the CDC 2000 growth charts[24] for 2–20 years of age as recommended by the CDC for infants born at full term. Former premature infants are plotted on these charts based on their corrected gestational age (as mentioned earlier). Although all premature infants may not achieve "good" placement on these growth charts, these charts provide an appropriate goal for growth. Also available as adjunct assessment tools are two series of postnatal growth charts: the Infant Health and Development Program charts for low-birth-weight (LBW, 1501–2500 g) and very low-birth-weight (VLBW, <1500 g) premature infants for boys[16,17] and girls[18,19] and the National Institute of Child Health and Human Development Neonatal Research Network Growth Observational Study[26] projected growth charts and tables for VLBW infants (available online at http://neonatal.rti.org). These charts provide a comparison of how a LBW or VLBW premature infant grows relative to two reference populations of similar infants. Although these postnatal growth charts are based on older data, more recent charts do not exist. As noted earlier, postnatal charts represent actual, not ideal, patterns of growth for former premature infants and may be used in conjunction with but not in place of the WHO growth charts.

CDC, NCHS, and WHO Growth Charts

2000 CDC Growth Charts

In 2000, the CDC and National Center for Health Statistics (NCHS) released an updated set of growth charts called the CDC growth charts (see

Appendix I, Figures I-9 to I-18).[24] These charts are available for boys and girls aged 0–36 months for weight, length, and head circumference by age and weight for length, and aged 2–20 years for weight, height, and BMI for age and weight for height. Further details on the CDC growth charts, including data exclusions, are reviewed in the 2000 CDC report.[24] The CDC growth charts are available on the Internet (www.cdc.gov/growthcharts).

2006 WHO Growth Charts

The WHO undertook the multicenter growth reference study to generate international growth reference standards based on a large healthy sample of infants and children. Data were gathered from Brazil, Ghana, India, Norway, Oman, and the United States. The sample was selected to reflect healthy children living under conditions (breastfed, nonsmoking environments) favorable for fully achieving growth according to their growth potential. The data combined a longitudinal follow-up from birth to 24 months as well as a cross-sectional survey of the children between birth and 71 months. The growth standards derived are prescriptive rather than descriptive; that is, they represent how children should grow as opposed to how they grew at a particular time and place, thereby underscoring that the new growth charts are consistent with growth outcomes occurring under the best health practices. The 2006 WHO reference standards include weight for age, length/height for age, weight for length/height, and BMI by age for children from birth to 60 months.[3] The CDC recommends the use of these charts to monitor the growth of infants and children (breast and bottle, or infant formula fed), birth to 2 years of age, and the use of the CDC 2000 growth charts for children aged 2–20 years.[27]

When comparing the 2000 CDC growth charts to the 2006 WHO growth charts, several differences are notable. The CDC growth charts used a population-based sample that included all children regardless of health status or feeding mode. On average, the CDC sample was heavier and shorter children than that of the WHO growth study. For this reason, the 5th–95th percentile is considered as the normal range. In contrast, the WHO growth charts are based upon a healthy population of breastfed infants, and two standard deviations above and below the median is considered as the normal range. Generally, the recommended cutoffs for these two respective growth charts, the WHO (two standard deviations from the mean for age, or the 2.3rd percentile) and CDC cutoff values (5th and 95th percentiles), are fairly similar when screening for shortness and overweight in the first two years of life,[28] although some age-specific

differences occur. For example, the use of the WHO growth charts results in a higher prevalence of underweight during the first 6 months of life and a lower prevalence thereafter.[29] Another difference between the charts is that the WHO weight for length curves span from 45 to 110 cm, whereas the CDC weight for length curves span from 45 to 103 cm. The extended range for length in the WHO weight for length curves facilitates the assessment of tall children who are unable to stand (for whatever reason). As a consequence of these differences in study design, selection of the sample, and resulting growth curves, slightly fewer US children will be identified as underweight using the WHO charts, and the slower growth among breastfed infants during ages 3–18 months will appear within the normal range. Finally, gaining weight more rapidly than indicated on the WHO charts might signal early development of overweight.[27]

In summary, there are age-specific differences in the WHO and CDC growth charts owing to differences in the study design and the samples used to generate the reference ranges.[29] Accordingly, the cutoffs used to identify children at risk of nutritional complications are different for these two sets of growth charts. The WHO charts are recommended for growth assessment up to the age of 2 years, and the CDC 2000 charts are recommended for children aged 2–20 years. These growth curves are included in Appendix I and Figures I-1–I-18.

Incremental Growth Velocity

Reference data are also available for incremental growth velocity for boys and girls for weight, stature, and head circumference from 0 to 18 years (see Appendix I and Tables I-4 and I-5).[30–35] These data are presented according to the time interval between measurements (1, 3, or 6 months) and are used to evaluate growth velocity percentile (3rd–97th or 5th–95th percentiles). New incremental growth standards for breastfed infants from the WHO are available for weight, length, and head circumference.[35] These detailed tables offer weight increments (grams) and velocity (grams per day) by birth weight group for the first 60 days of life, weight increments (grams) in 1-, 2-, 3-, 4-, and 6-month time intervals, and length (centimeters) and head circumference (centimeters) increments over 2-, 3-, 4-, and 6-month intervals up to 24 months of age. Because of the rapidly changing rate of growth during the first 2 years of life, the presentation by time intervals between measurements allows for more accurate and convenient assessment. Calculating growth velocity and comparing it to standards based on a larger or smaller measurement interval can yield

inaccurate assessment. Downloadable tables can be found at http://www.who.int/childgrowth/standards/en/.

In clinical practice, the incremental tables for weight, length, and head circumference[30,33–34] are helpful in the assessment of former premature infants and other children with growth failure from any cause. The growth increments are easily divided into daily, weekly, or monthly weight gain goals. Assessment of incremental growth is more sensitive in detecting growth faltering or catch-up growth than the use of growth charts that assess static growth status at one point in time based on cross-sectional data. However, incremental growth measurements are extremely sensitive to measurement error, so attention to measurement technique is required.

Growth charts for the assessment of height and height velocity in relation to the stage of sexual maturity based on US reference data are also available (see Appendix I and Figures I-23 and I-24).[36] These charts provide height growth for early, middle, and late maturers by sex and age at which peak height velocity was reached and explain some of the variation in growth related to different stages of puberty. The height velocity charts are often used in the care of children with poor growth and chronic illnesses.

Special Growth Charts

Although the WHO and CDC growth charts are recommended for the growth and nutritional assessment of all children, a number of disease-specific charts have been published (e.g., achondroplasia, Brachmann-de Lange syndrome, cerebral palsy, Down syndrome, Marfan syndrome, myelomeningocele, Noonan's syndrome, Prader–Willi syndrome, sickle cell disease, Silver–Russell syndrome, Turner's syndrome, Williams syndrome; see Appendix I and Table I-7). The weight-for-age and height-for-age growth charts for boys and girls with Down syndrome of ages 0–36 months and 2–18 years were published in the 1980s.[37,38] However, due to improvements in care of children with Down syndrome, these charts no longer represent the growth of contemporary children. Until new growth charts become available, the AAP recommends using the growth charts for typical children to monitor growth in children with Down syndrome.[39] Many other disease- or syndrome-specific growth charts are based on small samples of children and include children with suboptimal nutritional status. Disease-specific charts may be helpful to use in conjunction with the WHO or CDC growth charts for comparison to "peers."

A set of growth charts is also available for the assessment of alternate

stature measures,[8,9] including upper arm length (infants, 0–24 months; girls, 3–16 years; boys 3–18 years) and lower leg length (infants, 0–24 months; girls, 3–16 years; boys, 3–18 years). Similar to other measures of stature, these linear growth measures are used along with weight to help determine a child's nutritional status.

ASSESSMENT OF ANTHROPOMETRICS

Nutritional status indices are essential for the clinical interpretation of growth measurements. Every nutritional assessment requires one or more of the following indices for interpretation.

Percentiles for Age and Sex

When each growth measure is plotted on a growth chart, a percentile or rank of the individual compared to the reference population is determined. For example, the 25th percentile weight for age means that the individual weighs the same or more than 25% of the reference population of the same age and sex, and the 75th percentile weight for age means that the individual weighs the same or more than 75% of the reference population of the same age and sex.[40] Percentiles are easily interpreted and used clinically. Available growth charts provide reference growth of children ranging from the 5th to 95th percentiles or the 3rd to 97th percentiles, depending on the chart. In clinical practice, the WHO and CDC recommended cutoffs should be used for screening and follow-up of healthy children. Weight-for-age and height-for-age percentiles are also used to screen for malnutrition using published classifications (see Appendix I and Table I-6). BMI percentiles are used to identify patients at risk for under- or overnutrition; however, the Waterlow criteria are still used by many practitioners. Height-for-age is an indicator of long-term nutritional status, with low height-for-age reflecting stunting. Height-for-age is generally interpreted as short (<5th percentile), normal (5th–95th percentile), and tall (>95th percentile) for children aged 2–20.

Genetic Growth Potential: Midparental Height

In the assessment of a child's stature, it is helpful to estimate the genetic potential for stature as determined by the biologic parents' adult height.[41] This is important to distinguish whether the child is achieving their genetic potential for growth based on family genetic background or whether disease and/or poor nutrition might be affecting their growth. An

adjustment for parental height is used for a child's length (0–36 months) or height (3–18 years) and is based on the mean of the height of both biological parents. This allows adjustments to the child's stature for tall or short parents. The corrections are based on the Fels Institute and older NCHS data.[42] Parental height adjustment is appropriate for use with most of the parents and children in the United States; however, it should not be used when the parents do not meet their genetic potential for height (e.g., in situations of poor health and/or nutritional status during the parental childhood or adolescence).[41]

Weight for Length/Height

Weight relative to length/height provides information on growth and nutritional status that is different from weight-for-age or length/height-for-age alone; it helps to determine and classify nutritional status in the individual patient.[43] Although there is no routinely used measure of relative weight in preterm infants, there is evidence to suggest that there should be.[44] For children aged 0–2 years, the CDC recommends that weight-for-height is assessed by determining a percentile on the WHO growth charts.[25] Weight-for-height is generally interpreted as underweight (<5th percentile using the CDC charts; <3rd percentile using the WHO charts), within normal variation (5th–95th percentile using the CDC charts; 3rd–97th percentile using the WHO charts), and overweight (>95th percentile using the CDC charts; >97th percentile using the WHO charts) and is used in screening healthy children. Weight-for-height measures are also used for screening classification of protein–calorie malnutrition (see Appendix I and Table I-6).

BMI is another measure of weight relative to height. The CDC growth charts provide BMI for age and sex from age 2 to 20 years[24,45] and is the recommended assessment tool for children aged 2 years and older. The WHO growth charts also include infant BMI graphs; however, these are not widely used; the WHO BMI-for-age curves range from birth to 2 years of age and 2–5 years of age. Because both weight and height in children change over time, there is no fixed BMI value for the diagnosis of obesity in children as there is for adults (e.g., BMI ≥ 30). The BMI percentile for age must be used for interpretation. In the United States, the 85th and 95th BMI percentiles for age and sex are used to define "overweight" and "obesity" in children.[3] A comparison of BMI-for-age and weight-for-height to predict underweight and overweight in children and adolescents (2–19 years) showed good agreement, especially in young children (2–5

years of age), but BMI had the greatest sensitivity to detect overweight and obesity across the entire age range.[46] From the International Obesity Task Force, cutoff points for BMI to define overweight and obesity in children based on cross-sectional growth studies from six countries (Brazil, Great Britain, Hong Kong, the Netherlands, Singapore, the United States) are also available.[47]

Differences in BMI at the lower percentiles of the reference range largely reflect lean mass, whereas at upper percentiles of BMI, differences are largely due to fat mass.[48] BMI is not a perfect measure of adiposity, since height is not fully independent of weight in children. Stature has been postulated to affect BMI, and in populations with taller stature, BMI may overestimate the prevalence of obesity.[49] One study comparing techniques to evaluate adiposity (BMI, isotopic dilution, skinfold equations) in stunted and nonstunted children concluded that BMI predicted percent body fat in both groups of children.[50] An additional study showed that the relationship between BMI and adiposity varied across different populations.[51] BMI should be interpreted with caution in certain clinical conditions including edema, pregnancy, in individuals with a high tumor burden, and in individuals with increased lean body mass such as in well-developed athletes. BMI is a screening tool to identify children and adolescents at risk for overweight or obesity, and further assessments to determine adiposity should be considered as clinically indicated.

Percent Ideal Body Weight

Historically, percent of ideal body weight (IBW) was used to classify the degree of over- or undernutrition into clinical classification: >120% IBW as obese; 110%–120% IBW as overweight; 90%–110% IBW as normal range; 80%–90% IBW as mild wasting; 70%–80% IBW as moderate wasting; and <70% IBW as severe wasting. IBW is also used as a clinical weight goal in the nutritional rehabilitation of a child.

Percent IBW should be used with caution. A recent study[52] compared the use of BMI percentiles and percent IBW to screen for malnutrition in children with cystic fibrosis using data from the cystic fibrosis patient registry. Among children with stature between 25th and 75th percentiles, both percent IBW and BMI yielded similar estimates of ideal weights, and in the classification of malnutrition. However, compared with the BMI, percent IBW underestimated the severity of malnutrition in children with short stature (height <25th percentile), whereas the opposite trend was

found for the subjects with tall stature (height >75th percentile). These findings support the use of BMI in lieu of percent IBW for the classification of pediatric malnutrition, especially for children aged 2 years and older. Currently, BMI charts are preferred in the classification of overweight and obesity. The use of the BMI charts for classification of degrees undernutrition is not as well established. The WHO uses weight-for-height cutoffs of <–2SD for moderate undernutrition and <–3SD for severe undernutrition[53] and has proved to be an effective screen for identifying children at risk of nutrition-related morbidity and mortality.[54]

Percent Weight Loss

The percent of usual body weight loss is an important clinical indicator of nutritional status and nutritional risk. Percent weight loss is calculated as [(previous weight – current weight)/previous weight × 100]. A 5% or greater weight loss in one month may be considered an indicator of nutritional risk in children. However, it is important to also look at the absolute weight loss as opposed to the percent weight loss alone, as this may be additionally informative and clinically meaningful. For obese children, change in BMI is recommended for monitoring weight management.[55]

Growth Velocity

Growth velocity (change in the growth parameter over time) is useful to detect a change in nutritional status and to monitor the effectiveness of nutritional and medical therapy. As discussed earlier, age- and sex-specific charts and tables are available for the evaluation of weight, stature, and head circumference growth over time.[7,30–34,36]

Body Composition

In children with many acute and chronic diseases, the nutritional assessment requires measurement of body composition (body fat and protein stores) in addition to weight, stature, and head circumference (see Chapter 4) for a detailed discussion of this topic). The measures described below also are useful to perform in critically ill children for whom weight and length/height measurements cannot be performed easily, and in those conditions with significant fluid shifts and fluid retention.

Mid-Upper Arm Circumference

MUAC can be used as a measurement of growth, an index of energy and

protein stores and can provide information on fat patterning.[3] The measurement is taken at the midpoint of the upper arm, located halfway between the lateral tip of the acromion and the olecranon when the arm is flexed at a 90-degree angle (measured and marked). For the MUAC measurement, the child should be upright with the arm relaxed by the side. A flexible, nonstretchable measuring tape is placed perpendicular to the long axis of the arm. The measuring tape should encircle the arm without compressing the soft tissue, and MUAC should be recorded to the nearest 0.1 cm.[3] This measurement should be taken in triplicate and used as an average.

Triceps Skinfold Thickness

The TSF thickness is an indicator of subcutaneous fat (energy) stores and total body fat and provides information on fat patterning.[3] For the TSF measurement, the child should be upright with the arm relaxed at the side. The TSF thickness is measured at the midpoint of the upper arm (defined earlier) over the center of the triceps muscle on the back of the arm (measured and marked beforehand). The anthropometrist lifts the skinfold with the thumb and index finger, approximately 1 cm above the marked midpoint, and places the calipers at the marked point. Two to three seconds after the handles of the calipers are released, the measurement is taken and the calipers are removed. This measurement should be taken in triplicate, used as an average, and recorded to the nearest 0.1 cm.[3]

Reference data (age and sex specific) are available for the assessment of mid-upper arm circumference (MAC) and TSF thickness[56] (see Appendix I, Figures I-34, I-35, I-38, and I-39, and Tables I-1 and I-2). The MAC and TSF measurements are used to calculate upper arm muscle area and fat area.[56,57] These are clinical indicators of total body stores of muscle and fat.

$$\text{Upper arm muscle area (cm}^2\text{)} = [\text{MUAC (cm)} - (\text{TSF (cm)} \times \pi)]^2/(4 \times \pi),$$
where $\pi = 3.14$.

$$\text{Upper arm fat area (cm}^2\text{)} = \text{upper arm area (cm}^2\text{)} - \text{upper arm muscle area (cm}^2\text{)},$$
where upper arm area $(\text{cm}^2) = \text{MUAC}^2/(4 \times \pi)$.

Dual Energy X-Ray Absorptiometry

DXA is a noninvasive, rapid, indirect, low-radiation measurement that is used to assess BMD. Bone fragility is of a concern in a variety of pediatric disorders associated with altered bone mineral acquisition or increased fracture risk. A small number of pediatric disorders involve primary bone diseases, such as osteogenesis imperfecta or idiopathic juvenile osteoporosis, where the disorder directly targets bone formation. Secondary bone disorders involve diseases that affect the skeleton through other disease mechanisms such as inflammation, malabsorption, low physical activity, endocrine disturbances, hematological disorders, and poor dietary intake, or disease treatments such as glucocorticoid therapy.[58]

DXA scans can be performed on the lumbar spine, proximal and distal femur, forearm, and whole body. The recommended sites for children and adolescents are the lumbar spine and whole body; when these measurement sites are not feasible, the distal forearm and proximal femur should be considered. For older adolescents, the proximal femur may be a useful measure to obtain for long-term follow-up, since the lumbar spine and proximal femur are the preferred sites in adults.[59] DXA scans provide information on bone mineral content (BMC) in grams per centimeter or areal BMD (aBMD) in grams per square centimeter in different skeletal regions or the whole body. Although primarily used for the assessment of bone health, whole-body scans also provide body composition measures of fat-free mass, fat mass, and percent body fat.[60] Smoothed percentiles for percent body fat assessed by DXA are now available for children aged 8–19 years.[61]

As with other growth-related outcomes, BMC and aBMD values used to assess bone health must be compared with the reference data in healthy age- and sex-matched children and adolescents to interpret bone health status. The results for BMC and aBMD are expressed as a Z-score (standard deviation score), determined by the comparison of an individual child's BMC or aBMD with the reference database. A Z-score of 0 is the median (similar to the 50th percentile on a growth chart) for the reference data, with +1, +2, –1, and –2 representing plus and minus 1 and 2 standard deviations from the reference median. The International Society of Clinical Densitometry[62] defines low BMC or aBMD as a Z-score ≤ −2, adjusted for age, sex, and body size, as appropriate. Osteoporosis in children cannot be made solely on the basis of low BMC or aBMD. Osteoporosis is defined as low BMC or aBMD in the presence of a clinically significant fracture history. A "clinically significant fracture history" consists of a long bone fracture of the lower extremities, a vertebral compression fracture, or two

or more long bone fractures of the upper extremities.[62]

Recently, the ability to assess bone health in children aged 5–20 years has been improved by the availability of reference ranges based on a large multicenter, multiethnic sample in the United States from the National Institutes of Health Bone Mineral Density in Childhood Study.[63] Sex- and age-specific reference ranges are provided for African American and non-African American for BMC and aBMD of the total body, total body less head, lumbar spine, proximal femur, femoral neck, and radius. African American children and adults have higher bone density than other ethnic groups.[64,65] Age, sex, and ancestry group reference ranges for the lateral distal femur are also available[66]; this measurement is particularly helpful for children with metal implants or contractures for whom traditional measurement sites are not feasible. The use of ancestry group-specific reference ranges (African American vs. non-African American) is used as an indicator of whether a child is reaching their genetic potential for BMC or aBMD. As recommended by the International Society for Clinical Densitometry, adjustment of BMC/aBMD values for growth in children is preferred since DXA measurements are influenced by growth status. Several techniques have been proposed.[67,68] The least biased technique requires the calculation of height-for-age Z-score, and the BMC/aBMD adjustment is based on whether a child is tall for age or short for age.[69]

The advantages of the DXA are the low radiation exposure, fast scan time, and noninvasive nature. The precision of the instrument is excellent. The radiation dose is small (<1 mrem, Hologic Delphi Clinical Bone Densitometer product specifications) or less than that received during a standard airline flight across the United States.[70] A limitation of DXA in the assessment of body composition is that it provides a two-dimensional assessment of three-dimensional structures and is unable to distinguish between cortical and trabecular bone. However, it is the most widely used clinical technique for bone health assessment. The timing of initial DXA scans and frequency of follow-up measurements depends on the clinical needs, particularly the risk factors for poor bone acquisition, disease-specific patterns of bone loss, and medical therapies.[58] Patients with poor BMD measurements are rarely measured less than six months after the baseline assessment. Bone health in children and adults is altered by weight-bearing physical activity and intake/absorption of calcium and vitamin D. Other nutrients such as protein, vitamin K, magnesium, and zinc[71–73] have also been implicated in bone health.

Cortical and trabecular bone can be measured using quantitative

computed tomography (QCT). This technique describes volumetric BMD (grams per cubic centimeter) and also differentiates between cortical and trabecular bone. Specialized peripheral QCT and high-resolution peripheral QCT scanners have been developed to decrease radiation exposure for the peripheral skeleton, and the measure derived indices of bone structure and strength for the research setting.[74] Although peripheral quantitative computed tomography (pQCT) has provided insights into the nature of bone deficits in the children with chronic disease, lack of standardization of measurement sites and inadequate pediatric reference data limit the use of these techniques in clinical care.[75]

Air Displacement Plethysmography

Air displacement plethysmography method of body composition assessment is safe, noninvasive, and fast. There are two commercially available plethysmographs from Life Measurement, Inc. (Concord, CA): the BOD POD® for use in children and adults[76] and the PEA POD® for use in infants up to 6 months of age.[77,78] A pediatric option for the BOD POD now permits assessment of children aged 2–5 years.[79] The method requires the subject to sit (BOD POD) or lie (PEA POD) within a closed chamber in minimal, close fitting, or no clothing. The subject's total body volume is estimated indirectly by measuring the volume of air that he/she displaces inside an enclosed chamber.[76] This volume is used to compute body density (body mass or weight/body volume) and in turn fat mass (kilogram), fat-free mass (kilogram), and percent body fat. Overall, the BOD POD[76,79] and PEA POD[77] provide reliable and valid estimates of body composition; however, neither device is widely available in the clinical setting at this time.

Sexual and Skeletal Maturation

The tempo of growth and body composition changes are influenced by sexual/pubertal and skeletal maturation. Many factors, such as genetics and disease processes, can affect sexual and skeletal maturation. Overnutrition and undernutrition can also affect the tempo of maturation and are therefore important in the nutritional assessment of an individual patient and their growth potential. The physically immature child with likely growth delay has the potential to catch up to the size of his/her peers once maturity advances.

Sexual maturity is assessed using the Tanner staging system by the clinician physical examination[80] or as a pubertal self-assessment form

completed by the child/parent.[81–84] Pubic hair in both males and females should be assessed using the Tanner Pubic Hair stages 1–5. Breast development in girls and genital development or testes size in boys are also categorized into stage 1–5 based on the classifications of Tanner (see Appendix I and Figures I-19 to I-22).

Skeletal maturation (or bone age) is the second method for the assessment of physical maturity. Bone age is assessed by a left hand-wrist radiograph and scored using the standards developed by Greulich and Pyle[3] or the newly revised TW3 method developed by Tanner and colleagues[3] Bone age provides a measure of "how far a given individual has progressed along his or her road to full maturity"[3] regardless of chronologic age. Sexual and skeletal maturity provide a measure of physical maturity and are valuable in formulating the nutritional assessment of children and adolescents.

Laboratory Tests

Laboratory testing is a helpful but less essential part of a nutritional assessment in most children and is presented in detail in Chapter 3. Nutritional information can be obtained from plasma, serum, urine, stool, hair, and nail samples. The latter two are rarely used clinically. Depending on the underlying medical condition and related nutritional problems from the history and physical examination, a focused laboratory assessment may be obtained. Serum albumin and prealbumin reflect the adequacy of protein and calorie intake. Because the half-life of albumin is approximately 20 days, it also reflects long-term protein stores. The shorter half-life of prealbumin (two to three days) is a better short-term indicator of calorie and protein intake. However, the usefulness of prealbumin in the hospitalized patient may be limited by the fact that it is decreased in the setting of stress, sepsis, and acute illness. Checking a C-reactive protein level may help identify when the low prealbumin level is related to stress. Anemia can be attributable to multiple nutritional deficiencies (e.g., iron, vitamin B12, folate, vitamin C, protein, and vitamin E), and a careful analysis of the red blood cell indices and peripheral blood smear will help to determine what further nutritional laboratory tests should be obtained (e.g., iron studies, vitamin levels). In premature infants, nutritional anemias can be attributable to iron, vitamin E, and copper deficiencies. Nutritional tests to check for bone health may include serum, calcium, phosphorus, alkaline phosphatase, magnesium, and 25-hydroxyvitamin D. Additional information on bone health may be

obtained from a parathormone level, radiography, and DXA scan. Specific vitamin and mineral levels can be checked when deficiency or excess states are suspected. A urine analysis, along with serum electrolytes, is useful in assessing the hydration status of the patient. See Appendix Table I-8 for a list of selected clinical findings related to nutritional inadequacies and Chapter 3 for a more in-depth look at laboratory assessment of nutritional status.

NUTRITIONAL REQUIREMENTS

The estimation of nutritional requirements is the last step in a nutritional assessment. Recommendations for energy and protein intake, as well as specific vitamins and minerals, are needed for patient care (see Chapters 8–10). The history (medical and dietary), physical examination, and anthropometric and laboratory data obtained are used to help estimate these nutritional requirements. These provide a starting point for nutritional therapy and are modified over time based on the patient's ongoing health status and response to nutritional therapy. The adequacy of the nutritional therapy provided should be vigilantly monitored in children with failure to thrive and obesity and in those patients with conditions requiring enteral or parenteral nutrition.

The DRIs[85] provide updated protein recommendations (see Appendix II; also see Chapter 6). Adequate intakes (AIs) for protein in infants 0–6 months are based on the mean protein intake of healthy breastfed infants.[3] Nitrogen intake, nitrogen balance (the minimum protein intake necessary to maintain nitrogen balance), rates of protein deposition, and efficiency of protein use all influence protein requirements. For individuals 7 months through 18 years of age, the protein recommendations are based on a combination of these factors, plus a safety factor to account for individual variation.[85] The DRIs provide protein recommendations (grams per kilogram per day) by age from birth to 8 years and by age and sex starting from 9 years. Individualized needs can be estimated by multiplying the age/sex appropriate grams of protein per kilogram per day by the body weight (in kilograms). As previously noted, DRIs may be further individualized based on the child's nutritional, medical, and growth needs and should be adjusted over time based on clinical status and response to nutritional intervention.

There are a number of methods to estimate energy needs of children in the clinical setting, including the DRIs for estimates of total energy needs,[85] the WHO[86] and Schofield[87] prediction equations for estimates of

resting energy expenditure (REE), and a direct measurement of REE (see below). The DRIs include estimated average requirements, AIs, and tolerable upper intake levels for most nutrients; see Chapter 11 for details.[3] The DRIs are used in Canada and the United States, and nutrient intakes at the suggested levels promote nutrient function, biological and physical well-being, and disease prevention. DRIs are available for vitamins, minerals (see Chapters 8–10), energy, and macronutrient recommendations (see Chapters 5–7). Generally, the DRIs provide for the nutritional needs of the healthy individual and population. Therefore, DRIs may require adjustments in the clinical setting because they do not address energy or nutrient requirements for individuals who are malnourished or have acute/chronic disease.

Both the Food and Nutrition Board DRI and the Food and Agricultural Organization of the WHO recommendations for energy requirements in children 0–2 years are estimated from total energy expenditure (TEE) measurements (by the double-labeled water methods) and estimated energy needs for tissue deposition for growth "at rates consistent with good health."[85,86] For children at this young age, estimated energy requirements (EERs) vary based on weight. The EERs for children aged 3–8 years and 9–18 years are also from TEE and energy deposition costs (20 and 25 kcal/day, respectively) and are based on age, weight, height, and level of physical activity (see Appendix II). The important role of moderate physical activity in achieving and maintaining the appropriate energy balance for optimal health is emphasized in these new recommendations. Levels of physical activity are categorized into four levels: sedentary, low active, active, and very active.[3] EER equations are also available for use in children aged 3 years and above who are at "risk of overweight" defined as a BMI >85th percentile and "overweight" as a BMI >95th percentile.[3] DRIs provide an estimate of total energy needs in kilocalories per day and may be adjusted based on nutritional, medical, and growth needs of the individual patient.

The WHO and Schofield REE prediction equations offer another method to estimate energy requirements. These equations are based on the evaluation of several thousand children and are clinically useful. The WHO equations (see Appendix II and Table II-15) estimate REE by sex, age, and weight groups and approximate the basal metabolic rate.[88] Total daily energy needs are then estimated by multiplying the estimated REE by a factor to adjust for physical activity, medical status, and/or the need for catch-up growth. The Schofield equations (see Appendix II and Table II-13) use sex, age, weight, and height of the child and may more

accurately predict REE in children with altered growth and body composition (i.e., failure to thrive and obesity).[89] Schofield REE estimates are also adjusted for the patient's activity, stress, and growth needs (see Table 2-2) to approximate total daily energy needs.

The current DRI for EER provides additional guidance beyond the 1985 FAO/WHO/UNU report for energy requirements with respect to catch-up growth in undernourished or stunted children[90] based on limited data. Similarly, the 2001 FAO/WHO/UNU report on Human Energy Requirements does not specifically address energy requirements for children recovering from moderate or severe malnutrition or chronic illnesses.[91] Direction with respect to energy replacement to allow for twice the normal growth rate for children aged 6–24 months is provided. Similar to the new WHO growth charts, the emphasis in the WHO report is prescriptive as opposed to descriptive. Thus, it indicates how individuals should grow in response to appropriate energy intake in optimal conditions rather than reflect how they were observed to grow with inadequate energy intake or excess.

TABLE 2-2 Disease and Physical Activity Factors for Adjustment of Resting Energy Expenditure (REE)

REE Factor	Disease and Activity Factors
×1.0–1.1	Well-nourished children, sedated on ventilator, extracorporeal membrane oxygenation; minimal stress
×1.3	Well-nourished children with decreased activity, minor surgery, mild-to-moderate sedation; minimal stress
×1.5	Ambulatory child with mild-to-moderate stress Inactive child with sepsis, cancer, trauma, extensive surgery Minimally active child with malnutrition and catch-up growth requirements
×1.7	Active child with catch-up growth requirements Active child with severe stress

Resting Energy Expenditure and Indirect Calorimetry

Prediction equations to estimated energy needs in children are not designed to address the special needs of children with complex health

conditions. The indications for performing indirect calorimetry for REE measurements are to determine energy requirements for medically and nutritionally complex patients. These studies can be performed in critically ill and intubated patients, provided cuffed endotracheal tubes are used to measure gas exchange precisely.

The REE approximates basal metabolic rate and can be determined by indirect calorimetry. This technique measures gas exchange, specifically, the oxygen consumed and carbon dioxide produced as a product of the oxidation of a dietary substrate. The amount of heat or energy produced from the oxidation of a specific dietary substrate is determined by the ratio of carbon dioxide exhaled to the oxygen inhaled and is referred to as the respiratory quotient (RQ). Complete oxidation of pure glucose or carbohydrate will yield equal amounts of carbon dioxide produced for oxygen consumed, resulting in an RQ of 1. For fats and mixed meals, the RQ is less than 1, since they are oxidized less than a carbohydrate only meal.

Following consumption of a mixed meal for dinner in which the macronutrient proportions are known, an age appropriate overnight fast precedes the measurements of REE. Studies are performed early in the morning in a rested, awake state, with minimal preceding physical activity/exertion. For children who are unable to cooperate or limit their movement, the test is sometimes performed in a sedated state. For infants, REE is usually measured while sleeping after a feed. The study subject lies still on a bed and gas exchange is measured usually via a ventilated hood device. The studies typically take 30–60 minutes to complete. The REE values obtained are then compared to the WHO/Schofield equations[87,88] to calculate a REE as a percent of predicted values based on age, sex, and body size. The EER can also be calculated using a physical activity level (PAL) to estimate the needs for physical activity.

Table 2-2 provides an example of PAL adapted to estimate energy requirements in children with different types of illnesses and corresponding expected physical activity. Further research is required regarding REE adjustment factors for disease states and PAL needed, and their ability to determine the energy needs of children with difference severities of malnutrition and in the context of acute and chronic illnesses.

In summary, for the estimation of energy needs in the clinical setting, an REE based on indirect calorimetry is preferred for children with complex medical and nutritional needs. If an REE measurement cannot be obtained, then the WHO or Schofield equations are recommended. These estimates of REE are then adjusted based on activity, stress, and growth

for an estimate of total daily energy needs for the individualized patient. As mentioned earlier, the new DRIs for total energy recommendations may replace these estimates in the clinical setting. However, these estimates of TEE are not as reliable as those values obtained by more accurate research methods (e.g., doubly labeled water).[92] Finally, it should be remembered that all estimates are guidelines for the initiation of nutritional therapy. Adjustments in the nutritional regimen are made over time based on objective measures, such as weight gain, laboratory data, and medical condition.

CONCLUSION

In pediatric care, adequate nutrition must support both usual nutrient requirements and nutrients needed for optimal growth and development. However, nutritional status depends in part on current and past illnesses, and a child's response to illness is affected by his/her nutritional status. Thus, understanding and addressing the nutritional status of a hospitalized child are important components of clinical care. No single measure provides an adequate assessment of nutrition status. A nutritional assessment often includes the input of many members of the health care team. This chapter provides the factors to be considered in the nutritional assessment and monitoring of a hospitalized child. Initial nutritional goals are adjusted over time as the child's medical and nutrition status change to provide optimal care.

Laboratory Assessment of Nutritional Status

Clodagh M. Loughrey, MD, MRCP, FRCPath, MA and Ian S. Young, BSc, MD, FRCP, FRCPath

Nutritional assessment in pediatrics is primarily a clinical process, based on analysis of recent dietary intake and anthropometric measurement methods (as outlined in Chapter 2: Clinical Assessment of Nutritional Status). Laboratory assessment of nutritional status plays a complementary role that may be critical in specific situations, including:

- identification of suboptimal micronutrient status;
- objective and quantitative confirmation of nutritional deficiencies suggested by clinical assessment;
- provision of baseline and serial data with which to monitor response to nutritional interventions, particularly important in prevention of the refeeding syndrome (see Chapter 13: Protein–energy malnutrition);
- provision of clues to the underlying cause of growth failure, which may be related to undernutrition (e.g., malabsorption) or have alternative explanations (e.g., endocrine disorders, chronic kidney disease);
- epidemiological studies, which seek to identify associations

between disease and nutritional biomarkers.

Table 3-1 indicates the range of tests involved in assessing nutritional status. Table 3-2 lists age- and gender-based reference ranges for Exactly which supporting laboratory tests are used, when repeated and how often, will depend on the clinical status of the patient and whether monitoring or evaluation of nutritional support is also indicated.[2]

Effective use of the laboratory service demands an awareness of nonnutritional factors that can influence results. After a discussion of potentially confounding factors in the interpretation of laboratory data, we review laboratory assessment of protein and energy status, micronutrient status, and hematological and immunological testing relevant to nutrition, before finishing with a look at technologies that are likely to dominate nutritional testing in the laboratory in the foreseeable future.

POTENTIAL CONFOUNDERS OF INTERPRETATION

Interpretation of laboratory tests must take account of the range of biological and analytical factors that can influence results.[3] Some examples of relevance to nutritional assessment are given to illustrate these factors.

Biological Variation

Interindividual variation refers to differences in true concentrations of any nutrient between individuals. These may be dependent on several parameters unrelated to diet, including physiological, pathological, genetic, and environmental influences. Analytes that are significantly influenced by factors that cannot be controlled will often be unreliable indicators of intake. Examples include:

TABLE 3-1 Components of Assessment of Nutritional Status in Clinical Pediatrics

Clinical assessment	• Clinical history • Subjective global assessment[1] • Physical examination
Anthropometric assessment	• Height for age percentiles/Z-scores • Weight for age percentiles/Z-scores • Body mass index percentiles/Z-scores

	• Triceps skinfold and mid-arm circumference percentiles
Dietary assessment	• 24-hr recall • 72-hr diary • Semiquantitative food frequency questionnaire
Laboratory assessment	• CBC (Hb, hematocrit, total and differential WCC) • Albumin (or prealbumin if available)[a] + CRP; total protein • Renal function/hydrational status: BUN, creatinine, sodium • Potassium, phosphate, magnesium[a] • Liver function tests[a] • Fasting lipids[a] • Glucose[a] • Calcium, alk phos, vitamin D • Iron studies, vitamin B_{12} and folate • Selenium, zinc, copper • Prothrombin time • Other vitamins, other minerals • Nitrogen balance studies

Abbreviations: CBC, complete blood count; CRP, C-reactive protein; WCC, white cell count.

[a]Tests of particular relevance to monitoring in nutritional support

TABLE 3-2 Reference Ranges of Select Nutritional Laboratory Values

Nutrient	Age	Males	Either	Females
Albumin (g/dL)	< 5 d (<2.5kg)		2.0–3.6	
	< 5 d (>2.5kg)		2.6–3.6	
	1–3 y		3.4–4.2	
	4–6 y		3.5–5.2	
	>6 y		3.7–5.6	
Alkaline phosphatase (U/L)	1–30 d	75–316		48–406
	31–365 d	82–383		124–341
	1–3 y	104–345		108–317
	4–6 y	93–309		96–297
	7–9 y	86–315		69–325

	10–12 y	42–362		51–332
	13–15 y	74–390		50–162
	16–18 y	52–171		47–119
Calcium (mg/dL)	1–30 d	8.5–10.6		8.4–10.6
	31–365 d	8.7–10.5		8.9–10.5
	1–3 y	8.8–10.6		8.5–10.4
	4–6 y	8.8–10.6		8.5–10.6
	7–9 y	8.7–10.3		8.5–10.3
	10–12 y	8.7–10.2		8.6–10.2
	13–15 y	8.5–10.2		8.4–10.0
	16–18 y	8.4–10.3		8.6–9.8
Calcium, ionized (mg/dL)	0–1 mo		3.9–6.0	
Whole blood	1–6 mo		3.7–5.9	
	1–17 y		4.9–5.5	
Carnitine, total, fasting	1–12 mo		15–39	
(µmol/L)	1–7 y		18–37	
	7–15 y		31–43	
Cerulosplasmin (mg/L)	1–30 d	77–253		33–275
	31–365 d	154–484		154–429
	1–3 y	253–561		286–539
	4–6 y	286–561		264–539
	7–9 y	253–517		231–484
	10–12 y	209–506		209–484
	13–15 y	198–495		209–462
	16–18 y	198–451		220–495
Cholesterol (mg/dL)	1–30 d	54–151		62–155
	31–182 d	81–147		62–141

	183–365 d	76–179		76–216
	1–3 y	85–182		108–193
	4–6 y	110–217		106–193
	7–9 y	110–211		104–210
	10–12 y	105–223		105–218
	13–15 y	91–204		108–205
	16–18 y	82–192		92–234
Copper (µg/dL)	0–6 mo		38–104	
	6–12 mo		24–152	
	1–2 y		76–193	
	2–4 y		87–187	
	4–6 y		56–191	
	6–10 y		117–181	
	10–14 y		87–182	
	14–18 y		75–187	
Ferritin (ng/mL)	1–30 d	6–400		6–515
	1–6 mo	6–410		6–340
	7–12 mo	6–80		6–45
	1–5 y	6–60		6–60
	6–19 y	6–320		6–70
Folic acid (nmol/L)	0–1 y	16.3–50.8		14.3–51.5
	2–3 y	5.7–34.0		3.9–35.6
	4–6 y	1.1–29.4		6.1–31.9
	7–9 y	5.2–27.0		5.4–30.4
	10–12 y	3.4–24.5		2.3–23.1
	13–18 y	2.7–19.9		1.7–16.3
Glucose (mg/dL)	Outside neonatal period		70–126	
Glutathione peroxidase activity, U/L (serum)	Newborn (term)		180–890	
	1–5 y		554–985	

	6–15 y		567–1153	
	16 y - adult		780–1269	
Hemoglobin (g/dL)	1–3 d	12.5–16.6		12.7–16.4
	4–7 d	12.5–16.3		12.6–15.3
	8–14 d	11.9–15.7		12.7–14.9
	15–30 d	11.6–14.2		11.6–14.3
	31–60 d	10.2–12.7		11.1–13.7
	2–6 mo	10.5–13.0		10.7–13.4
	6 mo –2 y	10.4–12.5		10.8–12.6
	2–6 y	11.0–12.8		11.1–12.9
	6–12 y	11.0 13.3		11.3–13.4
	12–18 y	11.0–14.3		11.3–13.4
Homocysteine, total (µmol/L)	2 mo–10 y		3.3–8.3	
	11–15 y		4.7–10.3	
	16–18 y		4.7–11.3	
Insulin-like growth factor-1 (IGF-1) (ng/mL)	1–30 d	2–56		7–92
	1–6 mo	2–82		5–72
	6–12 mo	2–54		8–75

[a] Although there is no consensus on optimal 25-hydroxy vitamin D levels, many experts define deficiency as a serum level less than 20 ng/mL and insufficiency as a serum level less than 30 ng/mL Ref "Evaluation, Treatment, and Prevention of Vitamin D Deficiency: An Endocrine Society Clinical Practice Guideline *Journal of Clinical Endocrinology & Metabolism*, July 2011, 96(7): 1911–1930.
Source: Adapted from Soldin SJ, Wong EC, Brugnara C and Soldin OP, *Pediatric Reference Intervals*, 7th ed. Washington, DC: AACC Press, 2011.

- Age: The use of an appropriate age-matched reference range is particularly important for some analytes, for example, alkaline phosphatase, low-density lipoprotein (LDL) cholesterol (see Table 3-2 for age-related reference intervals of a variety of analytes of potential value in nutritional assessment).
- Sex: After puberty, males exhibit greater activity in muscle enzymes due to increased muscle mass.
- Hydration: Serum concentrations of sodium, the predominant extracellular ion, are influenced to a large extent by extracellular water content (total body stores of electrolytes that are predominantly intracellular, e.g., potassium, phosphate, and magnesium, are also poorly reflected by serum levels).
- Genetic factors: Predisposition to elevated blood lipids, bilirubin, and glucose.
- Physiological factors: Diminished tissue stores of specific nutrients may be masked when blood levels are maintained by homeostatic mechanisms (e.g., calcium); the reliance of vitamin E for transport of LDL particles (vitamin E levels in plasma are strongly correlated with cholesterol concentrations, and it is thus appropriate to correct for these).
- Geographical variation (due to seasonal variation) in plasma levels of vitamin D, the major source of which is sun-exposed skin; also the altitude effect on hemoglobin due to reduced PO_2.

Intraindividual variation refers to temporal differences in true concentrations of any nutrient in a single individual and may relate to time of sampling in relation to factors such as meals, time of day, and season.

Analytes influenced solely or mainly by such controllable factors may make better nutritional indicators. An awareness of the potential influence of these factors on test outcome remains necessary for correct interpretation of test results, for example, when making day-to-day comparisons, blood should ideally be taken at the same time of day. Factors potentially influencing evaluation of laboratory parameters of nutritional status include:

- Diurnal variation of serum iron, zinc, and growth hormone
- Seasonal variation of some vitamins, notably vitamins D and C (latter due to the availability of fruit and vegetables)
- Menstrual cycle: cyclical variations in plasma lipids, proteins, calcium, creatinine, and iron have been noted
- Postprandial elevation of plasma triglycerides, iron, and some amino acids (notably the branched-chain amino acids: leucine, isoleucine, and valine)
- Recent versus longer term dietary exposure (e.g., in assessment of iron status and some vitamins, different tests can reflect different lengths of exposure)
- Exercise, which can affect blood lipids, free fatty acids, serum lactate, blood urea nitrogen, creatinine, and urine constituents, as well as muscle enzymes, depending on duration and intensity of the physical activity
- Obesity: Serum concentrations of blood cholesterol and triglycerides are correlated with fat mass
- Prolonged application of a tourniquet causes potential elevation of serum ionized calcium
- Postural effect on plasma volume: Increased hydrostatic pressure in the upright position causes increased concentrations (up to 8%) of all plasma proteins, including enzymes, hormones, calcium, hemoglobin, and other protein-bound compounds; bed rest has the opposite effect
- Effect of disease (notably when associated with an acute inflammatory process): Metabolic stress has a very significant effect on plasma proteins and some micronutrients (see sections on plasma proteins and micronutrients and Chapter 64: The Critically Ill Child for more detail).

Preanalytical variation refers to differences in the measured level of an analyte due to factors that may influence this at any stage from when the blood sample is drawn to its entrance into an analyzer system, for

example, sample collection, transport, separation, and storage.

- Sample collection proximal to the site of an intravenous infusion ("drip-arm sample") or via an indwelling central venous catheter will result in dilution of the blood with constituents of the infusion and can result in, for example, low sodium, high glucose, high potassium. Ideally an alternative limb should be selected and, if practical, the infusion should be shut off for three minutes prior to obtaining the specimen.
- Stress associated with blood drawing, particularly in children, may result in elevated blood glucose, growth hormone, cortisol, and prolactin. Higher blood lactate and lower pH may also be noted. Physical restraint may cause increased muscle enzyme activity.
- Capillary blood collection or the use of a very fine-bore needle can result in hemolysis that can affect both actual and measured levels of many blood constituents. Other potential interferents include sample lipemia, in patients receiving fat emulsion preparations, and icterus, common in neonates. Prolonged time before sample separation will have an effect similar to sample hemolysis, due to erythrocyte membrane "leakage."
- Appropriate collection tubes are of particular importance in the estimate of blood trace metal levels, which, being of low micromolar concentrations or less, are particularly susceptible to contamination by inappropriate vial constituents, including glass and rubber.
- Some analytes, such as ammonia, blood gases, gastrin, parathyroid hormone, homocysteine, lactate, and pyruvate, are unstable at room temperature and require the blood sample to be transported on ice and separated as soon as possible. This is facilitated by advance notice to the laboratory that the sample is being collected. Vitamin A is light sensitive, so samples need to be transported rapidly to the laboratory while being shielded from light to inhibit degradation.

Analytical variation refers to differences in measured levels of an analyte due to factors involved in the actual biochemical analysis.[4] Issues to consider include analytical sensitivity, specificity, precision and accuracy, and the source of the reference interval. Imprecision may arise due to methodological problems such as fluctuations in ambient temperature or automated fluid dispensing, or bias due to different

methods being used (important to consider when comparing results obtained from different laboratories) or to a problem with a batch of reagents. However, advances in instrumentation and methodology have led to improved precision and sensitivity and have considerably reduced much of the random error associated with biochemical analysis. This is generally the least significant error relating to a given analysis, with a coefficient of variation of <5% for most automated assays. Rigorous checks are made by laboratory staff to ensure that results are not issued unless control specimens fall strictly within an acceptable range of values.

Standardization of Laboratory Tests

Many nutritional biomarkers are poorly standardized so that significant between-laboratory differences may exist. Standard reference materials (SRMs) should be used where available to calibrate manufacturer or laboratory standards. Reference intervals and decision limits derived from published literature may not be valid in the absence of standardization. It is important for all laboratories to maintain good internal quality control, to participate in appropriate external quality assurance programs for each analyte, to ensure that quoted reference intervals are appropriate for each assay that they use, and that guidance is provided to clinicians about correct clinical decision limits.

Close liaison between clinical and laboratory staff will provide advice specific to each laboratory and facilitate accurate interpretation of results. However, some general points may be made, and the remainder of this chapter will review the laboratory assessment of macronutrient status followed by status of individual micronutrients.

SPECIFIC TESTS OF NUTRITIONAL STATUS

Although measurement of a nutrient in a single serum or plasma sample at a single point in time may not always be representative of its body stores, distribution, or functional metabolic significance, it is still the most practical means of evaluating availability of many nutrients. For some (e.g., folate and selenium), serum concentrations are indicative only of recent intake, whereas serum levels of vitamins D and B_{12} reflect total body stores; for others, notably plasma proteins, there is a very poor correlation between adequacy of protein intake and plasma concentrations. Various other approaches have been employed. Functional assays based on measurement of activity of an enzyme, which is dependent on a specific

micronutrient, are useful in some situations. Urine measurement is generally not helpful as excretion of micronutrients is more likely to reflect very recent intake than whole body stores. Measurement of nutrients in red cells, white cells, or other tissue stores (including hair and nails) may be a more reliable index of total body status for some nutrients, but the difficulty in isolating cell populations means that these are not often used in the clinical setting. Analysis of hair and nails is greatly subject to external contamination, for example, by shampoo and is generally not used outside the research setting, where some value may be derived from easier accessibility of samples. Similarly, assessment of stores via metabolic balance techniques and isotopic measures of nutrient status are largely research tools.

Macronutrient Assessment

Protein

Apart from water, protein is the most abundant chemical compound in the body. All human cells and tissues contain fundamental structural and functional proteins. These proteins are in a continuous state of flux, constantly being turned over through synthesis and degradation. In childhood, protein synthesis exceeds degradation so that there is net deposition of protein in new tissue. Newborn infants synthesize about 12g protein/kg/d, which falls to about 6g/kg/d by 1 year of age, and 4g/kg/d by adulthood. Insufficient dietary protein intake in childhood manifests with growth retardation.

There is no way of directly measuring the body's protein content. However, most protein is present in lean tissue (~43% in muscle and 15% in skin, in adult males), and the estimation of fat-free body mass has been used as a surrogate measure.

Somatic Protein

Assessment of lean body mass is most readily carried out in the clinical setting by anthropometric measures such as mid-arm muscle circumference (see Chapter 2: Clinical Assessment of Nutritional Status). It can also be estimated relatively inexpensively by bioelectric impedance, although this is subject to influence by factors including hydrational status. More complex methods include magnetic resonance imaging, underwater weighing, assessment of total body water, total body potassium, and total body nitrogen (see Chapter 4: Body Composition and Growth). Stable isotope studies can also be used to look at relative rates of protein

synthesis and degradation.

Because muscle creatine is directly metabolized to creatinine that is freely excreted in urine, urinary creatinine has been used as a biochemical indicator of total muscle mass. Analysis of 24-hour excretion of creatinine is compared to height-standardized reference values to give a creatinine-height index (CHI), which is expressed as a percentage of the reference value. This quick and inexpensive test has been used as a marker of muscle protein status,[5] although it is also influenced by factors that cause increased protein catabolism and by impaired renal function. A deficit of <15% is classified as mild, 15%–30% as moderate, and >30% as severe depletion in muscle mass. Urinary 3-methyl-histidine excretion may also be used as a marker of tissue breakdown, particularly in the absence of protein intake.

Nitrogen Balance

Nitrogen (N) balance is one of the oldest methods of nutritional assessment. Although subject to well-described limitations,[6] it remains an accessible tool for estimating adequacy of protein intake.

N balance studies have classically been used to define amino acid requirements,[7] since inadequate ingestion of an essential amino acid will result in negative N balance. Children (as well as others who should be actively gaining lean body mass) should normally be in positive N balance, whereas healthy adults may be said to be in nitrogen equilibrium if N loss is within 5% of N intake. Negative N balance can result from inadequate energy intake, inadequate protein intake, or catabolic stress and lean body mass breakdown. Positive N balance implies adequate energy and/or protein intake. It should be noted, however, that the mere demonstration of positive N balance does not disclose any information about protein distribution throughout the body, nor about the accumulation of lean body mass, and this test should not be used in isolation.

Urea is the main excretory product of N metabolism; approximately 85% of the body's N is lost in the urine. Other sources of N loss include fecal losses, integumental losses (e.g., desquamating skin, sweat, hair and nail growth), and miscellaneous losses (e.g., tissue fluid, saliva, vomitus, blood drawing, and menstrual losses). These losses can be high in patients with wounds or burn injuries. Since most proteins contain 16% N, dietary protein intake is customarily divided by a factor of 6.25 to estimate N intake.

The equation for calculating N balance is

$$\begin{aligned}\text{N balance} &= \text{N intake} - \text{N output}\\ &= (\text{24h dietary protien intake in grams}/6.25)\\ &\quad - \text{24 hrs UNN} - \text{Factor}\end{aligned}$$

where UUN is urine urea nitrogen (in grams), and Factor is the allowance made for uncollected N loss in stool, skin, and miscellaneous sources. In adults, this factor is 2–4 g per day, and in children, an estimate of 10 mg/kg/d may be used. If there are other significant unmeasured N losses (such as high output ileostomy), this approximation becomes invalid.

Recent work has focused on the development of stable isotope-labeled amino acid kinetic studies that do not depend on the same assumptions as nitrogen balance studies and may give more accurate estimations of amino acid requirements.[8] However, these techniques are at present confined to the research arena, and the assessment of dietary protein adequacy in the clinical setting remains inherently difficult.

Plasma Proteins

Proteins synthesized by the liver have long been used to assess protein status, decreased blood concentrations being presumed to reflect a reduced supply of amino acid precursors or decreased hepatic (and other visceral) mass. However, plasma proteins are subject to influences more dominant than nutritional status, particularly in the presence of an acute inflammatory process, and also fluid shifts. (See chapter 64: The Critically ill Child for a description of altered protein turnover in metabolic stress.) Plasma proteins may be classified according to whether their concentration increases or decreases in the setting of acute infection or catabolism (see Table 3-3). The concentrations of positive acute-phase proteins are increased in infectious or other catabolic illnesses due to preferential secretion by the liver. Conversely, negative acute-phase proteins, made up of labile protein stores that are catabolized early in starvation complicated by metabolic stress, are decreased in these circumstances. The magnitude of a positive acute-phase response is attenuated in protein–energy malnutrition.[9]

Albumin

Albumin is the most abundant protein in blood and is the most commonly used biochemical marker to assess protein status. However, its use for this purpose has significant limitations. Serum albumin is a poor marker of uncomplicated protein malnutrition (“simple” starvation); it is characteristically normal or even raised in severe advanced anorexia

nervosa. More than half of body albumin is extravascular (primarily in skin and muscle), and maintenance of normal plasma levels can occur from mobilization of these stores despite prolonged dietary protein inadequacy. Combined with its long half-life of 20 days, these factors make serum albumin a relatively insensitive marker of nutritional status and an insensitive measure of nutritional recovery. Nonetheless, hypoalbuminemia is a reasonable predictor of morbidity and mortality in hospitalized patients.

Hypoalbuminemia can be seen in situations of decreased synthesis (e.g., liver disease), increased losses (e.g., nephrosis, protein-losing enteropathy, burn injuries), or increased losses to extravascular spaces (e.g., acute catabolic stress with capillary leak). Fluid overload can also dilute albumin concentrations, and bed rest can decrease by 0.5 g/dL over several days due to redistribution into extracellular fluid.

TABLE 3-3 Plasma Proteins and the Acute Phase Response

Positive Acute Phase Proteins	Negative Acute Phase Proteins
C-reactive protein	Albumin
Fibrinogen	Prealbumin
Haptoglobin	Retinol-binding protein
Ferritin	Transferrin
Ceruloplasmin	
Alpha-1-antitrypsin	
Alpha-1-glycoprotein	

Prealbumin

Prealbumin, so named because of its proximity to albumin on an electrophoretic strip, is a transport molecule for thyroxine; hence its alternative name, transthyretin. It circulates in plasma in a 1:1 ratio with retinol-binding protein. It is subject to the same influences as serum albumin concentration, which limits its clinical utility; most notably, it is a negative acute-phase reactant. Like albumin, a single measurement may be considered to be a better indicator of those at a risk of malnutrition than those who are malnourished.[10] However, its short half-life (two days), small body pool, and high ratio of essential to nonessential amino acids make it a better measure of visceral protein status, and it may be more sensitive than albumin as a measure of nutritional recovery. In some studies, changes in prealbumin concentration have correlated with changes in nitrogen balance,[11] and it has been suggested that a weekly increase of

>40 mg/L in prealbumin concentrations reflects a switch away from hepatic synthesis of acute-phase proteins to visceral proteins.[12]

Retinol-Binding Protein

Retinol-binding protein (RBP) has similar properties to prealbumin in that it has a small body pool and a rapid response to protein–energy depletion and repletion. Its half-life is 12 hours. Since RBP is excreted by the kidneys, levels are high in renal failure. RBP levels drop in vitamin A deficiency and, as with albumin and prealbumin, with infectious or other catabolic stresses.[13]

Transferrin

Transferrin is another plasma protein sometimes used to assess visceral protein status. It is synthesized primarily in the liver and has a half-life of eight days. Transferrin concentrations are decreased in all situations, which lower serum albumin, as well as with steroid therapy, iron overload, and anemia of chronic disease. Increased concentrations are seen in pregnancy, oral contraceptive use, and iron deficiency anemia.

Reference ranges for these plasma proteins are given in Table 3-2.

Other Biochemical Indicators of Protein Status: Amino Acid Profiles

Quantitative amino acid analysis can be carried out by laboratories that possess an amino acid analyzer. In practice, actual amino acid concentrations in plasma are not as helpful as they might seem, since individual amino acids are subject to considerable physiological variation and their levels poorly reflect release or uptake by tissues. However, concentrations of the essential branched-chain amino acids such as leucine, isoleucine, and valine tend to be lower in protein–energy malnutrition and relatively higher in infection and injury. This may reflect the fact that branched-chain amino acids, unlike most others, are only minimally metabolized by the liver and are therefore available for muscle protein synthesis, which is not prominent in infection or injury.

Energy

Quantitative assessment of energy status of an individual is largely an exercise in metabolic balancing in that an estimation of energy requirements, based on measured expenditure, is compared to dietary calorific intake. It is also informative to have some perception of which

specific nutrients the body is using for energy sources, and the interpretation of this requires an understanding of how energy is normally provided. For detailed information on energy metabolism and expenditure, see Chapter 13: Energy Metabolism.

Energy Production From Nutrients

In humans, all energy is supplied by the hydrolysis of phosphate bonds in adenosine triphosphate (ATP). This is provided by the following related biochemical pathways:

1. Glycolysis (Embden–Meyerhof pathway)
2. Tricarboxylic acid (Krebs) cycle
3. Electron transport (respiratory chain)
4. Beta-oxidation of fatty acids

The substrate for glycolysis is glucose, either exogenous, from dietary carbohydrate, or derived from the breakdown of glycogen stores. The usual substrate for the Krebs cycle is acetyl CoA derived from glycolysis via pyruvate, and the Krebs cycle provides substrate for ATP production via respiratory chain reactions. However, fatty acid and some amino acids can also enter the Krebs cycle via acetyl CoA when intake is surplus or if there is a deficit in glucose availability through dietary insufficiency or depletion of glycogen stores. The main source of energy in a healthy diet is glucose derived from carbohydrate, with a smaller contribution from fat and a minor contribution from protein. Diets consisting of excess fat or protein in relation to carbohydrate will provide a greater proportion of energy in the form of fatty acids and some amino acids. Inadequate provision of energy from dietary sources triggers the mobilization of fat stores and nitrogen wasting for energy production.

Estimates of Energy Requirements

Plasma glucose, which is normally regulated by insulin and other hormones, is not a good indicator of energy status. Hypoglycemia in childhood is not a nutritional disorder but an indication for metabolic investigation. Hyperglycemia, which may be accompanied by glycosuria, may be due to frank diabetes mellitus or to a more temporary state of insulin resistance, not infrequently noted in acute metabolic stress and/or in association with parenteral feeding.

In estimating whether an individual's energy intake meets requirements, it is generally more helpful to use nonlaboratory-based procedures to assess energy expenditure. Total energy expenditure (TEE)

equals the sum of energies of physical activity, growth, obligatory losses of energy in stool and urine, diet-induced thermogenesis, and the basal metabolic rate (BMR). There are several equations for estimating energy expenditure (see Appendix II), although all are associated with a significant margin of error.

Estimates of TEE, however, are of limited value in critically ill patients, in whom formal assessment of resting energy expenditure (REE), which approximates BMR, is likely to be of most relevance. Indirect calorimetry (IC) estimates resting energy expenditure based on oxygen consumption and carbon dioxide production, providing a real-time, reproducible measurement in an individual patient with an acceptable degree of accuracy. Meticulous attention must be paid to potential confounding factors, particularly in ventilated patients. This procedure can be carried out at the bedside in a few minutes using portable gas analyzers. Recent data have suggested that targeting ICU patients at a high risk of metabolic alterations is an efficient manner of utilizing IC.[14]

Clinical Utility of the Respiratory Quotient. Calculation of the respiratory quotient (RQ), which is the ratio of carbon dioxide production to oxygen consumption, also helps to predict energy balance in addition to giving some insight into the type of fuel being utilized for energy production. Specific fuels have specific and constant respiratory quotients. Oxidation of glucose yields an RQ of 1.0, while oxidation of fat and proteins yield RQs of 0.7–0.8. With lipogenesis, the RQ can exceed 2.0; therefore, any measured RQ > 1.0 suggests that calories are being provided in excess of requirements.

Although the human body stores energy mainly in the form of fat, normal diets supply most of the energy required as carbohydrate (50%–55%), with a smaller contribution from fat (25%–40%), and only approximately 10% or less from protein. In starvation, the body tries to compensate for a lack of nutrient intake by reducing energy expenditure to divert substrate into maintaining essential functions such as the central nervous system. Initially, energy is provided by glycogen stores and amino acids derived from proteins, but the fuel source then switches primarily to fatty acids, ketones, and glycerol, with reduced protein catabolism to conserve lean body mass. This results in a marked production of ketone bodies, with a less significant urinary nitrogen loss. IC would give a low respiratory quotient of 0.6–0.7, indicating that the primary fuel source is fat. In contrast, however, in a hypermetabolic state, energy expenditure may be dramatically increased and catabolism may be rampant, with

indiscriminate concurrent breakdown of glycogen stores, body fat, and lean body mass. This state is indicated biochemically by significant urinary nitrogen losses with relatively less dramatic ketone body production. A higher RQ of 0.8–0.9 indicates a mixed fuel source.

Overfeeding Syndrome and the RQ. Postoperative stress, sepsis, trauma, burns, and chronic disease may sometimes be associated with a hypermetabolic state in which resting energy expenditure may be considerably increased. However, the nature of the metabolic stressor causes a variable response, even among subjects with similar type and severity of injury, and any increased energy demands may be offset by decreased physical activity. Accurate assessment of requirements is necessary, not only to meet increased needs with the aim of limiting protein catabolism for energy production but also to avoid causing hyperglycemia, which is often apparent in hypermetabolic patients, particularly in those receiving carbohydrate supplementation. This results in lipogenesis, as indicated by a high RQ (>1.0) and causes substantially increased CO_2 production. Overfeeding has been implicated in respiratory compromise, causing ventilatory dependence, hepatic steatosis, and increased risk of mortality. Patients with severe injury and those at extremes of life, that is, infants, especially preterm infants, and the elderly, are at particular risk.

Lipids and Fatty Acids

Fatty acids are classified according to carbon chain length and the presence or absence of double bonds. Long chain fatty acids (LCFAs) are the most common fatty acid configuration found in nature and have a backbone of 12–20 carbon atoms. Saturated LCFAs, which have no double bonds (e.g., stearic acid, C18:0), and monounsaturated LCFAs, which have one double bond (e.g., oleic acid, C18:1), can be synthesized in vivo from medium-chain fatty acids and are found in large quantities in adipose tissue triglycerides, where they constitute an important energy reserve. Both excess and insufficient intake of dietary fat can cause clinical problems, although in developed countries, by far the greater problem results from overconsumption of energy-dense foods with high saturated fat content. Part IV of this textbook comprehensively details the clinical consequences of pediatric obesity.

Plasma lipids and lipoproteins are poor indicators of nutritional status, being strongly influenced by genetic and environmental factors. Although plasma lipids tend to rise in obesity, elevations are also associated with

disease states, including hepatic, renal, and thyroid disorders, as well as diabetes mellitus. In addition, plasma low-density lipoprotein, which transports cholesterol, decreases in response to acute metabolic stress, with an accompanying drop in plasma total cholesterol. Normal and abnormal lipid metabolism is discussed in Chapter 65: Dyslipidemia.

Clinical deficiency states of essential fatty acids (EFAs) have been well documented. Although polyunsaturated long-chain fatty acids can also be mobilized for energy, their main physiological functions are structural and metabolic, for example, synthesis of cholesterol and some hormones, cell wall phospholipids, fat-soluble vitamins, and prostaglandins. LCFAs are further classified as ω-9 (omega-9, n-9), ω-6, or ω-3, depending on the number of carbon atoms between the terminal methyl group and its nearest double bond (see Chapter 7: Fats and Fatty Acids). The human organism can introduce double bonds in the ω-9 position only; ω-6 and ω-3 fatty acids must be supplied preformed in the diet and thus are essential nutrients. The EFAs in humans are linoleic acid ($C_{18:2}$ ω-6) and linolenic acid ($C_{18:3}$ ω-3), which by chain elongation can be metabolized, respectively, to arachidonic acid (AA; $C_{20:4}$ ω-6) and to eicoisapentanoic acid EPA ($C_{20:5}$ ω-3) and docosahexaenoic acid (DHA; $C_{22:6}$ ω-3), although these are more efficiently provided in the diet and are termed conditionally essential fatty acids. Arachidonic acid and DHA comprise the main lipid moiety of neural membrane structure. ω-6 fatty acids are the precursors of eicosanoids and thromboxane and may be classed as proinflammatory, whereas the ω-3 group is the basis for leukotrienes and some cytokines and may be classed as anti-inflammatory.

Infants are much more susceptible to EFA deficiency due to their limited body stores and rapid growth, resulting in high requirements. Three relatively common clinical scenarios of EFA deficiency are (1) prolonged fasting, or reliance on lipid-free parenteral nutrition, (2) extended use of a formula with a predominance of medium-chain fatty acids, and (3) fat malabsorption. The clinical signs of linoleic acid deficiency include poor growth and a desquamating skin rash, or redness and oozing in skin creases (deficiencies of zinc and biotin should also be considered with such skin features); however, it is much more common to diagnose EFA deficiency by biochemical profile.

Laboratory assessment of fatty acid status is complex. Most individual fatty acids can now be measured using sophisticated chromatographic techniques; results are generally expressed as a percentage of the total fatty acids. When EFA deficiency occurs, the nonessential fatty acid,

eicosatrienoic acid ($C_{20:3}$ ω-9) increases in serum; its three double bonds make it a "triene."Conversely, arachidonic acid ($C_{20:4}$ ω-9, i.e., a "tetraene") is reduced. A triene to tetraene ratio of >0.4 is consistent with EFA deficiency.[15] However, clinical features may be apparent at this level, and some laboratories use a lower cutoff.

Carnitine

Carnitine is a small, water-soluble molecule recognized to play two major physiological roles: (1) facilitating the transport of long-chain fatty acids, as acylcarnitines, into the mitochondrion for generation of energy and (2) facilitating the removal of short- and medium-chain fatty acids that accumulate inside the mitochondrion. The main dietary sources of carnitine are red meat and dairy products, but it can be synthesized endogenously from peptide-bound lysine and methionine. In strict vegetarians, this latter source provides more than 90% total available carnitine. It is stored mainly in the muscle (98%); the liver stores comprise 1.6% and a very minor proportion exists in extracellular fluid.[16]

Carnitine is generally considered a conditionally essential nutrient, although a clinical deficiency state has not yet been well defined in subjects who do not possess one of the rare primary inherited defects. Acquired carnitine deficiency is most likely to develop where there is reduced intake, reduced synthesis, increased requirements, or increased excretion. Both strict and lacto-ovo vegetarian children have lower plasma carnitine than their omnivorous peers (about 30% and 20%, respectively). Newborn infants, who depend heavily on lipids as a concentrated fuel source for rapid growth in early life, also have relatively low plasma and tissue carnitine, probably due to immature synthetic pathways and a lower renal threshold for excretion.[17] This may be of particular relevance in preterm infants, whose carnitine stores are very low compared to term infants. Critical illness has been reported to cause increased carnitine excretion, and parenteral nutrition formulas do not normally contain carnitine. Thus, the preterm sick infant who is maintained exclusively on intravenous feeding is likely to be at a greatest risk for functional carnitine deficiency, which may conceivably manifest with defective energy-dependent processes (e.g., hypoglycemia, respiratory distress, delayed growth, hyperlipidemia, and developmental delay). However, administration of carnitine to preterm infants has not been shown to result in improved weight gain compared to controls.

Plasma carnitine, constituting a very small proportion of total body

stores, does not necessarily reflect tissue levels, though plasma and urine are the most amenable to sampling. Carnitine is present both as free carnitine and bound to fatty acids as acylcarnitine esters. Both total and free carnitine must be measured, since reductions in total and/or free acylcarnitines, as well as altered ratios, have been described in both hereditary and acquired carnitine deficiencies. The recent advent of tandem mass spectrometry has enabled the identification of abnormal acylcarnitines, which has been of great value in expanded newborn screening for inherited metabolic disorders and may also help broaden our understanding of disordered carnitine metabolism.

Micronutrients and Major Minerals

Classical deficiency states of most micronutrients are well described but rare. See Chapter 8: Trace Elements and Chapter 10: Vitamins. Much more common are suboptimal levels that are not overtly associated with disease, and it may be in this arena that the value of laboratory assessment of nutrient status is greatest.

Childhood micronutrient requirements are weight and age dependent. Although tables of reference intake in health are widely available, little is known about the effects of disease on whether, how, and to what extent requirements might change.

Vitamin deficiency is more common among lower socioeconomic groups and those on a very restricted diet for therapeutic (e.g., phenylketonuria management) or other reasons; in adulthood, alcoholics and the elderly are at relatively greater risk. A recent observation has been the development of fat-soluble vitamin deficiency in aggressive obesity management either by pharmacological pancreatic lipase inhibition (orlistat, now sold over the counter) or by pancreatico-biliary diversion. Bariatric surgery for severe obesity associated with comorbidities in adolescence is increasingly recognized to be more effective than medical management. Data concerning late nutritional complication rates in children are not yet available, but it seems likely that the same spectrum of micronutrient deficiencies will be apparent in children as are recognized in adults after bariatric surgery (particularly when intestinal bypass is employed). In addition to fat-soluble vitamin deficiency, decreased vitamin B_{12}, iron, calcium, thiamine, and folate have all been recognized to occur.[18]

Clinical aspects of micronutrient and mineral deficiencies are given in detail in Chapter 8: Trace Elements, Chapter 9: Iron, and Chapter 10:

Vitamins. This chapter focuses on laboratory assessment of total body status of vitamins and specific issues that may influence interpretation of results. Similar descriptions relating to assessment of trace metals are given in Chapter 8, while Chapter 9 comprehensively details the laboratory assessment of iron status.

Reference intervals for vitamins and minerals, as well as various other laboratory nutritional parameters, are given in Table 3-2. As with plasma proteins, when interpreting plasma levels of micronutrients, it is important that care is exercised with results obtained during metabolic stress. In addition to the potential for whole body deficiencies of specific micronutrients via reduced intake, increased requirements, and increased losses, it is widely accepted that acute illness results in difficulty with interpretation of serum levels of micronutrients due to redistribution of vitamins and trace elements for various reasons, including acute-phase response of some carrier molecules (see Table 3-4). Monitoring of trends and magnitude of the acute-phase response (e.g., by measuring C-reactive protein concentrations) will facilitate interpretation of blood micronutrient levels. It has been suggested that plasma micronutrient concentrations can only be reliably interpreted if the C-reactive protein is <20 mg/L (plasma zinc), <10 mg/L (plasma selenium and vitamins A and D), or <5 mg/L (vitamins B_6 and C).[19]

TABLE 3-4 Effects on Plasma Concentrations of Micronutrients by Metabolic Stress

Micronutrient	Direction of Change	Reason for Change
Iron	Decreased	↓ Transferrin
Copper	Increased	↑ Ceruloplasmin
Zinc	Decreased	↓ Albumin; redistribution
Selenium	Decreased	↓ Selenoprotein P
Vitamin A	Decreased	↓ Retinol-binding protein
Vitamin B_6	Decreased	? Redistribution
Vitamin C	Decreased	↑ Transfer into tissues
Vitamin D	Decreased	? Redistribution
Vitamin E	Decreased	↓ LDL

In circumstances that make interpretation of serum concentrations difficult, indicators of function may be better predictors of status. Changes in serum concentration of micronutrients may occur rapidly in response to

recent ingestion or in the presence of the acute-phase response, whereas tissue stores or functional indicators may remain adequate. For examples, see iron, B vitamins, vitamins D and K, selenium, and copper.

Fat-Soluble Vitamins

Vitamin A

Vitamin A includes retinol/retinal/retinoic acid/retinyl ester, which are fat-soluble 20-carbon compounds that differ in their chemical group at the C15 terminal. They are yellowish oils, which are sensitive to oxygen and ultraviolet light. Retinol, the principal active form of vitamin A, can undergo reversible oxidation to the biologically similar retinal; further oxidation leads to retinoic acid that has less biological activity. Vitamin A is stored principally as retinyl palmitate. Some dietary carotenoids (~50 of them have been identified) are classified as provitamin A, since they are cleaved to produce retinol; these include β-carotene, α-carotene, and β-cryptoxanthine. The most common carotenoid in human plasma β-carotene is also the most effective provitamin A; it is a water-insoluble orange or purple solid that oxidizes in air to inactive metabolites.

The most widely used laboratory assessment of vitamin A status is high-performance liquid chromatography (HPLC) using plasma or serum.[20] Plasma concentration does not fall off until hepatic stores are critically low, so it is a late indicator. Compared to earlier spectrophotometric methods, HPLC is highly accurate, reproducible (between-batch coefficient of variation [CV], a maximum of 10%), specific, and sensitive (lower limit of detection <0.07 μmol/L). It also has the advantage that β-carotene and vitamin E can be measured at the same time. RBP has a close relationship with serum retinol levels and its use has been suggested as an alternative biomarker of vitamin A status that can be easily measured by immunoassay.[21]

Vitamin D (25-OH-Cholecalciferol)

Vitamin D status is best assessed by measuring serum levels of 25-OH cholecalciferol.[22] 25-OH D_2 and D_3 are generally considered biologically equivalent, so it is important to use an assay that measures both forms. The predominant form may vary in different countries, depending on supplement use and the preponderance of different dietary sources. Recently, epi- forms of both 25-OH D_2 and D_3 have been recognized (stereoisomers differing at only one stereo center). Their biological significance and activity is currently uncertain, but they generally account

for less than 10% of total serum cholecalciferol, although the proportion may be greater in children.[23] Clinical cutoffs for deficiency and insufficiency have been suggested in a number of guidelines, although this remains a controversial area. Vitamin D metabolites have recently been recognized as negative acute-phase reactants,[24] and levels show significant seasonal variation in nonequatorial countries depending on sunlight exposure, and these factors need to be taken into account when interpreting levels.

25-OH cholecalciferol can be measured by immunoassay or by liquid chromatography-mass spectroscopy (LC-MS). LC-MS is considered to be the gold-standard approach and allows the separation of the various forms of circulating vitamin D described earlier, if this is desired. LC-MS can also be utilized to measure the biologically active form of vitamin D (1,25-OH cholecalciferol), although the clinical usefulness of this measurement is not proven.[22]

Immunoassays show variable accuracy and bias in relation to MS-based assays. Depending on the antibodies used, immunoassays may differ in how they recognize the various forms of circulating vitamin D, and this in part explains the differences between them.[25] It is particularly important for laboratories to be aware of the accuracy of the immunoassay they use at critical decision limits.

Vitamin E (alpha-Tocopherol)

Vitamin E status is best assessed by measurement of circulating levels of alpha-tocopherol, the predominant form of vitamin E in serum. Gamma-tocopherol is present in serum in smaller amount, and other circulating tocopherols and tocotrienols are generally insignificant. Vitamin E circulates mainly within lipoproteins, of which low-density lipoprotein is the most prominent, and levels are closely related to serum lipids. Vitamin E is a negative acute-phase reactant because lipoprotein levels fall significantly as part of the acute-phase response. Measurement of serum cholesterol may therefore aid in the interpretation of vitamin E measurements, and the expression of results as an alpha-tocopherol:cholesterol ratio has been proposed.[26] Vitamin E is measured using a chromatographic approach, most commonly high- performance liquid chromatography, where alpha- and gamma-tocopherol are measured along with retinol and carotenoids.[27]

Vitamin K

Phylloquinone (K_1) is the main vitamin K produced by plants and is the main human dietary form. Vitamin K_2 (menaquinone) is produced by colonic gram-positive bacteria, although its contribution to vitamin K status is not clear. Synthetic vitamin K used in human nutrition is mostly derived from vitamin K_3 (menadione). Its relatively low plasma concentration (~1000-fold less than vitamins A and E) has caused difficulties with direct laboratory measurement, and the pragmatic solution has been to utilize functional measurement.[28]

The role of vitamin K has been best defined as a cofactor in the gamma-carboxylation of glutamyl residues in specific proteins to gamma-carboxyglutamyl (gla) residues. Important gla proteins include prothrombin as well as other clotting factors, which have led to measurement of clotting time, primarily prothrombin time (PT), as a proxy for vitamin K status. This is assessed by adding tissue thromboplastin to recalcified plasma, and the clotting time is compared with a normal control sample. Normal PT is 10–14 seconds: in vitamin K deficiency, this will rise by at least two seconds and can be greater than 30 seconds. Immunological measurement of undercarboxylated prothrombin (protein induced by vitamin K absence: PIVKA II) is more sensitive than tests of clotting and may be useful in the diagnosis of vitamin K deficiency that leads to bleeding in neonates.

Another gla protein, osteocalcin, which is present in bone matrix, has been shown to be affected by vitamin K deficiency; although any clinical implications for bone health are not yet clear, measurement of undercarboxylated osteocalcin (ucOC) may be an even better marker of vitamin K status. Direct measurement of plasma phylloquinone by HPLC[29] shows the best correlation with dietary intake, but requires several steps and is laborious, and thus not widely used. Between-batch CV is typically 11%–18%, with lower limit of detection around 50 pmol/L. Some relation to plasma triglycerides has been reported, and it may be useful to report vitamin K as a ratio to triglycerides.

Water-Soluble Vitamins

Vitamin B_1 (Thiamine)

The vitamin B_1 family consists of thiamine and its phosphate esters: thiamine monophosphate (TMP), thiamine diphosphate (TDP), and thiamine triphosphate. The principal biologically active form of thiamine is the diphosphate, TDP, a required coenzyme for the essential

decarboxylation reactions by which carbohydrates, fats, and alcohol are metabolized to produce energy. The majority of the total thiamine content of whole blood is found in erythrocytes as TDP. Because TDP concentrations are depleted from erythrocytes at a rate similar to depletion from other organs, measurement of TDP in erythrocytes or whole blood provides a good indication of the adequacy of body stores.

Historically, the most widely used test of thiamine status was measurement of the activity of the thiamine-dependent enzyme transketolase in red cells or whole blood and its increase when additional thiamine is added.[30] From these two measures, an activation coefficient can be calculated, with the normal range for erythrocyte transketolase activation coefficient (ETKAC) being <1.25. Currently, if a biochemical measurement of thiamine status is required, the measurement of thiamine diphosphate in whole blood or erythrocytes is generally preferred, most frequently by HPLC.[31] However, if thiamine deficiency is suspected, administration of thiamine should not be delayed while waiting for the results of biochemical tests.

Vitamin B_2 (Riboflavin)

Riboflavin is essential for the function of flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD), which act as coenzymes for a wide variety of oxidative enzymes that remain bound to the enzymes during the oxidation-reduction reactions. Riboflavin status is most commonly assessed using the erythrocyte glutathione reductase activation coefficient assay (EGRAC).[32] EGRAC reflects the availability of the FAD cofactor for glutathione reductase in red blood cells. Although EGRAC is generally considered to be a functional measure of riboflavin status, the exact relationship between EGRAC values and any specific function has not been well established. An activity coefficient (EGRAC)>1.30 is indicative of biochemical riboflavin deficiency. Riboflavin and its coenzyme derivatives, flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD), can be detected with high sensitivity using high-pressure liquid chromatography,[33] although these measures are not widely used for clinical purposes. As for thiamine, if deficiency is suspected, administration of riboflavin should not be delayed while waiting for the results of biochemical tests.

Vitamin B_3 (Niacin)

Niacin is required for the function of nicotinamide adenine dinucleotide

(NAD), and related metabolites and severe deficiency lead to the clinical condition of pellagra.

When biochemical assessment of niacin status is required, this has been most frequently achieved by the quantification of the major urinary niacin metabolites 1-methylnicotinamide (1-MN) and 1-methyl-2-pyridone-5-carboxamide (2-PYR), and sometimes the more minor metabolite 1-methyl-4-pyridone-5-carboxamide, typically by HPLC in timed urine collections.[34] Niacin status is usually expressed as the concentration ratio 2-PYR:1-MN or as the concentrations of the individual metabolites relative to creatinine. Spot urine samples may also be more conveniently used to assess deficiency. Measurement of whole blood or erythrocyte NAD or NADPH has also been recommended, using enzymatic assays, but some studies have suggested that these are a less reliable indicator of niacin deficiency.[35]

Vitamin B_6

Pyridoxal phosphate (PLP) is the main active form of vitamin B_6 and is involved as a cofactor in a wide range of enzymatic reactions. Measurement of PLP in serum of plasma is currently the most widely used biochemical measure of B_6 status,[36] with values <10 nmol/L generally considered to be indicative of vitamin B_6 deficiency. Urinary B_6 metabolites, specifically urinary 4-pyridoxic acid, have been utilized more rarely. Erythrocyte alanine aminotransferase (EALAT) activity coefficient was used historically but has largely been replaced by plasma PLP measurement.

Vitamin B_{12}

The serum concentration of vitamin B_{12} which constitutes true insufficiency is poorly defined. Macrocytosis is a well-known but late sign of B_{12} deficiency. Vitamin B_{12} is a cofactor in the remethylation of homocysteine, and a raised plasma homocysteine can demonstrate a metabolic “block” due to B_{12} deficiency. However, B_{12} is not the only cofactor involved in this pathway: folate deficiency in the presence of a common genetic polymorphism will also result in a raised homocysteine. A more specific functional test of B_{12} deficiency is urinary methylmalonic acid: this metabolite is not normally seen, but appears in urine if there is a block in the conversion of methylmalonyl CoA to succinyl CoA, for which

B_{12} is the only cofactor.[37] However, the most sensitive indicator of B_{12} status is currently considered to be serum holotranscobalamin measured by immunoassay, using a locally determined cutoff which is assay-dependent.[38]

Folate

Folate status is most commonly assessed by measurement of serum folate, although red cell folate may also be used.[39] Red cell folate reflects longer term folate status, but also shows greater analytical variability due to the sample preparation steps that are required. In addition, the red cell assay is more expensive and less convenient, and genetic variation of methylenetetrahydrofolate reductase (MTHFR) influences red cell folate values significantly.[40] For all of these reasons, serum folate measurement is the most widely used approach.

Vitamin C

Plasma ascorbate is the most commonly used biomarker of vitamin C status and can be measured by either enzyme assay with fluorimetric detection[41] or chromatographic techniques, most commonly HPLC.[42] Ascorbate is unstable in serum or plasma, so samples need to be stabilized by the addition of metaphosphoric acid shortly after sample collection before analysis. Clinical symptoms of vitamin C deficiency are rare if plasma ascorbate is >10 μmol/L. Leucocyte ascorbate has been suggested as a better indicator of body stores of vitamin C but is much more cumbersome to measure, and reference intervals are not well described.

Minerals and Trace Elements

Assessment of the status of key transition elements, including iron, selenium, zinc, copper, molybdenum, and manganese is described in the subsequent chapters.

Other Laboratory Indicators of Nutritional Status

Hematological Tests

The complete blood count is readily available and may yield useful early, though nonspecific, nutritional indicators.

Anemia may be attributable to deficiencies of iron, vitamin B_{12}, or folate, or a combination, and red cell indices may be helpful in discriminating between these. The total lymphocyte count (TLC), the

product of the total leucocyte count and the percentage of lymphocytes on a peripheral blood film, has been correlated with general nutritional status. Decrease in TLC to <15,000/uL is frequently noted in malnutrition and may be the only abnormal laboratory parameter noted in uncomplicated malnutrition, such as due to anorexia nervosa. It has been suggested that TLC 800–1200/uL represents a moderate nutritional deficit, while TLC < 800/uL indicates severe malnutrition.[43] However, lymphopenia is not specific for malnutrition and is not invariably present.

Immunological Tests

Cutaneous anergy— delayed or absence of response to subcutaneous administration of antigens such as *Candida albicans*, tetanus, diphtheria, and so forth—is consistently to be demonstrated in moderate to severe malnutrition, although lack of specificity is again an issue, as well as the requisite delay in result. There is growing recognition of the specific effects of nutrient status on immunocompetence, and sophisticated immunological testingis beginning to find a role in nutritional research, particular in intervention studies.[44]

Immune defense mechanisms can be organized into three main groups: physical defenses (mucosal epithelium and secretions), cellular responses, and humoral or circulating defenses (i.e., antibodies). Innate immunity comprises the generic cellular responses, including phagocytes, neutrophils, natural killer cells, and the complement system as well as the mucosal barriers to pathogens. Adaptive immunity is derived from the host response to recognition of nonself-antigens and involves B lymphocytes, which generate circulating antibodies, and T lymphocytes, which mediate cellular immunity resulting in immunological memory. Specific micronutrients have been shown to work in synergy to support these different components[45] (Table 3-5).

Despite the important roles that individual micronutrients play in maintaining immunocompetence, specific tests of immune competence, as stand-alone observations, have not found an important role in nutritional assessment. Although diet is one of the major exogenous factors involved, immune function tests are also influenced by a spectrum of endogenous and other exogenous factors unrelated to nutritional status, such as gender, age, lifestyle (e.g., smoking/exercise), psychological stress, and hormonal factors (e.g., menstrual cycle).[46] Also, the clinical relevance of small changes in single markers of immune function is far from clear: there is considerable redundancy in the immune system, such that change in functional capacity of one component due to nutritional deficiency may be

compensated for by a change in the functional capacity of another which is not dependent on the deficient nutrient.

TABLE 3-5 Specific Micronutrients Involved in Different Groups of Immune Defense Mechanisms

Mucosal Barriers	Cellular Defenses	Antibody Production
Vitamin A	Vitamin A	Vitamin A
Vitamin C	Vitamin B_6	Vitamin B_6
Vitamin E	Vitamin B_{12}	Vitamin B_{12}
Zinc	Vitamin C	Vitamin D
	Vitamin D	Vitamin E
	Vitamin E	Folic acid
	Folic acid	Zinc
	Iron	Copper
	Zinc	Selenium
	Copper	
	Selenium	

The observation that specific dietary constituents may exert a variety of positive effects on the immune system has led to investigation over the past 1–2 decades of the potential role of "nutritional immunomodulation" in ill patients. As a result, immune function tests may find a more useful role in the assessment of the effects of dietary manipulation on immune response. Such tests include in vivo measurement of response to controlled exposure to attenuated or killed microorganisms; this functional assessment has clear clinical relevance. Ex vivo assessments of immune function involve in vitro assays following in vivo dietary modification; although of less direct clinical relevance, these assays may shed light on mechanisms of effects noted in in vivo experiments and may in addition be more sensitive. Measurement of circulating cells and factors give less functional information in that they do not assess immune response to a challenge. A review by Albers et al.[46] scores a variety of immune function markers for their usefulness, based on biological relevance, biological variability, and practical feasibility and gives most weight to four in vivo markers and least to circulating markers. It is recommended that in vivo assessments are used and can be supported by the medium-scoring markers that will give additional information. If only the medium-scoring markers

are available, full combinations of markers should be used to provide the most reliable conclusions.

Emerging Technologies

The emergence of genome-based approaches may in years to come revolutionize the approach to the assessment of nutritional status.[47] However, currently, these techniques are mainly utilized for research purposes. Given the broad impact of many dietary constituents on physiological function, an integrated approach that includes assessment of the genome, epigenome, transcriptome, proteome, and metabolome may ultimately be required. This will present very considerable challenges in terms of data handling and interpretation, which will require substantial processing power and intelligent systems to aid in interpretation.

Genomics

Genetic variation may influence absorption, metabolism, elimination, or biological effects of nutrients.[48] For instance, genetic variation of the methylenetetrahydrofolate reductase gene significantly affects red cell folate status at a given level of folate intake. In turn, the intake of key nutrients may impact on gene expression, altering the transcriptome or epigenome through, for instance, altered methylation (in the case of folate). In the future, it is possible that genotype-specific dietary recommendations may be made.

Proteomics

As a consequence of impact on gene expression, intake of key dietary constituents impacts on the proteome and patterns of protein expression may act as dietary signatures. Dietary components may influence protein expression or posttranslational modification of proteins, and limited availability of cofactors may lead to modification of protein function, including enzyme activity, regulatory properties, or molecular recognition.[49]

Measurement of expression or activity of key individual proteins, through activity assay (for instance, glutathione reductase for selenium) or measurement of mass by immunoassay (for instance, holotranscobalamin in the case of vitamin B_{12}) is well established. Broader assessment of the proteome through mass spectroscopy-based techniques or two-dimensional gel electrophoresis is currently mainly a discovery technique and is limited by relatively poor reproducibility and high coefficients of variation.

Quantitative mass spectroscopy using stable isotope-labelled standards is beginning to gain traction for individual proteins but is currently beyond the scope of most routine laboratories.

Metabolomics

The metabolome is particularly attractive as a marker of dietary intake and nutritional status, since there is a close relationship between diet and metabolism. Large numbers of metabolites can be measured simultaneously using modern analytical approaches, and alterations in specific metabolites or patterns of change characteristic of certain nutritional deficiencies or excess might be easily identified.[50]

Important challenges in relation to assessment of the metabolome include defining preanalytical conditions for sample collection, and the influence of metabolites of pharmaceutical agents, particularly in the context of polypharmacy. In general, currently, urine is the preferred matrix rather than serum or plasma. Two main analytical approaches are used—mass spectrometry and nuclear magnetic resonance.

CONCLUSION

Laboratory testing is a significant component of nutritional assessment but is best interpreted in conjunction with clinical, dietary, and anthropometric evaluations. Laboratory assessment of nutritional status in children may be most meaningful in the investigation of suboptimal micronutrient status, but also plays an important role in gauging response to nutritional support and detection of complications. Clinicians must be aware of any limitations of specific laboratory tests, including limitations posed by the specific methodologies and instrumentation utilized by a particular laboratory. Appropriate liaison between clinical and laboratory staff allows more effective use of laboratory services, for example, by allowing meaningful discussion regarding test availability, response time, or clinical utility of newer tests and technologies to meet clinical and budgetary requirements.

Body Composition and Growth

4

Kenneth J. Ellis, PhD

Traditionally, the most basic model of body composition partitions the body into two compartments: fat mass and all the other tissues, called the fat-free mass (FFM). Fat mass is based on the ether-extractable lipids in the body, whereas adipose tissue contains not only fat, but also includes its supporting cellular and extracellular structures. A glossary of other commonly used body composition terms is given in Table 4-1. Although FFM is treated as a single compartment, it consists of many different tissues. The three major components of FFM are water, proteins, and minerals, with water being the most abundant. In very obese individuals, however, the excess adipose tissue mass can equal or exceed the amount of body water. The concept of FFM was derived mainly to provide a way to estimate the body's fat mass using the two-compartment (2-C model). In general, some property of the FFM, such as body water, is measured and assumed to be directly proportional to the total FFM. Fat mass is then calculated as the difference between body weight and the estimate of FFM. The 2-C model continues to be widely used, partly because of the simplicity of its interpretation. The basic assumptions used with this model, however, can be problematic when the composition of FFM changes with any number of conditions.[1–4] To address this limitation, more advanced multicompartment models have been developed in which more than one component of the FFM is measured.[5]

TABLE 4-1 Glossary of Body Composition Terms

Term	Definition

Fat mass	All ether-extractable lipids in the body, including nonessential lipids (~90%), triglycerides, and essential lipids
Essential lipid	Lipids in bone marrow, cell membranes, phospholipids in neurons
Adipose tissue	Fat (80%–85%) and its supporting cellular and extracellular structures (2% protein and 13%–18% water)
Lean body mass (LBM)	Body mass free from adipose tissue
Fat-free mass	Nonfat mass, with four major constituents: water, protein, glycogen, and mineral; equals LBM plus nonfat components of adipose tissue
Total body water (TBW)	Total water amount in the body
Intracellular water (ICW)	Water content of the cellular compartment
Extracellular water (ECW)	Non metabolizing fluid surrounding cells; distributed primarily in the plasma and interstitial fluid compartments
Body cell mass	Cellular components of the body
Extracellular solids	Extracellular chemical compounds distributed in organic (collagen, reticular, and elastic fibers) and nonorganic (bone minerals, bicarbonate, and citrate) material
Bone mineral content (BMC)	Bone mineral content (g/cm), as measured by absorptiometric techniques
Bone mineral density (BMD)	Ratio of BMC to bone width (g/cm^2), as measured by absorptiometric techniques

MULTICOMPARTMENT MODELS

The advances in methodology allow for the measurement of several body compartments at the same time overcoming the limitations of the assumptions of the 2-C model. As a result, body composition analysis has evolved to three and four compartment models. These models have different levels of complexity as illustrated in Figure 4-1.[6–8] The five models are atomic, molecular, cellular, functional, and the whole body. The different equations and methods used to estimate components at the five levels are presented in Table 4-2.

Atomic Level

In the human body, there are more than 50 different elements, but six (oxygen, carbon, hydrogen, nitrogen, calcium, and phosphorus) account for more than 98% of body weight.[9] The remaining 44 elements make up less than 2% of body weight.[8,9] For years, elemental analysis of the human body was possible only in cadavers, which could be confounded by the potential alterations in composition caused by disease and death. Because of the availability of neutron activation analysis (NAA), it has been used for the in vivo measure of eight elements directly (hydrogen, carbon, nitrogen, calcium, phosphorus, sodium, chlorine, and magnesium). Whole-body counting can provide values for body potassium, and isotopic techniques can be used to measure body water. This information, determined at the atomic level, has been used to calculate more than ten body composition compartments in living humans.[10,11] The equations in Table 4-2 illustrate how atomic data can be used to calculate multiple levels of body composition.[8,11]

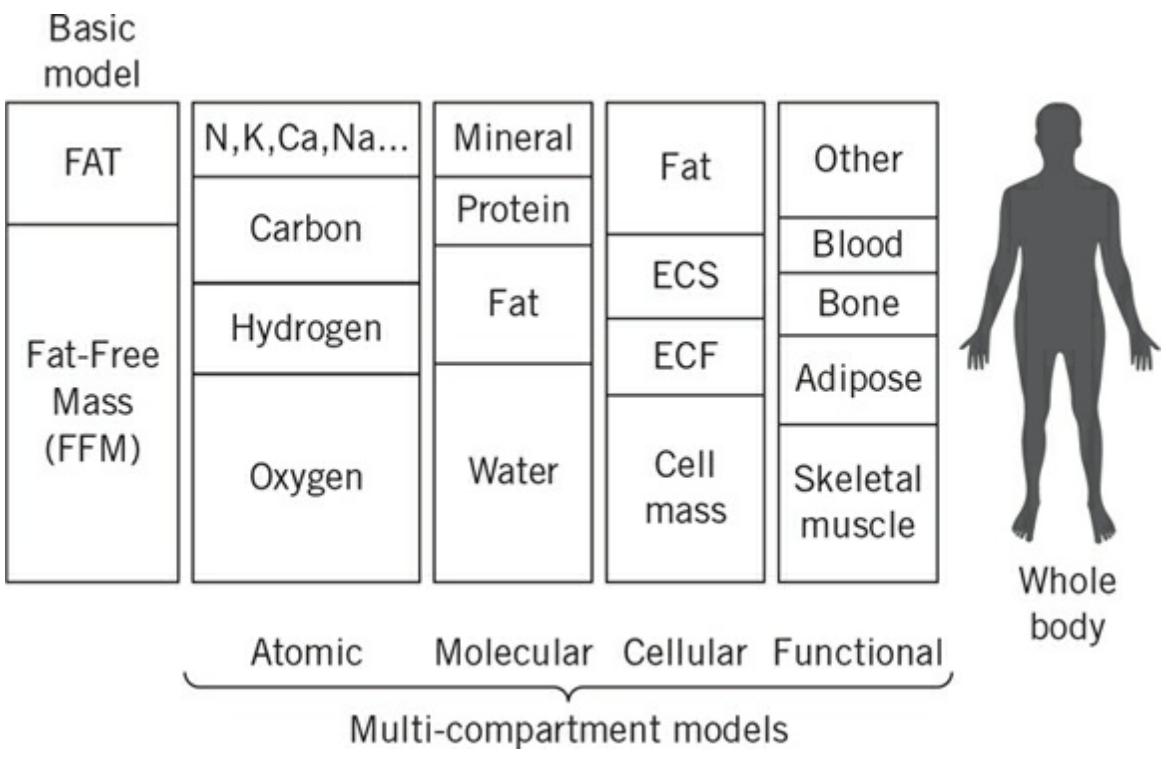

Figure 4-1 Body composition models (reproduced from

TABLE 4-2 Equations and Methods for Measuring

Body Composition by Level

Atomic level	Equation or Method
Na, Cl, Ca, N, C, P	Neutron activation analysis
K	^{40}K counting
H_2O	Isotope dilution
Body weight = TBO + TBC + TBH + TBN + TBCa + TBP + TBK + TBCl + TBNa + TBMg	
Molecular level	
Fat	Carbon in fat*/0.774
TBW	Isotope dilution
Total body protein	TBN × 6.25
Bone mineral	TBCa/0.364
	DXA
Soft tissue mineral	
K	TBK
Mg	TBK × 0.06
H_2PO_4-	TBK × 1.7
Na	TBNa
Cl	TBCl
HCO_3	TBCl × 0.43
Body weight = lipid mass + total body water + total body protein + bome mineral + soft tissue mineral	
Cellular level	
Body cell mass	0.00833 × TBK
ECW	Bromine isotope dilution
	Multi frequency bioelectrical impedance Analysis (BIS)
Extracellular solids	TBNa + TBCl + TBHCO3 + TBCa/0.177
Fat	Carbon in fat*/0.774
Body weight = body cell mass + extracellular water (ECW) + extracellular solids + fat	
Functional level	
Adipose tissue	Computed tomography (CT)
	Magnetic resonance imaging (MRI)
	Ultrasound
	Infrared interactance
	Anthropometry
Skeletal muscle	0.0196 × TBK – 0.0261 × TBN

Bone	TBCa
	DXA
	Quantitative CT
Other tissues	DXA
	CT
	MRI
	Ultrasound
Body weight = adipose tissue + skeletal muscle + bone + other tissues	
Whole body level	
	Anthropometry
	Densitometry
	Total body electrical conductivity
	Bioelectrical impedance

* Carbon in fat = TBC – [(3.37 + TBN) + (0.052 × TBCa) + (0.085 × TBCl)].
Data from Refs. 6,8,11.

Molecular Level

The molecular model of body composition is usually based on three main chemical groups: water, mineral, and organic.[5] The minerals are further separated into bone mineral and soft tissue components, and the organics are mainly defined by protein and fat components. Therefore, Body weight = fat (lipid mass) + total body protein + bone mineral + soft tissue mineral + TBW.[5,6] At this level, TBW can be determined directly by isotope dilution and bone mineral by whole-body dual-energy X-ray absorptiometry (DXA).[8] The remaining components must be estimated indirectly. For example, protein can be determined from TBN by making two assumptions: that all body nitrogen is in protein and that 16% of protein is nitrogen.[8,11] Total body fat can be calculated by subtracting the nonlipid carbon from total body carbon and then converting this into fat, assuming that triglycerides are 77.4% carbon.[12] Bone mineral can also be calculated from total body calcium.[11] An important aspect of these estimates is that there are no known age dependency on their relationships. That is, the proportions of carbon, nitrogen, and calcium are known and relatively constant for lipid, protein, and bone mineral, respectively.

Cellular Level

At the cellular level, the body is divided into four main compartments:

body cell mass (BCM), extracellular fluid, extracellular solids, and body fat. BCM is the work performing, oxygen consuming tissues of the body. The extracellular fluid is the fluid surrounding the cells, while extracellular solids consist of the organic and inorganic tissues, for example, collagen, reticular, elastic fibers and the mineral content of bone.[8] Extracellular fluid volume can be quantified directly by bromine dilution methods. Body cell mass can be estimated from the measurement of TBK or on the basis of the difference between TBW and ECW. Extracellular fluid and solids can also be estimated from the measurements of total body calcium, sodium, and chlorine by neutron activation analysis (NAA).[6,8,11]

Functional Level

The fourth level of complexity comprises tissues, organs, and systems. Three specific tissues are particularly important in body composition studies: bone, adipose tissue, and muscle, which together comprise about 75% of body weight.[8] The methods used to estimate these major compartments are usually the imaging techniques, such as computed tomography (CT), nuclear magnetic resonance imaging (MRI), and ultrasonography (US). These techniques are used to determine tissue volumes for regional and total body adipose tissues, skeletal muscle, liver, kidney, heart, spleen, and brain volumes. Alternately, DXA can be used to estimate the general compartments of fat mass, bone mineral, and skeletal muscle mass. Measurements of TBK, and body nitrogen and calcium by NAA allows the equal estimations of skeletal muscle mass, protein mass, and bone mass.[6]

Whole Body Level

The whole body level for body composition assessment is based on measurements of body size, shape, and physical characteristics.[8] The techniques used are mainly anthropometry, while body densitometry can also be considered part of this level. Anthropometric evaluations, although less accurate, are much simpler and easier to perform than are some of the techniques needed for the other four levels. Anthropometric techniques are often well suited for large-scale population studies or for field work. More recently, air displacement plethysmography (ADP), a densitometric method, has been used with children 5 years and older, as well as for infants until about 6 months of age.

MEASUREMENT METHODS

A number of methods have been developed for measurement of the composition of the human body.[5,6,8,11,12] Each of these methods provides information that relates, directly or indirectly, to one or more of the various components of the different body composition models described in the previous section. In some cases, these models are method-driven, meaning that to use that particular model, a specific measurement method must be used. Clearly, a multicompartment model would be the most informative, but these advanced models tend to require a combination of several different methods. Also, whether the information is to be used at the population level, such as in epidemiological or field studies, or for the assessment of an individual, such as in a clinical setting, can also strongly influence the choice of models and methods. Once a measurement is performed, the measured parameters have to be translated to their corresponding body composition value(s), which usually requires several assumptions.[6,13] For adults, the translation from the measured value to a body composition value often assumes relatively constant relationships, with occasional minor adjustments for age, sex, and ethnicity. For infants and children, these relationships are not always as stable, and can be easily perturbed during periods of rapid growth and sexual maturation. Of the various methods described in this section, only a few research centers can perform all of the assays. The information obtained from a combination of these assays, however, provides our best estimates of body composition and often serve as the basis for calibration of less sophisticated techniques. In most cases, only one of the methods is available to the investigator or clinician.

Anthropometry-Based Techniques

The measurement of body weight is probably the most basic of anthropometric measurements of the human body. This measurement requires a minimum of equipment, can be obtained relatively quickly, and as frequently as needed. Height or stature may be the second most measured parameter. These measurements are routinely used in anthropological and epidemiological studies, apart of public health surveys, and are commonly obtained as part of routine clinical exams. Often, the classification of subjects vulnerable to under- or overnutrition is based on these measurements alone. In recent years, BMI (body weight/stature^2) has been promoted as an international standard for the assessment of obesity in children[13,14] despite its limited relationship with

body fatness.[15]

Clearly auxology has contributed to our basic understanding of the general patterns of physical change of the body with growth and development. Many anthropometric-based measurements have been proposed for assessing body composition.[16] Whenever one of these indices has been directly compared with a more direct measure of body composition, the correlations have usually reached statistical significance only on a population basis. For the individual, however, these indices tend to be less reliable, except for extreme outlines in the population. Although, BMI appears to have the best validity of all the different weight-and-height indices,[17] its sensitivity and specificity for the individual is limited.[15] Standardized BMI curves for children (Appendix 1) are available from the US Centers for Disease Control and Prevention. Use of this index alone is quickly coming a routine part of health screening programs, including those in schools. The measurement of the subcutaneous fat layer using skinfold thickness is another anthropometric technique that has been used for many years. This technique is based on the assumption that the thicknesses of the fat layers below the skin are proportional to the total amount of fat in the body. In practice, skinfold thickness measurements need to be performed at standardized regions on the body and by experienced and well trained examiners The triceps has been the site most frequently selected, but no single body region appears to be consistently representative of the whole subcutaneous fat layer, much less the total fat mass. A number of different prediction equations have been published, some using the same measurement sites. To learn more on this topic, we would direct the reader to the literature for the use of skinfold measurements.[18,19] Alternate techniques, without the use of calipers, have been developed for the measurement of the subcutaneous fat layer. These techniques are based on the differences in the absorbance and reflectance properties of skin, fat, and lean tissue at different wavelengths.[20,21] These techniques are well tolerated by the subject being examined, and provide an alternative to skinfold measurement. Only a limited number of studies in different age groups have reported using this technology.[21–24] However, many of the same limitations for skinfold measurements equally apply, namely extrapolation to total body fat content. These techniques may be more useful for monitoring intrasubject changes than for intersubject comparisons. Also, there are no studies where it has been used in conjunction with a more direct method for measuring total body fat.

In Vivo Chemical Analyses

Historically, analytical chemical analyses of tissues are the quantitative basis for human body composition, and have contributed to our understanding the metabolic function of tissues. The advancement of modern physics lead to the development of nondestructive nuclear-based assays of tissue samples, which was later transferred to direct in vivo analyses in the 1970s.[25,26] The method, called neutron activation analysis (NAA), is based on the principle that when atoms are exposed to neutrons, there is a finite probability that some of the neutrons will interact with the nucleus of atoms, resulting in the production of gamma-rays that are characteristic of the interactions. These gamma-rays can be produced during the time of the neutron interaction, or observed for several minutes following the exposure to a low-intensity beam of neutrons. For body composition measurements, the gamma rays are detected external to the body.[25,26] Using this approach, the total body content of calcium, sodium, chlorine, phosphorus, nitrogen, carbon, oxygen, and hydrogen have been measured in humans.[26–28] This in vivo elemental information can be used for the chemical model, or converted to estimates of body protein, water, fat, and bone mass.

Body Potassium Measurement

A very small fraction (~0.012%) of all potassium atoms found in nature is radioactive. This isotope, called ^{40}K, decays emitting high-energy gamma-rays (1.46 MeV) about 11% of the time. At this energy, about half of the gamma-rays produced within the human body will escape and can be detected external to the body. To improve the precision of this measurement, the detectors must be shielded to reduce background interference from gamma rays originating from other radioactive sources in the environment. This type of instrument is called a whole-body counter.[26] The availability of stable electronics, high-efficiency detectors, and PC-based analyzers, has significantly decreased the cost of this technology. When properly calibrated, the whole body counting procedure can produce an accurate and precise measure of TBK, which is directly related to body cell mass, the actively metabolizing tissues in the body.[29] Since most of TBK is in the ICW volume at a relatively constant concentration, this measurement has also been used to estimate the ICW volume.[26] TBK is no longer recommended as a measure of the FFM because changes in the ECW compartment of FFM can occur without changes in body potassium. The most recent application of TBK is for

modeling of total body protein mass in adults and children.[30]

Body Water Measurements

Isotope Dilution Methods

Body water is the major component of the FFM, and is also the major contributor to body weight, with the exception of fat in extremely obese subjects. Hence the measurement of TBW may give one of the most reliable estimates of FFM, and when coupled with body weight, an estimate of body fat mass. The most common procedure used for the measurement of TBW is the tracer dilution technique, using nonradioactive isotopic labeled water. At least two body fluid samples are needed (blood, urine, or saliva), one before administration of the oral tracer dose and one at least several hours later. Both deuterium and ^{18}O-labeled water are used, with the quantitative assays based on mass spectroscopy or infrared absorbance.[31] The fluid samples are usually frozen for later analysis. In the clinical setting, this approach would not be practical when there is an immediate need for the results. To repeat the assay, there must be a sufficient time lapse in order for any earlier tracer to clear the body. Typically, this is 3–5 times the biological clearance of the tracer. Partly for these reasons, alternative methods such as bioelectrical impedance have been developed for the assessment of body water.

In a normally hydrated state, the ratio of TBW to FFM is assumed relatively constant for the individual. On average, for healthy adults and adolescents, this ratio is typically 0.732. At birth, the ratio is much higher (~0.80–83) and decreases during early infancy and childhood. Therefore, to estimate fat as the difference between body weight and FFM, age- and gender-specific adjustments for the hydration of FFM should be used.[1] The extracellular component of body water can also be determined using nonradioactive dilution methods. Bromide is the most commonly used tracer, and its concentration in blood or saliva is analyzed using either HPLC or X-ray fluorescence.[6] For infants, a sucrose tracer has also sometimes been used.[2] When these assays are obtained in conjunction with the TBW measurement, the difference between TBW and ECW be used to indirectly estimate ICW volume. Again, repeat measurements are limited by the amount of time needed for the tracer to clear the body from any earlier study. Partly for these reasons, multi frequency bioelectrical impedance methods have been developed for the assessment of extracellular body water volume in addition to TBW.

Bioelectrical Methods

In electrical terms, impedance is a measure of a conductor's frequency dependent opposition to the flow of an alternating electric current.[20] Because the body's fluids contain electrolytes, and the lean tissues in the body contain virtually all of body water, these tissues can conduct an electrical current. This is the core basis for the bioelectric impedance analysis (BIA) methods used to measure body composition in humans. How these tissues conduct a current is also dependent on the capacitance properties of the cells. At lower frequencies, the cell membranes are assumed to act like capacitors and not allow current to pass through the cells. At high frequencies, the capacitance properties of cells are significantly diminished, and the current is now assumed to also pass through the cells. That is, at low frequencies the current passes mainly through around the cells (e.g., the extracellular fluid volume), while at high frequencies the electric current passes both around and through cells (total body water). Since fat is a poor conductor of electricity at any frequency, a measurement of the body's impedance or resistance should be related to the body's water content. Most BIA instruments use a single frequency (50 kHz), while some instruments can make measurements at multiple frequencies.[33] The short-term precision of BIA measurements for an individual is good, but the accuracy of its translation of body composition values continues to be questioned in some studies.[34–36] Unfortunately, this has lead to a multitude of BIA-based prediction equations in the literature, most of which are incompatible with each other.[6,25] One factor that may account for some of these inconsistencies is the difference in body shapes among individuals of the same stature, as well as the placement of electrodes. In the simplest electrical model, the assumed shape (geometry) of the conductor affects the circuit's impedance value. In the case of the human body, where the electrodes are typically placed near the wrist and foot on one side of the body, the smaller cross-sectional areas of the arm and leg contribute the most to the resistance value. This is also the case when multiple segmental measurements are obtained. Altered states of hydration, such as edema or malnutrition can influence the resultant impedance values leading to inaccurate estimates of the true body composition. In diseased populations, the predicted body composition values for an individual should be independently verified with a more established method.[8,11,25] Recently, advanced models for the multifrequency method have been reported.[37,38] The single-frequency BIA method, however, continues to be the popular choice in many research

studies.

The BIA methods are not the only technique used for measurement of the body's resistance to the passage of an alternating electrical current through the body. If the body passes through an external uniform electromagnetic field, the body's tissues will interact with the external field. This method, developed in the 1980s is called.[39] The short term precision of the measurement was good and this approach showed promise.[6,35,36] However, the lower cost of the BIA method and that it could be performed relatively quickly, and offered portability, the total body electrical conductivity was not developed further.

Densitometry Methods

To measure the density of the whole body, one needs to accurately know the body's weight and volume, with density defined as weight/volume. Body weight can easily be measured with high precision with an accurate scale. A precise measurement of body volume, on the other hand, is more difficult to obtain. The classical method, used since the 1950s, has been to measure a subject while totally submerged underwater and with as much air as possible exhaled from the lungs.[29] By comparing the subject's weight in air and underwater, the volume of water displaced is the same as the subject's body volume. A person's weight is equal to the sum of its body composition compartments. Likewise, a person's volume is equal to the sum of the volumes of the same compartments. If the body is composed of two parts (e.g., fat and FFM), and the density of each is known, then the weight and volume equations can be rearranged to calculate the mass of either compartment.[31] This is the basic principle of all methods based on the measurement of body density. The underwater weighing technique has been considered by many as the "gold standard" measurement of body composition.[29,31] It is not feasible to use this method, however, in infants and young children, nor in most diseased populations or hospitalized patients. Hence, the development of air-displacement plethysmography has provided an alternative approach to the measurement of body volume.[40,41] For this approach, the body displaces a volume of air inside a closed chamber to determined body volume, replacing the need for total submersion in water. Corrections for lung volume are still needed, along with adjustments for the adiabatic effects of the skin.[42] However, once a body volume is obtained, the same calculations used in underwater weighting apply. At present, only one commercial instrument (BOD POD^{TM}, Cosmed, Concord, CA) is

available. Its performance has been shown to be in good agreement with underwater weighing for adults and children.[40,41] An infant-sized air-displacement plethysmography instrument (PEA POD™, Cosmed, Concord, CA) has also been developed.[43] Body composition results in healthy infants for this instrument were in good agreement with those obtained using the deuterium dilution method and four-compartment body composition model.[44,45] Further testing, however, is needed for preterm infants and in sick infants where there may be significant alteration of normal hydration.

Dual-Energy X-Ray Absorptiometry

This technology originated with the use of a collimated radioactive source passed over the distal end of the radius, and monitoring of the intensity of the transmitted photons on the opposite side of the arm.[6,25] Attenuation of the transmitted signal is related to the chemical makeup and thickness of the tissues in the beam path. In the mid-1990s, the radioactive sources were replaced with X-rays sources, different types of detectors were used, and measurements were made at two energies.[46] A low intensity X-rays are used and the exposure time is relatively brief resulting in a minimal exposure, comparable to natural background sources of radiation exposure one encounters daily.[6,25] DXA (sometimes denoted as DEXA) has emerged as a principal method for measuring bone mineral and body composition at all ages.[46–51] It has high precise for bone mineral measurements in adults and older children, and has become the de facto standard for assessing bone status. DXA measurements have also been obtained in a number of studies of infants and children.[46,48,52,53,] It should be noted that the adult-based software used with the initial pencil-beam instruments provided inaccurate body fat and lean tissue values for younger children.[49] The accuracy of DXA for use in infants has also been questioned.[51,59] The newer fan-beam DXA instruments, however, have improved software for body composition and bone mineral analysis specifically developed for use in pediatric populations. Another point to be noted is that DXA does not measure the true bone density (g/cm^3), but instead areal density (g/m^2) based on a reconstructed 2-D image.[6,25,46] To measure true bone density, a quantitative 3-D imaging method is needed. A technique, called peripheral quantitative computed tomography has been developed for this purpose. It has been used to measure the trabecular and cortical regions in the radius and tibia, and pediatric reference ranges are available.[54,55] Another feature of this technique is that the cross sectional

geometry of the bone can be measured.

Body Imaging Techniques

The most recent advances in measurement methods of body composition have been the use of imaging techniques.[56] Both CT and MRI have been used. Both methods can provide accurate reconstructed 3-D images of the body. An advantage for CT is that true density (g/cm^3) is obtained, while its major limitation is that a substantial high radiation dose is required. MRI, on the other hand, uses no ionizing radiation, and provides better images, but the information is more qualitative compared with CT. Furthermore, a CT scan typically takes only a few seconds to complete, whereas an MRI scan can take considerably longer, although the newer MRI instruments have reduced these differences. A strength of the CT and MRI techniques is that organ-specific information can be obtained which supports the Functional model (see Figure 4-1). To date, most of the emphasis using CT and MRI has been on the measurement of the subcutaneous and visceral components of abdominal adiposity.[56–58] Whole-body MRI has also been used to monitor changes in body composition during infancy, but only during early life.[59] An alternate magnetic-based technique has also been developed, but has had only limited use.[60]

Growth and Body Composition

Measurement of body composition, in both clinical and research settings, has advanced the understanding of human energy expenditure, metabolism, and physiologic changes seen during growth and disease. Growth is the maturation process characterized by change, compensation, and adaptation; it is affected by hormonal, nutritional, and environmental factors interacting with genetics. Changes in the components of body mass for an individual are a result of the dynamic events preceding the time of assessment. The importance of changes in body composition that can occur during acute and chronic diseases, and their treatment has led to the need for refinement of the techniques used in measuring these changes. Nutritional status can no longer be based on height and weight alone. In many diseases, such as protein-energy malnutrition, cancer, inflammatory bowel disease, chronic renal disease, acquired immune deficiency, and obesity, assessment of only body weight or weight-for-height can give an erroneous impression about the nutritional well-being of the subject. It is possible to achieve an acceptable weight while having excess body fat or

body water, thus confounding the benefits of traditional nutritional therapy. A closer look at body composition can illuminate the loss of lean tissues associated with disease, and may permit a more customized approach to nutritional management. The study of body composition helps identify the interactive effects of genetic, nutritional, and physical activity on changes in fat, muscle, and bone. It is important to monitor the amount of each component as well as their rates of growth and potential localized variations in an effort to better define possible relationships with current and future health risks.[61,62] Changes in body composition that occur during fetal life, infancy, childhood, adolescence, adulthood, and aging are presented as part of this chapter. An emphasis is placed on the changes in fluids, fat, muscle, and bone mass in the different stages of the life cycle. The measurement of body composition continues to become an important clinical tool in the monitoring of variations in growth of healthy subjects as well in the nutritional management of patients with acute or chronic illness.

The previous description of the various methods and models used for measurements of body composition is crucial in the interpretation of nutrition literature. Each method can provide a unique perspective, taking advantage of certain physical or chemical principles. On the whole, the use of different methods in the same set of subjects has allowed the cross-validation of the various techniques and has permitted a more detailed understanding of body composition.

BODY COMPOSITION CHANGES DURING GROWTH

The relative changes in body composition with age, as a percentage of body weight, are shown in Figure 4-2. More specific details of the compositional variation during typical growth are presented in Table 4-3. Figure 4-3 depicts the changes in body composition that occur during fetal development. These reference data can be helpful when assessing the growth of preterm infants.[6]

Changes in Body Fat Mass

Fat is the most variable of body components, ranging from as low as 5% to more than 50% of body weight. The normal range, however, is narrower and varies from about 10% to 25%–30%. During intrauterine life, the differentiation of fat starts in the second trimester of gestation, between the

fourteenth and twenty-fourth weeks of pregnancy. It becomes evident in the head and neck regions, followed by progressive increases for the trunk, arms, and, finally, the lower limbs. At the beginning of the third trimester, at approximately the twenty-eight weeks gestation, adipose tissue is already present in the principal fat deposit areas. This may indicate that the second trimester of pregnancy is a sensitive period for the later development of fat tissue.[66] Abnormalities in infant fat mass can be attributed to changes in maternal nutrition in late gestation, during the period of maximal fetal growth.[67] The possibility that nutritional alterations at critical periods of development influence nutritional status, such as for adult obesity, has been suggested by some authors.[67–69] Follow-up studies of adults with a history of maternal famine prenatally or during early in life and of infants of diabetic mothers strongly suggest that early under- or overnutrition influences the development of fatness and its related diseases in later life.[70,71] Altered maternal nutrition has been shown to change the expression of appetite-regulating neuropeptides in the fetal brain, enhancing the later risk for obesity.[69] Increased birth weight and postnatal growth are positively correlated with lean body mass, an effect that may persist throughout life.[63,72] Increased birth weight is positively correlated with body mass index (BMI) and inversely with central adiposity.[72,73] In general, low birth weight infants have higher percent body fat and less lean body mass, with an increased later risk for central obesity.[73,74] These data suggests that preventing growth failure in utero and in early life are important for body composition, and could have long term consequences.

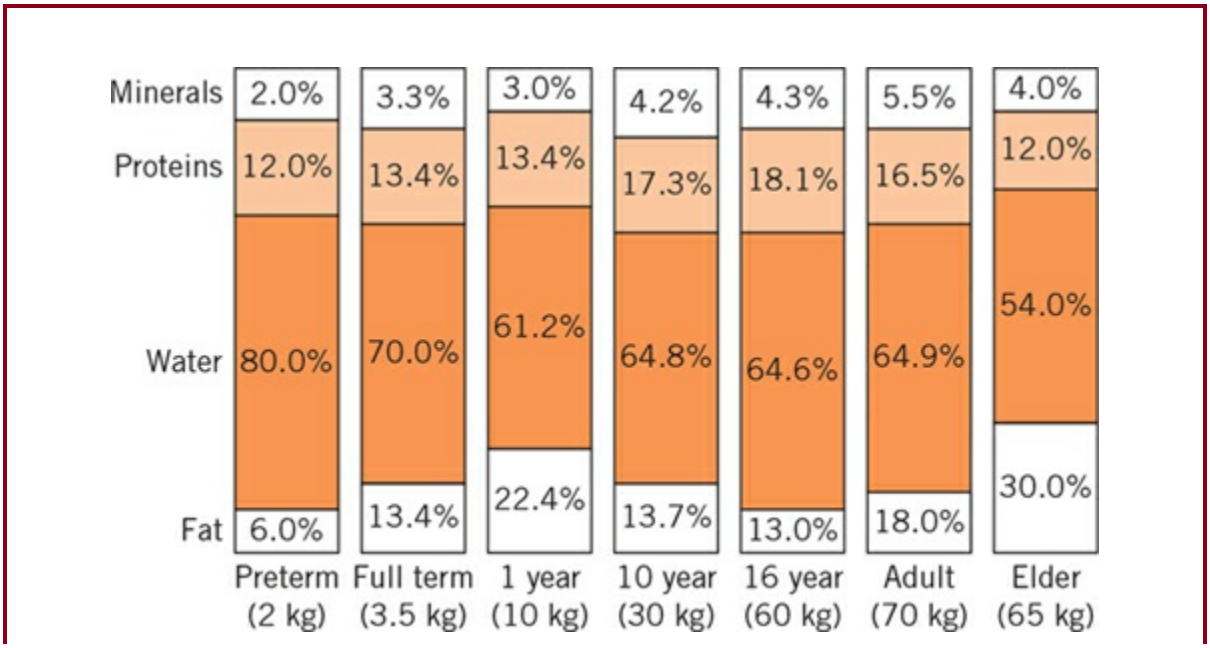

Figure 4-2 Relative changes in major body composition compartment with age.

On-going research also indicates that certain genes involved in embryonic development may play important roles in adipocyte development and fat distribution.[75] Before birth, there appear to be regional differences in fat accumulation that could have important significance for the future health. Cell characteristics and normal growth patterns differ among the fat depot sites. After birth, hormonal responsiveness of fat tissue also varies among these location.[66] It has also been suggested that the postnatal environment may equally influence the development of obesity in later life. Weight gain in the first weeks of life may be a critical determinant of adult obesity. In utero, the fetus increases its fat content from ~2.5% at 1 kg weight of a fat mass of 14%–15% at full term.[63] After birth, there is a progressive accumulation of fat mass peaking at 29%–32.0% at 6 months of age.[65] This effect is probably due to a high intake of energy during a period of relatively little activity. Breast-fed infants have a different accumulation of fat than formula-fed infants, with breast-fed infants having less fat, with the greatest differences evident at 9–15 months of age. Differences in body fat accumulation can also depend on the type of fat contained in certain formulas and the proportion of protein. However, some studies have reported that these differences do not persist after 1 year of life. Whether the choice of infant feeding mode affects body composition later in life is still uncertain.[76] Increasing with age in early life, the body fat mass decreases over the next several years to a minimum of ~13% at 7 years in boys and 16% at 6 years in girls. This follows a discrete increase to about 10 years of age, often referred to as "adiposity rebound."[63] Although there is evidence of some sexual differences in body composition at birth and during early life, the predominance of increased fatness in girls becomes notably evident during adolescence. For both sexes, puberty is characterized by substantial increases in total number of adipocyte and the fat content. There is also a shift of fat from peripheral sites to truncal storage sites, which is especially marked in males. In general, males attain their peak percentage fat during early puberty, and then decrease during adolescent growth.[76] Females show an initial decline in fatness, followed by a continuous increase in fat percentage thereafter. There are also significant gender differences in subcutaneous fat distribution, with a prevalence of an increase in adipose

tissue in the upper part of the body (above the umbilicus) in males and in the lower part in females. Despite this tendency for concentration of fat in the abdomen of males and the hips of females is clearly evident in adolescence, there are some indications it may be present as early as 4 years of age. Some of this variation can be attributed to the effects of hormones, with estrogen and progesterone inducing a slight increase in adipocyte volume and number, whereas in males, androgens appear to affect a decrease.[66] With aging in males, body fat slowly increases from about 18% in young adulthood to about 36% by 65 to 85 years of age. For females, there is a gradual increase from 33% to 45% of similar age groups. In a multiethnic longitudinal study of Americans, percentage fat in males increased from about 22% at age 18 years to about 26% at age 60–69 years. For the same ages in females, the increase was from about 32% to about 39%.[77] The increased fat mass in females of all ages, especially in the lower part of the body, could be related to their capacity for childbearing as an adaptive mechanism for the preservation of the species. There is a need for ample energy reserves for successful fetal and newborn growth.[78] At the same time, in a minority of normal adults, the adipose tissue distribution is reversed for the sexes.[78] In women with an android fat distribution, the risk factors for developing diabetes, hypertension, or hyperlipidemia are similar to those of men. In these women, there is no clear explanation for this different pattern of fat, although it has been suggested there might be an inherited increased sensitivity of adipocytes to androgens, and possibly for cortisol.[78] Ethnic differences in fat accumulation during growth have been observed. A study that included African-American and Hispanic girls showed their percentage of fat values to be higher than in the white group. Bone mineral content and lean tissue mass were also greater for the African-American girls than the white girls, whereas there were no differences in the Hispanic girls.[52] A similar multiethnic study of boys showed greater bone mineral content and lean tissue mass, with lower percentage fat for the African-American group. The Hispanic males had similar bone and lean tissues as the white group, but a higher percentage of body fat.[53] In another longitudinal study, no difference in total body fat was found across ethnic groups in males.[77] For females in this same study, total body fat was highest in the African-American group, followed by Mexican-Americans (Hispanic) and then white females.[77] It is to be noted, however, the BIA was used for the latter study, while DXA was used for the previous study. In general, white children have a more peripheral distribution of body fat than Latin

American, Japanese, or African-American children. African-American children tend to have a more centralized fat pattern. These ethnic differences are evident as early as the preschool period and continue throughout adolescence. The pattern of less peripheral fat has also been found in studies of children from several Latin American countries.[79] These differences could reflect genetic differences as well as different lifestyles and nutritional and health habits. Ethnic differences have also been found for Asian adolescents and adults. When combined, these studies suggest the need for ethnicity-specific references for body composition during growth. It appears that most overweight 1-year-olds exhibit normal levels of fatness as adolescents and adults. Overweight in early childhood is also not well correlated with adult obesity, whereas overweight in later childhood and adolescence is.[80] Long term follow-up studies in children have found that truncal fat predominance and increased BMI in childhood were associated with an increased risk of central obesity in adulthood.[81] However, in a longitudinal study from birth until age 43, it was found that for any given adult body size, those who had been lighter in childhood were more at risk for abdominal obesity, suggesting that insulin resistance may be linked to low weight in childhood.[82] The degree of body fatness as early as 7 years of age was shown to be correlated with risks for coronary heart disease and diabetes.[83] Overweight adolescent males also have an increased risk of mortality from all causes and from coronary heart disease after age 55 years.[84] Fat distribution also plays impacts the risks of developing cardiovascular disease, diabetes, hypertension, gallbladder disease, stroke, and overall mortality. It appears that at least three principal features of body fat are associated with health outcome: total amount of fat expressed as a percentage of body weight, amount of subcutaneous truncal or abdominal fat, and quantity of visceral fat located within the intraabdominal cavity.[85] Adult diabetogenic or atherogenic obesity tends to be more truncal than peripheral, That is more the abdominal “apple” shape than the gluteo femoral “pear” shape, more intra abdominal visceral than extra abdominal subcutaneous, and more in the upper body than in the lower body.[78] Risk factors for the development of obesity are both genetic and environmental, such as changes in diet, exercise, or lifestyle.[75] Correlation between body fat and the amount of time spent watching television have been reported by some, but not others.[86,87] Regular exercise can help decrease body fat as well as increase bone mineralization and muscle mass.[3] In general, athletes have a lower percentage of body fat and greater lean body mass than their nonathletic size-matched peers.

However, there is considerable variation among individuals and types of activities. Athletes participating in sports in which body weight is supported (e.g., swimming, cycling, kayaking) or in which there is minimum body movement (e.g., throwing, lifting) generally has a higher percentage fat than athletes who participate in sports that require horizontal or vertical body movement (e.g., running, jumping). In sports in which weight is a factor, such as gymnastics, ballet, and wrestling, the effort to decrease body fat can affect performance and induce eating disorders. This phenomenon occurs in athletes independent of gender.[88] In obese adults, intensive and extensive aerobic exercise can induce moderate losses of thigh fat and also central subcutaneous fat. This effect is more noticeable in males with excessively high truncal fat. The increased percentage of body fat seen in elderly populations may be attributable, in part, to decreased physical activity. With aging, there is a decline in muscle mass and strength that may be partly counteracted by regular physical exercise throughout life. The capacity for some increase muscle mass and strength is retained into old age. Physical training, especially resistance exercise of considerable intensity, frequency, and duration, may slow the loss of muscle mass and bone mineral, while decreasing fat mass. This, in turn, may reduce the associated abnormalities of diabetes, coronary heart disease, osteoporosis, and fractures.[89]

TABLE 4-3 Body Composition of Reference Children and Adolescences

ECW, extracellular water; ICW, intracellular water; TBW, total body water.
Adapted from Refs. 63–65.

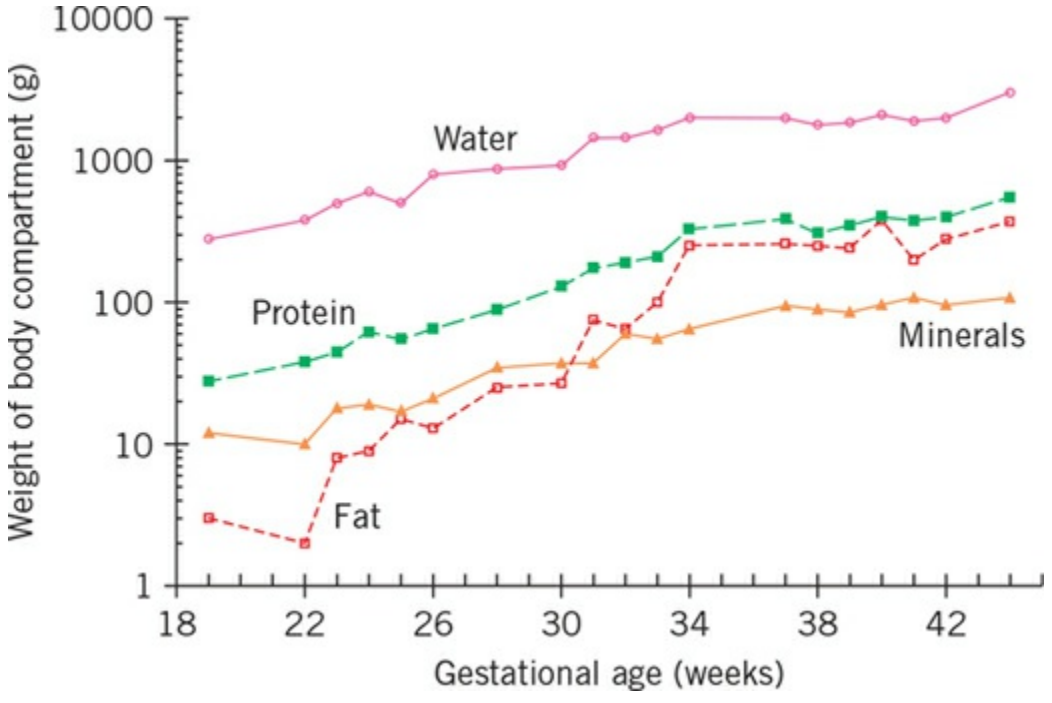

Figure 4-3 Changes in water, proteins, minerals, and fat during fetal development and early life. (Reproduced from Ref. 6).

Changes in Body Water

The body's content of water is greatest during fetal life—about 88.6% of weight at 24 weeks gestation, decreasing to about 75% at full term. After birth, the water content continues to decline rapidly, reaching about 60% of body weight at age 4 months. There is a continued, but slower, decline to adolescence, where the range between 60 and 65%.[90] During the first years of life, the extracellular water (ECW) volume exceeds the intracellular water (ICW) volume, while this ratio slowly decreases with growth and is reversed at older ages. Initially, ICW is about 25%%–30% of body weight, increasing to about 35%–40% by adolescence. This change is largely attributable to the increase in muscle mass. At the same time, ECW slowly drops from about 40% to about 20%–25% of body weight.[9,52,53,90] In the elderly there is a small decrease in total body water (TBW) and an increase in the ECW/ICW ratio, which can differ somewhat by race, with African Americans showing the greatest relative increase in ECW.[77,91] Preterm and small-for-gestational-age term infants have a greater proportion of body water at birth than do their appropriate peers, suggesting that fetal growth deficits in these groups are not attributable to abnormalities in body water regulation.[32,92] In disease states such as malnutrition, there is an expansion of ECW. Similar water distribution patterns have been observed in sepsis, after surgery, and in patients with cancer.[93] There is increasing evidence that changes in the ECW/ICW ratio may be an accurate predictor of clinical outcome and mortality.[93] A strong correlation between changes in the ECW/ICW ratio and protein and energy intakes has been observed. For this reason, measurements that can assess these two water compartments may aid the clinician in monitoring nutritional rehabilitation in the acute care of critically ill patients.[93]

Changes in Body Mineral Content

Throughout life, there are both accretion and resorption of bone. This process of bone modeling is characterized by changes in the shape, length, and strength of bones. During normal growth, accretion exceeds resorption. Thereafter, the bone tissues within the existing skeletal structure are being continuously formed and resorbed, with minimal change in bone volume.[94] Skeletal growth continues during infancy,

childhood, and adolescence. The rate of bone modeling varies greatly during these different biologic stages. By one year of age, skeletal mass has doubled and approaches about 37% of the total skeletal mass of an adult. The next major stage of bone growth is during puberty with over 25% accumulation of the final adult skeletal bone.[95,96] Although often ignored, there is a third phase during early adulthood where the skeletal mass continues to increase by about 7%–9%. This level of change is small, but it is important when considering the losses that occur at older ages, especially during menopause.

The annual increment in bone areal mineral density (BMD) is high during the first 3 years of life and decreases thereafter until puberty. This reflects an initial mineralization of bone that exceeds the increase in bone volume. The opposite tends to occur during puberty where there is accelerated height velocity followed by mineralization. The adult reference man has a calcium content of 1.2 kg.[9,29]

During the initial 10 weeks of gestation, the human skeleton is composed of cartilage, which is chemically and histologically distinctive from cortical bone. The next phase of fetal bone growth is ossified, starting with the shafts of long bones (e.g., femur, humerus). The ossification process gradually extends along the shaft, replacing the cartilage and also forming trabecular bone, such as the metaphyses.[97] Near the end of the second trimester, the fetal skeleton has a mass of about 500 g and about 42% cartilage. At full term, the total skeleton is about 33% cartilage and about 30 g of calcium, most of which was deposited during the last trimester.[9,94,98] Fetal calcium accretion increases dramatically during the last trimester, ranging from 130 mg/kg/d at 28 weeks gestation to 150 mg/kg/d at 36 to 38weeks gestation.[9,98] For a preterm infant, these rates are higher than what human milk alone can supply. Insufficient intake of calcium and phosphate is the primary cause of osteopenia and rickets of prematurity.[99,100] In premature infant studies, where supplementation of mother's milk or specialized preterm formula were used, bone mineralization increased significantly, leading to a more normal bone mass at expected term.[101,102] Intrauterine bone mineralization has been examined by measuring the BMD in appropriate for gestational age infants born at between 30 and 41weeks gestation and for infants born between 22 and 42 weeks gestation.[103,104] Bone width and areal BMD at birth were correlated with gestational age and birth weight and have provided reference curves for births at 30–41 weeks gestation.[105,106] BMD increases over the first year of life, initially at a lower rate during the first 6 months,

and can vary with the type of feeding.[107] Higher BMD values have been reported for supplemented breast-fed infants or cow's milk formula-fed infants, when compared with unsupplemented breast-fed infants.[101,108] In a study of preterm infants no difference in bone mineralization and total bone mass was found when fed either preterm formula or fortified breast milk.[105] Lower BMD values, however, have been observed in infants receiving soy-based formula compared with infants receiving cow's milk formula.[109] In later studies where the soy formula was modified to improve the bioavailability of minerals, no differences in BMD were found when compared with cow's milk formula.[110] The long-term consequences of the differences in BMD with various types of feedings in early infancy remains unknown. One study found that bone accretion is lower in infants fed human or low-mineral formula in the first 6 months of life, but those fed human milk had greater bone mass accretion in the second 6 months than those fed formula, such that was no difference in bone mass among the feeding groups at 1 year of age.[111] Similarly, no differences in BMD at 4 years of age were found in children who had been breast fed or formula fed.[112] Likewise, no gender or ethnic differences in BMD have been found in full-term or preterm newborns, while older males had higher BMD regardless of feeding type.[105,112] A wide variation in BMD values as a function of age, gender, and ethnicity have been reported, with gender is more important than race and boys having slightly higher BMD values than girls [113–115] children of African decent have higher values than whites.[52,53,116,117] Ethnic differences in BMD among blacks, whites, Lebanese, and Asians have also been reported in adolescents and adults.[113,117]

In the lumbar spine, there is a gradual, linear increase in BMD with age in both sexes before puberty, followed by accelerating increments during puberty. Until the age of 15 years, BMD values are generally higher in girls, possibly because of earlier pubertal development or Tanner Stage.[113,118] In girls, peak bone mass in the spine and femoral neck is usually achieved by 15 years of age, with the maximal peak mineralization rate occurring earlier at about 12.5 years.[96] In boys, the most rapid increase in lumbar BMD occurs at about 14years of age, with full bone mass achieved at about 17–18 years or Tanner Stage IV is reached.[96,118] By the end of puberty, skeletal bone mass reaches over 90% of its maximum, not peaking until age 25–30 years.[119] These studies show the relative importance in accumulating bone mass of early adolescence in girls as compared with late adolescence. This was confirmed in a study of

calcium kinetics in girls, ages 5–17 years old where calcium deposition and the size of the exchangeable bone pool reached a maximum during early puberty and decreased in late puberty,[120] Because peak bone mass accumulation is achieved during adolescence, current recommendations for calcium nutrition reflect a greater requirement for these age groups (See Appendix 2 for Dietary Reference Intakes). It has been suggested that prevention of osteoporosis consists, in part, of maximizing peak bone mass during growth, although there remains insufficient knowledge to verify this link.[121] Genetic factors, estimated to contribute 70–80% of the variance in bone mass, are perhaps the strongest predictors of peak bone density and loss with aging. A genetic influence has been observed in premenopausal women and premenopausal daughters of postmenopausal women with osteoporosis.[122,123] Additionally, BMD correlates more closely in monozygotic than in dizygotic twins.[122,124]

Within the modifiable environmental factors, calcium intakes can play a significant role in achieving peak bone mass. For the growing individual, there is a significant positive relationship between calcium intake and retention. Variations in calcium intakes early in life could account for as much as 5%–10% of the difference in peak bone mass. It is to be noted that older children and adolescents in the United States do not achieve the recommended intake of calcium, which may be important in reducing the risk of fractures and osteoporosis later in life.[125] However, a firm link between bone mineral status in childhood and the risk of future fractures has not been fully established.[121] Finally, physical exercise and weight-bearing activities throughout life have a positive impact on peak bone mass. From this prospective, prevention of osteoporosis has become a domain for the pediatrician as the relationship of genetics, nutrition, and activity is better understood. There is an increasing prevalence of obesity in childhood, and overweight children may have an increased risk of fractures owing to lower BMD.[126] Other studies, however, have not shown a difference in bone mineral content between obese and lean children.[122] In practical terms, the pediatrician should encourage the attainment of normal body weight for height and an adequate calcium intake at all stages of growth.

Changes in Skeletal Muscle Mass

There is no definitive in vivo method of measuring total muscle mass. Neither total body potassium (TBK) nor total body nitrogen (TBN) can specifically identify muscle cells. However, because about 60%–70% of

TBK is found in skeletal muscle, accurate models to predict skeletal muscle mass have been developed using these measurements. Although metabolic end products released from myocytes—creatinine and 3-methyl-histidine—have been proposed for estimation of whole body muscle mass, their application is limited by a number of constraints.[20,127] Although acceptable in certain well-controlled conditions (research lab), their general clinical use is restricted.[128] Approximate estimates of muscle mass can be obtained with anthropometric measurements of the mid-arm, mid-thigh, and mid-calf circumferences, which offers an inexpensive useful field method. This technique has been particularly useful in the clinical setting when subjects can be followed overtime, and more direct methods are not available. At full term birth, the skeletal muscle mass represents 22%–25% (~850 g) of the infant's body weight. As an adult, skeletal muscle mass is about 30%–45% (~28 kg) of body weight.[9] About 27% of TBN, 33% of TBK, and 28% of TBW is contained in the skeletal muscle of a newborn.[9,29,97] The chemical change in the composition of skeletal muscle during early development is a decrease in the percentage of water concurrent with an increase in the protein concentration. As the fibers increase in number and size, the extracellular material, which makes up a large part of fetal skeletal muscle, is replaced by muscle fibers.[97] The muscle mass constitutes the largest part of the soft tissue mass for normal individuals. For extremely obese individuals, the adipose tissue can dominate.[97] Depending on gender, age, and health status, between one-third and one-half of total body protein is within skeletal muscle.[9,127] During growth, the increase in total muscle mass is not uniform, developing slowly during childhood, and then a growth spurt in the adolescent (puberty) years, which continues longer in boys than girls.[29] The development of muscle mass is impacted by several factors, including age, sex, ethnicity, nutritional, hormonal and metabolic states, and exercise. Estimated muscle masses as a percentage of body weight in boys increases from about 42% at age 5 years to 54% by 17 years of age. In girls, the increase is from about 40 at age 5 years to 45% at 13 years of age, with a small decrease thereafter due to increasing body fat. From birth through adulthood, males tend to have higher muscle mass than females. There is a gradual decrease in muscle starting in the fourth decade of life with a more dramatic loss after 65 years of age.[113,129] This decrease is greater in men and in African-Americans. Low physical activity, tobacco smoking, and low testosterone are risk factors for sarcopenia in these populations.[129] For men and women over 64 years of age, sarcopenia was

reported at 22%–27% and increased further with advancing age.[130] It has been hypnotized that the sarcopenia that occurs in the elderly could be delayed by regular exercise, although numerous attempts have had minimum success.[89] Physical activity may need to be promoted during the early periods of life in order to create positive habits that favor the cardiovascular system, muscle, and bone.

Changes in Visceral Mass

Growth and development of the viscera parallel the changes in chemical compositions for muscle mass, in that there is a decrease in the proportion of water and an increase in the proportions of proteins and minerals.[9] Extracellular elements such as sodium and chloride decrease, whereas intracellular elements such as potassium, magnesium, and nitrogen either remain the same or increase. The brain grows rapidly from mid-gestation to 18 months after birth, when it reaches about 70% of its adult mass. Growth and development of the brain are characterized by a decrease in the percentage of water and an increase in protein, but differs from most other tissues in that lipids form an integral part of the structure. Myelination begins before birth, but most of it takes place between birth and 3 years of age, when the brain is about 80%–90% of its mass at maturity. Up to the age of 3 years there is a considerable increase in the concentration of lipid, with consequent decrease in the percentage of water. After 3 years, the changes in composition are relatively small.[97] During the myelination period there is a rapid accumulation in the brain of the omega-3 and omega-6 long chain polyunsaturated fatty acids (PUFAs)—docosahexaenoic acid (DHA; 22:6–3), arachidonic acid (AA; 20:4–6), and adrenic acid (22:4–6)—which are important structural components of the cell membrane phospholipids. The type of lipid that accumulates in the brain during these first few years is influenced by early nutrition and might have functional implications, especially related to visual maturation and cognitive development.[131] Preterm infants who receive formulas with a high linoleic to linolenic acid ratio and practically devoid of longer-chain PUFAs show a marked decrease in the DHA-to-AA ratio in brain and retina.[132] On the other hand, human milk contains enough precursors and long-chain PUFAs to fulfill the infant's requirements for brain growth. These factors have led to the study and development of infant formulas containing DHA and AA, which have been successful in approaching the fatty acid accretion pattern of breast-fed infants in babies who are fed with these formulas.[131]

The other major organs—liver, kidney, lung, heart, skin, and spleen—also change in chemical composition in a similar way, with a decrease in the proportion of water and an increase in proteins and minerals. At all ages, the kidney has more sodium and less potassium than muscle or liver.

Skin is an organ that changes in the composition. For the fetus, less than 20% by mass is collagen, the remaining being mainly elastin. By term, the collagen represents 63% and in the adult it is 90%.[97] The immune system is also an important component of the body's lean non muscle compartment, with lymphocytes accounting for about 2% of body weight and 8% of fat-free solids in the adult. The status of the immune system is intimately related to body composition via the known effects of cytokines on muscle protein metabolism.[2]

The relative proportions that major organs and tissues contribute to body weight are presented in Table 4-4. At any age, muscle, skeleton, skin, liver, and brain account for more than 70% of body mass. With increasing age, some organs, such as liver, spleen, and kidneys, appear to atrophy, whereas hypertrophy is common with others, such as prostate, lungs, and heart.[133]

General Changes in Fat-Free Mass

As noted earlier, fat-free mass (FFM) is not a true body composition compartment, but a concept developed in order to construct a two compartment model of body composition. FFM consists of multiple compartment, with water being the major component. Changes in FFM should not be over interpreted as necessarily reflecting similar changes in each of its subcomponents.

FFM increases rapidly during the late fetal and newborn periods, followed by a rapid slow down between the first and third years of life, and then a slow increase about 10 years of age, when the adolescent growth spurt is initiated. During the first years of life and childhood, there is a slightly higher FFM in males, which becomes more pronounced during the adolescent period. For boys, FFM increases rapidly between 12 and 15 years of age and continues until about to age 18 years. For girls, FFM increases steadily until about 15 years of age, then remains relatively constant.[134,135] The patterns of increase in FFM are correlated with changes in height.[29] At older adult ages there is a progressive loss of FFM, mainly reflecting loss of skeletal muscle and bone mass.[89]

Achieving Chemical Maturity

Healthy young adults have usually achieved chemical stability of their body composition by puberty.[1,9] The composition of FFM is relatively constant, with a water content of 72%–74%, a protein content of ~19%, and a mineral content of 6.8%.[1,29] The potassium content of the body is about 60–70 mmoles/kg for males and 50–60 mmoles/kg for females.[27] The completion of chemical maturation is also reflected in the stabilization of various constants relating one component of body composition to another, such as potassium to nitrogen and ECW to ICW, and intracellular potassium concentration.[90] However, in conditions such as pregnancy, advanced aging, disease, nutritional status, and genetics where an individual's FFM composition can be effected, the convenience of these constants is reduced. For example, the relative changes in the composition and density of FFM with age are shown in Figure 4-4. During growth, chemical maturity occurs at different stages for different constituents of FFM. Muscles, visceral tissues, and bone all reach chemical maturity at different rates. For example, bone mineral maturation appears to occur in the third decade of life. Muscle mass, reflected mainly by body potassium, increases gradually from birth to puberty for both sexes, then rapidly increases, reaching a plateau at about 20 years of age in males, and at about 17 years of age in females. Differences in peak muscle mass as it relates to timing of puberty are apparent between genders and among ethnicities.[135] By the end of the 3rd decade, there is a gradual decline in body potassium indicative of loss of muscle mass with aging.[27,29] (Figure 4-4A). In childhood, FFM contains relatively more water than that of adults. The hydration of FFM decreases from 80% to 83% in the newborn to about 75% in early puberty and then finally to about 73% in adults (Figure 4-4B). The body's protein content is about 15% at birth, increasing to about 19.5% in boys and 18.7% in girls by 10 years of age.[135] Approximately 0.6% of the FFM is carbohydrate or glycogen. Bone mineral content increases during early childhood and especially during adolescence. It is about 3.7% of FFM in infancy, increasing to about 5.02% in the prepubertal ages, then to about 6.2% in the late teen years, continuing to increase to about 6.8% in the adults.[1,27,52,53] A small gain in bone mass continues during the third decade of life and then it plateaus or has a slow decrease for the next several decades. Bone loss begins by the start of the 5th decade of life, with varying rates among skeletal sites and between sexes (Figure 4-4C). The density of the FFM (Figure 4-4D) also changes with age as it is dependent on its relative proportions of water, protein, and minerals. During growth, the water content decreases, while

the protein and mineral contents increase, resulting in an overall increase FFM density. With advanced aging, there are significant declines in muscle and bone mineral, such that FFM density declines at older ages (Figure 4-4D).[10] Consequently, estimates of body composition in children will be incorrect if adult constants for FFM hydration or density are used. For example, fat mass would be underestimated if calculated on the basis of adult TBW hydration and overestimated when calculated on the basis of body density.[136] Constants, adjusted for age and gender during childhood and adolescence, have been developed for FFM, making it possible to more accurately compare body composition by age, gender, and ethnic group.[1,135,136]

TABLE 4-4 Relative Contribution of Organs and Major Tissues to Body Weight

		Percent Age of Body Weight		
Organ or Tissue	**Fetus (20–24 weeks)**	**Full-Term Newborn**	**Adult Male**	**Adult Female**
Skeletal muscle	25.0	25.0	40.0	29.3
Skeleton	22.0	18.0	17.1	17.1
Skin	13.0	15.0	3.7	3.1
Liver	4.0	5.0	2.6	2.4
Brain	13.0	13.0	2.0	2.1
Lungs	3.3	1.5	1.4	1.4
Kidneys	3.1	1.6	0.4	0.5
Heart	0.6	0.5	0.5	0.4
Spleen	0.1	0.2	0.3	0.3

Adapted from Refs. 9 and 97.

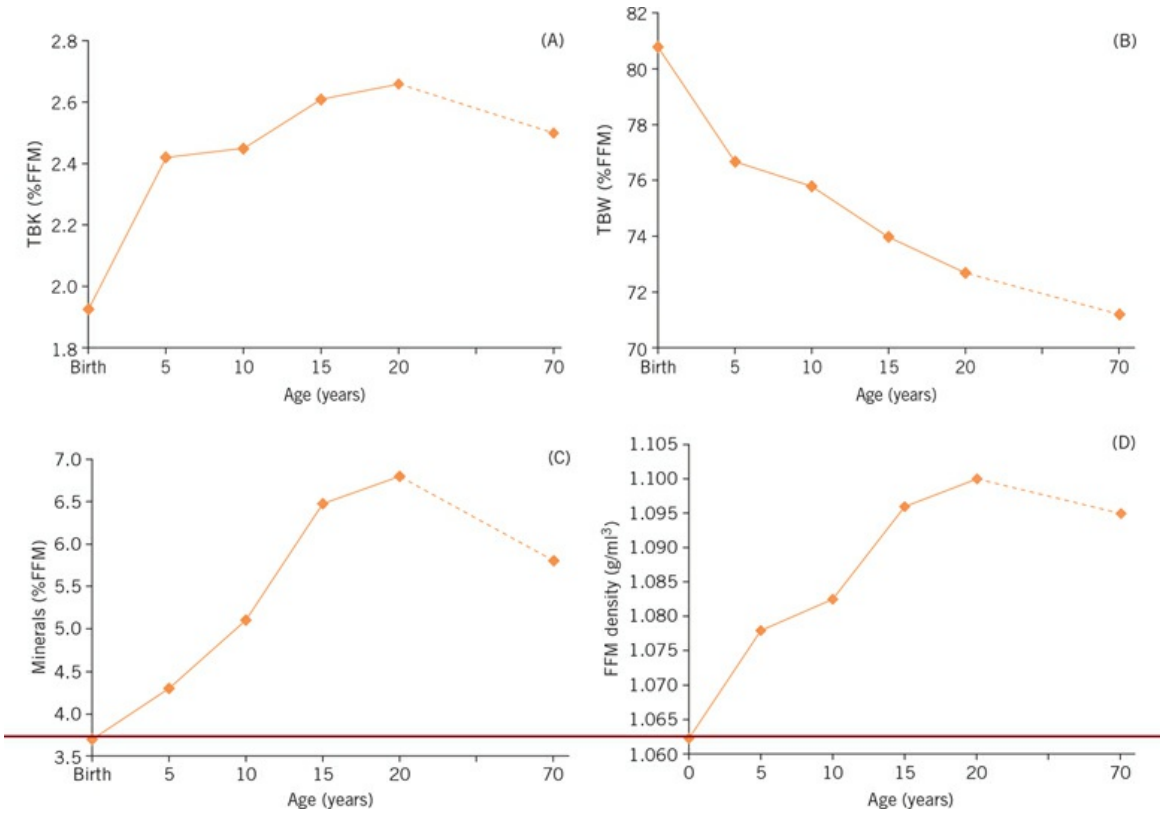

Figure 4-4 Changes in body composition components of the fat-free mass (FFM) over the human life span expressed as a percentage of FFM. (A) Total body potassium (TBK), (B) total body water (TBW), (C) Minerals, and (D) density of FFM (g/ml^3). (Adapted from Refs. 7,9,63,64.)

Changes in Linear Growth

During gestation, the fetus reaches its peak linear growth rate of 10–12 cm/month between the 10th and 30th weeks, reducing to about 3 cm/month (36 cm/year) at birth. Linear growth continues to decrease over the next three years: 15 cm/year at the end of the first year, 9 cm/year at the end of the second year, and 8 cm/year at the end of the third year. Linear growth continues to decrease over the next 2 years to about 6.5 cm/year, and is then relatively stable at about 5–6 cm/year until puberty. The start of puberty is both sex and ethnic dependent. Girls of European descent start their pubertal growth spurt at about 12 years of age, with a peak height velocity of 9 cm/year within 24 months. Boys of a similar ethnic decent start their pubertal growth spurt 2 years later, at about 14 years of age, with a higher peak velocity at 10 cm/year. Once peak height

velocity is achieved, annual growth increments decrease significantly.[137] In the Fels longitudinal study, adult stature was reached at 17.3 years for females and 21.2 years for males. Changes in body composition were related more to physiologic age than chronological age. Children who begin their adolescent growth spurt earlier tend to be taller and heavier than those who mature later.[134] Maximal height can also vary with ethnicity, where African-American males grow significantly taller than European-American males who are, in turn, taller than Mexican-American boys.[53,135] Similar ethnic differences are evident for females.[52,135] Tanner staging, an index of sexual maturity, is also an important component of growth assessment in children, particularly during the pubertal age period.

Changes with Weight Loss or Weight Gain

The range of weight gain, following full term birth, of healthy infants is 19–24 g/day. This decreases to roughly 9–10 g/day by the end of the first year, and to about 7 g/day by the end of the second year. Thereafter, weight gain is normally relatively stable at about 5.5 g/day until puberty. Weight change involves all the components of FFM and fat, with their contributions affected by the causative factors.[138] While BMI is considered a reliable indicator of excessive weight gain, changes in BMI often do not accurately reflect changes in body composition.[15,139] Malnourished children, for example, can continue to have abnormalities in body composition even after fully regaining weight.[140] The situation is similar for individuals who have a significant body weight increase in response to excessive intake. The composition of the weight gain is both fat and FFM. Though short-term weight gain is initially associated with proportionately greater increases in fat mass, both fat and FFM will be increased.[141] In obesity studies, the weight gained or lost is associated with about a 20%–30% changes in FFM. In subjects of low weight, such as malnourished children, premature infants, or patients with anorexia nervosa, the proportion of weight gained as FFM is larger, around 60%–75%, depending on the individual and type of diet. The excess weight of obese children is obviously composed of increased fat mass, but there are also increases in the protein and mineral masses. A propensity for greater fat accumulation in the trunk can promote greater mineral accumulation in the legs for older children.[142] An exception to this trend may be small for gestational age infants, who, following a catch up weight gain, tend to have greater adiposity and abdominal fat than appropriate for similar gestational age infants.[143] These features may be linked to long term risks

for central adiposity and insulin resistance later in life.

Changes in Body Composition during Malnutrition and Disease

Malnutrition and disease often results in body composition alterations beyond those expected from only underfeeding. Some of the methods used in the measurement body composition, and how it changes, may rely on assumptions derived from healthy children, which may have limited applicability in these cases. For example, electrolyte derangement and altered body water distribution related to a disease or clinical condition can invalidate the interpretation of the results of some techniques.[144,145] Disease-induced malnutrition can produce body compositional changes distinct from those caused by food deprivation alone. Significant changes in body composition may be masked by overall weight normalcy. Children with severe protein-energy malnutrition usually have increased TBW in relation to body weight, with ECW as an increased percentage of TBW. These changes are indicative of severe losses of cell mass, which may be detected by TBK measurements and loss of body fat. The cells retract and lose potassium, magnesium, and phosphorus. Body sodium is increased both extracellularly and intracellularly. The extracellular increase of sodium is generally less than the increase in ECW resulting in hyponatremia. Although serum potassium levels are usually normal, TBK is decreased. There are also deficiencies in magnesium, calcium, phosphorus, and trace elements (zinc, copper, selenium, and chromium). In severe cases, bone demineralization has been reported. The low TBK marked loss of muscle mass indicates depletion of body protein. If the energy imbalance continues, there can be slowing or cessation in linear growth, resulting in stunting. Therefore, alterations in ECW, sodium, and potassium should be taken into account early in the management of children with acute malnutrition. The process of recovery should start carefully and slowly, correcting for the water and electrolyte derangements, avoiding dangers associated with refeeding syndrome, particularly heart failure.[146] (See Chapter13, “Protein Energy Malnutrition: Pathophysiology, Clinical Consequences and Treatment”). In protein deprivation, there is an associated loss in non subcutaneous fat along with losses in muscle and visceral tissues. The ICW decreases, often with an expansion of the ECW as indicated by edema. These effects can obscure the severity of the malnutrition if body weight alone or a weight-for-height index alone is used to assess the child.

Changes in body composition are routinely observed in children with chronic diseases. These changes may be a direct consequence of the disease and caused by the treatment options (e.g., steroid associated osteopenia). Typically, lean mass is compromised during the most acute phase of illness, while the combination of lean and fat mass depletion is observed in less serious chronic conditions. Cancer, Crohn's disease, and cystic fibrosis are among the diseases where body composition abnormalities have been described. Children in remission from cancer have a greater percentage fat than healthy size-matched controls.[147–149] Similarly, children with Crohn's disease have reduced lean body mass, compared to controls, without significant concomitant reductions in fat mass. It has been shown that the degree of lean body mass loss is correlated with disease severity.[150] Cystic fibrosis is associated with deficits in lean body mass, fat mass, and bone BMD, with negative relationships with disease severity.[151] This suggests abnormalities in body composition are widespread in disease, and could be linked to patient outcome.[152]

CONCLUSIONS

Energy homeostasis is known to be important to human health, and the body's lean mass is the major contributor to metabolism and energy expenditure. Thus, assessment of body composition is an important aspect of understanding energy requirements during health and disease.[153] Body composition changes during normal growth, as well as in diseases and with their treatment. Growth includes chemical maturity of tissues, which occurs at different stages of development of the components of FFM. Fat mass also varies greatly during the life cycle and can be influenced by heredity, nutrition, lifestyle, and health status.

Body weight alone cannot be used as an acceptable measure of nutritional efficacy or status. The expansion of growth standards to include body composition reference ranges in childhood and adolescence could help in the recognition of abnormalities.[154] Body composition standards related to age, gender, body size, and ethnicity could also help in the recognition of differing patterns of distribution or accretion. In this sense, the beneficial role of exercise and the negative impact of a sedentary lifestyle could be emphasized. The possibility of critical periods for fat accretion and an understanding of the long term consequences of different body fat distributions might have important implications in the nutritional

management of children and adolescents.

As new and more accurate methods emerge, refinements for the reference infant, child, and adolescent models may be developed. The improvements will provide a measure of the biological diversity with age, gender, and ethnicity that can assist in the calibration of less expensive, surrogate methods more suitable for office practices and field studies. Although an ideal field method should be inexpensive, easy to use, reliable, noninvasive, and portable, it still needs to be validated and calibrated with one of the more advanced techniques. The clinician now has a variety of options in the body composition assessment armamentarium. The final interpretation of any results, however, should be assessed knowing the limitations and assumptions of the method selected.[155]

ACKNOWLEDGMENT

This chapter is a revised and updated version of the previous Body Composition and Growth chapter by Bechard L, Wroe E, and Ellis K in *Nutrition in Pediatrics: Basic Science and Clinical Applications*, 4th edition. Walker WA, Watkins JB, Duggan C, editors, 2006.

Carbohydrates

5

Clemens Kunz, PhD, Lena Geiger, MSc, and Christoph Fusch, MD, PhD

BACKGROUND AND OBJECTIVES

Carbohydrates (CHO) play an essential role with regard to the development of physiological functions of the entire gastrointestinal (GI) tract in neonates, infants, and children. In this chapter, we will not review the general aspects of digestion and absorption of CHO but select some special topics that are currently discussed. We focus on

i. the influence of CHO on intestinal microbial composition and activity;
ii. differences between prebiotics in human milk versus oligosaccharides added to milk and other food products;
iii. potential risks of a high fructose (Frc) intake;
iv. recommendations for CHO intake;
v. disorders involving CHO.

The nutritional status of pregnant women has been recognized to play a major role in fetal development, which may affect the manifestation of diseases later in life (metabolic programming).[1–4] From the time of birth, nutrition of the infant becomes most important. Here, the intestinal microbiota is of particular relevance owing to its strong impact on the development of the unspecific defense and on the immune system.[5–11] Currently, the question is intensely discussed how composition and activity of the microbiota can be modulated by the intake of dietary components such as CHO.[12,13] Products enriched with special components or mixtures, such as prebiotic oligosaccharides (PBOs), play a major role in the nutrition of infants and children.

Amongst CHO, Frc has received special attention in recent years not only because its intake increased markedly during the last 10 years but also the metabolic processes of Frc is also considered to be potentially linked to

various health risks. Therefore, the controversy about Frc and its health effects, for example, the potential contribution to the obesity pandemic, will be covered as well.

The principle how to establish recommendations for digestible CHO intake as well as for distinct CHO members are reviewed; actual figures are given and the role of body growth is critically discussed. Second, the basis of recommendations for the intake of nondigestible CHO, that is, dietary fibers (DFs) is delineated. Finally, an overview about diseases that lead to or involve CHO metabolism is given.

In the following, we will first give a short introduction into some basic aspects of CHO followed by their functional roles in human nutrition.

DEFINITION, ORIGIN, AND CLASSIFICATION OF CARBOHYDRATES

CHO consist of carbon, hydrogen, and oxygen in the ratio of 1:2:1 (empirical formula $C_nH_{2n}0_n$). They are found in a variety of foods in the human diet and are largely derived from plant sources. However, sugars are also widely used in many products that are not of plant origin.

In humans, CHO occur as a product of the intermediary metabolism (gluconeogenesis, glycogenesis). Under starvation, the body can produce CHO from glycoplastic amino acids; synthesis from glycerol of triacylglycerols (fat) and fatty acids is also possible.

Classification

Like other macronutrients, CHO are classified into four main groups, based on their molecular size, which is determined by the degree of polymerization:

- Monosaccharides
- Disaccharides (2 monosaccharides)
- Oligosaccharides (3–9 monosaccharides)
- Polysaccharides (>9 monosaccharides)

The term “sugars” comprises monosaccharides and disaccharides. They occur as single and small molecules and are the building blocks of the more complex CHO. These can be stored or can be used as structural components.

Monosaccharides and Disaccharides (Sugars)

Monosaccharides are the smallest building blocks of CHO. In contrast to disaccharides, oligosaccharides, and polysaccharides, monosaccharides cannot be further degraded by acid hydrolysis. They are composed of a chain of three to seven carbons. Based on the number of carbons, the monosaccharides are classified into trioses, tetroses, pentoses, hexoses, and heptoses. Only 3 of the 12 naturally occurring hexoses can be absorbed and metabolized by the human body. These are glucose, galactose, and Frc.

Disaccharides are composed of two equal or different monosaccharides. The common disaccharides are lactose, sucrose, and maltose. Lactose is found in very high amounts in milk and dairy products and is the major source of CHO in the nutrition of milk-fed infants.

Oligosaccharides (3–9 Monosaccharides)

Oligosaccharides are found in fermented products as well as in vegetables. Various oligosaccharides are also highly abundant in breast milk.

Oligosaccharides are a diverse group of soluble CHO, including trisaccharides and tetrasaccharides such as raffinose and stachyose, maltodextrins from partial degradation of starch, fructosaccharides and galactooligosaccharides, and inulin. Many of the oligosaccharides are resistant against the enzymes of the intestinal tract and are fermented in the colon. Therefore, they are called nondigestible oligosaccharides.

Polysaccharides (>9 Monosaccharides)

The most important building block of natural polysaccharides is glucose. In nature, many polysaccharides are used for energetic purposes as building blocks for structural components. Polysaccharides may be divided into starch and nonstarch polysaccharides (NSP). They are distinguished by the presence of α-glucosidic bonds.

Starch

The most common storage form in plants is starch, which is composed of α-glucan and a mixture of the two polymers amylose and amylopectin. Amylose, which usually comprises 20%–30%, is a polymer of α-1,4 linked D-glucose. The molecule consists of linear chains that are turned into a tight helix. The second and quantitatively major component of naturally occurring starch (70%–80%), amylopectin, contains additional α-1,6 glycosidic linkages, resulting in the highly branched structure of this polymer.

NSPs are mostly components of plant cell walls. Other NSPs are also present in plant food as gums or mucilages. Cell wall NSPs are quantitatively more significant and are found in all fruits, vegetables, cereals, and nuts. They escape digestion in the upper gut and pass into the large intestine where they are fermented by the microbiota.

The classification of CHO and their food source is given in Table 5-1.

FUNCTIONAL ASPECTS OF CARBOHYDRATES

Carbohydrates and Intestinal Microbiota

As summarized in Figure 5-1, CHO is either a source of energy or essential for various systemic effects after being absorbed. Local effects within the GI tract include being a substrate for the microbiota or by directly influencing and thereby modulating epithelial cell functions.

Interactions between microorganisms and the human host are strongly influenced by the fermentation of CHO with a subsequent effect on, for example, (a) growth promotion of bacteria that can utilize CHO, (b) formation of short-chained fatty acids (SCFAs), which are an important supplier of energy for epithelial cells, or (c) systemic effects of SCFA, which eventually may affect CHO and lipid metabolism.[14]

The use of CHO for fermentation strongly depends on the microbial composition of the GI tract, which changes from infancy to adulthood. Current studies aim at defining the dominant forces, which shape the microbiota.[15] As microorganisms differ in their preference for CHO, the dietary supply with various CHO as well as glycans from mucosal secretions has a direct influence on the microbial balance in the gut. CHO are of particular importance in situations when the normal gut microbiota has been destroyed and needs to be restored or when the microbiota has to be established, as is the case in the postnatal period.

TABLE 5-1 Classification of Carbohydrates and Sources

Class (DP)	Subgroup	Principal Components	Source(s)
Sugars (1–2)	Monosaccharides	Glucose Galactose Fructose	Fruits and vegetables
	Disaccharides	Lactose Sucrose	Milk and milk products

			Fruits and vegetables
Oligosaccharides (3–9)	Malto-oligosaccharides Nondigestible oligosaccharides	Maltose Stachyose, raffinose Fructo-oligosaccharides (FOS) Galacto-oligosaccharides (GOS)	Glucose syrups Sugar-beet root, legume, cucurbits Vegetables Milk and milk products
Polysaccharides (≥9)	Starch	Amylose Amylopectin Modified starches	Cereals, potatoes
	Nonstarch polysaccharides	Cellulose Hemicellulose Pectin	Vegetables, cereals, fruits

Abbreviations: DP, degree of polymerization.

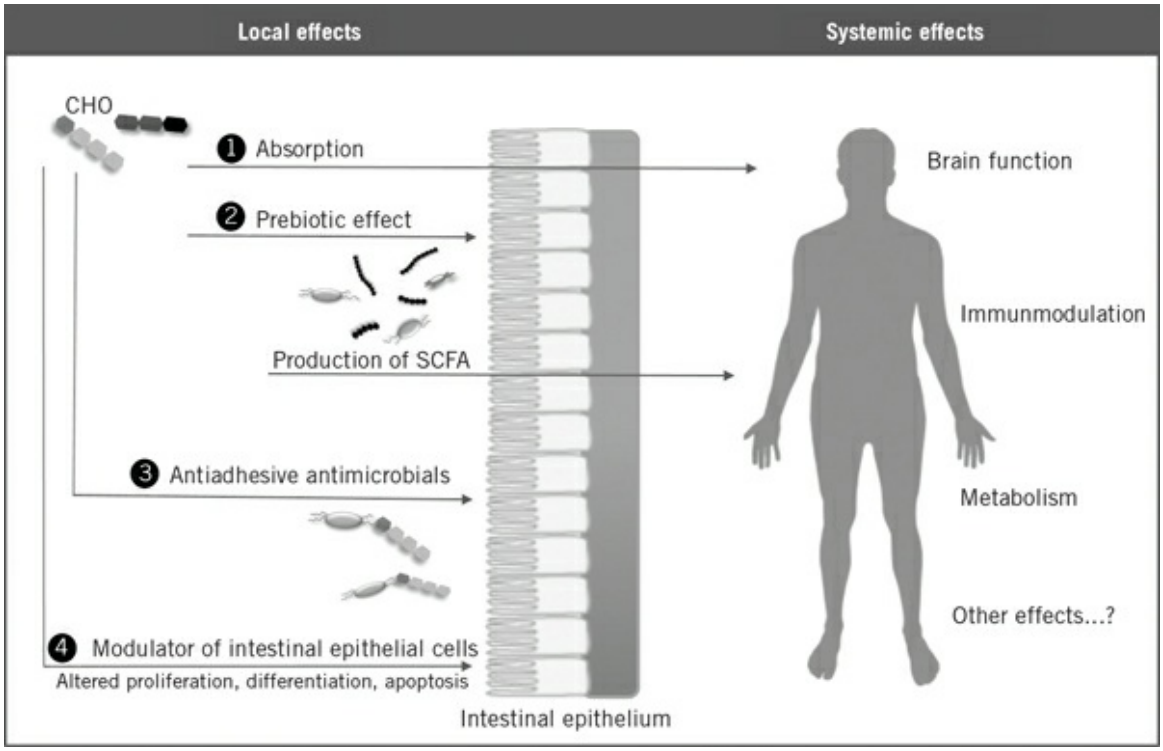

Figure 5-1 Generalized local and systemic effects of carbohydrates. The numbers 1–4 indicate specific functions, i.e., (1) absorption of carbohydrates, (2) influence on the microbiota composition and/or activity, (3) prevention of pathogen adhesion, and (4) direct effects on epithelial cells and systemic effects.

A schematic overview about changes in the microbial composition from birth to adulthood is shown in Figure 5-2.

The figure demonstrates the importance of bifidobacteria soon after birth. As anaerobes, they grow well in an oxygen-depleted environment, such as the infant's colon. The lactic acid produced keeps the surrounding pH low, thereby preventing the growth of potential pathogens. Although many factors, such as the mode of delivery or the environment, influence the development of the microbiota, human milk is considered to have a major impact as well.[11,17] Obviously, human milk contains components that favor the growth of bifidobacteria, which is discussed later. After exclusive breastfeeding, the introduction of solid food marks an important change in the microbial composition, which slowly leads to an adult microbiome. The first years after birth are a sensitive time frame where, among others, nutritional factors are of particular importance for the establishment of the microbiota. Our knowledge of the development of the microbiota and factors influencing the changes will certainly be modified due to the vast number of publications in recent years based on the availability of methods such as 16sRNA or pyrosequencing, which allow a much better characterization of microbial communities.[6] Here, recent observations of a specific "enterotype" of an individual are of particular interest.[18] It means that single persons can be grouped to a certain gut microbiome within a population, although the microbial composition varies substantially from person to person. Current data indicate that the human population can be associated with at least three enterotypes, and within one group, only few species dominate. *Enterotype 1* is characterized by bacteroides with a broad spectrum of saccharolytical (i.e., galactosidases, hexosaminidases, etc.) and proteases activities, as well as the enzymatic equipment for glycolysis and pentose phosphate pathway. *Enterotype 2* is comparable to type 1 with additional sulfate-reducing bacteria (*desulfovibrio*). This type is possibly important for mucin-degrading pathways with the simultaneous existence of *Prevotella*, which releases sulfate during the degradation of mucins. Sulfate is removed by *desulfovibrio* in order not to inhibit the degradation of mucins by the rising sulfate concentration. *Enterotype 3* is characterized by the family of Lachnospiraceae, which produces butyrate. Besides, they contain mucin-degrading and sugar-metabolizing enzymes that allow them to ferment a wide variety of CHO. This ensures that otherwise indigestible CHO are actually metabolized.[18] The products of hydrolysis can then be fermented, resulting in the production of SCFA that provide about 10% of the daily energy.

Interestingly, those enterotypes seem to be influenced by the nutrition pattern of the respective individual: a diet rich in lipids will lead to a cluster being dominated by bacteroides, whereas a diet rich in CHO will lead to a dominance of *Prevotella* (firmicutes). This also confirms observations made in other studies, which show that diet substantially affects the microbial composition of the intestine and thus the overall health. The question which mechanisms are underlying these observations has not been answered yet. In the case of preventive and therapeutic measures, it is important that the microbial composition of the intestine can be changed within one day, but it is unclear whether the predominant pattern of enterotypes can actually be changed in long-term studies.

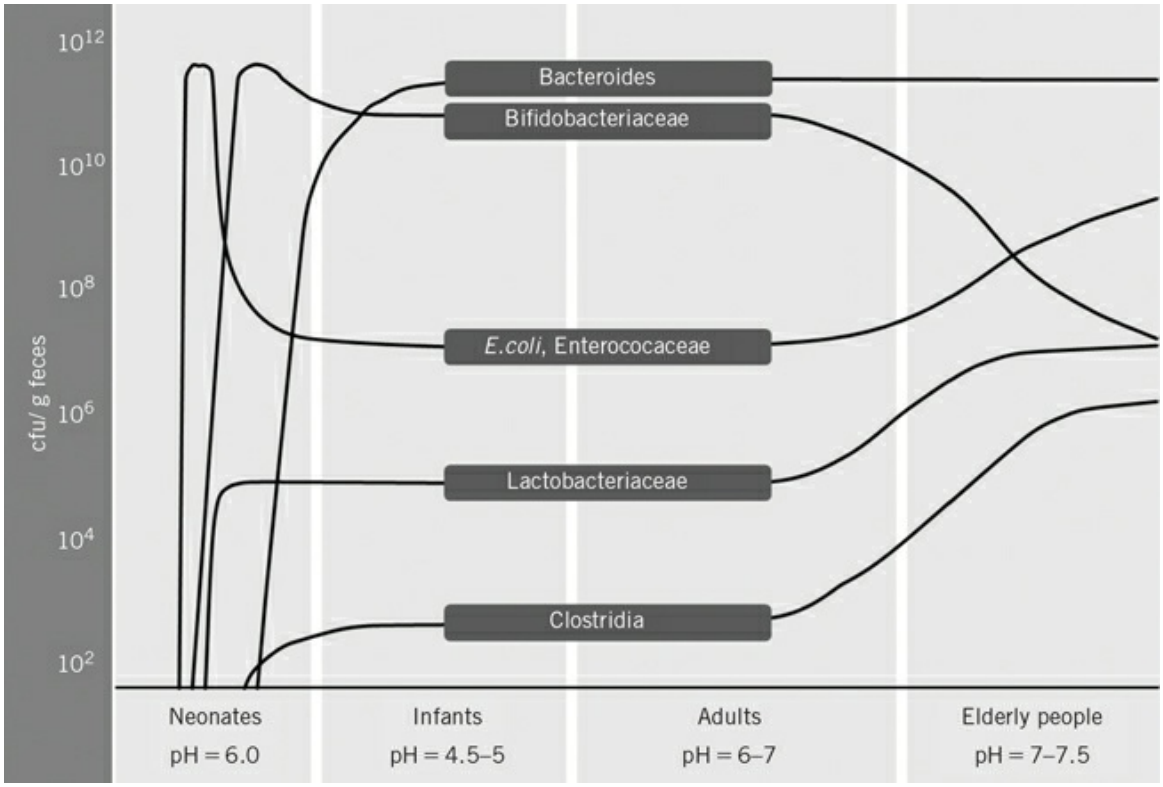

Figure 5-2 Changes in microbial composition from birth to advanced age (according to Walker et al. [2000]). CFU, colony-forming units.

Importance of Milk Oligosaccharides and Gut Microbiota Development

Intestinal colonization with a balanced microbiota is of major importance for an appropriate development of the immune system, and there is an

enormous scientific and commercial interest in modifying the microbiota for health promotion.[19] As the gut is sterile at birth, it is an organ sensitive to environmental influences. Furthermore, there is an intensive cross talk between gut microbes and the intestinal epithelium throughout life.[20–22] The mechanisms by which the intestinal mucosa perceives and responds to microbes, both pathogenic and commensal, are not completely known yet. Here, it is intriguing to investigate the role of human milk oligosaccharides (HMOs) or specific single monosaccharides and their effects on the selective growth of microorganisms in the gut.

As there are major differences in the CHO composition of human milk and bovine milk, and hence in the composition of infant formula, the effects of these types of feeding within the GI tract are different. For comparison, the overall composition of human milk and bovine milk is shown in Table 5-2.

Since the pioneering work of György et al. in the middle of the last century demonstrating the effect of *N*-acetylglucosamine (GlcNAc) containing oligosaccharides on the growth of *Bifidobacteria bifidum* subsp. *Pensylvanicum*, a strain György et al. isolated from infant feces, this topic is still of great scientific interest today.[26–28]

TABLE 5-2 Macronutrients and HMO in Mature Human Milk and Cow Milk

	Human Milk	Bovine Milk
Protein (g/L)	10	35
Fat (g/L)	41	37
Lactose (g/L)	65	48
Oligosaccharides (g/L)	5–15	0,05
Number of identified oligosaccharides	>150	~40
% Neutral oligosaccharides	~70%	~1%
% Sialylated oligosaccharides	~30%	~90%

Refs. 23–25 and cited references in these reviews.

Recently, Marcobal et al. showed that *Bifidobacterium longum* subsp. *infantis* can use HMO as the sole carbon source, whereas most of the other intestinal bacteria they studied were unable to assimilate HMO.[29] The genome of *B. longum* subsp. *infantis* (ATCC15697) contains a large gene cluster that comprises several glycosidases and specific transporters

suggested to be involved in the metabolism of HMO.[30] From the results of a comparative genomic survey, the conclusion was that the occurrence of the cluster correlates with the survival of this subspecies on HMO.[31] Therefore, David Mills and coworkers suggested that a HMO-consuming phenotype (HMO^+) of the subspecies can be attributed to the presence of this cluster (designated as the HMO cluster-1).[31]

Using a different methodological approach, Asakuma et al. reported the occurrence and localization of HMO-degrading enzymes in different bifidobacterial strains (Table 5-3).[32] The presence of external enzymes such as specific fucosidases and lacto-*N*-biosidases, which are secreted by bacterial cells and specific transporters for lacto-*N*-biose (LNB; Gal-β-(1-3)-Glc*N*Ac) and galacto-*N*-biose (GNB; Gal-β-(1-3)-Gal*N*Ac) explains why specific HMO can be used differently by bifidobacteria. Kitaoka et al. have recently elucidated that *B. bifidum*, which is another consumer of HMO, has a special pathway for degrading type-1 HMO.[33,34] The authors reported that *B. bifidum* uses a secretory lacto-*N*-biosidase to hydrolyze lacto-*N*-tetraose (LNT) to LNB and lactose. The liberated LNB is then incorporated into the cells by an ABC transporter specific for LNB and GNB.[35] LNB and GNB are converted to galactose and Glc*N*Ac-1-phosphate or Gal*N*Ac-1-phosphate by the action of GLB/LNB phosphorylase.[33]

This pathway, the GNB/LNB pathway, which involves LNB as a key intermediate, occurs in *B. bifidum* and some strains of *B. longum* subsp. *longum*, but apparently does not work in *B. longum* subsp. *infantis* because all of the genomes having been determined so far do not contain lacto-*N*-biosidase homologs.[31,34] *B. longum* subsp. *infantis* possesses a GNB/LNB phosphorylase, but this enzyme exclusively acts on the disaccharide and not on LNT.[33,36]

In a study on *B. longum* subsp. *Infantis*, Yoshida et al. demonstrated that this strain directly incorporates LNT and hydrolyses it inside the cell by a specific β-galactosidase. This β-galactosidase seems to have the substrate specificity for the type-1 chain (Galβ1-3Glc*N*Ac), but this strain also has another β-galactosidase that is specific for lactose and type-2 chain (Galβ1-4Glc*N*Ac).[37,38] This new data indicate that the organism uses two different β-galactosidases to selectively degrade type-1 and type-2 HMO. It also supports the view that the HMO^+ phenotype of this subspecies should not be attributed solely to the presence of the HMO cluster-1.

So far, investigations on growth-promoting factors have primarily been

focused on neutral HMO, although a few studies on the effects of sialylated oligosaccharides have been published. Sialidases have been found in *B. longum* subsp. *infantis* and *B. bifidum*.[39,40]

Prebiotic Oligosaccharides from Different Matrices

CHO with prebiotic effects belong to a functional food concept claiming to positively influence GI health through various mechanisms. The concept has been introduced in 1995 by Gibson and Roberfroid who defined prebiotics as a nondigestible food ingredient that beneficially affects the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon, thus improving host health.[41]

Prebiotics are considered to have specific effects, especially in the GI tract, such as influencing the microbial composition, digestive processes, regulatory mechanisms, hormone activities, and nutrient availability. This directly or indirectly also affects the immune system (Figure 5-3).

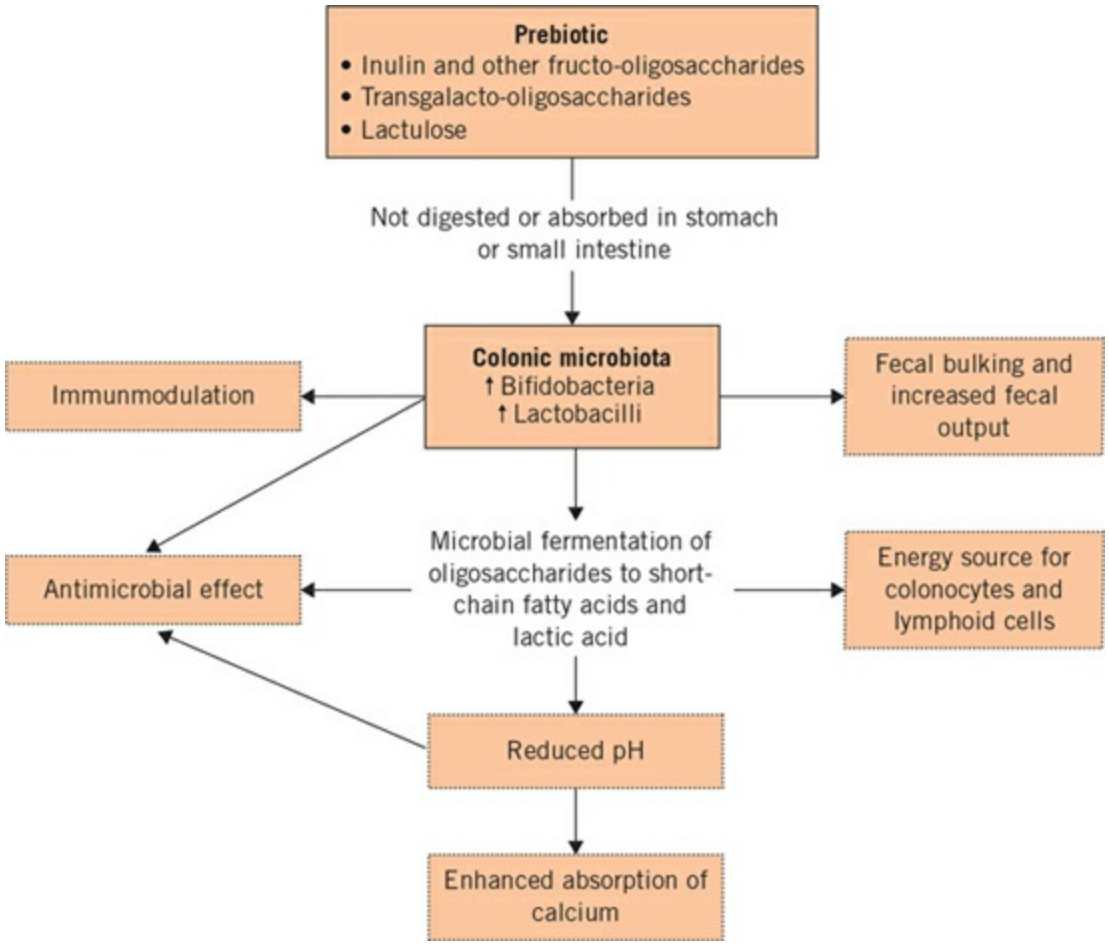

Figure 5-3 Representation of potential effects of prebiotics in the intestinal tract (Sherman et al.[43]).

The bifidogenic effects of oligosaccharides, especially of inulin and oligofructose, have been well proven even in humans. In one of their first experiments, Gibson and Roberfroid have shown that within a few days after the oral administration of oligofructose (15 g for 14 days) to healthy volunteers, a marked change of the microbiota toward the predominance of bifidobacteria occurred.[42] Switching back to the original diet restores the microbiota within a few days.

Currently, research concentrates on searching for ways how to improve the growth of bifidobacteria as these microorganisms dominate in the infants' GI tract. A direct influence of bifidobacteria on the growth of colon cells by differentiation, proliferation, and apoptosis is considered to

be the mechanism underlying the postulated effects of prebiotic products. In this context, the SCFA butyrate, propionate, and acetate, which are formed during fermentation, play a special role.

Galacto-oligosaccharides (GOS) and fructo-oligosaccharides (FOS) belong to the best-known prebiotics, but moreover, numerous other CHO can be found as prebiotics on the global market.[43,44] There is a huge number of publications of studies using prebiotic components in different clinical settings or for various reasons (for review see Refs. 43 and 45). Most often, the overall aim of these studies is to improve the GI health by investigating the effects on (a) the bifidobacterial composition, (b) on the production of SCFA, or (c) on changes in the fecal pH. Each of these effects would be beneficial to the infant. However, often, the data are rather difficult to interpret, and the impression is being created that if an effect on the microbial composition cannot be found, although it was the major aim of the study, the authors focus on the difference in SCFA production or, if this fails as well, they concentrate on differences in the pH in various groups. In agreement with pediatric authorities, there is still a lack of RCTs in this area to recommend a special prebiotic to be used.[46]

Figure 5-4 shows a scheme of the postulated effects of milk oligosaccharides and prebiotic plant-derived oligosaccharides. It needs to be shown which specific process and underlying mechanism is induced by which substrate and whether there are similarities between different prebiotics. Like with other functional food components, special attention needs to be addressed as to whether prebiotics are recommended for preventive purpose in healthy persons or for therapeutic considerations in certain diseases.

However, there are very interesting data worthwhile for further investigations. Besides the important observation that the amount of calcium absorbed can be influenced by prebiotics, it has been shown for the first time that applying prebiotics implies the need of differentiating between responder and nonresponder.[47] This observation may explain that in many studies, the interpretation of data is rather difficult as no distinction between a different individual responsiveness has been made.

Another difficulty is that most studies do not allow unambiguous statements regarding structural interactions. CHO, in general, have a high potential to exert health effects besides the delivery of glucose as energy source. However, much remains speculative in their prebiotics functions. Most studies in recent years concentrated on the impact on the growth of bifidobacteria themselves, where as the effects of bacterial metabolites and their impact on health have been neglected.[48] Important questions still

cannot be answered, such as (i) should the prevailing microbial composition throughout the whole GI tract be modified in healthy humans and (ii) is it actually of importance to have an intestinal microbiota dominated by bifidobacteria? Apart from promoting a microbiota dominated by bifidobacteria in neonates, further research should consider possibilities how to influence the metabolic activity of colon cells, the increase of mineral bioavailability, or systemic effects regarding CHO and lipid metabolism.

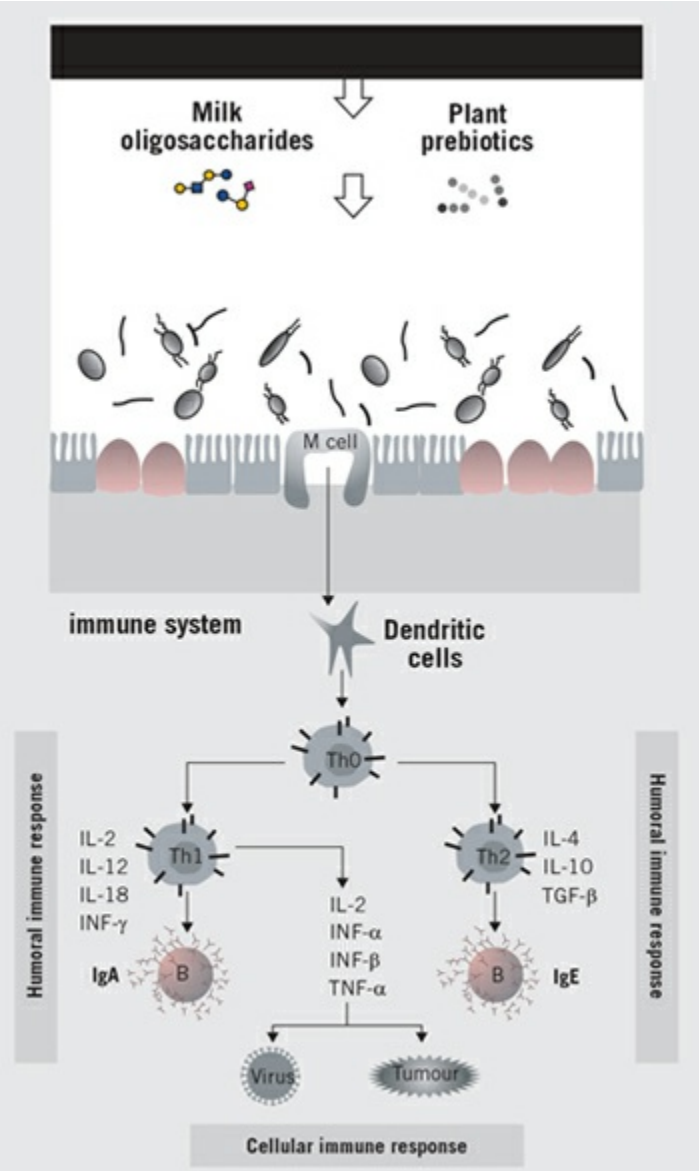

Figure 5-4 Metabolic fate of an oral fructose load in healthy subjects.

In our view, discussion needs to take into account whether prebiotics are useful for primary prevention in healthy people, for secondary prevention in case of a given risk (e.g., genetic predisposition), or for therapy in case of certain diseases.[46]

Human Milk Oligosaccharides Versus Prebiotic Oligosaccharides

In many scientific publications, including reviews on functional aspects of PBOs, these components are often compared with HMOs as those CHO are believed to also exert a bifidogenic effect on the infant. Some formula producing companies go as far as claiming in consumer information that both groups of CHO share great functional as well as structural aspects.

However, PBOs and HMOs do not share any structural similarity that is required to speculate about similar biological functions. A brief summary is given regarding the structural diversity of PBOs and HMOs.

TABLE 5-4 Monosaccharide Composition of Human Milk Oligosaccharides and of Representative Prebiotics

Sialyl-lactose	α 2-3, α 2-6, β1-4,
Sialyl-lacto-*N*-tetraose	α 2-3, α 2-6, β1-4, β1-3

Definition of HMOs and of PBOs

HMOs are solely produced in the lactating mammary gland. Their core structures are based on lactose, which is then modified by the addition of specific monosaccharides like the amino sugar Glc*N*Ac and galactose that are present as lactosamine units and/or fucose, or acidic components (*N*-acetylneuraminic acid, also called sialic acid) (Table 5-4).[49] An important core structure is LNT and its fucosylated derivatives (Table 5-5a). Hence, there is a large variability of HMOs with a total number of more than 150 compounds characterized so far. The total concentration is rather high (5–10 g/L) compared to the protein content of human milk.[50]

For supplementation of infant formula, galactosylated and/or fructosylated oligosaccharides are often used. They may be derived from plants or produced by technological means, for example, by transgalactosylation using the galactose moiety of hydrolyzed lactose. Such components are not present in human milk.

So far, the main monosaccharides in PBOs are galactose, glucose, Frc, xylose, and arabinose with a great potential for new components to be available soon (Table 5-4).[48] With the exception of glucose and galactose, these monosaccharides are not present in human milk.

Linkage Specificity Between Monosaccharidesin HMOs and PBOs

FOS like inulin or oligofructose are well-characterized components. They consist of a number of β1-6-linked galactosyl residues bound to a terminal glucose unit through an α1-4-linkage. A thorough review on this topic has been given by Rastall.[51] In human milk, however, small oligosaccharides are fucosylated or sialylated, but solely galactosylated components do not occur. In addition, the linkage between monosaccharides is important for biological effects as well. Therefore, examples for some specific linkages in HMOs and PBOs are shown in Table 5-5b.

In recent clinical studies, it was shown that the addition of GOS and FOS to a formula may increase the number of bifidobacteria. However, it has not been convincingly demonstrated yet that, at the same time as the number of bifidobacteria increases, the number of potentially pathogenic microorganisms in the infants' colon decreases, which then leads to the bifidus-predominant gut flora in breastfed infants. Milk oligosaccharides

are thus thought to exert direct effects on the adhesion of microorganisms, and even their toxins, by competitive inhibition of their adhesion to the intestinal wall. For detailed information, see reviews by Bode[52] and Kunz et al.[53]

Potential Risks of a High Fructose Intake

A typical westernized diet is characterized by a high intake of refined CHO and fats combined with a reduced intake of plant polysaccharides. Often, this pattern involves an increasing consumption of Frc, sugar substitutes, or artificial sweetener, which is controversially discussed as one major factor for the obesity pandemic.[54,55]

TABLE 5-5B Specific Monosaccharide Linkages in Prebiotics

Oligosaccharide	Monosaccharide Linkage
Fructo-	β1-2,
Galacto-	α 1-2, α 1-4, α 1-6,
Transgalacto-	and
Soybean-	other linkages

Frc is a monosaccharide naturally occurring in many fruits and vegetables. Its contribution to the overall energy intake is estimated to be about 10%.[56] In comparison to the amount of Frc, for example, in high corn fructose syrup (HCFS), the amounts in fruits and vegetables are relatively low. HCFS consists of free Frc and glucose. The ratio may be very different often being 55–45. Currently, the question as to whether the marked increase of Frc intake is a particular high risk for obesity is highly controversially discussed.[57–62]

Negative effects might be due to different satiety effects compared to glucose with a subsequently higher intake of energy. It is conceivable that a lower increase in blood glucose results in a lower secretion of insulin followed by a diminished increase in leptin and, subsequently, by a lower ghrelin suppression.

Bray and Popkin were the first to describe the link between Frc and obesity. Since then, Frc has often been associated with the negative effects, especially concerning the promotion of cardiovascular disease. Frc is found to have negative effects on blood lipids, uric acid, blood pressure, body weight, glucose, and insulin regulation, which is schematically

shown in Figure 5-5b.

Metabolic Aspects of Fructose

Special effects of Frc metabolism in the liver result in the preference of the lipogenic pathway with an influence on the de novo lipogenesis (DNL).[63] In contrast to glucose dietary, Frc does not stimulate insulin or leptin, which are important regulators of energy intake and body adiposity. Stimulated triglyceride synthesis most likely leads to the hepatic accumulation of triglyceride, which has been shown to reduce hepatic insulin sensitivity, as well as an increased formation of very low-density lipoprotein (VLDL) particles due to higher substrate availability, increased apo B stability, and higher microsomal triglyceride transfer protein, a critical factor in VLDL assembly.[63]

The intestinal absorption of glucose and Frc is distinctly different. Frc is primarily absorbed through the GLUT-5 transporter. After the transport through the portal vein, a complete uptake of Frc by the liver through GLUT-2 follows, where Frc can be converted to glucose and/or lactate or stored as glycogen (Figure 5-6). There is the decisive point, where one part of the absorbed Frc can be used for the DNL.

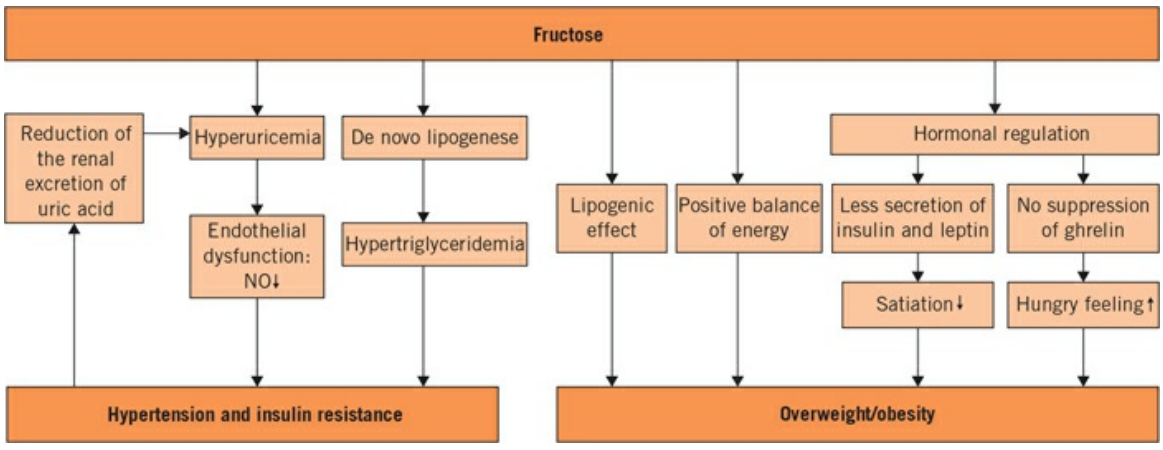

Figure 5-5 Fructose and the potential link to hypertension, insulin resistance, and obesity.

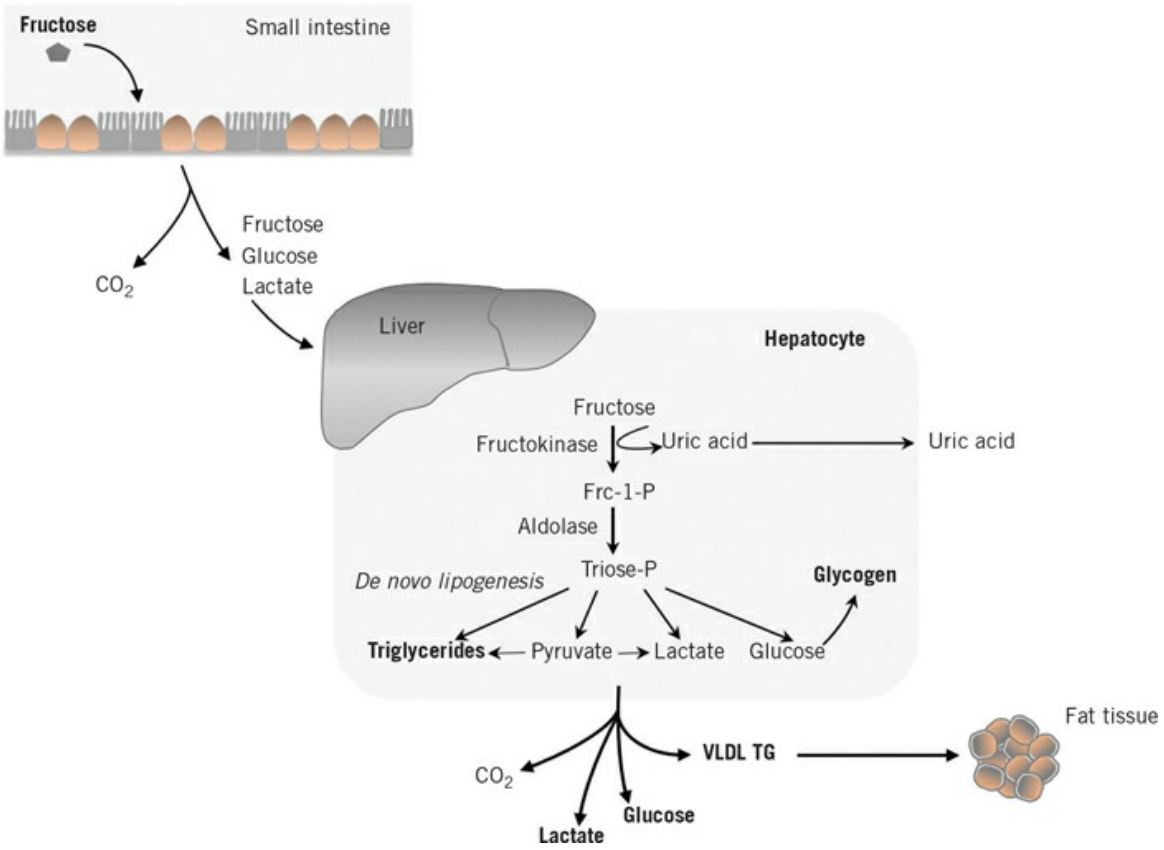

Figure 5-6 Potential of milk oligosaccharides and plant-derived prebiotics to influence the intestinal immune system.

On the extent of DNL after the intake of Frc, the opinions, however, differ greatly (see below). The assumption is that with Frc, in contrast to glucose, the regulation through phosphofructokinase as the most effective controlling enzyme is avoided so that the whole Frc is available as a substrate for DNL.

Controversial Opinions

Intervention studies with high amounts of Frc (e.g., with a 25% energy excess) are regarded as evidence for the negative effects. But a negative metabolic implication has not been shown in investigations with isocaloric diets, in which Frc was exchanged by other CHO sources under energy-matched conditions. In contrast, studies with hypercaloric diets lead to strongly and permanently increased triglycerides and apo-B-values.

However, this mechanism of DNL has been proven so far only in animal and not in human studies. In animal models, however, the

proportion of CHO being available for DNL is much higher than in humans (up to 96% in mice, >50% in rats, and only 5% in man).[64] In addition, there is even evidence that smaller amounts of Frc (<10g) positively influence the regulation of blood glucose through an increase of glycogen synthesis in the liver and a decreased glucose production. Apart from that, 60% of the energy intake consists of Frc in animal studies, whereas it is only 10% in man.

Despite those serious doubts concerning the negative interpretation of many studies, nutrition guidelines are very restrictive regarding the Frc intake.

In various studies, no indication for negative effects of Frc on blood lipids, uric acid, blood pressure, body mass index (BMI), or insulin has been found as long as low to moderate amounts of Frc (<60 g/d or <10% of energy) are consumed together with an isocaloric exchange with other CHO. It seems that the risks of a too high Frc supply will rise, if intake exceeds 100g/d (relevant for all population groups), intake exceeds 60 g/d in case of diabetes mellitus (DM) type 2, and in case of hypercaloric nutrition (>20% excess energy).

Dyslipidemia, increased uric acid levels, and a gain of weight are observed. In case of hypercaloric nutrition, however, it may be that the surplus of calories may be causing the negative effects and not Frc itself.[64]

The situation regarding the potential harm of a Frc intake is still a matter of most controversial discussion. For a detailed overview, see Refs. 58–62.

In general, it should be kept in mind, irrespective of whether studies found negative impacts or not, that all studies so far have shown more or less striking shortcomings with respect to study design, methods applied, duration, and so forth.

To finally evaluate the current discussion, one may conclude that free Frc is to be evaluated similar to bound Frc; Frc as HFCS or sugar in soft drinks differs from Frc consumed as part of a diet rich in fruits; and transferability of results from animal studies to humans is not always given due to (i) unphysiologically high doses of Frc, (ii) different metabolic situation (e.g., rats have uricase), and (iii) the fact that not all effects observed in animals can be found in human studies.

The controversial topic of Frc and its negative effects is, in our opinion, best summarized by Tappy and Mittendorfer (2012)[65]:

- There is some evidence suggesting excessive Frc consumption, especially in combination with excess energy intake may have

adverse effects on metabolic health.

- The results from clinical trials do not support a significant detrimental effect of Frc on metabolic health when consumed as part of a weight-maintaining diet in amounts consistent with the average estimated Frc consumption in Western countries.
- Public health policies to eliminate or limit Frc in the diet should be considered to be premature.
- Crucial studies providing definitive answers to the concerns of Frc toxicity and others, which should guide decisions of public policy makers, are still missing.

RECOMMENDATIONS

Preamble

The following paragraph will deal with recommendations for CHO intake: its first part will refer to the "digestible" fraction of the CHO family, and the second part will deal with the "nondigestible" fraction, also called dietary fibers (DF).

Due to the fact that child physiology is influenced by physical growth, pediatric recommendations for nutrient intakes usually vary with age and body weight; it is also a fact that recommendations have not been established for all age groups by sound research, but were delineated for some age groups by extrapolation, thereby applying known data from other age groups. For example, frequent recommendations for toddlers and school kids are based on extrapolating data established for newborns and adolescents. These different approaches lead to different types of recommendations and are summarized as follows[66]:

Estimated average requirement (EAR) meets the estimated nutrient needs in half of the population.

Recommended dietary allowance (RDA) covers the needs of 97%–98% of the population and is, therefore, equal to EAR plus twice the coefficient of variation (CV).

Acceptable macronutrient distribution range (AMDR) is the range of adequate macronutrient intakes that are associated with reduced risks of chronic disease while providing recommended intakes of other essential nutrients. AMDRs are especially useful in subjects with special energy needs and are therefore given as percentage of total energy intake.

Adequate intake (AI) is the observed average or experimentally determined intake by a defined population or subgroup that appears to

sustain a defined nutritional status such as growth rate, normal circulation nutrient levels, or other functional indicators of health. AI is used if sufficient scientific evidence is not available to derive an EAR. AI is not equivalent with RDA. For infants, AI of CHO intake is derived using what is consumed from human milk and complementary foods.

Composition of Carbohydrates During Childhood

The composition of ingested CHO varies during childhood and—as gut matures—becomes more complex. During fetal life, the sole source of CHO is provided as a monosaccharide, that is, glucose. Postnatally, glucose is still the only CHO of choice when a newborn cannot be enterally fed and is in need for intravenous nutrition. In healthy newborns who can be enterally fed, the sole source of CHO becomes a disaccharide (lactose); with introduction of solid food and later family meals, the CHO source expands to starch and other disaccharides like sucrose, maltose, and maltodextrin, a glucose-based oligosaccharide (chain length of n = 3–20, also known as glucose syrup). Comparative data from international studies indicate that lactose intake drops from 20% to 25% (of total energy intake) during the first year of life toward <10% after the age of two years.[67] However, currently, no recommendations exist that address the composition of CHO during childhood.

Recommendations Based on the Intake of Digestible Carbohydrates

As mentioned earlier, digestible CHO consist mainly of sugars and starches, and their primary role is that of an energy source to the tissue. Muscle, heart, kidneys, and especially the brain rely mainly on CHO as an energy substrate. The recommended dietary intake (RDI) is therefore based to provide sufficient CHO as primary energy source for the brain and to avoid the formation of keto-bodies. Besides the intake that is needed to support brain metabolism, there is an AMDR, which takes into account the role of CHO in maintaining a constant body weight/composition or—as it is the case in children—in achieving adequate growth.[66] AMDR also takes into account specific circumstances like the physical activity level (PAL).

As a general rule, it is said that for children beyond 2 years of age, more than 50% of energy intake shall be provided by CHO.[68–70] Thus, the dietary recommendations for CHO—on one hand—are strongly related to energy requirements and intake. On the other hand, there is strong

evidence that the brain of infants consumes up to 60% of all CHO; thus, in childhood, RDI for CHO is also closely correlated to brain size and growth. The brain of a term baby weighs 380–400 g; at 12 months of age, it grows up to about 1000 g; at the age of 5 years, the brain weight is about 1300 g; and that of a young adult is between 1350 and 1450 g.[66] Brain glucose consumption has been found to be approximately 8 g/100 g brain tissue/d. Term infants will therefore need 32 g/d as adequate cerebral CHO supply. Infants 1 year of age will require 80 g of CHO per day and young adults 100–110 g/d. In addition to cover the energetic needs of the brain, glucose must also be provided for those body cells that rely on anaerobic glycolysis like red and white blood cells (approximately 35 g/d in adults). On the other hand, endogenous gluconeogenesis from proteins and fatty acid oxidation contributes to about 30 g of glucose production per day in young adults. Beyond the first year of age, the estimated average of requirements (EAR) for CHO intake seems therefore to be 100 g/d. Assuming an adequate energy intake contributed by the other macronutrients, this amount should be appropriate to provide sufficient energy to the brain, thereby preventing the formation of keto-bodies. The RDA (calculated as EAR plus twice the CV of 15%) is thus 130 g/d.

In infants below 12 months of age, the EAR/RDA approach to calculate CHO intake solely based on its role to provide sufficient cell fuel is not valid. In this age range, the effect of growth on energy and CHO requirements needs to be taken into account more specifically. Growth rates are highest around birth. From 40 weeks of gestation until 3 months of age, yearly growth rates are 70%, decreasing afterward to about 10% until the age of 6 months and to 3% per year at 12 months. On the other end, premature born infants experience even higher growth rates of up to 200% during their period from 26 to 34 weeks of gestation. Adequate growth requires sufficient intake of macronutrients, so that they can be deposited as new body cell mass, but also the synthesis of new cell mass itself is an energy-consuming process.

The dietary requirements of infants below 1 year of age can basically be divided into those needed for maintenance (like in young adults) and those needed for growth. Although figures for maintenance (expressed as kilocalories per kilogram per day) do not vary significantly during the first 12 months of life, the needs for growth are considerably higher during the first 3 to 5 months of life because growth rates are highest during that period; thus, at 1 month of age, requirements for growth account for 40% of total intake, at 3 months for 22%, at 6 months for 7%, and at 12 months for 3.5%. Infants born very premature may even need up to 70% of their

intake for growth. As a consequence, there is a fundamental difference in the composition of those macronutrients that are either needed for growth or to provide energy for maintenance. Appropriate growth from –3 until + 12 months after term can only occur by providing excess energy as well as sufficient protein, that is, the amount purely needed for growth exceeds that one needed for maintenance by a factor of 2–4.

As a consequence, recommendations about a safe intake of CHO can therefore not be made for this young age group by focusing only on the role of CHO for brain metabolism. The picture will become more complete by taking into account (i) theoretical considerations about the composition of growth (i.e., factorial approach) as well as (ii) the CHO intake achieved from breast milk, which is assumed to be the reference nutrition for healthy term infants. Assuming an average digestible CHO content of 6.2–7.5 g/100mL in mature breast milk,[71–74] and a total fluid intake (TFI) of 150–160 ml/kg/d, a term infant will thus achieve a CHO intake of 10.5–12 g/kg/d or 32–50 g/d. At 3 months of age, the intake increases to 50–65 g/d and to 90–120 g/d at the age of 9–12 months.

In premature born infants, the previous approach is not valid because breast milk has not been designed by nature to meet the enhanced nutritional needs for growth in very low-birth-weight (VLBW) infants. Applying the factorial approach leads to an overall requirement of 100–135 kcal/kg/d.[75] Approximately one half of these calories should be provided in the form of CHO (i.e., 50–65 kcal/kg/d), which translates into an enteral CHO intake of 12–17 g/kg/d. The upper value of this range comes closer to the upper limit of 16 g/kg/d needed for CHO oxidation.[74,75] It has also been shown that it is beneficial for protein accretion and longitudinal growth to provide nonprotein calories preferentially as CHO. Providing >50% of non proteincalories as CHO reduces amino acid breakdown, protein oxidation, and urea formation.[74,75] Applying standard fortification (3 g lactose per 100 mL) of human breast milk provides an intake of 15–17 g CHO/kg/d at a standard TFI of 150–160 mL/kg/d. It has been shown that growth rates above 17 g/kg/d can be achieved and lead to postnatal growth that is parallel to intrauterine growth curves.[76]

Table 5-6 summarizes data about RDA, EAR, and AIs for CHO in different age groups. It also shows data of a recent review paper about total intake of CHO, sugar, and starch in infants and toddlers.[67]

Recommendations Based on the Intake of Dietary Fibers

DFs consist of complex, partially branched, chained polysaccharides originating mainly from plants (see Chapter 2). The spectrum of enzymes in the human intestine is unable to cleave and digest these molecules. However, some intestinal bacterial strains may use them as a substrate. DFs have an impact on gastric emptying, absorption of lipid components, blood glucose response, the gut microbiome, laxation, and stool weight. A recent commentary by the ESPGHAN reviews the basics of non digestible CHO in childhood.[77]

DFs seem to have no systemic effects as they are not being absorbed. For the same reason, serum concentrations of DFs cannot be measured and —unlike for other nutrients—can therefore not provide a basis for recommendations. Current recommendations are derived from adult epidemiological studies that investigate DF intake and adult risk for hyperlipidemia, hypertension, and coronary heart disease. Different studies in adults have shown that a DF intake (particularly from cereals) of 12.9–14.4 g per 1000 kcal significantly reduces the risk for coronary heart disease.[78–80] There are no further studies available that could provide the basis for specific recommendations for DF intake during childhood. Current recommendations of DF intake for the period beyond 1 year of age are therefore mainly based on adult data. It might be questioned whether endpoints like adult CHD risk are appropriate to guide recommendations in infants older than 1 year of age.

For term and preterm newborns, AI can be calculated from the composition of breast milk assuming standard TFIs. Assuming that breast milk contains 1.3–2.1 g of DF per 100 ml, newborns will ingest between 2.1 and 3.5 g DF/kg BW/d. For infants up to 1 year of age, the additional intake of complementary solid foods needs to be taken into account. There are actually no published data available about the DF intake in that age group. However, several manufacturers of commercially available solid food products give ranges from 0.3 to 2.5 g DF/100g of product. Although this content is not very different from that of breast milk, AI of DFs may be assumed to be in the order of 1.8–3.0 g/kg BW/d.

Table 5-7 gives a summary of recommended intakes of DFs during childhood.

There are currently no recommendations available that address from which source DFs preferably should be taken from. For infants on human milk or formula, there is an ongoing debate whether artificial DFs like GOS and FOS added to formula products have the same biological properties as the natural spectrum of oligosaccharides in human milk (see also Chapter 3).[81,82] Results of this debate could have an influence on

whether there is a justification for current practice of supplementing formula or solid foods with artificial DFs.

TABLE 5-6 Recommendations for Intake of Digestible Carbohydrates

Age		Criterion	EAR[66](g/d)	RDA[66](g/d)	AI(g/d)	Energy Requirements Boys/Girls[66]	Reported Intakes[67] Total/Sugars/ Starch
Newborn	Preterm	Factorial approach			10.5–12.0g/100 kcal[71,75]	100–135 kcal/kg/d[71,75]	
	Term	Composition of breast milk			35	90–110 kcal/ kg/d	
Infants	0–6 mo	Composition of breast milk			60[66]	570/520	90–115
	7–12 mo	Composition of breast milk and solid food			95[66]	740/680	90–115/ 60–75/35–40
Children	1–3 y		100	130		1050/1000	130–190/ 90–115/60–80
	4–8 y		100	130		1740/1640	
	9–13 y		100	130		2300/2100	
	14–18 y	Brain glucose utilization	100	130		3200/2400	

General: For children older than 2 years of age 50% of caloric intake should be provided as carbohydrates.[2–4]

TABLE 5-7 Recommendations for the Intake of Dietary Fibers (DF)

Age		Fibers[66](g/d) Boys/Girls	Energy Requirements[66](Kcal/d) Boys/Girls
Newborn	Preterm	1.3–2.1 g/100 mL BM[72]	100–135 kcal/kg/d[71,75]
	Term	1.3–2.1 g/100 mL BM[72]	90–110 kcal/kg/d
Infants	0–6 mo	2.1–3.5 g/kg BW/d	570/520
	7–12 mo	1.8–3.0 g/kg BW/d	740/680
Children	1–3 y	19	1050/1000
	4–8 y	25	1740/1640

9–13 y	31/26	2300/2100
14–18 y	38/26	3200/2400

General: Data for newborn and infants are based on composition of ingested breast milk (and complementary solid food) in these age groups. Breast milk contains 1.3–2.1 g/100 g, and commercially available solid foods contain 0.3–2.5 g/100 g.

For all other age groups: A dietary intake of 14 g per 1000 kcal has been identified as most protective for coronary heart disease.[66]

DISORDERS INVOLVING CARBOHYDRATES

A variety of acute and chronic disorders can affect different steps of CHO metabolism. All of these lead usually to a more severe clinical picture. Due to space restrictions, we will not be able to discuss these diseases in detail, but will aim to give rather a high-level overview.

Only monosaccharides can be absorbed by the intestinal border. *Malabsorption* describes various acute and chronic conditions where CHO escape intestinal digestion and absorption. Different from lipid and protein digestion, pancreatic exocrine insufficiency does not play a major role in CHO malabsorption. It is only α-amylase that is provided by the pancreas and it cleaves the α-1,4 glucose–glucose bonds of starch. CHO malabsorption is usually caused by an insufficient activity of brush border located enzymes that cleave disaccharides. Such enzymes are lactase (cleaving galactose–glucose bonds), sucrase isomaltase (glucose–glucose and glucose–Frc bonds), and gluco amylase (cleaving glucose from glucose polymers). The resulting monosaccharides are transported into the blood through specific transporters (like GLUT-2 and GLUT-5). Activity of disaccharide-cleaving enzymes can be decreased due to individual genetic conditions (rare), or can secondarily develop as “adult-onset” type (common in Asians, African Americans, and Mediterranians), or as a consequence of mucosal injury (i.e., gastroenteritis, drugs, radiation). Rarely, activity of transluminal monosaccharide transporters can be decreased due to genetic defects. Clinical symptoms of malabsorption are chronic diarrhea, abdominal distension, and failure to thrive. H-breath tests are helpful in making the diagnosis. A comprehensive review of malabsorption is found in Ref. 83.

Fructose intolerance: Frc is absorbed by two major transporters: GLUT-2 and GLUT-5, although, currently, GLUT-8 and GLUT-12 have also been identified to play a role.[84] Deficiency of these transluminal transporters leads to bacterial fermentation of Frc with increased intraluminal gas production and distension and also to osmotic influx of

water, resulting in severe abdominal pain and diarrhea. Secondary effects in skin integrity, chronic respiratory, and urogenital infections have been described.[85] Diagnosis may be made with H-breath tests. Dietary restrictions of Frc intake as well as novel enteral enzyme replacement therapies help to cure the symptoms.[86] A comprehensive review of Frc intolerance is given in Ref. 87.

Glycogen is a multi branched glucose polymer ("animal starch") and serves as a short-term energy storage for excess glucose. *Glycogen storage diseases* comprises a group of 11 inherited enzymatic defects that either impair the release of glucose molecules from the glycogen polymer or lead to incorrect phosphorylation of released molecules or build up poorly branched glycogen with altered solubility in the cellular and extracellular matrix. Symptoms arise from hypoglycemia due to poor glucose release in periods of hunger and accumulation of glycogen in a variety of organs, leading to impairment of function. Depending on the nature of the underlying enzyme defect, life expectancy can be severely reduced and also mental function might be severely impaired. There is no causative cure, some forms benefit from dietary regimes, high-dose vitamin supplementation, or enzyme replacement therapy. Gene therapy or stem cell applications have not yet reached a stage of maturity to be tested in humans. A comprehensive review of glycogen storage diseases is given in Ref. 88.

Galactosemia is caused by a group of three inherited enzyme defects that are needed for the regular metabolism of galactose into glucose. The enzyme block leads to an accumulation of galactose that leads to the formation of galactitol, an alcohol of galactose. Galactitol itself is an end product that accumulates in the body and leads to hepatomegaly and cirrhosis, renal failure, cataracts, and brain damage. Undiagnosed, lethality is high (>75%). Therapy consists of eliminating lactose and galactose from the diet. Early detection of affected newborns by determining enzyme activity in dried spot blood is now part of many newborn screening programs. A comprehensive review of galactosemia is given in Ref.[89].

Hyperinsulinism describes a series of disorders with hypoglycemic episodes caused by an overproduction and secretion of insulin. This can be the effect of acute pancreatic overstimulation like in newborns from diabetic mothers or of chronic overproduction by autonomously producing islet cells (focal or diffuse form). Hyperinsulinism is due to peripheral resistance of insulin, which usually leads to hyperglycemia and will be described in the following paragraph. The main risk rising from unregulated insulin hypersecretion in the presence of a disturbed feedback

loop are repeated episodes of hypoglycemia. These pose a significant threat to neuronal integrity and function. A comprehensive review about hyperinsulinism is given in Ref. 90.

DM is the insufficient secretion of insulin, or peripheral resistance to insulin impairs uptake of glucose into body cells. This lack results in elevated glucose levels in the extracellular compartment as well as to disturbed intracellular energy supply. The latter leads to an acute metabolic crisis either as a ketoacidosis or as a nonketotic hyperosmolar state, both are potentially life-threatening disorders. Elevated blood glucose levels induce osmotic polyuria and can acutely culminate in shock due to dehydration. On the other hand, chronically elevated glucose levels induce glycation of structural proteins in the vessel walls. The silent denaturation of these proteins advances aging of vessels, induces chronic endothelial inflammation, and promotes activation of different metabolic cascades because blood cells interact with the altered vessel walls and get stimulated. Clinically, this leads to an increased risk of hypertension, cardiovascular events, and stroke (macroangiopathy). Early signs of microangiopathy can be best assessed in the eye (cataract, retinal vessels).

Insufficient secretion of insulin is more frequently observed with type-I DM as a result of an acute injury to pancreatic islet cells (infection, autoimmune disorder, for example) and affects younger individuals. In contrast, peripheral insulin resistance (type-II DM) is more frequently observed during ageing; or because a subtle, but chronic increase in fat mass during lifetime (obesity) induces secretion of adipokines like leptin that directly causes insulin resistance. Treatment strategies for type-II DM are normalization of body weight and fat mass, increasing physical activity, changing the dietary regime, and/or oral antidiabetic drugs that stimulate pancreatic insulin secretion or—in severe cases—subcutaneous insulin injections. The latter one is also usually required to treat type-I DM.

Obesity describes conditions with increased body fat. On one hand, obesity leads to disturbed metabolism with high serum levels of glucose and fatty acids because there is an imbalance between energy-consuming body mass (lean and muscle mass, respectively) and energy reserves (fat mass). On the other hand, recent research confirmed that adipocytes are metabolically highly active and secrete adipokines as feedback signals to the body. For example, the release of leptin is proportional to the amount of body fat and thus provides information of how much energy is stored within the body. As a consequence, distinct metabolic or signaling pathways will be switched on or off: like a certain level of leptin is needed

to switch on the LH-RH axis to allow menstrual cycle and ovulation. An excess of fat mass leads to higher levels of adipokines, some of them induce inflammation (like C-reactive protein). In addition to the known negative effects of chronically elevated substrate levels on vascular integrity (see paragraph about “Diabetes”), obesity needs to be considered as a condition with chronic inflammation. Obesity reduces life expectancy and increases the risk for preceding morbidity in all body organs. Worldwide, the incidence of obesity is dramatically increasing and is affecting more frequently young adults and children. Obesity seems to be the result of an imbalance between nutrient intake and energy expenditure, with a higher incidence in populations with a lower socioeconomic status. Lifestyle in modern societies leads to permanent availability of highly palatable food and to reduced physical activity. Education and change in lifestyle can reduce the incidence of obesity, and recent data suggest that some populations have managed to stop the increasing incidence. BMI is a parameter that tries to reflect nutritional status and body fat. For clinical use, cutoff values have been established that define overweight and obesity; however, genetic disposition or lifestyle-induced changes of muscle mass (e.g., weight lifting) are not taken into account. In contrast to adults, the amount and distribution of body fat changes during childhood. Age and gender-specific percentile curves are available for BMI during childhood.

Proteins and Amino Acids

6

Johannes B. van Goudoever, MD, PhD

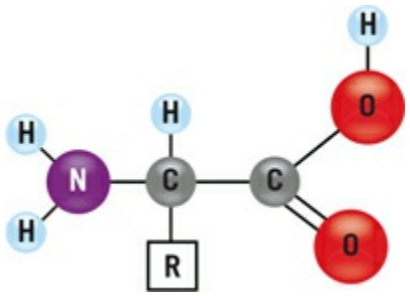
Protein is the major functional and structural component of all the cells of the body. The defining characteristic of protein or amino acid is its requisite amino nitrogen group. This nitrogen group distinguishes an amino acid from, for example a sugar. Proteins are macromolecules consisting of long chain of amino acid subunits. In the protein molecule, the amino acids are joined together by peptide bonds. In biological systems, the chains formed might be anything from a few amino acids (di-, tri-, or oligopeptide) to thousands of units (polypeptide). The sequence of amino acids in the chain is known as the primary structure. A critical feature of proteins is the complexity of their physical structures. Polypeptide chains do not exist as long chains, but they fold into a three-dimensional structure. The chains of amino acids tend to coil into helices (secondary structure). Sections of the helices may fold on each other due to hydrophobic interactions between nonpolar side chains and, in some proteins, to disulphide bonds so that the overall molecule might be globular or rod-like (tertiary structure). Their exact shape depends on their function and for some proteins, their interaction with other molecules (quaternary structure).[1]

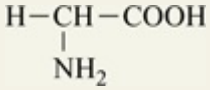
AMINO ACIDS

The amino acids that are incorporated into mammalian protein are α–amino acids. This means that amino acids have a carboxyl group, an amino, nitrogen group, and a side chain attached to a central α-carbon (Figure 6-1).

Proline is the only exception, being unique among the 20 protein-

forming amino acids in that the amine nitrogen is bound to not one, but two alkyl groups, thereby making it an α-iminoacid. Functional differences among the amino acids lie in the structure of their side chains (Table 6-1).





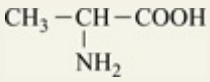


Figure 6-1 An amino acid: an amino (NH_2) group, a carboxyl group (COOH) and a side chain attached to a central α-carbon (R).

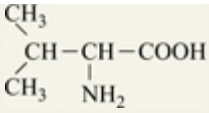
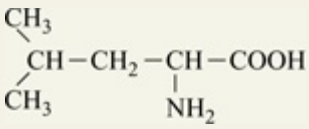
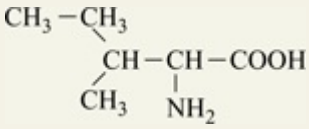
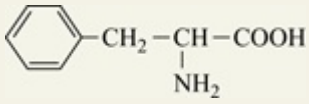
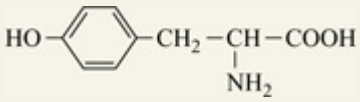
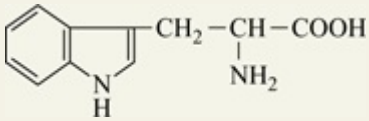


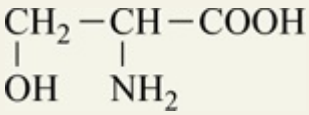


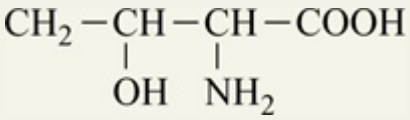


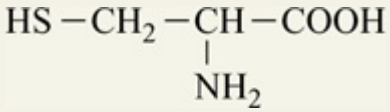


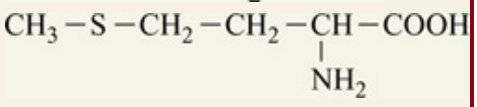


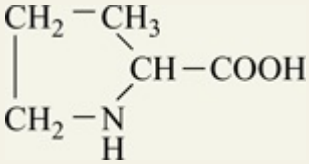


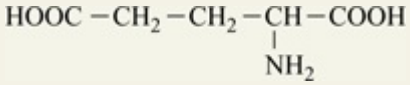




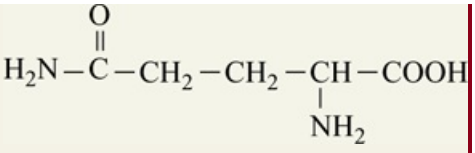


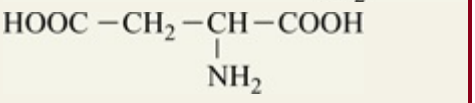


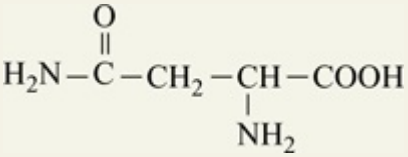


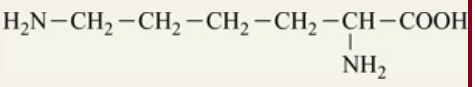


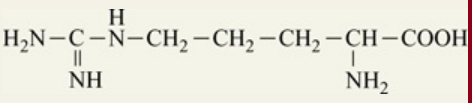
Classification of amino acids was initially based on the classic studies of Rose and co-workers.[2,3] These studies were based on the qualitative significance of each amino acid in human nutrition. Rose defined amino acids as essential or nonessential based on their capacity to maintain nitrogen balance in young men (Table 6-2). Hol[4], Snyderman,[5–7] and Fomon[8] extended Rose's studies to the pediatric population. In their studies, of which only a few are referenced here) they demonstrated that only the "essential" amino acids were needed to maintain growth in young infants and therefore conformed according to the original definition of "essentiality of amino acids." Through the following decades it became evident that Rose's classification was limited and that a distinction between essential and nonessential amino acids was complex and could not be defined based solely on the nutritional criteria of maintenance of nitrogen balance or growth.[9] For example, histidine, an nonessential amino acid in the rat that was considered nonessential in humans in the original Rose classification, has been proven to be essential in health and disease, and was included as an essential amino acid by the Food Agricultural Organization/World Health Organization/United Nations University (FAO/WHO/UNU) expert report in 1985 and subsequent reports.[10]

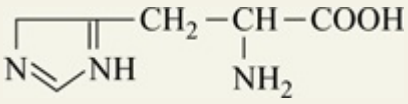












Over the past decades the concept of essentiality based on maintenance of growth or of nitrogen equilibrium has been revisited and, with contributions by many[11–15] the concept of amino acid essentially has changed. Mitchell[16] considered a more dynamic concept of "essentiality"

based on the ratio of supply to demand, rather than on the maintenance of nitrogen balance or growth. The term “conditionally indispensable” has been used to refer to those nonessential or dispensable amino acids that become essential or indispensable under pathophysiologic conditions. Because the carbon skeleton of the amino acid is the moiety that determines its nutritional indispensability, some classification of amino acids has been based on the ability to synthesize and/or aminate the carbon skeleton.[13] In metabolic terms, the amino acids that are generally considered to be nutritionally essential contain specific chemical structures, the synthesis of which cannot be catalyzed by mammalian enzymes, such as the branch aliphatic side chain of leucine, isoleucine, or valine; the primary amine of lysine; the secondary alcohol of threonine; the secondary thiol of methionine; the indol ring of tryptophan; the aromatic ring of phenylalanine; or the imidazole ring of histidine. Table 6-3 summarizes the classic nutritional classification of amino acids and Table 6-4 shows an updated classification of amino acids It is important, however, to remember that an amino acid classification should not be based solely on nutritional (growth and maintenance), metabolic (de novo synthesis, tissue utilization, and catabolism), or chemical aspects of the amino acids, but also, and perhaps most importantly, on the maintenance of amino acid function. Some amino acids that would be considered truly dispensable in nutritional, metabolic, and chemical terms are utilized as precursors of other amino acids that maintain important physiologic functions, such as glutamate and serine, which serve, respectively, as precursors of glutamine and cystathionine. Other dispensable amino acids like alanine and aspartate contribute to physiological and pathophysiologic events.[17,18] The involvement of amino acids in physiological and metabolic functions is extensive and a partial description is shown in Table 6-5.

TABLE 6-1 Amino Acid Structure

Name	Abbreviation	Formula
Aliphatic side chains		
Glycine	Gly	
Alanine	Ala	
Valine[a]	Val	

		
Leucine[a]	Leu	
Isoleucine[a]	Ile	
Aromatic side chains		
Phenylalanine	Phe	
Tyrosine	Tyr	
Tryptophan	Trp	
Hydroxyl groups in side chains		
Serine	Ser

TABLE 6-2 Amino Acid Classification by the FAO/WHO/UNU Expert Report, 1985

Essential	Non-Essential
Lysine	Glycine
Tryptophan	Alanine
Threonine	Serine
Isoleucine	Cystine
Leucine	Tyrosine
Methionine	Aspartic acid
Phenylalanine	Glutamic acid
Valine	Proline
Histidine	Hydroxyproline
	Arginine

TABLE 6-3 Nutritional Classification of Amino Acids

Indispensable

(a) Carbon skeleton cannot be synthesized.

(b) Rate limiting enzymes of catabolism regulated in relation to adequacy of intake and tissue supply.

Conditionally Indispensable

(a) Indispensable amino acid is a precursor (i.e., phenylalanine-tyrosine).

(b) Synthesis and degradation are modulated by dietary supply (i.e., arginine, glycine).

(c) Stressful states cause tissue depletion where rates of synthesis are insufficient to meet the increased rate of metabolic demand (proline, glutamine, arginine, glycine, taurine) or match the catabolic rate.

Dispensable

(a) Rate of synthesis is not down regulated by intake of amino acid; metabolism largely a function of metabolic status of major energy-yielding substrates and/or overall nutritional status (alanine, glutamate, aspartate).

PROTEIN METABOLISM AND DISTRIBUTION

Most proteins in the body are constantly being synthesized from amino acids and degraded back to them. The turnover rate of proteins in neonates and children is twice to three times higher than in adults, resulting in a higher energy demand for children per kilogram body weight than for adults.

The "pool" of amino acids is in dynamic equilibrium with tissue protein as depicted in Figure 6-2. Amino acids are continually taken from the pool for protein synthesis and replaced by the hydrolysis of dietary and tissue protein.

There are three main reactions essential for amino acid metabolism: transamination, oxidative deamination and hydroxylation. Transamination

converts one amino acid into another by catalyzing the transfer of the α-amino (NH_3^+) group from an amino acid to an α-keto-acid. All transamination reactions are fully reversible and therefore this pathway is. Lysine and threonine do not transaminate. The second reaction, which is irreversible, is the oxidative deamination. It removes the amino group, leaving behind the carbon skeleton. The ammonia (NH_4^+) formed enters the urea cycle and the carbon skeletons are all glycolytic and TCA intermediates. These products can, depending on the energy status of the cell, either be oxidized in the citric acid cycle to generate energy or used to synthetize glycogen or fat. Phenylalanine, tyrosine and tryptophan can be hydroxylated. Tryptophan hydroxylase controls levels of serotonin in the brain and the gastrointestinal tract, while tyrosine hydroxylase controls levels of dopamine, epinephrine, and norepinephrine in the brain and the adrenal medulla. Deficiency in phenylalanine hydroxylase causes hyperphenylalaninaemia, and when blood phenylalanine levels increase above 20 times the normal concentration, the metabolic disease phenylketonuria results.

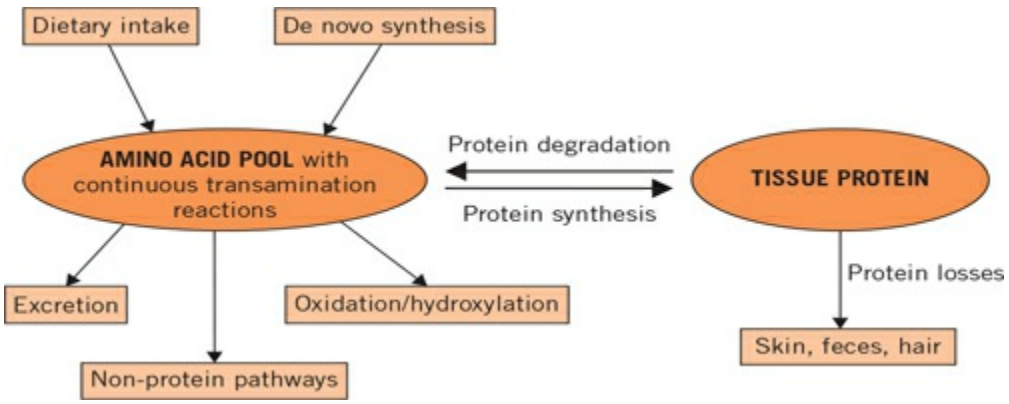

Figure 6-2 Exchange between body protein and free amino acid pools (adapted from Ref.1).

The distribution of protein among the different organs varies with developmental age. Children have, proportionally, a larger amount of visceral (liver, kidney, brain, heart, and lung) protein than in the skeletal muscle, while in adults protein constitutes about 15% of their weight. During starvation or low protein intake, visceral protein is mobilized. This is called the "labile protein content." However, these "reserves" account only for 1% of total body protein.[19] During disease states muscle becomes

the main contributor to protein loss.[20]

Not all proteins in the body have a similar turnover rate. Figure 6-3 shows the protein synthesis rate of different tissues in pigs and rodents, expressed as % of the protein pool of a specific organ that is synthesized per day. Despite the high fractional turnover rate of gut proteins, most protein synthesis and degradation occurs in the muscle because of the large pool size. Nevertheless, the relatively high turnover rate of the gut indicates that the intestines are metabolically a very active organ. This is illustrated by the fact that first pass uptake or splanchnic utilization is high.

DIGESTION AND ABSORPTION OF PROTEINS

Proteins are digested and absorbed along the upper part of the intestinal tract, with for human milk proteins an almost complete removal from the lumen. Proteins are broken down in the stomach to smaller polypeptide chains via hydrochloric acid and proteases in the duodenum and jejunum. Peptides and free amino acids can be absorbed by the enterocyte. However the systemic availability of amino acids is not 100% because 30%–50% of the amino acids are utilized within the intestine.

These amino acids are used as substrate for (glyco-)protein synthesis and as an energy source during high protein intakes.[26–30] The rate of first pass utilization is different for each individual amino acid as is shown in Figure 6-3. However, also dietary amino acids that are used within the gut to synthesize constitutive proteins or proteins that are being secreted in the lumen may become available to the systemic circulation in a later phase due to recycling of these proteins further on in the gastro-intestinal tract.[28] The availability depends on the digestibility of the (glyco-)protein. The structural component of the mucus layer, which forms a physical barrier between the underlying epithelium and the lumen of the gastrointestinal tract is secretory mucin 2 (MUC2). MUC2 is secreted by goblet cells of the intestine and gives intestinal mucus a high density and viscoelasticity. MUC2 is a glycoprotein rich in oligosaccharides, O-linked to threonine and serine residues in the peptide backbone. This glycoprotein with its high threonine content reaches almost completely intact the colon, where proteins amino acids are not absorbed, with subsequently a low systemic availability of threonine.[31]

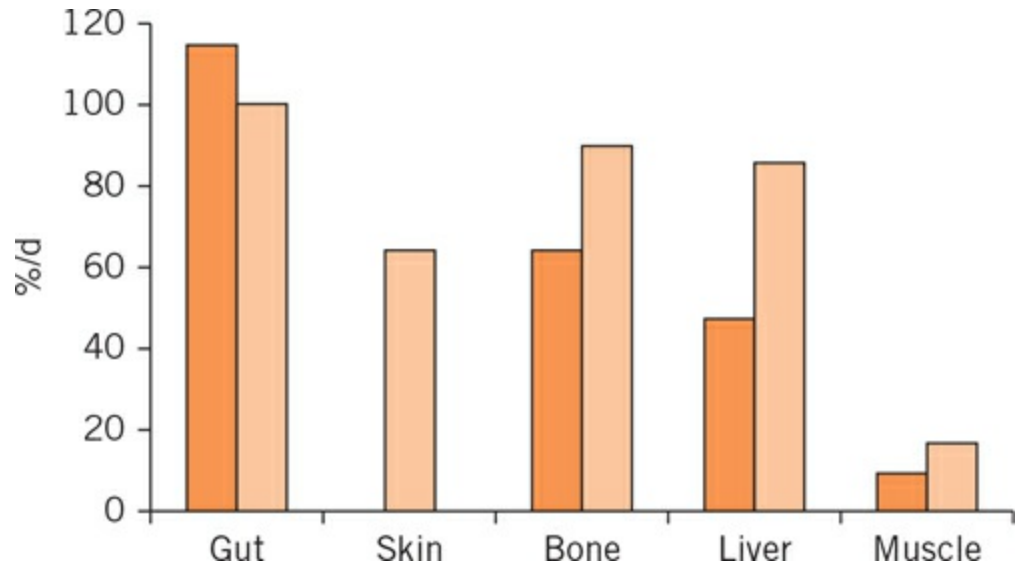

Figure 6-3 Fractional protein synthesis rates of different organs expressed as percent per day in pigs (dark orange bars) and rats (light orange bars).[21–24]

REQUIREMENTS FOR PROTEINS

Adequate nitrogen (protein) intake is essential for growth, development, and function. However, estimating "adequate" protein or specific amino acid requirement for the pediatric population is a complex and challenging endeavor.[32] First, the pediatric population constitutes a dynamic group, involving different clusters of individuals from newborn to adolescence. The pediatric population shows marked differences among the age groups regarding weight, rate of growth, hormonal milieu, activity, and other factors that may affect nutritional and metabolic status. Second, dietary recommendations for macro- and micronutrients among the different pediatric groups have been largely based on limited and inadequate data.[33–38] Because of ethical constraints that prevent the use of healthy children for more invasive research studies, data in the pediatric population are based on nitrogen balance studies, many times obtained from children recovering from malnutrition.[38,39] Hence, pediatric data are rather limited. Third, with new knowledge emerging on nonnutritional function of nutrient hyperhomocysteinaemia with folic acid[40] as well as the physiological and pharmacological properties of amino acids, the concept of amino acid requirement has changed from the traditional

nutritional criteria based on growth or weight maintenance, to a broader functional outcome. Therefore, "adequacy" of nutritional support is ill defined and conditional to the end goals to be achieved. Based on this new knowledge about nonnutritional functions of amino acids,[11,13] a key question regarding nutritional adequacy is "what is the objective to be achieved?" Is the objective to promote growth and weight maintenance? To maintain nonnutritional functions? To prevent pathophysiologic events? To act as pharmacological agent(s)? To induce gene expression? Or for nutritional rescue? These important questions are just beginning to be explored and will be better answered in the future.

TABLE 6-6 Protein Needs for Growth and Maintenance in Children of Different Ages

Age	Protein Gain (g/kg/d)	Maintenance (g/kg/d)	Maintenance/Total (%)	Growth/Total (%)
0–1 mo	1.00	0.56	36	64

METHODS TO DETERMINE PROTEIN OR AMINO ACID REQUIREMENTS

Dietary protein requirements can be estimated by essentially two different methods. The first method calculates the daily requirement theoretically, by a factorial approach which is based on estimating the nitrogen (obligatory) losses that occur when a person is fed a diet that meets energy needs but is essentially protein free and, when appropriate, also relies on

estimates of the amount of nitrogen that is accreted during periods of growth or lost to mothers during lactation. The second, the empirical approach, measures biochemical or physiological responses to graded intakes. It includes anthropometry, chemical indices like serum albumin, total protein, immunoglobulin, retinol-binding protein and transthyretin and biochemical markers of protein excess such as blood urea nitrogen (BUN), pH, pCO_2, bicarbonate. They also include nitrogen balance and isotopic studies of whole-body nitrogen kinetics.

FACTORIAL APPROACH

The factorial approach is based on the assumption that the basal requirements of a component are the same throughout the life cycle and requirements in infants and children are higher than those in adults due to growth. The factorial approach considers the total requirement for a nutrient as the sum of obligatory losses (e.g., urine, faeces, skin), plus the amount incorporated into newly formed tissues. This method, originally described for use in humans by Hegsted[41] has been useful for estimating requirements and designing experiments for obtaining definitive empirical data.[42] In this method the obligatory losses (maintenance requirement) are added to the nutrients needed for protein synthesis (growth requirement).

NITROGEN BALANCE

Historically, descriptive or gross measures like growth and nitrogen balance have been used. In this method an increasing intake of the test amino acid results in an increase in growth rate (usually weight gain) or nitrogen balance until the required level is met for the test amino acid, after which there is no further increase in either growth rate or nitrogen balance. Nitrogen balance is the difference between nitrogen intake and the amount excreted in urine, faeces, skin, and miscellaneous losses such as breath and sweat. A limitation of the method is the need for a 7-day adaptation time to the diet since the body urea pool needs 7–10 days to adapt. In addition, intakes of nitrogen are often being overestimated and excretion is often underestimated.[43] Since it is considered unacceptable to maintain children or infants on either deficient of excessive intakes for longer periods nowadays, alternative methods were needed. The availability of isotopically labeled tracers made it possible to determine the metabolic fate of a labeled amino acid at varying dietary intakes as will be

discussed next.

ISOTOPIC TRACER METHODS

Isotopic tracer methods measure amino acid oxidation, and are based on the principle that the oxidative losses are reversible and need daily replenishment, and that the amino acids provided in excess of the needs of protein synthesis, are preferentially oxidized. A ^{15} N- or a ^{13} C-labeled amino acid is administered enterally or parentally and is distributed throughout the body's free nitrogen pool. Stable isotopes are used: atoms with an extra neutron in the nucleus which slightly increases the mass which can be detected by mass spectrometry techniques. Different techniques using stable isotopes have been developed to determine the requirements of the indispensable amino acids like the direct and indirect amino acid oxidation methods, in both healthy and disease state.[44–46] Isotopically labeled tracers are used to determine the metabolic rate of a labeled amino acid at varying dietary intakes. Amino acids consumed in excess of requirements for protein synthesis are oxidized. Deficient intake of an indispensable amino acid will result in only minimal obligatory losses. As intake increases above the required level, the oxidation of the amino acid will also increase linearly. In the direct amino acid oxidation (DAAO) technique a known dose of labeled indispensable amino acid, for example ^{13} C-lysine is provided to subjects fed graded dietary intakes of lysine, with all other dietary factors being constant. The inflection point at which oxidation begins to increase rapidly over the obligatory minimum is referred to as the breakpoint and represents the dietary requirement for that individual (Figure 6-4).[47] A refinement of the direct oxidation technique is the 24h tracer balance (24-h DAAB).[48,49] This method uses a daily balance of the amino acid that is measured and determines the requirement level of the test amino acid as the minimum intake at which the estimate of daily balance is zero.[50] El-Khoury et al. showed that the short (3–6 h) direct oxidation method was within 5% of the 24 h estimate and thus is a valid representation of daily amino acid requirements.[49] Since a 6-day adaptation to the study diet is needed, this method is not applicable to study vulnerable populations like infants.

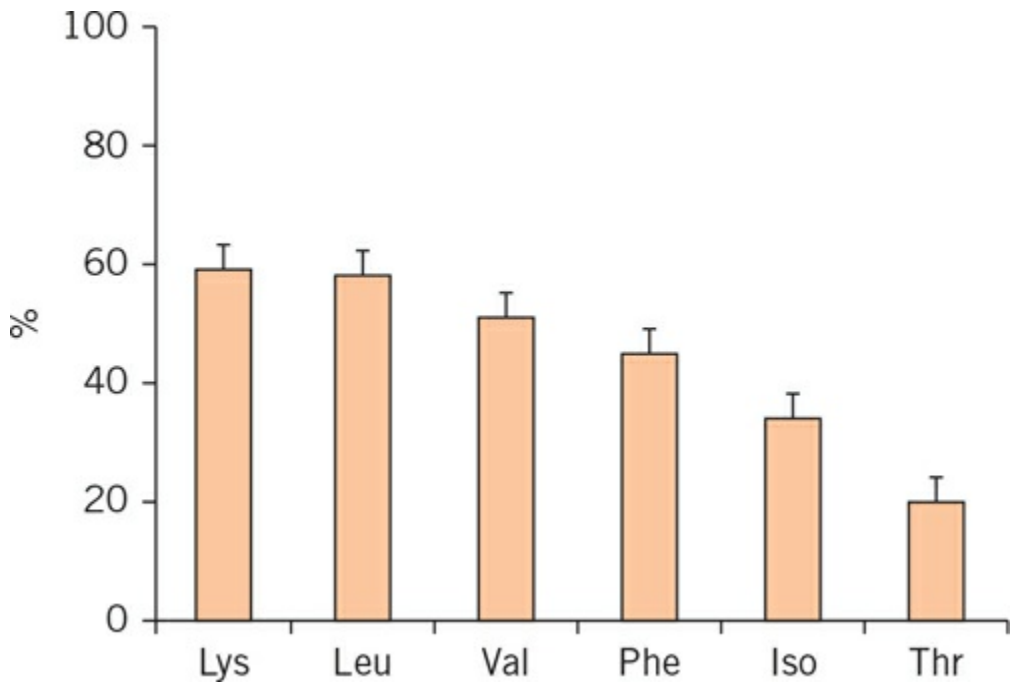

Figure 6-4 Systemic availability (expressed as percentage of intake) of enterally ingested amino acids in newborn pigs.[25] *Adapted from the previous version of this chapter.*

An alternative approach of estimating indispensable amino acid requirements using amino acid oxidation is the indirect amino acid oxidation (IAAO) technique (Figure 6-4). The main principle of this method is that because there is no storage of free amino acids, deficiency of one essential amino acid will limit protein synthesis. If the tested amino acid is deficient in the diet, this will limit protein synthesis and the indicator amino acid will be oxidized. If the dietary intake of the test amino acid increases, the oxidation of the indicator will decrease until requirement of the test amino acid is met. When intake meets the requirement, then protein synthesis occurs at an optimum capacity and the oxidative degradation of all other essential amino acids plateau. The mean requirement or estimated average requirement (EAR) of the test amino acid is identified by this breakpoint (Figure 6-4).[51–53]

The advantage of the DAAO and IAAO method are the short adaptation time needed (only one day) to the study diet which makes them applicable to study vulnerable groups such as infants and children.[54] A limitation of the DAAO method is that it is not applicable to all indispensable amino acids, whereas with the IAAO method the

requirements of any essential amino acid or conditionally indispensable amino acid can be studied. Thereby there is no dietary restriction on the test amino acid intake in the IAAO technique as a result of the fact that requirement of one amino acid is determined by the oxidation of another amino acid. This makes it possible to study all possible dietary levels of essential amino acids. Recent studies have used these techniques to determine amino acid and protein requirements, both in healthy and sick children.[55–60]

CURRENT PROTEIN AND AMINO ACID REQUIREMENT RECOMMENDATIONS

Chapter 11 describes in detail the different definitions and ranges, including the upper safe level and how the requirements are established. The requirements for the different age ranges are provided in Appendix B. The factorial method and nitrogen balance technique have been the methods of choice most frequently since not enough data are available using the amino acid oxidation method yet. However, this method will be used in the future as more data are emerging, since it has been shown that current recommendations using older methods might be an underestimation.[59,61]

AMINO ACID TOXICITY

The risk of harmful interactions elicited by pharmacological doses of single amino acid supplements may be significant. In addition, supplement purity is a major concern. Hence, to date, there is controversy about single amino acid supplementation. The safe upper level of intake is defined as the maximum level of habitual intake from all sources of a nutrient or related substance, which is judged to be unlikely to lead to adverse effects in humans (Chapter 11). Because of the higher risk of adverse effects, the safe upper level or tolerable upper level of intake is not desirable. There are limited data on amino acid toxicity in humans, and more extensive data in animal models. In regard to branched chain amino acids, and despite the role of these amino acids in protein synthesis, there is no consensus on its use in pathophysiological conditions.[62,63] The tolerable upper level for leucine in adults was determined using indicator amino acid techniques as well recently,[64] no data are available for infants or children. Sulfur amino acids exert beneficial effects through their role as precursor of glutathione,

DNA methylation reactions, and synthesis of important substrates, such as creatine, choline, etc. Sulfur amino acids also increase high-density lipoprotein and decrease very low density lipoprotein.[65] However, methionine supplementation can be associated with increased homocysteine, a marker of cardiovascular risk and promoter of oxidative injury.[66] A large intake of methionine has been associated with fatalities in the pediatric population.[67] Toxicity of sulfur amino acids can be significant and supplementation is not indicated. However, supplementation with N-acetyl cysteine appeared promising in conditions of oxidative injury[68] but a large recent RCT did not confirm a beneficial effect.[69] N-acetyl cysteine may be of some benefit in acute airway infections.[70]

CONCLUSION

In summary, the current recommendations for amino acid and protein intakes are based on limited data, although recently great progress has been made using stable isotope techniques. There is great need for further investigation on nutritional and functional requirements of amino acids and their safe upper levels of intake. Amino acid metabolism and requirements under pathophysiological conditions of the enteral and parenteral routes need to be further studied. The effect of developmental influences on the interactions between amino acids and energy (glucose and fat) metabolism needs to be closely explored.

Macronutrient Requirements for Growth: Fats and Fatty Acids

7

Kathrin Krohn, MD, Hans Demmelmair, PhD, and Berthold Koletzko, MD, PhD

INTRODUCTION

An adequate fat intake is essential for growth and development of infants and children. Dietary fat provides a large portion of energy and is the source of lipid soluble vitamins and essential polyunsaturated fatty acids. The composition of dietary fat influences lipid absorption, metabolism and tissue deposition, and thereby growth and body composition.

Fats or lipids can be defined as substances that have no or very limited solubility in water, but are soluble in organic solvents (e.g., chloroform, hexane). Most of our dietary fats are triglycerides containing three fatty acids esterified to a glycerol backbone. Vegetable oils, for example, consist almost entirely of triacylglycerols. Physicochemical properties of triacylglycerols (e.g., the melting point) are determined by the composition of its fatty acids. Watery foods may contain triacylglycerols either as a separate lipid layer (e.g., lipid droplets on a clear soup) or as an emulsion (e.g., milk or intravenous lipid emulsion). Emulsification is facilitated by amphipathic lipids that contain both hydrophobic parts, which associate with neutral lipids, as well as hydrophilic components, which interact with polar molecules such as water. Amphipathic lipids include phospholipids, monoglycerides and unesterified cholesterol and plant sterols, and lipid soluble vitamins bound to hydrophilic groups such as vitamin E acetate (tocopherol acetate). In contrast, cholesterol esters (esterified with a long-

chain fatty acid) and vitamin A esters such as retinol palmitate are non polar.

FAT DIGESTION

Fat digestion and absorption involve

i. intraluminal solubilization and hydrolysis of lipids,
ii. the subsequent intestinal absorption of hydrolyzed fatty acids and monoacylglycerols, re-esterification of fatty acids and secretion into the lymphatics in chylomicrons, or release of unesterified fatty acids into the portal venous system, and
iii. uptake of unesterified fatty acids or chylomicron triacylglycerols into the tissues.

Triacylglycerols represent the major portion of dietary lipids and are hydrolyzed in the gut by intestinal lipases. The digestion process begins in the stomach and continues throughout the intestinal tract. The major proportion of fat is hydrolyzed in the duodenum, but initial partial hydrolysis in the stomach may be critically important to increase efficiency of pancreatic lipase.[1,2] About 10%–30% of dietary fat is hydrolyzed in the stomach.[3] The rate of hydrolysis may be influenced by the initial droplet size in the stomach. A fine emulsion results in a higher degree of lipolysis compared to a coarse mixed emulsion.[4] This may not have major consequences for normal digestion since the capacity for hydrolysis is high, but it may become important in fat malassimilation, for example, due to exocrine pancreatic insufficiency and with tube feeding.[3]

Gastric lipase has an acidic pH optimum. When exposed to the pancreatic proteases (trypsin, chymotrypsin) it is rapidly inactivated. In healthy individuals, gastric lipase may not be important for intraduodenal fat digestion. However, in patients with pancreatic insufficiency, such as cystic fibrosis patients, the low intraluminal concentrations of pancreatic proteases and acidic pH may favor its function.[5]

Gastric lipase has a functional specificity for the sn-3 ester bond of triacylglycerols and gives rise to free fatty acids and sn-1,2 diglycerides. Monoglycerides and free fatty acids enter the duodenum and stimulate the release of cholecystokinin in the duodenum. This in turn stimulates the release of biliary secretions and pancreatic enzymes. Digestion products are emulsified by bile salts, thereby increasing the available surface. Free fatty acids, which are released by gastric lipase, induce the binding between the colipase-lipase complex and fat globules.[6] Colipase-

dependent lipase has a specificity for sn-1,3 ester bonds to give rise to sn-2 monoglycerides and free fatty acids. The level of enzyme secreted into the intestinal lumen changes with age. The level of colipase-dependent lipase secreted in adults is estimated to be 1000-fold in excess of what would be necessary to hydrolyze the dietary fat ingested daily. However, in neonates postprandial luminal levels are much lower, since the pancreas is not fully developed after birth.[5] In addition to a low activity of colipase-dependant pancreatic lipase, neonates have a limited bile salt pool, and low intraluminal bile salt concentrations.

In infants fed human milk, hydrolysis of triacylglycerols results from the combined action of bile salt stimulated lipase (BSSL), which is produced in the mammary gland and secreted into the milk and the endogenous intestinal lipases. BSSL hydrolysis triacylglycerols at all three ester bonds resulting in the formation of free fatty acids and glycerol[3] and is present in milk from about 26 weeks of gestation.[6,7] The considerable contribution of BSSL to the lipolytic activity in breast milk is eliminated by pasteurization which inactivates BSSL.[8] This effect on fat absorption is clinically relevant in preterm infants. A study in preterm infants born with a gestational age below 32 weeks showed significantly higher weight gain with raw human milk as compared to pasteurized milk.[9] The addition of recombinant BSSL to pasteurized human milk is currently evaluated in preterm infants.[8]

FAT ABSORPTION

Unsaturated fatty acids are more readily absorbed than saturated fatty acids.[10] The preferential absorption of unsaturated fatty acids may be facilitated through better solubilization by bile salts, greater gastric lipolysis, preferential binding to intracellular fatty acid binding protein and subsequent re-esterification or a decreased tendency to form soaps.[10,11]

Fat absorption is modulated by the chain length and degree of unsaturation of the fatty acids. High proportions of monounsaturated oleic acid (18:1) and polyunsaturated linoleic acid (18:2n-6) from vegetable oil triacylglycerols are absorbed (>90%).[12] In contrast, absorption of the saturated fatty acids myristic acid (14:0), palmitic acid (16:0), and stearic acid (18:0), is lower and decreases with increasing fatty acid chain length.

Absorption of saturated fatty acids depends on the position of the fatty acid in the triacylglycerol molecule.[13] In human milk, palmitic acid is the predominating saturated fatty acid. Most human milk palmitic acid is

present at the sn-2 position of the triacylglycerol molecule.[14] Formula milks contain smaller quantities of palmitic acid compared to human milk, but the saturated fatty acids from the originating vegetable oils are largely esterified at the outer sn-1,3 positions of the triacylglycerol molecule.[15] The lipolytic enzymes gastric and colipase-dependent lipases cleave fatty acids preferentially in sn-1- and sn-3-position (Figure 7-1). Whereas 2-monoglyceride of palmitic acid is readily absorbed, free palmitic acid and palmitic acid in the sn-1 and sn-3 positions of monoglycerides are not.[16] Therefore, infants fed formula milks with palmitic acid in these positions may be more likely to excrete more soaps and pass firmer stools than breast fed infants.[17] Soaps result from binding of free fatty acids released by lipolysis of triacylglycerols from the sn-1 and sn-3 positions and calcium, resulting in reduced fat and mineral absorption.[18] However, the difference in fat absorption may easily be compensated for by the infants' ability to adapt the amount of milk consumed daily.[19] Structured lipids with palmitic acid enzymatically esterified into the beta (sn-2) position have been used in formulas for term and particularly preterm infants with the key aim to soften stools.

Monoacylglycerols with a fatty acid in the sn-2 position are well absorbed, and fatty acids are preserved in this position during the absorption process.[20] In contrast, fatty acids originating from the sn-1,3 positions are randomly re-esterified during triacylglycerol re-synthesis via the monoacylglycerol pathway. Following reassembly, the triacylglycerols are secreted as components of chylomicrons.

Medium chain triacylglycerols (MCTs) contain predominantly saturated fatty acids with 8 and 10 carbon atoms. MCTs have high water solubility, are rapidly cleaved by lipases and are readily absorbed even in the presence of low amounts of intraluminal bile salts and pancreatic lipases.[21] MCTs are used in low birth weight infant (LBWI) formulas to increase fat absorption. Preterm infant formulas in the USA contain up to 50% and in Europe up to 40% of total fat as MCT. Proposed advantages of MCT when compared to long chain triacylglycerols (LCT) with saturated fatty acids in LBWI formulas include rapid, portal venous transport of the albumin-bound medium chain fatty acids (MCFAs) to the liver, the carnitine-independent transport into the mitochondria, and subsequent oxidation that is more rapid than for longer chain fatty acids. However, the energy content of MCT is about 16% lower than that of LCT (Figure 7-2). Therefore, a benefit of providing MCT rather than LCT with respect to increased energy absorption and supply can only be expected in subjects

with a very severe degree of fat malassimilation, such as children with severe cholestasis, whereas most patients will not achieve enhanced energy absorption with the use of MCT. Indeed, a Cochrane review did not demonstrate an advantage of preterm infant formulas containing high amounts of MCT (40% or more) versus formulas with low amounts of MCT (20% or less) with respect to weight gain achieved.[22] In patients with short bowel syndrome, MCTs are used to improve fat absorption.[23] In adult short bowel patients the colon as been suggested as a digestive organ for medium chain fat, probably absorbed as MCFA.[24] However, the available data on clinical effects achieved are limited. Since MCFAs are preferentially oxidized, their provision spares polyunsaturated fatty acids (PUFAs) from oxidation. Randomized trials in preterm infants demonstrated that enteral and parenteral MCFA supply enhanced PUFA availability.[25,26]

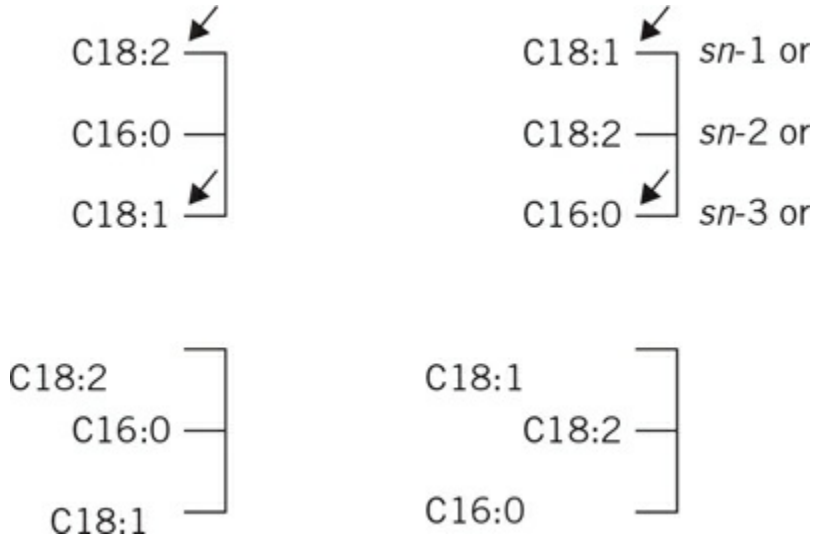

Figure 7-1 Intestinal lipases preferentailly hydrolyse triglyceride fatty acids in the sn-1 and sn-3 positions. Human milk lipids, lard, and some specifically structured lipids contain the saturated palmitic acid (C16:0) predominantly in the sn-2 position (left panel). Hydrolysis of these substrates produces most C16:0 as a monoglyceride, which is highly water soluble and absorbed to a large extent. In contrast, saturated fatty acids in vegetable oils are more or less randomly esterified to the different positions of the molecule, and a greater proportion of C16:0 is liberated as a hydrophobic free fatty acid, which tends to bind to cations (soap formation), resulting in poor absorption of both fat and calcium. Benficial effects of structured lipids with saturated fatty acids in the sn-2

position for both fat and mineral absorption have been shown in infants.

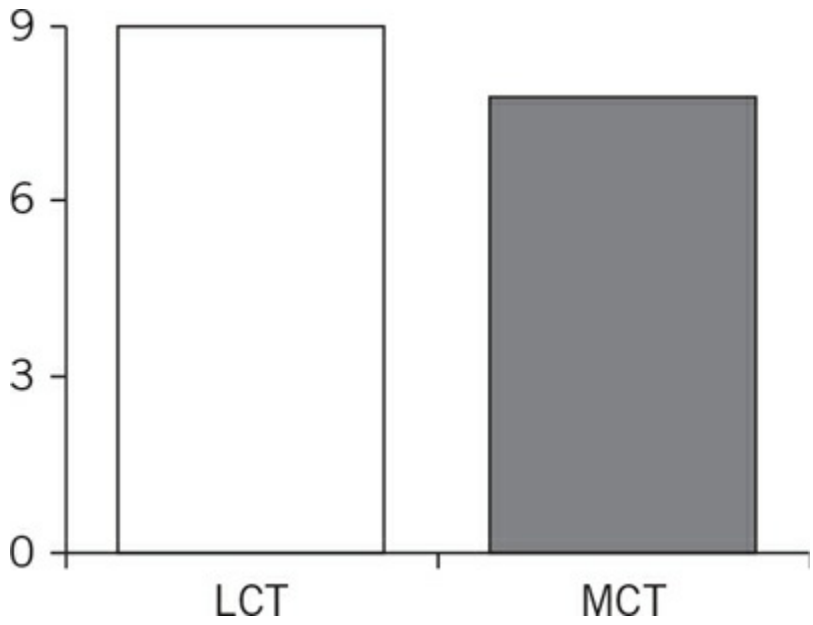

Figure 7-2 The energy content (kcal/g fat) of medium chain triacylglycerols (MCTs) is about 16% lower than that of long-chain triacylglycerols (LCTs). Therefore, an increased energy absorption by the use of MCT can only be expected in subjects with very severe fat malassimilation, such as children with severe cholestasis.

TRANSPORT OF LIPIDS

Some lipids are transported predominantly via the portal vein, whereas others are preferentially transported via the lymphatic system. The route of transport is generally related to chain length, the level of unsaturation and the structure of the lipid. The chain length is the most important factor affecting portal transport of fatty acids.[3]

MCT may be incorporated directly into mucosal cells and hydrolyzed. Liberated MCFA are then transported bound to albumin predominantly via the portal system. However, the separation of MCFA to be transported as unesterified, albumin-bound fatty acids via the portal venous route, and of fatty acids of carbon chain length 14 and longer to be transported in chylomicron triacylglycerols via the lymphatic system, is not complete. Physiologically significant amounts of saturated and unsaturated fatty acids, including linoleic acid (18:2n-6) and alpha-linolenic acid (18:3n-3),

are transported via the portal pathway,[27] while MCFAs are found in chylomicron triacylglycerols.

ASSEMBLY OF LIPOPROTEINS

In the enterocyte, absorbed lipids are packed into lipoproteins, which enable transport in the aqueous environment of blood plasma. The major lipoproteins secreted by the intestine are chylomicrons and very low-density lipoprotein (VLDL). Chylomicrons contain triacylglycerols, cholesterol ester, free cholesterol and phospholipids.[3] They are secreted in the small intestinal epithelium after a meal to transport absorbed lipids.[28] VLDL-sized particles are formed in intestinal cells during fasting.[3] The intestinal lipoproteins are secreted into the lymphatic system and enter the bloodstream via the thoracic duct.

Triacylglycerol constituents of intestinal chylomicrons and hepatic VLDL are hydrolyzed by lipoprotein lipase released from adipose tissue, muscle, and possibly other tissues to the capillary endothelium.

TOTAL DIETARY FAT INTAKE IN INFANTS

Dietary fat is essential for growth and development. It provides a source of energy that covers the needs for energy expenditure, fat oxidation and fat deposition during growth. However, there is limited evidence on acceptable ranges of dietary fat intake in infants and current intake recommendations are guided be the fat intake with human milk.[29,30]

With an energy content of about 9 kcal/kg, LCT have more than twice the energy content per unit weight than carbohydrates or protein. Growing infants have a very high energy requirement estimated to be about 120 kcal/kg per day during the first month of life and close to 100 kcal/kg per day during the rest of the first year of life. The tissue deposition of fat in healthy infants is very high: about 90% of the total energy deposited in growing tissues during the first six months of life consists of fat.[31] To achieve this high fat deposition, about 25% of dietary energy supply is deposited as fat during the first two months of life, but the proportion rapidly decreases with the slower growth rate to less than 5% after six months of life.[32]

While lipids can be synthesized *de novo* from carbohydrates or proteins,[33] endogenous net lipogenesis has a limited capacity and forms only non-essential fatty acids. Considerable amounts of energy are lost in

the process, because the synthesis of fatty acids from glucose consumes about 25% of the energy content of glucose invested. In contrast, fat deposition from dietary fat requires only about 1%–4% of the energy provided by the fat.[34]

In studies supplying isoenergetic diets with different fat contents, groups receiving higher fat intakes achieved a higher body weight and fat gain at a lower energy expenditure.[33,34]

The Committee on Nutrition of the European Society for Paediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) recommended a total fat intake of about 40% to 50%–55% of energy intake for young infants.[35] Similarly, global expert committees concluded that fat supply with infant and follow-up formulae should be in the range of 4.4–6.0 g/100 kcal which is equivalent to about 40%–54% of energy content and similar to values found typically in human milk.[29,30,36] Energy needs per kg bodyweight and the proportion of dietary energy deposited as fat decrease rapidly in the first months of life.[32] Therefore, in the second half of the first year lower dietary fat intakes can meet the needs for growth. In a randomized intervention study in Finland, infants receiving a mean dietary fat intake of about 28% of energy from the age of 6 months onwards showed normal growth and long term development.[37]

DIETARY FAT INTAKE IN CHILDREN

Similar to infants, also for children there is no firm evidence on which to set lower and upper limits of advisable lipid intakes. Both excessive and low supply of dietary lipids may be associated with adverse effects.

Concentrations of plasma total and LDL-cholesterol increase with high intakes of saturated and *trans* unsaturated fatty acids,[38] which is considered a risk factor for vascular lipid deposition and the occurrence of early vascular lesions.[39] Consequently, low intakes of saturated and *trans* unsaturated fatty acids and their replacement by unsaturated fats are recommended to reduce the long term risk of heart disease.[40] It has been recommended that saturated and *trans* fatty acid intake should not exceed 10% and 1% of energy intake, respectively.[41] While there is some concern that the advice to markedly lower fat intake, for example as part of dietary treatment of hypercholesterolemia, might cause adverse effects on child growth, observational studies did not report adverse effects of low fat diets on growth and biochemical measures of nutritional status.[42,43] A study in 663 children with hypercholesterolemia comparing reduced fat intake in

the intervention group (28.6%) to usual care (33%) did not demonstrate a correlation of percentage of dietary energy intake as fat to weight, height, body mass index or skinfold thickness.[44] However, other studies reported impaired growth in children with hypercholesterolemia treated with a low fat diet.[45] Modification of the quality of dietary fat intake rather than a reduction of the quantity of fat intake, which has beneficial effects on plasma lipoprotein concentrations, is possible without any adverse effects on child growth.[46]

It is unclear whether the adverse effects on growth and weight gain observed in some studies with a reduced fat intake are attributable to a low energy intake rather than lower fat intake per se. Diets with a low fat intake tend to have a lower energy density, which may reduce total energy intake and thereby reduce weight gain and eventually length gain.

It is controversial to which extent fat reduced diets may be associated with biologically significant reductions of the intakes of lipid soluble vitamins and micronutrients. Some studies showed low intakes of vitamins and micronutrients, accompanied by lower energy intake,[42,47] whereas others did not find a compromised intake of these nutrients associated with reduced fat intake.[43,48]

FATTY ACIDS

The fatty acids esterified into lipids comprise the major component of fats in the diet and in the body, and they play a key role in modulating the physicochemical, metabolic and functional properties of lipids. Fatty acids are conventionally classified according to their chain length as short chain fatty acids (chain length <8 carbon atoms), medium (8–11 carbons), intermediate (12–15 carbons), and long chain fatty acids (>16 carbons). Short formulas are used to describe fatty acids, which indicate the number of carbon atoms and double bonds as well as the position of the terminal double bond (Table 7-1). The chain length of a fatty acid is the major determinant of melting point, energy content (kcal/g), the degree of solubility in polar (e.g., water) and non-polar solvents (e.g., hexane) and hence the efficacy of absorption in relation to the availability of conjugated bile salts in the intestinal lumen, as well as metabolic properties such as effects on lipoprotein metabolism, oxidative degradation and tissue fat deposition. Fatty acid properties also depend on the number, type and position of the double bonds of which there may be none (saturated fatty acids), one (monounsaturated) or two or more (polyunsaturated) (Figure 7-3).

Unsaturated fatty acids are widely classified according to the number of carbon atoms between the methyl end of the acyl chain and the first double bond from this end of the chain, that is the omega end of the fatty acid (Figure 7-3). In human metabolism, enzyme-mediated biochemical reactions, such as chain elongation, chain shortening by β-oxidation or the introduction of new double bonds occur at the carboxyl end of the molecule. In contrast, the omega end of a fatty acid is usually unchanged in intermediary metabolism, unless the fatty acid undergoes complete β-oxidation. Since humans and other higher organisms cannot introduce double bonds in the n-6 or n-3 positions, n-6 PUFA (e.g., linoleic acid) and n-3 PUFA (e.g., α-linolenic acid) are essential nutrients that must be provided with the enteral or parenteral substrate supply.

TABLE 7-1 Biologically Important Fatty Acids

Name	Short formula
Saturated Fatty Acids	
Acetic acid	C2:0
Propionic acid	C3:0
Butyric acid	C4:0
Caproic acid	C6:0
Caprylic acid	C8:0
Capric acid	C10:0
Lauric acid	C12:0
Myristic acid	C14:0
Pentadecanoic acid	C15:0
Palmitic acid	C16:0
Margaric acid	C17:0
Stearic acid	C18:0
Arachidic acid	C20:0
Behenic acid	C22:0
Lignoceric acid	C24:0
***cis*-Monounsaturated Fatty Acids**	
Palmitoleic acid	C16:1n-7
Oleic acid	C18:1n-9
Vaccenic acid	C18:1n-11
Essential Fatty Acids	
Linoleic acid (LA)	C18:2n-6
α-Linolenic acid (ALA)	C18:3n-3

γ-Linolenic acid	C18:3n-6
Dihomo-γ-linolenic acid	C20:3n-6
Mead acid	C20:3n-9
Arachidonic acid (AA)	C20:4n-6
Eicosapentaenoic acid	C20:5n-3
Docosahexaenoic acid (DHA), Cervonic acid	C22:6n-3
***trans*-Fatty Acids**	
Elaidic acid	C18:1n-9t
trans-vaccenic acid	C18:1n-11t
Linolelaidic acid	C18:2n-6t
Conjugated linoleic acids (CLA)	C18:2-9c11t, C18:2-10t,12c, and others

Short formulas are used to describe the number of carbon (C) atoms, the number of double bonds, the omega-position of the last double bond (n-x) and the double bond configuration in *cis* (c) or *trans* (t) position.

There are two isomeric forms of double bonds, *cis* and *trans* (Figure 7-3). Plant and mammalian cells introduce almost entirely *cis*-configurated double bonds into fatty acids, in which both adjoining carbon chains point in the same direction of the double bond and, therefore, the molecule is bent and becomes more flexible and fluid. *Trans*-isomeric fatty acids are formed primarily by rumen bacteria (in the forestomach of cows, goats, and sheep) and during technical fat hydrogenation.[49] *Trans*-fatty acids have a straight carbon chain, with a geometry similar to saturated fatty acids (Figure 7-3), and they have higher melting points and less fluidity at body temperature than their respective *cis*-isomers. *Trans*-fatty acids may exert adverse effects on lipoprotein and essential fatty acid metabolism as well as fetal growth.[46,50,51] Therefore, the intake of dietary *trans* fatty acids from foods produced with partially hydrogenated fats, French fries and other deep fried foods, baked goods with hydrogenated fats and other foods high in *trans* fatty acids should be limited.

Positional and *trans* isomers of linoleic acid in which the double bonds are conjugated are called conjugated linoleic acids (CLAs). CLAs are formed primarily by biohydrogenation in ruminants. CLAs in the Western diet are predominantly supplied with cows' milk and cheese. CLA contents in bovine milk are in the order of about 1%–2% of total fatty acids, with higher amounts resulting from barn feeding in the winter than from pasture feeding in the summer. Human milk contents depend on maternal dietary intake primarily from dairy products and reach a mean of

about 0.4% CLA in human milk, with considerable intra- and interindividual variation.[52] CLA was found to be a high affinity ligand and activator of the peroxisome proliferator-activated receptor alpha and appears to have marked effects on lipid and energy metabolism. Studies in different species of experimental animals show that the consumption of CLA leads to a reduced energy intake, increased metabolic rate, and loss of fat and total body weight. In addition, these studies show that CLA also reduces the plasma concentrations of total and LDL cholesterol, has an anti-inflammatory effect, and can inhibit the development of mammary, skin and prostate cancers. While mixtures of CLA isomers as supplements or CLA-enriched products are widely marketed for human consumption, only a few studies in healthy humans with relatively small sample sizes have been published so far. A recent systematic review concluded that there is not enough evidence yet to show that CLA has an effect on weight and body composition in humans, while some of these studies have observed that the administration of various CLA isomers has adverse effects on lipid profile with a decrease of high-density lipoprotein (HDL) cholesterol concentration and increased Lp(a) levels, glucose metabolism, lipid oxidation, inflammation, or endothelial function.[53] Therefore, long-term randomized clinical trials with placebo controls with sufficient power to evaluate the efficacy and safety of CLA isomers in humans are needed before its use in human beings can be recommended.

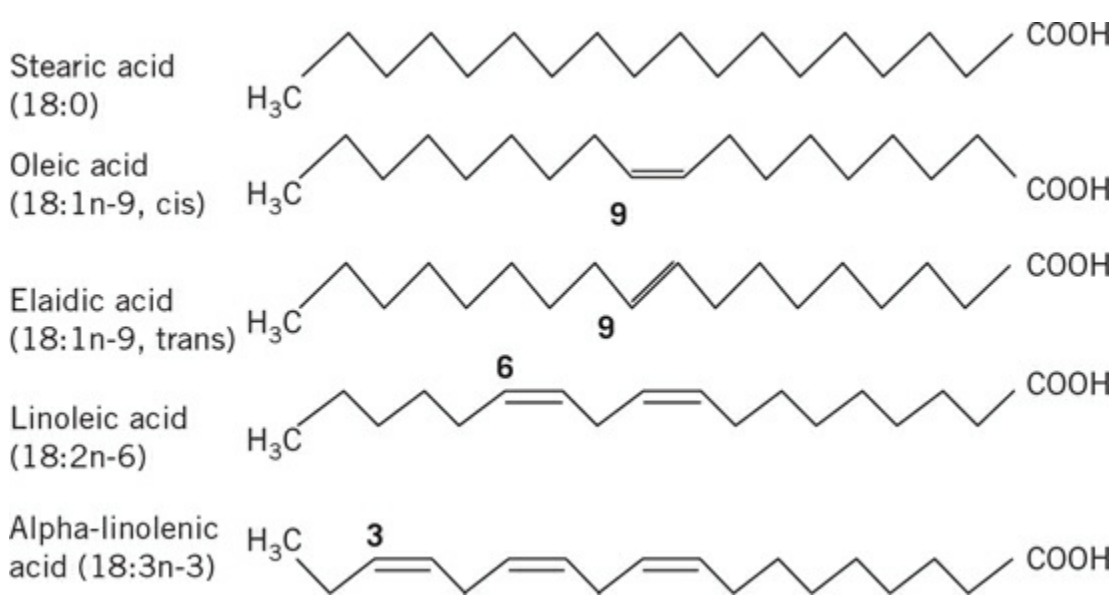

Figure 7-3 Structural formula of the saturated fatty acid stearic acid (18.0), the *cis*-monounsaturated fatty acid oleic acid (18:1n-9, one

double bond located 9 carbon atoms from the methyl end of the molecule), the *trans*-monounsaturated fatty acid elaidic acid (18:1n-9, *trans*, one *trans*-double bond located 9 carbon atoms from the methyl end of the molecule), the n-6 polyunsaturated fatty acid linoleic acid (C18:2n-6; n-6 fatty acid with the terminal double bond located 6 carbon atoms from the methyl end of the molecule), and the n-3 polyunsaturated fatty acid α-linolenic acid (18:3n-3; n-3 fatty acid with the terminal double bond 3 carbon atoms from the methyl end).

ESSENTIAL FATTY ACIDS

Saturated fatty acids, and unsaturated fatty acids of the n-9 and n-7 series can be synthesized *de novo* from acetyl CoA. In contrast, humans cannot introduce double bonds in the n-6 or n-3 positions, therefore, n-6 PUFAs (linoleic acid and metabolites) and n-3 PUFAs (α-linolenic acid and metabolites) are essential nutrients that must be provided with enteral or parenteral substrate supply. An inadequate dietary supply of linoleic acid induces a specific deficiency syndrome with a dry, scaly dermatitis and a variety of other signs and symptoms (Table 7-2). Linoleic acid deficiency has been observed mostly in infants, and a few adult patients with glucose-based, lipid-free parenteral nutrition. Infants are at a far higher risk of deficiency because of higher requirements for polyunsaturated fatty acids due to their rapid growth, while their body stores are very limited. Deficiency of n-3 fatty acids both in animals and in a limited number of human subjects on long-term tube feeding without adequate n-3 PUFA supply was reported to induce alterations of visual and neural functions.

The n-6 and n-3 fatty acids are not interconvertible, and they have different functions. Conversion of the dietary precursor essential fatty acids linoleic acid (18:2n-6) and α-linolenic acid (18:3n-3) occurs by alternating desaturation (insertion of double bonds) and elongation (addition of two carbon units) of the carbon chain (Figure 7-4) to highly unsaturated, long-chain polyunsaturated fatty acids (LC-PUFAs) with 20 and 22 carbon atoms and 3–6 double bonds. The LC-PUFA arachidonic acid (20:4n-6; AA) and docosahexaenoic acid (22:6n-3; DHA) are of particular importance for pregnancy outcomes, infant growth and development.[54]

TABLE 7-2 Signs and Symptoms of Essential Fatty Acid Deficiency

Scaly, hyperkeratotic dermatitis
Loss of hair
Growth faltering
Reduced utilization of dietary energy
Reduced nitrogen retention
Increased susceptibility to infection
Disturbed wound healing
Fatty liver, hepatomegaly, increased levels of ALAT & ASAT
Anemia
Thrombopenia, reduced platelet aggregation

PERINATAL SUPPLY OF LC-PUFA

There is accumulating evidence for an important functional role of the LC-PUFA supply and metabolism in nervous system development and function.[55] LC-PUFAs, especially AA (22:4 n-6) and DHA (22:6 n-3), are preferentially deposited in relatively high concentrations in developing neural cells during the perinatal brain growth spurt. In humans, most brain LC-PUFAs are accumulated during the phase of rapid brain growth in the last trimester of gestation and the first 2 years after birth. The importance of brain DHA accumulation mainly relates to its roles in maintaining neurological and visual development; decreases in brain and retina DHA result in altered visual acuity, disturbed electroretinographic measurements and learning impairment in various species. AA is a major component of structural phospholipids and serves as precursor for eicosanoids, which play important roles in cell division, signal transduction and many other physiological processes. The pathways to form DHA from the precursor essential fatty acid alpha-linolenic acid exist in humans (Figure 7-4), and the formation of LC-PUFA from the essential fatty acid precursors has been demonstrated even in newborn infants,[56] but the rate of essential fatty acid conversion is low.[57] The relative conversion of alpha-linolenic acid to n-3 LC-PUFA appears to be greater in women than in men, which may contribute to meeting the demands of the fetus and the breast fed neonate for DHA and hence represent a protective mechanism. In non-human primates, the supply of preformed dietary DHA is about an order of magnitude more efficient as a source for the neonatal brain accretion of DHA than is alpha-linolenic acid.[58] Therefore, adequate supplies of preformed n-3 LC-PUFA, and in particular DHA, during perinatal

development appear important for maintaining optimal tissue function.[59]

GENETIC VARIATION, ESSENTIAL FATTY ACID METABOLISM, AND HEALTH CONSEQUENCES

Recent data indicate a considerable inter-individual variation in the ability to convert the precursor alpha-linolenic acid to n-3 LC-PUFA, related to common polymorphisms in the human genes for the rate-limiting enzymes in this pathway delta-5 and delta-6 desaturases, that is the genes FADS1 and FADS2.[60] In 2006, the first genetic association study of the fatty acid composition in serum phospholipids revealed significant associations of SNPs in the *FADS* genes with several omega-6 and omega-3 PUFA.[61] Carriers of the minor alleles of the investigated SNPs showed higher concentrations of the desaturase substrates and lower concentrations of the desaturase products compared to major allele carriers. This led to the hypothesis that minor allele carriers have less ability to endogenously convert the precursor fatty acids to their longer-chain products. Several other (candidate-gene and genome-wide) studies involving populations of European, Asian, and African descent and including also other tissues such as erythrocyte membrane phospholipids, adipose tissue, and breast milk replicated the findings by Schaeffer et al.[61] Moreover, several genome-wide association studies on complex lipid traits reported associations of *FADS* polymorphisms with serum phosphatidylcholines, and the blood lipid parameters low-density lipoprotein (LDL), HDL, total cholesterol, and triacylglycerols.[60]

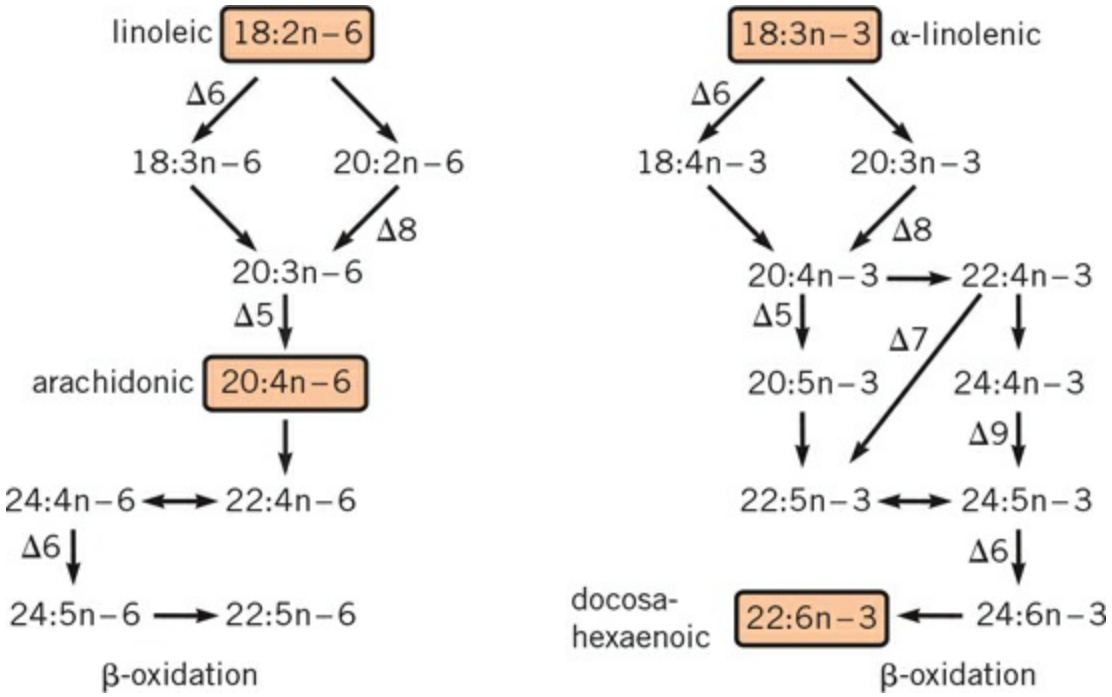

Figure 7-4 Pathways for the enzymatic conversion of the essential fatty acids linoleic acid (18:2n – 6) and α-linolenic acid (18:3n – 3) to long-chain polyunsaturated fatty acids (LC-PUFA).

FADS SNPs have also been associated with health endpoints including cardiovascular disease, type 2 diabetes mellitus, childhood eczema, and attention-deficit/hyperactivity and bipolar disorder.[60] Steer et al. found a strong modifying effect of genetic variation in the *FADS* SNPs on breastfeeding effects on later IQ in the Avon Longitudinal Study of Parents and Children.[62] There was an overall benefit from having been breastfed on full-scale IQ at 8 years, with higher mean values of eight points (unadjusted) or three points (adjusted) in previously breastfed compared to non-breastfed children. However, children homozygous for the minor allele had the lowest IQ scores when not having been breastfed (4.3 IQ points below not breastfed carriers of the major allele), but showed the highest benefit when having been breastfed (thereby reaching similar scores as breastfed major allele carriers) (*P*-value for interaction = .0091). Similar results were obtained in two Spanish birth cohorts.[63] These results suggest that breastfeeding is beneficial for cognitive development, but the effect size depends on the genetically determined variation in PUFA metabolism: children who have a limited ability to convert linoleic and alpha-linolenic acids to LC-PUFA have a greater benefit from

breastfeeding which provides preformed LC-PUFA. The data also provide evidence for a causal role of LC-PUFA availability of brain function.

We wish to emphasize that the polymorphisms referred to here are very frequent in the general population, with a minor allele frequency of around 30% and higher in Europeans. Thus, these nutrigenetic effects have a large public health importance.

PLACENTAL FATTY ACID TRANSFER

Numerous studies reported significant differences between the fatty acid composition of maternal plasma lipids at the time of delivery and cord plasma lipids. Percentages of saturated and monounsaturated fatty acids are very similar between maternal plasma phospholipids and cord blood phospholipids, but in cord blood the parent essential fatty acid levels are significantly lower whereas the LC-PUFA metabolites are clearly higher.[64] These observations point to a preferential transfer of LC-PUFA by the placenta.[65] Using stable isotope labeled fatty acids we investigated the placental transfer in vivo in humans.[66–68] Palmitic-, oleic-, linoleic- and docosahexaenoic acids labeled with the natural carbon variant ^{13}C were administrated orally 12 hours before elective caesarean section to pregnant women. Tracer concentration was analyzed in maternal blood samples until delivery, in cord blood and in placental tissue. The ratios between tracer concentrations in placental tissue or cord plasma, respectively, and in maternal plasma were similar to the saturated palmitic acid, the monounsaturated oleic acid, and the parent essential fatty acid linoleic acid, but were clearly higher for DHA pointing towards a preferential DHA transfer across the placenta (Figure 7-5). It can be deduced that incorporation of DHA into placental tissue and transfer of DHA across the placenta is more than three times as intense as of the other studied fatty acids.

The placental transfer of fatty acids is a complex process. Fatty acids bind to membrane proteins and cytoplasmatic transport proteins.[65,69] The placenta takes up circulating non-esterified fatty acids (NEFAs) as well as NEFA released from maternal circulating lipids by placental lipases and in addition human placental tissue express receptors to VLDL, LDL, and HDL lipoproteins,[70] which can provide fatty acids to the placenta for transfer once they are released by intracellular lipases. Nonesterified fatty acids may enter placental tissue both through passive diffusion, and by a carrier protein mediated transport (Figure 7-6). This facilitated transport

mechanism seems to involve plasma membrane fatty acid binding protein (FABPpm/GOT2). fatty acid translocase (FAT/CD36), fatty acid transport proteins (FATPs), and fatty acid binding proteins (FABPs).[71] It was proposed that a further fatty acid binding protein located exclusively on the maternal-facing membranes, placental plasma membrane fatty acid-binding protein (p-FABPpm), is also involved in the preferential uptake of LC-PUFA by trophoplast cells,[72] but definitive evidence on the possible structure and function of p-FABPpm must await analysis of its complete amino acid and/or cDNA sequence. Several FABPs are involved in the fatty acid transfer to the fetal circulation, for example heart-FABP (H-FABP), liver-FABP (L-FABP), and adipose tissue (A-FABP) have been identified in placenta.[73] The expression of the fatty acid transfer proteins FATP-1 and FATP-4 are correlated with placenta phospholipid DHA contents, which seems to indicate that they play a key role in facilitating preferential DHA transport from the mother to the fetus.[71] The presence of such an active and preferential materno-fetal DHA supports the hypothesis that fetal DHA supply is of biological importance.

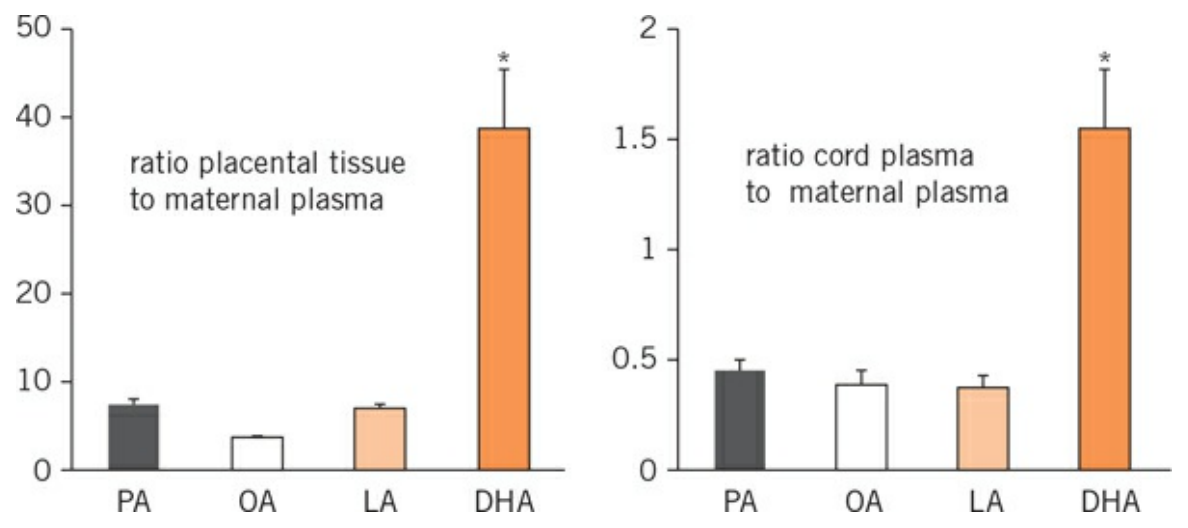

Figure 7-5 Ratios (%, *M*+SEM) between placental or cord plasma, respectively, and maternal plasma concentrations of studied ^{13}C-fatty acids. PA, palmitic acid; OA, oleic acid; LA, linoleic acid; DHA, doscosahexaenoic acid. $^{*}P<.05$ *post hoc* Bonferroni. Modified from Gil-Sanchez et al.[65]

DHA SUPPLY TO PREGNANT AND BREASTFEEDING WOMEN

Enhanced maternal dietary intakes of DHA increase fetal supply and lead to higher DHA concentrations in cord blood.[74] The effects of supplementing pregnant women with n-3 LC-PUFA from fish oil or DHA rich single cell oils on pregnancy outcomes have been evaluated in a number of randomized controlled clinical trials, which provided daily DHA intakes of 150–200 mg up to about 1200 mg/day, or up to 2.7 g total n-3 LC-PUFA/day. Systematic evaluation of these studies in recent meta-analyses revealed that n-3 LC-PUFA prolonged gestation by a mean of 1.6 or 2.6 days in two independent analyses, respectively, accompanied by a slight increase of birth weight by a mean 47 or 54 g, respectively.[75,76] Moreover, the supply of n-3 LC-PUFA reduced the risk of early preterm birth before 34 weeks of gestation by 31% in all pregnancies and by 61% in high-risk pregnancies.[54,76,77] Except for some reported discomfort associated with the intake of omega-3 oil capsules, such as belching and unpleasant taste, no adverse effects were detected up to the highest intake of 2.7 g total n-3 LC-PUFA/day tested in randomized controlled trials in pregnancy. A higher DHA supply to the fetus during pregnancy and to the infant after birth was associated with beneficial effects on the development of visual acuity, cognitive functions and attention, maturity of sleep patterns, spontaneous motor activity, immune phenotypes in a limited number of randomized clinical trials as well as in several prospective cohort studies.[59] Based on the information available, evidence-based consensus recommendations concluded that pregnant women should aim at achieving an average intake of at least 200–300 mg DHA/day.[59,59a] Supplementation of lactating women with 200 mg DHA/day increased human milk DHA content by about 0.2% of fatty acids to a level considered desirable for infant outcomes. Therefore, an average dietary intake of at least 200 mg DHA/day appears to be also adequate during lactation. An intake equivalent to 200 mg DHA/day is usually achieved by one to two meals of ocean fish per week, which includes fatty fish. This level of fish intake usually does not lead to an unacceptable daily intake of environmental pollutants.[59,78,79]

LC-PUFA SUPPLY TO INFANTS

Breastfed infants are provided with a dietary source of the LC-PUFA AA and DHA.[80] A systematic review of effects of LC-PUFA supplementation

of infant formulae on infant weight gain, based on original data analysis, indicates that the addition of DHA and AA to infant formula supports growth comparable to that seen in infants fed unsupplemented formula.[81] The available evidence indicated benefits of adding both DHA and AA to infant formula which has been supported by international expert recommendations.[30] DHA contents in infant formulas should reach at least 0.2%–0.3% of fatty acids, because lower contents have not been convincingly shown to provide benefits.[82] The amounts of added AA in infant formula should at least be equal to those of added DHA, and the amount of eicosapentaenoic acid added should not exceed the amount of added DHA. It appears advisable that dietary sources of DHA are also provided after the first six months of life because the effects of DHA status on indicators of neural function have been demonstrated in older infants and in children.[30] Recently, the European Food Safety Authority proposed that all infant formula should contain DHA levels of 20–50 mg/100 kcal (0.4–1% of fat), which are higher than the currently used DHA levels in term infant formula (near 0.3% of fat), but without the need to add AA.[83] This novel concept deviates from established European and global formula standards[84,85] that require AA contents in formula at least as high as DHA contents, which reflects the greater pre- and postnatal brain deposition of AA vs. DHA and the typically higher content of AA vs. DHA in human milk,[86] providing high amounts of n-3 LC-PUFA without AA-induced adverse effects on growth in preterm infants.[87,88] Concerns regarding adverse effects on development arise from the results of a double-blind, randomized trial in term infants fed formula either with no LC-PUFA or with DHA contents of 0.32, 0.64, and 0.96% at the same AA level of 0.64%, with developmental testing up to age 6 years.[89] Positive effects on word production, a card-sorting task, and an intelligence test were observed with the two lower DHA doses, but performance of children receiving 0.96% DHA with a reduced ratio of dietary AA to DHA was attenuated. Infant baboons fed the same formula showed reduced brain AA content with the formula providing 0.96% DHA but reduced dietary AA-to-DHA ratio.[90] Any major change in infant formula composition should be evaluated for nutritional adequacy and safety prior to market introduction.[91,92] Given the indications for adverse effects of providing formula with high levels of DHA without a concomitant increase in the provision of AA, it seems premature to accept the use of formula for infants from birth with the addition of 20–50 mg/100 kcal DHA without added AA in the absence of accountable data on the suitability and safety

from a thorough clinical evaluation of this novel approach.[86]

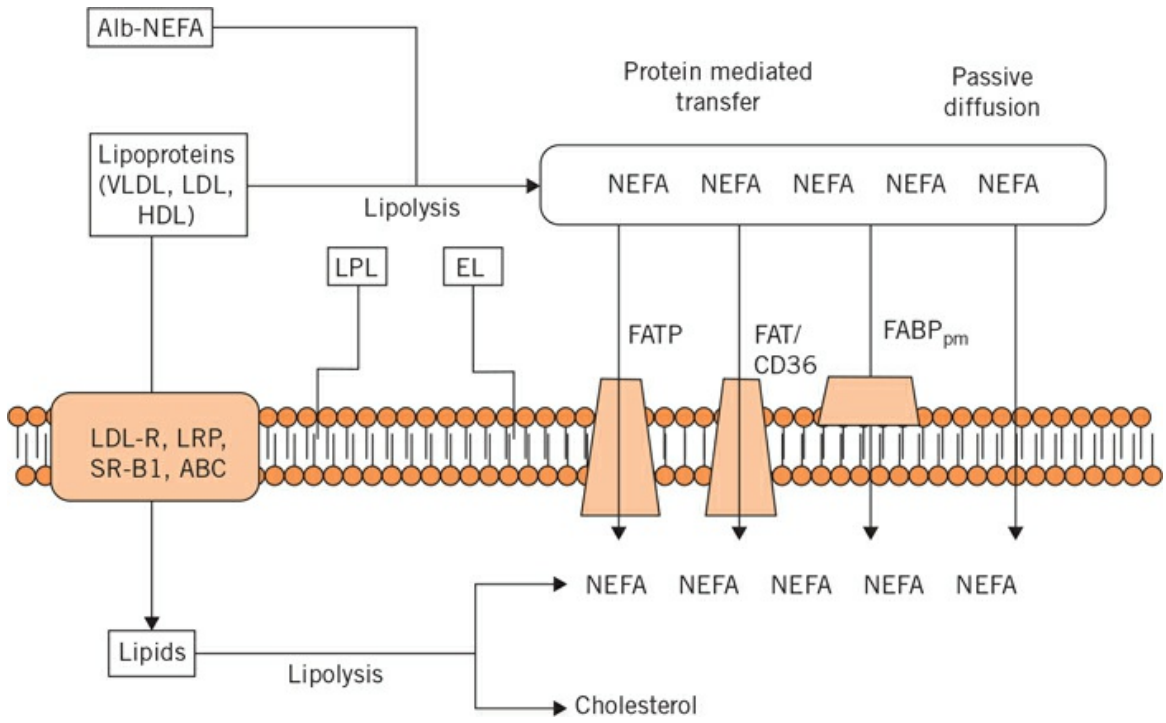

Figure 7-6 Mechanisms involved in the trophoblast fatty acid uptake. Intact lipoproteins can be taken up via lipoprotein receptors (LD-R), Scavenger receptor class B type 1 (SR-B1), lipoprotein related protein (LRP), ATP-binding cassette (ABC) transporters ABCA1 and ABCG1 or non-esterified fatty acids (NEFA) liberated by lipoprotein lipase (LPL) or endothelial lipase (EL). NEFA enter the cell by passive diffusion or carrier mediated. FATP, fatty acid transfer protein; FAT/CD36, fatty acid translocase: FABPpm, membrane bound fatty acid binding protein. Modified from Larque et al.[68]

CONCLUDING REMARKS

A large body of evidence has accumulated to show that the quantity and quality of dietary fat intake are of major importance for child growth and long-term health, including the modulation of risk of obesity, type 2 diabetes, and cardiovascular disease, visual, cognitive and neuromotor development, as well as immune response and the risk of allergy and autoimmune diseases. Enormous methodological progress enables future research to further explore lipid supply and metabolism as well as its effects at the molecular level, and to identify the effects of inter-individual

genetic variation in the relationship between fat intake and health outcomes. New scientific information should enable us to provide better advice on optimal lipid supplies to infants and children, both in health and disease.

Trace Elements

8

Nancy F. Krebs, MD, MS and K. Michael Hambidge, MD, ScD

More than 99.7% of the body weight is accounted for by 11 elements, termed the major elements (Table 8-1). The remainder of the body weight consists of approximately 25 trace elements, each of which contributes less than 0.01% to the body weight. Of these, a mammalian nutritional requirement has been established for iron, iodine, zinc, copper, chromium, selenium, molybdenum, manganese, cobalt, nickel, vanadium, silicon, arsenic, boron, and fluoride. Although it is reasonable to assume that the trace elements required by humans are similar to those required by other mammalian species, currently, a human nutritional requirement is accepted only for iron, iodine, zinc, copper, chromium, selenium, molybdenum, manganese, and cobalt (as vitamin B_{12}). Because of its beneficial effects in the prevention of dental caries, fluoride is also included in this list.

BIOLOGIC ROLES

Many enzyme systems depend on one or more specific trace elements, either as key components of metalloenzymes or as catalysts of metal ion–activated enzymes. The roles of metal ions in metalloenzymes may be structural, that is, maintaining the conformation of the protein, catalytic, or both. Iron, copper, zinc, molybdenum, selenium, and manganese have been identified as constituents of specific enzymes. Certain trace elements are of fundamental importance in the structure or metabolic activity of other compounds, including hemoglobin (iron), nucleic acids (multiple trace elements), transcription factor proteins (zinc), and vitamin B_{12} (cobalt). The roles of iodine in thyroxine (T_4) and triiodothyronine (T_3), zinc in steroid hormone receptors, and chromium in facilitating the action of insulin are examples of the importance of trace elements in the activity of certain hormones. The dependence of many vital metabolic processes on trace elements confers a physiologic importance of these micronutrients

that is analogous to that of vitamins and is out of proportion to their small contribution to body weight. Although considerable progress has been achieved in determining the functions of several trace elements, little is yet known about the biochemistry of others.

Table 8-1 Elements with a Role in Human Physiology

Major Elements	Recognized	Probable
Trace Elements		
Carbon (C)	Iron (Fe)	Nickel (Ni)
Hydrogen (H)	Iodine (I)	Vanadium (V)
Nitrogen (N)	Zinc (Zn)	Silicon (Si)
Oxygen (O)	Copper (Cu)	Arsenic (As)
Sodium (Na)	Chromium (Cr)	Boron (B)
Potassium (K)	Selenium (Se)	
Phosphorus (P)	Molybdenum (Mo)	
Sulfur (S)	Manganese (Mn)	
Chloride (Cl^-)	Cobalt (Co)	
Calcium (Ca)	Fluoride (F^-)	
Magnesium (Mg)		

DOSE RESPONSE

An elementary but important concept is that the biologic effect of any trace element depends on the dose or, more specifically, on the level of intake and on tissue concentrations (Figure 8-1). For each element, there is an optimal range of intake, the magnitude of which varies considerably between different elements and depends on a number of factors, including the efficiency of homeostatic mechanisms. Obviously, if intakes are sufficiently high, any element will prove toxic. In the case of non essential elements (e.g., mercury), harmful effects can result only from toxic levels of intake. However, in the case of the “essential” trace elements, problems may result from intakes that are too low as well as too high. In animal husbandry, the economic importance of trace deficiency states has been recognized for many years.[1] However, in human nutrition, only iron and iodine deficiencies were recognized prior to the 1960s, and it is only more recently that a broader concept of trace element nutrition has started to

develop with the recognition of zinc, copper, chromium, selenium, molybdenum, and possibly manganese deficiency states in humans. Likewise, greater appreciation has emerged for potential adverse effects of very high intakes, for example, from copper contamination of drinking water.

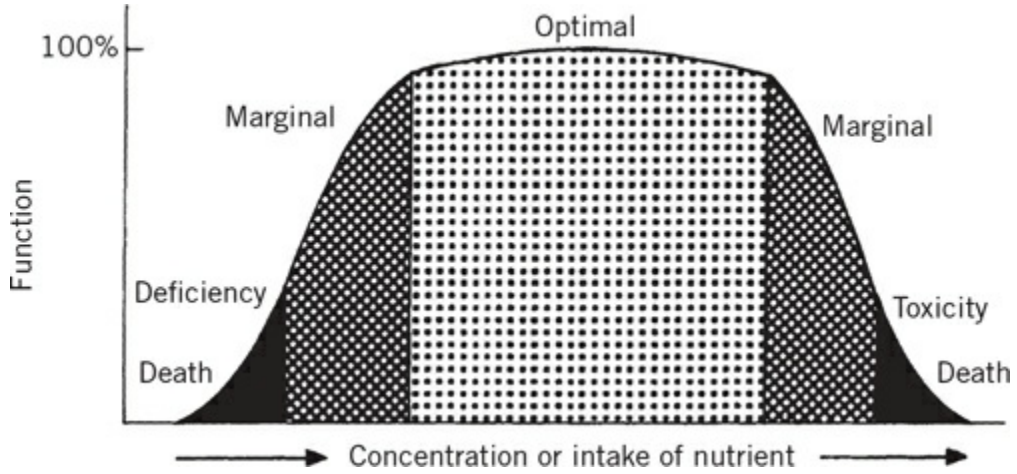

Figure 8-1 Dependence of biologic function on tissue concentration or intake of a nutrient. Reproduced from Mertz W. The essential trace elements. Science 1981; 213:1330.

ETIOLOGY OF HUMAN TRACE DEFICIENCY STATES

The last several decades have been notable not only for the number of new trace elements implicated in deficiency disease, but, perhaps more surprisingly, for the wide variety of different factors that have been discovered to play a role in the etiology of these deficiency states (Table 8-2). These include inherited or acquired alterations in metabolism and other special circumstances leading to increased nutritional requirements as well as factors that contribute to inadequate intakes of one or more of the trace elements.

TABLE 8-2 Etiology of Trace Mineral Deficiencies

Etiology	*Trace Elements* [a]
Inadequate Intake	

No special circumstances required but risk increased during infancy and pregnancy	Fe, Zn
Losses during food processing, including preparation of “humanized” infant milk formulas	Zn, Cr, Cu, Se
Poor bioavailability	Fe, Zn
Local deficiencies in geochemical environment	I, Se
In association with protein-energy malnutrition	Zn, Cu, Cr
Synthetic diets, including intravenous feeding	Zn, Cu, Cr, Se, Mo
Other Circumstances	
Prematurity	Fe, Cu, Zn
Diseases and other unusual circumstances	Zn, Cu, Cr causing impaired intestinal absorption or excessive losses of trace elements
Inborn errors of trace element metabolism	Zn, Cu, Mo

[a] Elements given are notable examples, but not necessarily a complete list.

Notable examples of the inborn errors of trace element metabolism are represented by Acrodermatitis enteropathica and “Menke steely hair syndrome” (MSHS), which are genetic defects in zinc absorption and copper trafficking, respectively.[2,3] Although these entities are rare and not strictly nutritional deficiency diseases, some of them are important in a nutritional context because of the insight they provide into the clinical and metabolic effects of severe nutritional deficiencies. Moreover, in some instances, manipulation of dietary intake has remarkable therapeutic benefits. Both of these points are well illustrated by Acrodermatitis enteropathica, which is discussed below. Although unresponsive to dietary supplements, Menkes’ is attributable in part to a de facto deficiency of copper in certain tissues and subcellular sites, resulting from deranged copper transport, including out of the enterocyte.

Diseases that cause intestinal malabsorption of fat and other nutrients may also lead to trace element deficiencies.[4] Excessive losses of trace elements occur in certain diseases through the kidneys, gastrointestinal tract, sweat, exudates, or hemorrhage. Low blood plasma concentrations of specific trace elements can occur in certain disease states in association with the redistribution of these elements within the body. For example, movement of zinc and iron from the plasma to the liver occurs in stress

situations, including infectious diseases. Correction of hypozincemia in these circumstances may be contraindicated, although the host response may depend on the specific cause of the stress.

The premature infant with very low birth weight provides a unique nutritional challenge that includes the provision of adequate trace elements.[5] Some elements, notably copper, iron, and zinc, are stored extensively by the fetus during the last trimester. These stores, which are available to the term infant in early postnatal life, are diminished in the premature infant. Immaturity of intestinal absorption mechanisms and relatively high losses of endogenous zinc have been reported. These problems are aggravated further by the high nutritional requirements that are imposed by the rapid growth of the premature infant after the early postnatal period. Nutritional requirements may also be relatively high during periods of rapid growth in the term infant and in later childhood, as well as during pregnancy and lactation.

Although nutritional requirements for trace elements are small and these nutrients are ubiquitous in the environment, the quantities present in food and water are usually correspondingly low. Hence, contrary to earlier concepts, it is not surprising that humans are at risk of nutritional deficiencies of the trace elements. Iron deficiency, although outside the scope of this chapter, remains one of the most common human nutritional disorders. Other trace deficiencies occur in more restricted geographic locations owing to localized deficiencies in soils, plants, or water. The classic example of a geographic deficiency is that of endemic goiter, and low body content of selenium is observed in some countries, for example New Zealand, while marked selenium depletion and deficiency were documented and subsequently treated through public health initiatives in large areas of China. Diets deficient in energy and other nutrients may also contain inadequate quantities of trace elements. Thus, deficiencies of zinc, copper, selenium and chromium have been documented in association with protein-energy malnutrition.

Variations in bioavailability are a major factor in determining the adequacy of dietary intake of some of the trace elements. This also applies especially to the infant because of its dependence on one major food staple. Thus, if the milk or milk substitute that provides most or all of the nutrients consumed by the infant is low in available trace elements, there is no chance that this deficit will be compensated for by a more favorable supply in other food items. Although our understanding of this complex subject is far from complete, it is known that human milk confers important advantages with respect to the bioavailability of iron and zinc.

Although not proven, it seems probable that this may also be true of other trace elements. As a corollary, the trace element concentrations in breast milk should be considered a minimum guideline for corresponding concentrations in infant milk formulas, and higher concentrations of at least some elements, including iron and zinc, are necessary in the latter. However, indiscriminate supplementation may have adverse consequences, especially through undesirable interactions with other trace elements. Additional research directed at mineral–mineral interactions is needed to determine optimal fortification levels in foods and formulas.

The use of synthetic diets in medical practice, including those used in intravenous feeding, has provided some of the most dramatic examples of acquired trace-element deficiency states. Deficiencies of zinc, copper, chromium, molybdenum, and probably selenium were all documented in association with long-term intravenous feeding without adequate provision of these micronutrients. Current pediatric trace mineral formulations routinely used in major pediatric centers have greatly reduced the incidence of deficiencies.

NUTRITIONAL REQUIREMENTS

The evolving nutritional importance of trace elements has been recognized by the publication of guidelines, including those of the Food and Nutrition Board of the National Academy of Sciences (see Appendix 2).[6] A formal Recommended Dietary Allowance (RDA) has been established for copper, iodine, iron, molybdenum, selenium, and zinc. An Adequate Intake (AI) has been set for chromium and manganese, which reflects the more limited data available on which to base an Estimated Average Requirement (EAR). Information is limited to the quantities of some of these elements in individual food items, which limits the application of these guidelines by nutritionists and other health professionals.

Guidelines have also been published for intravenous administration of trace elements to children who have to be maintained with total intravenous nutrition (Table 8-3).[7] Intravenous requirements for zinc and selenium vary according to the extent of ongoing losses, especially from the gastrointestinal tract and kidney, respectively. Hence, it is desirable to monitor status at regular intervals. In contrast, copper and manganese may accumulate in cholestatic patients who are receiving long-term parenteral nutrition support, in which case, monitoring and adjustment of the administered dose may also be warranted.

LABORATORY ANALYSES AND THE DETECTION OF TRACE ELEMENT DEFICIENCY STATES

Fundamental advances in analytic instrumentation, especially the advent and progressive refinement of atomic absorption spectrophotometry, have facilitated the quantitative measurement of trace elements that are present in the parts-per-billion as well as parts-per-million concentration ranges. Yet formidable analytic difficulties remain. For example, accurate measurement of chromium, which now appears to be present in blood plasma, urine, and milk in only parts-per-trillion concentrations, is extraordinarily difficult. Even for relatively simple measurements, such as those of zinc in plasma or serum, substantial inter-laboratory differences in analytic results continue to be evident, and it is ideal that each laboratory establish its own normal range. Even when analytic data are accurate, interpretation is frequently problematic. Plasma concentrations of zinc, for example, may be depressed for reasons other than a nutritional deficiency, and thus may fail to provide a sufficiently sensitive or reliable guide to body status. Established physiologic indices, such as the measurement of the activity of an enzyme that depends on a specific trace element, are generally unavailable. The depression of glutathione peroxidase activity in selenium deficiency states is one exception, but the clinical significance of this observation remains uncertain. Overall, laboratory indices for detection of “newer” trace element deficiencies are not as dependable as those available for the detection of iron deficiency. Hence, for research purposes, more cumbersome approaches are necessary to confirm the suspicion of a specific deficiency, including especially the effects of supplementation on specific physiologic parameters and functional outcomes under carefully controlled conditions. Meanwhile, the health professional needs to be aware of the circumstances in which there is a risk ofspecific trace deficiencies and of the clinical features that may be attributable to such a deficiency.

Table 8-3 Guidelines for Maintenance Intravenous Administration of Trace Elements during Parenteral Nutrition

Trace Element	Maintenance Requirement (µg/kg/day)
Zinc	100[a]

Copper	20
Chromium	0.2
Manganese	1
Selenium	2
Iodine	1

[a] Requirements for zinc may be much greater in patients who continue to excrete excessive quantities of zinc; also, in premature infants, 300 µg/kg/dayshould be administered

Hair analyses merit special mention because of their widespread misuse and the unsubstantiated claims for this diagnostic tool. Currently, the value of chemical analyses of hair in clinical practice is extremely limited.[8] Because of the inherent difficulties in interpretation of analytic data, it is unlikely that future research will lead to more useful clinical applications of hair analyses. Multi-element hair analyses continue to be available commercially, often accompanied by interpretations of questionable validity, and the results merit caution and additional confirmatory evidence prior to therapeutic interventions.

ZINC

A nutritional requirement for zinc was first recognized in microorganisms in 1869, in plants in 1914, and in mammals in 1934.[1] In 1954, zinc deficiency was shown to be the cause of porcine parakeratosis. The first of the zinc metalloenzymes to be identified was carbonic anhydrase in 1940. Subsequently, over 100 zinc metalloenzymes have been identified, including at least one in every major enzyme classification. Understanding of the role of zinc in cell growth and differentiation took a major step forward with recognition of “zinc fingers” as the most frequent deoxyribonucleic acid (DNA) binding motif for transcription factor proteins.[9] The first reports of human zinc deficiency attributable to dietary factors emerged in the Middle East in the early 1960s in relation to the syndrome of adolescent nutritional dwarfism.[10] In the 1990s, the importance of zinc deficiency on childhood morbidity and mortality in the developing world was documented by a number of carefully conducted, large-scale, randomized, controlled supplementation trials in vulnerable populations.[11]

CLINICAL FEATURES OF ZINC DEFICIENCY

The clinical features of human zinc deficiency range from a life-

threatening disease state, characterized by acro-orificial skin rashes, diarrhea, growth arrest, anorexia, depressed mood, and increased susceptibility to infection, to a mild impairment of growth velocity, often accompanied by other problems, including poor appetite (Table 8-4). In addition to the severity of the zinc depletion, the clinical sequelae appears to depend on other factors, including the speed of onset and associated clinical and dietary factors such as protein-energy malnutrition.

Decreased growth velocity or growth arrest is a consistent and early result of even mild zinc deficiency in young experimental animals and in infants, children, and adolescents. In severe acute zinc deficiency states (e.g., Acrodermatitis enteropathica), there is an abrupt cessation of weight gain when the skin rash becomes manifest, and "catch-up" growth occurs when adequate zinc supplements are administered.[12] A meta-analysis of trials in prepubertal children that met strict criteria indicated that supplementation was associated with significant responses in both height and weight increments. Responses were strongest in those initially underweight and in children >6 months of age with evidence of stunting.[13,14] These collective results suggest that zinc deficiency is a common cause of retarded growth velocity in the developing world. Zinc deficiency has also been linked to poor growth in association with certain diseases, including cystic fibrosis and sickle cell anemia.[15–17]

TABLE 8-4 Clinical Features of Zinc Deficiency[a]

Decrease in growth velocity
Impaired appetite and decreased food intake
Diarrhea
Increased susceptibility to infection with associated abnormalities of the immune system
Acro-orificial skin lesions; other epithelial lesions, including glossitis, alopecia, nail dystrophy, and hair loss
Behavioral abnormalities, including impairment of hedonic tone Delayed sexual maturation and impotence
Eye lesions, including photophobia and lack of dark adaptation. Delayed healing of wounds, burns, and decubitus ulcers
Hypogeusia or dysgeusia
Low birth weight
Prematurity

[a] Features are dependent on severity of deficiency and other factors.

Anorexia is an early manifestation of zinc deficiency in experimental animals. Although this has long been recognized as a feature of Acrodermatitis enteropathica and is also noted in association with milder zinc deficiency syndromes, it has been difficult to acquire objective evidence of a direct cause-and-effect relationship in humans. However, a significant effect of zinc supplementation on food intake has been observed in some double-blind, controlled studies.[18,19]

Diarrhea is one of the hallmark features of the early descriptions of acrodermatitis enteropathica and occurs in a high percentage of cases of severe zinc deficiency. There is growing evidence that zinc deficiency contributes to the incidence, severity, and duration of acute infectious and persistent diarrhea in infants and young children in the developing world. On the basis of pooled analysis of zinc supplementation trials, a substantial reduction in the rate of treatment failure or death in children given zinc supplements has been estimated. Diarrhea can itself also contribute to zinc deficiency because of the losses of endogenous zinc in diarrheal fluids. Thus, requirements for zinc are likely to be greater in the presence of diarrhea. In recognition of the beneficial effects of zinc supplementation and the high prevalence of marginal zinc status in young children in international settings, WHO and UNICEF have recommended routine administration of zinc supplements along with fluid replacement and continued feeding in all episodes of acute diarrhea.[20,21]

The skin lesions of severe acute zinc deficiency syndromes have a characteristic distribution, primarily in the extremities and adjacent to the body orifices (Figure 8-2). However, lesions do occur elsewhere and may become generalized. Most commonly, the rashes are erythematous, vesiculobullous, and pustular. Secondary infection is common, especially with staphylococci or *Candida*. In hereditary Acrodermatitis enteropathica, the skin lesions typically occur in early infancy, although they are often delayed until several months of age, especially after weaning if the infant is breast-fed. Other epidermal lesions include gingivitis, dermatitis, glossitis, conjunctivitis, blepharitis, alopecia, and, in chronic cases, nail dystrophies.

Behavioral abnormalities are a notable feature of severe zinc deficiency states. Irritability, lethargy, and depression occur typically in conjunction with the skin rash of severe zinc deficiency. Hedonic tone and motivation to engage in the environment, improve dramatically after the commencement of zinc therapy.[22] Cognitive development is impaired in young zinc-deficient animals, and there is some evidence that the same applies in the human, although results of trials have been inconsistent.[23,24]

Figure 8-2 The acute skin lesions of acrodermatitis enteropathica are demonstrated in this 10-month-old infant. Reproduced from Hambidge KM, Nichols PL Jr, editors. Zinc and copper in clinical medicine. Jamaica (NY): Spectrum Publications; 1978.

Frequent bacterial and monilial infections, associated with abnormalities of the immune system, contribute to the progressive and often fatal course that characterizes untreated acrodermatitis enteropathica (AE). Abnormalities of the immune system also occur in less severe zinc deficiency states.[25] Compared with studies of zinc and diarrhea, the data are less consistent linking zinc deficiency with incidence, prevalence and severity of respiratory infections, including pneumonia. A recent systematic review, based on six randomized, controlled trials in children from 2 to 59 months of age, found approximately a 13% reduction in the incidence of pneumonia, and a 41% reduction in prevalence; findings of subgroup analysis emphasized importance of clear definitions of

diagnostic criteria.[26] The distinction between an apparent response due to correction of pre-existing zinc deficiency versus a pharmacologic effect of zinc supplementation is rarely clear.

BIOCHEMICAL CORRELATES

Although there is now extensive knowledge about the biochemistry of zinc, especially its role in a wide range of enzyme systems and in gene transcription, the biochemical correlates of the clinical features of human zinc deficiency remain poorly defined. Many of the features of zinc deficiency, including growth retardation, poor wound healing, and abnormalities of fetal development and the immune system, are thought to be attributable, at least in part, to disturbances in nucleic acid metabolism and protein synthesis. Its role as a stabilizer of the molecular structure of subcellular constituents and membranes is exemplified by the observation of altered membrane signaling and postreceptor events that coordinate the response to insulin-like growth factor 1 when zinc availability is limited.[27,28] Such observations provide another plausible link to the growth retardation and impaired immune function during zinc deficiency. The so-called zinc fingers are the most common motif for the repetitive sites of transcription proteins that bind to DNA to initiate transcription.[9] Through this mechanism, which can be compromised by zinc restriction, zinc has an extraordinarily important role in gene expression. Additionally, several of the enzymes involved in nucleic acid synthesis are zinc dependent, including DNA and ribonucleic acid (RNA) polymerases, reverse transcriptase, and thymidine kinase, the activity of which is known to be reduced in human zinc deficiency.

Zinc is critical for normal immune function and interacts with several components of the immune system, ranging from the skin and its barrier function to aspects of both cellular and, to a lesser extent humeral, immunity.[25] In vitro studies emphasize the responsiveness of some components to zinc concentrations, with both deficiency and supraphysiologic levels leading to impaired immune function. Two recent studies examining zinc as an adjunct therapy for treatment of pneumonia[29] and probable bacterial sepsis[30] found reduction in case fatality rates and treatment failure, respectively, in young children and infants. Zinc in the form of lozenges has been investigated in developed countries for its ability to shorten the duration and reduce the severity of “the common cold,” or upper respiratory infections. This is an example of a

pharmacological therapeutic effect, since most individuals would be presumed to have sufficient zinc status at baseline. Reviews to date have concluded that, despite the likelihood of efficacy, data are insufficient to make recommendations regarding dose, formulation and duration.[31] Reviews address in vitro and in vivo studies of the role of zinc in normal immune function and the impact of zinc deficiency on common childhood illnesses.[25,32,33]

ETIOLOGIC FACTORS IN ZINC DEFICIENCY

The prototype of the severest forms of human zinc deficiency is provided by acrodermatitis enteropathica (AE), a rare autosomal recessively inherited disorder. The phenotypic expression of this disease is attributable entirely to a severe zinc-deficiency state. Although total body zinc is not greatly reduced in AE, plasma zinc concentrations are typically extremely low. Before the beneficial effects of zinc therapy were recognized, this was a severe, progressive, and often fatal disease. The zinc deficiency results from a partial block in the intestinal absorption of this trace metal due to mutations in the SLC39A4 gene, also known as the ZIP4 gene, that codes for a transmembrane, histidine-rich protein which functions in zinc uptake. The gene is expressed abundantly throughout the intestine, and accumulates at the apical surface of the enterocyte.[34] Mutations of SLC39A4 are now thought to be observed in only about half of the index AE cases tested, with ~40% of the patients found to be homozygotes or compound heterozygotes, and 8% found to be heterozygotes.[35] Clinical diagnosis by mutation analysis is now possible, although not yet routinely available.[36]

There have been numerous reports of severe zinc deficiency states in both term and pre-term breast-fed infants the presentations have been attributable to a condition now termed “acquired zinc deficiency of lactogenic origin,” which is characterized by an inability of the mother’s mammary gland to secrete normal quantities of zinc into the milk despite otherwise apparently normal maternal zinc status. Specific mutation(s) of the SLC30A2 gene for zinc transporters localized to the mammary gland is responsible for this condition.[37] The result is markedly low milk zinc concentrations (~25% of normal for stage of lactation), and severe zinc deficiency in the exclusively breastfed infant. Supplemental zinc to the infant easily treats the infant’s deficiency, as there is no absorptive defect in the infant. The prevalence of this defect is unknown, but clinical

impression is that it is not rare. In a large cohort of Chinese women, two polymorphisms of the SLC30A2 gene explained 3.23% of total variance in milk zinc concentrations.[38]

Zinc deficiency has also been well documented in premature and low-birth weight infants if supplemental zinc is not provided. Contributory factors may include immaturity of the gastrointestinal homeostatic processes, including both absorption of exogenous zinc and conservation of endogenous zinc; relatively high urine losses; and relatively high zinc requirements when rapid postnatal growth commences. In one large series from a hospital population, the strongest clinical risk factors include low gestational age, small for gestational age (SGA), and intestinal resection.[39] Fortification of human milk and use of fortified formulas designed to meet the needs of premature infants have been associated with positive net absorption and retention of zinc.[40] The results of zinc supplementation trials in low birth weight infants in developing countries have resulted in a striking reduction in morbidity and mortality, illustrating the apparent vulnerability of these infants with-out a generous dietary intake to zinc deficiency.[41,42]

A wide variety of etiologic factors may contribute to more moderate and mild zinc deficiency states. An “absolute” dietary deficiency is considered to be less common than relative deficiency due to reliance on dietary sources of poor bioavailability. Older breast-fed infants are susceptible to mild zinc deficiency because of the low zinc concentrations in human milk after 6 months. Deficiency has been documented in infants in developing countries, where a combination of complementary foods with low zinc content and/or bioavailability and a high infectious burden likely contribute to the risk of deficiency.[19] As phytate intakes are high in many developing countries owing to dependence on plant staples such as maize, wheat, or legumes, there is particular concern about the adequacy of zinc intake in infants and young children in these settings.[43] Even in western cultures, the traditional progression from iron fortified infant cereals to fruits and vegetables, with relatively late introduction of meats, may pose a risk for mild zinc deficiency in older breastfed infants.[44]

The risk of zinc deficiency is enhanced in conditions of gastrointestinal pathology such as short gut syndrome, intestinal failure, or other causes of malabsorption and/or increased endogenous intestinal losses.[45] Fat malabsorption or intestinal inflammation may impair zinc absorption and enhance losses of intestinal endogenous zinc, as in regional enteritis, celiac disease, and cystic fibrosis.[15,46] In children with celiac disease, institution

of a gluten free diet has been reported to result in normalization of plasma zinc levels, with or without zinc supplementation.[46,47] Excessive urinary losses of zinc occur in liver disease,[48] diabetes mellitus, sickle cell disease,[17] nephrosis, and catabolic conditions.[4] A number of chelating agents, diuretics, and other drugs can also cause excessive zinc excretion, but the extent to which this is of practical significance is unclear.

DIAGNOSIS OF ZINC DEFICIENCY

The characteristic distribution of the skin lesions facilitates the clinical diagnosis of severe zinc deficiency states. Unfortunately, however, the clinical features of moderate and mild zinc deficient states are nonspecific. Hypozincemia is not a consistent feature of mild chronic zinc deficiency states. Currently, laboratory parameters are of only limited value in the confirmation of zinc deficiency. Plasma zinc concentrations are markedly depressed (<40 μg/dL) in the severest deficiency states, and moderate hypozincemia (40–60 μg/dL) occurs in more moderate zinc deficiency states. However, plasma zinc levels are also depressed to this extent with the effects of various stresses, including infections, which result in hepatic sequestration of circulating zinc. Interleukin-6 and other cytokines are responsible for the decline in plasma zinc associated with infections. Underlying zinc deficiency can obviously co-exist with acute infection, and thus consideration of the benefit of zinc supplements should be given in settings of high risk of nutritional zinc deficiency.[49] Fasting is associated with higher plasma zinc levels, and the effects of meals results in progressively lower concentrations over the course of a day. An analysis of national data for children under 10 years suggested a lower cutoff of 65 μg/dL for morning non-fasting sampling, and 57 μg/dL for afternoon sampling.[50] Serum zinc levels have been reported to be higher than plasma zinc levels; this is attributable to a delay in separation from red cells. Erythrocyte zinc is little affected by zinc deficiency and is not a sensitive index, nor are leukocyte zinc concentrations. Urine excretion rates are diminished in severe zinc deficiency, but this is also not a sufficiently sensitive assay for clinical use. Serum alkaline phosphatase activity is depressed in moderate to severe zinc deficiency states and increases with zinc supplementation in cases of moderate zinc deficiency, but this assay is not a sufficiently specific diagnostic tool used alone. Because of the limitations of currently available laboratory indices in the detection of mild zinc deficiency states, the most reliable approach remains the demonstration of a functional response to a trial of zinc supplementation

under adequately controlled conditions.

TREATMENT OF ZINC DEFICIENCY

Acrodermatitis enteropathica can be treated effectively with 40 to 50 mg/day of elemental zinc administered as the sulfate, gluconate, or other salt. Requirements in infants and toddlers with AE may be considerably less (e.g., 20 to 30 mg/day). Most other milder cases of zinc deficiency can be treated effectively with 1 mg elemental zinc/kg body weight/day, typically up to a maximum of 20 mg zinc/day. Somewhat larger quantities may be required in the presence of excessive ongoing losses or malabsorption. In severe zinc deficiency in premature breast-fed infants, temporary zinc supplements are necessary to replete tissue pools until other sources of zinc are added to the diet. One milligram of elemental zinc is equivalent to 4.4 mg of $ZnSO_4 7H_2O$; 7 mg of zinc gluconate; and 2.8 mg of zinc acetate (anhydrous).

Maintenance intravenous requirements for adults are approximately 2 mg and for infants 100 µg/kg body weight/day. In premature infants, 300µg/kg body weight/day has been recommended.[7] Ongoing losses through the kidney or, more commonly, the gastrointestinal tract owing, for example, to intractable diarrhea may substantially increase the intravenous requirement. For intravenous administration, zinc chloride is frequently used; 1 mg zinc is equivalent to 2.1 mg $ZnCl_2$.

TOXICITY

Acute toxicity is rare but can occur, for example, from the ingestion of large quantities of pharmacological preparations of zinc or from the consumption of acidic drinks from galvanized cans. Symptoms are usually limited to diarrhea and vomiting, but there may be severe lethargy. Administration of zinc in quantities of 50 mg/day to adults can cause anemia owing to copper deficiency (see below) and may depress plasma high-density lipoprotein cholesterol levels. More moderate supplementation has generally not been found to be problematic. For example, 10 mg/day for 4 months in infants was not associated with hypocupremia.[51] Similarly, neither 5 or 10 mg of daily supplemental zinc in addition to dietary zinc for 4 months in adolescent boys was associated with adverse effects on an extensive array of indicators of copper status.[52]

ABSORPTION AND METABOLISM

The gastrointestinal tract, specifically the small intestine and the pancreas, have the major role in maintaining whole body Zn homeostasis.[4] Over 20 zinc transporters have been identified in these organs, with the ZnT family generally functioning as zinc exporters and the ZIP family functioning in zinc uptake into the cytoplasm. Gene expression of the transporters is a major component of homeostatic regulation, including regulation of zinc absorption via the small intestine and excreting zinc via both the pancreas and small intestine.

Of note, studies in humans applying stable isotope techniques indicate that the quantity of zinc ingested, rather than host zinc status, is the principal factor triggering regulation of expression of the transporters involved with zinc absorption into and through the enterocyte.[4] Zinc absorption is known to be a saturable transport process.[53] Fractional absorption, therefore, declines with increasing Zn intake and vice versa. Regulation of the quantity of endogenous Zn excreted has a major role in maintaining whole body Zn homeostasis in most circumstances, and appears to be influenced by host zinc status, with conservation in the face of marginal zinc intake.

Fractional absorption of zinc averages about 60% when ingested in solution in water, but is usually only in the range of 20%–40% from composite meals or infant formulas. The favorable bioavailability of zinc in human milk is undoubtedly in part due to the relatively modest concentrations; actual amount of absorbed zinc is lower than from fortified formulas.[54] On the other hand, fractional absorption is depressed by dietary phytate (inositol hexaphosphate), which is found in whole grains and legumes.[55] The intestine is the major route for excretion of endogenous zinc, and conservation of intestinal endogenous zinc appears to be critical in maintaining or restoring zinc balance.[4] The ability of the intestine to conserve endogenous zinc may be impaired by malabsorption, including cystic fibrosis[15], and possibly environmental enteropathy.[56]

About 10% of total body zinc, 100–200 mg in adults, intermixes with circulating plasma zinc within 2 days.[57] This zinc is thought to be of special physiologic importance to many of the zinc-dependent metabolic processes in the body, and it is also this zinc that is vulnerable to dietary zinc restriction. This is likely to explain why the symptoms of zinc deficiency occur with very little change in total body zinc. It has been found that the quantity of readily exchangeable zinc has a strong positive correlation with dietary zinc and an even stronger correlation with a

quantity of zinc absorbed.[4,44] A substantial part of this rapidly exchanging zinc is located in the liver.

In the systemic circulation, approximately 75% of the plasma zinc is loosely bound to albumin, and most of the remainder is tightly bound to α_2-macroglobulin. The normal zinc concentration in plasma averages about 0.85 µg/mL (13 µmol/L), with a range from 0.70 to 1.00 µg/mL. The zinc concentration in erythrocytes, most of which is incorporated in carbonic anhydrase, is approximately 12 µg/g wet weight. Bone, prostate, and hair all have concentrations near 100 µg/g. Muscle, liver, and kidney contain about 50 µg/g. The total body zinc content of an adult has been calculated to be about 2 g.[1]

DIETARY REQUIREMENTS

The results of recent studies of breast-fed and formula-fed infants using zinc stable isotope techniques allow reasonably accurate factorial estimates of zinc requirements. In fully breast-fed infants receiving mature human milk, conservation of endogenous zinc is critical to maintaining positive net absorption.[54] Because the amount of endogenous fecal zinc is positively correlated with dietary zinc intake and absorbed zinc, this figure is considerably higher in formula-fed infants receiving zinc-fortified formulas[58] Allowing for urine, sweat, and integumental losses as endogenous losses and average fractional absorption of approximately 0.5, a dietary zinc requirement of approximately 150 µg zinc/kg/day is estimated. Actual zinc intake of breast-fed infants varies considerably over the first 3 months of life as milk zinc concentrations decline. Mean intakes at 5 months of age have been found to be close to this projected dietary requirement. The physiologic requirement, the amount of zinc that must be absorbed to match endogenous losses and the zinc retained for new tissue synthesis, has been estimated to be 0.84 mg/day for infants 7–12 months of age, and 0.74 mg/day for 1–3 year olds.[6] Factorial estimations are higher for rapidly growing premature infants, for malnourished infants during the "catch-up" growth phase, and in situations with high endogenous losses, for example, with diarrhea and malabsorption.

The EARs and RDAs for older infants and children have been calculated by extrapolation from factorial data for infants, as described above.[6] The Tolerable Upper Intake Levels (ULs) failed to take into account the fact that many North American infants and young children who are not exclusively breast-fed consume substantially more zinc than

the ULs, with no detectable evidence of any harm.[59]

ZINC IN FOODS

The highest concentrations of zinc are found generally in animal products, especially meats; whole grains, nuts, and legumes also contain substantial quantities of zinc, but the absorption of zinc from these foods is less bioavailable due to phytic acid. The zinc content and bioavailability of typical complementary foods for the older breast-fed infant vary widely both in developed and developing countries.[44,60] As noted above, unfortified plant food sources of zinc are often inadequate to meet the needs of the older infant and toddler. Several ready-to-eat breakfast cereals and some infant cereals in the U.S. are now fortified with zinc as well as iron and other micronutrients. The zinc content of human milk declines by several-fold from colostrum to mature milk. Concentrations seem to be minimally influenced by maternal zinc intake.[61] Infant formulas and a wide range of special formulas are now routinely zinc fortified. An overview of the zinc and copper content of major food items is given in Table 8-5.

COPPER

Copper-dependent redox reactions developed very early in the evolutionary process. Because the earth's atmosphere changed from a reducing to an oxidizing environment, copper, together with iron, has been involved in the active sites of respiratory proteins. Recognition of copper as an essential trace mineral for humans followed demonstration of a role in the treatment of some cases of hypochromic anemia in infants. Copper deficiency has subsequently been identified in several special circumstances, but its frequency and the extent of its clinical importance in some conditions remain unclear, for example, in the very low birth weight premature infant.

Although beyond the scope of this chapter, an introduction to copper would not be complete without reference to two inborn errors of copper metabolism, which have attracted more clinical interest than has human dietary copper deficiencies. The central role of copper in the pathophysiology of Wilson's disease was recognized in 1945 and of Menkes' Steely Hair Syndrome (MSHS), or now termed simply Menkes disease, in 1962. The research stimulated by these inborn errors of copper metabolism has led to a clearer understanding of normal human copper

metabolism. It is now recognized that these two conditions represent a disruption of copper transport across cell membranes. The two homologous cation-transporting P-type adenosine triphosphatases (ATPases), the Menkes' P-type ATPase (MNK protein, ATP7A) and Wilson ATPase (Wilson protein, ATP7B), are the gene products primarily responsible for cellular copper homeostasis. The MNK functions in copper trafficking to the secretory pathway for efflux from cells, including enterocytes. In Menkes' syndrome, there is reduced copper absorption and placental copper transport, resulting in reduced availability of the mineral to peripheral organs and tissues. Although the pathophysiology of MSHS is complex, at least some of the principal clinical features can be attributed to a de facto severe copper deficiency state, including in the brain. The WND P-type ATPase also functions in copper trafficking to secrete excess copper into the biliary canalicular system. In Wilson's disease, mutations of the Wilson ATPase results in copper accumulation, especially in the liver, brain, and cornea.[62] Hence, recognition of the role of disordered copper metabolism in these diseases has helped to improve our understanding of the effects of severe human copper deficiency and of copper toxicity.[63,64]

TABLE 8-5 Trace Element Content of Common Foods

Item	Zinc (mg/100 g)	Copper (mg/100 g)
Meat group		
Regular ground beef	4.4	0.06
Round steak	5.8	0.05
Beef liver	5.1	4.6
Chicken—drumstick, fried	2.7	0.01
Pork chop	2.4	0.01
Bologna, all meat	1.8	0.02
Hot dog, all meat	1.6	0.08
Fish group		
Oyster, raw, Atlantic	74.7	3.62
Perch fillet	1.0	0.21
Tuna—in oil, drained, solids	1.1	0.01
Dairy and egg group		
Whole milk	0.4	0.005

Cheddar cheese	3.1	0.11
American cheese	3.0	0.11
Ice cream, vanilla	1.06	0.005
Eggs, hard-boiled	1.0	0.05
Infant formula	0.5	0.06
Nuts and legumes		
Common beans, cooked (red, kidney, pinto)	0.6	0.25
Peanut butter	2.9	0.61
Roasted peanuts	3.0	0.43
Bread and cereal group		
Whole wheat bread	1.0	0.17
Graham crackers	1.1	0.04

Oatmeal, cooked	0.5	0.02
Macaroni, cooked	0.5	0.02
Rice	0.4	0.02
Vegetable and fruit group		
Green beans, canned	0.3	0.02–0.04
Potatoes, boiled	0.3	0.10
Potato chips	0.8	0.29
Lettuce	0.4	0.04
Apple	0.05	0.01
Banana	0.2	0.11
Orange juice	0.02	0.008

CLINICAL FEATURES OF COPPER DEFICIENCY

Copper deficiency usually occurs during development. The principal features of copper deficiency are hypocupremia, a hypochromic, normocytic anemia that is unresponsive to iron therapy, neutropenia, cardiovascular disease and osteoporosis later in life. The bone marrow shows megaloblastic changes and vacuolization of the erythroid series. Iron deposits may be seen by electron microscopy in mitochondria and in some of the cytoplasmic vacuoles in red blood cell precursors. Maturation arrest of the granulocytic series may be evident. Iron stores in the intestinal mucosa, reticuloendothelial system, and liver cells are increased. The anemia is initially hypoferremic, but later becomes hyperferremic because of the decreased uptake of transferrin-bound iron by the developing

erythrocytes. Early radiologic findings are osteoporosis of the metaphyses and epiphyses and retarded bone age. Typical findings in the established case are increased density of the provisional zone of calcification and cupping with sickle-shaped spurs in the metaphyseal region.[65] Other skeletal abnormalities include periosteal layering and sub metaphyseal and rib fractures.

Other clinical findings have been observed in association with copper deficiency, including pallor, decreased pigmentation of skin and hair, prominent superficial veins, skin lesions similar to those of seborrheic dermatitis, cardiac hypertrophy, and hepatosplenomegaly. Features suggestive of central nervous system involvement are hypotonia, lack of interest in outside surroundings, psychomotor retardation, ataxia, apparent lack of visual responses, seizures and apneic episodes.[66] Demyelination and myeloneuropathy have been reported in case reports of adults with hypocupremia, in one case with overuse of zinc supplements and in another with an apparent zinc overload syndrome without clear exposure to excessive zinc.[67,68] Thus, caution is warranted and zinc intake should be in proportion to copper in order to avoid potential adverse effects. In Menkes', there is severe and eventually fatal central nervous system involvement owing to disordered copper metabolism within the brain cells, which probably results in localized intracellular deficiencies at physiologically important subcellular sites. Other features attributable to copper deficiency in this complex entity include the hair changes, which are reminiscent of the wool of copper-deficient sheep and which led to the initial recognition of the role of disordered copper metabolism; hypothermia; and evidence of defective elastin and collagen formation.

BIOCHEMISTRY AND BIOCHEMICAL CORRELATES

Copper is an essential component of several oxidase enzymes, the reduced activity of which can explain many of the features of copper deficiency. Cytochrome oxidase is the terminal enzyme in the electron transport chain and catalyses the oxidation of reduced cytochrome *c* by molecular oxygen, which is itself reduced to water. This enzyme, which is necessary for normal cellular respiration, has been shown to be markedly reduced in the brains of copper-deficient lambs suffering from swayback.

More than 90% of the circulating copper in plasma is tightly and specifically bound to ceruloplasmin, a glycoprotein that contains six

copper atoms per molecule. The functions of this protein, which was first identified in 1948, have been and continue to be the focus of considerable interest and controversy. Roles in copper metabolism include copper transport, mobilization of iron to transfer in the plasma, and regulation of the biogenic amines.[69] Ceruloplasmin (ferroxidase I) exhibits enzymatic ferroxidase activity and is necessary for the oxidation of ferrous iron stored in the liver and bone marrow to ferric iron. This is an essential step in the release of iron from body stores and its attachment to transferrin for transport to developing erythrocytes in the bone marrow. Aceruloplasminemia, an autosomal recessive condition in humans, does not produce obvious disordered copper metabolism, but results in iron accumulation in tissues.[70] Depressed activity of the ferroxidase role of ceruloplasmin is likely to be related to the hypoferremic, hypochromic anemia of copper deficiency. However, there are, in addition, abnormalities of iron metabolism within the erythroid cell line, and it appears that intracellular transport of iron is defective, so that, despite an abnormal accumulation of iron, there is a lack of iron available for normal heme synthesis in the mitochondria.[69] The pathologic mechanisms for the neutropenia remain unexplained.

The bone lesions of copper deficiency are attributable, at least in part, to a lack of copper dependent lysyl oxidase, which acts on lysine and hydroxylysine side chains of collagen and elastin, and is required in the cross-linking of these connective tissue components. These defects are responsible for the gross structural defects seen in arteries and veins in copper-deficient animals and in MSHS.

Among other copper-containing oxidases is tyrosinase, which catalyzes the first two steps in the oxidation of tyro-sine to melanin. Lack of pigmentation is a prominent feature of copper deficiency in some species, but is only mild in human copper deficiency. Copper proteins previously given other names such as cerebrocuprein, hepatocuprein, and erythrocuprein are now known to be superoxide dismutase, which catalyzes the dismutation of superoxide-free radical ions.

Superoxide dismutase protects against oxidative damage. Detoxification of dangerous free radicals within the cell is of the greatest importance, but little is known about the activity of this enzyme in human copper deficiency states and what role decreased activity may play in the pathophysiology of copper deficiency.

ETIOLOGIC FACTORS IN COPPER DEFICIENCY

The first cases of human copper deficiency were reported in infants and children in Peru who were recovering from protein-energy malnutrition. Prior to their initial hospitalization, the infants had long histories of inadequate nutrition, which consisted mainly of diluted cow's milk, which is a relatively poor dietary source of copper. Copper supplementation was associated with improved growth rates in copper-deficient Chilean infants recovering from malnutrition.[71]

The term infant accumulates substantial hepatic stores of copper, which is attached to metallothionein, during the last three months of gestation. These stores are released postnatally and are thought to ensure protection of the young infant against copper deficiency. Very low birth weight infants born prematurely do not have the benefit of these stores and have very little copper at birth. Although premature infants are at risk for copper deficiency, positive copper balance is apparently achieved in early postnatal life in premature infants with current fortification of human milk and formulas, although the adequacy of retention is not yet clear.[5] Other causes of human copper deficiency include intestinal malabsorption syndromes, prolonged parenteral nutrition without copper, chronic diarrhea, short gut syndrome, and chelation therapy.[72,73] Extremely high intakes of zinc can precipitate a deficiency of copper,[67] but, as described above, this is unlikely under typical levels of zinc supplementation.

DIAGNOSIS OF COPPER DEFICIENCY

Both serum copper and ceruloplasmin levels are depressed in copper-deficiency states and are often used as biomarkers to determine moderate and severe copper deficiency. Unfortunately, these parameters are also influenced by other factors, some of which are likely to be operational when the possibility of copper deficiency, especially marginal, is considered. Ceruloplasmin synthesis is limited in the liver of the term neonate, and neither serum copper nor ceruloplasmin concentrations reach adult levels until at least 1 month of age. In the very low birth weight infant, copper concentrations are even lower, averaging about 0.30–0.40 μg/mL, and do not start to increase until 41 weeks of gestational age.[74] It has been suggested that concentrations lower than 0.25 μg/mL may be abnormal in the young preterm infant and may be associated with neutropenia. However, the interpretation and value of the data on serum copper levels prior to 40 to 44 weeks of gestational age remain uncertain. By 6 months of postnatal age, serum copper and ceruloplasmin

concentrations are similar to, or higher than, adult levels.[75] In addition, ceruloplasmin synthesis in the liver may be reduced in protein-energy malnutrition, and protein-losing enteropathy is associated with losses of ceruloplasmin. Based on a recent systematic review of 16 studies and 16 possible copper biomarkers, serum copper concentration remains the most commonly used population-based biomarker.[76] However, it is not reliable under specific health status/different population groups. For example, hypocupremia is a feature of both Wilson's disease (copper toxicity) and Menkes' disease (copper deficiency). Copper deficiency can also be masked and difficult to confirm by laboratory assays when there is an increase in synthesis of ceruloplasmin, which is regarded as an acute-phase reactant and is elevated in response to inflammatory stimuli. Hence, hypercupremia occurs, for example, in association with infections, in the postoperative period, and in patients with neoplasms. Several hormones cause hypercupremia, most notably oestrogens, and levels are increased substantially throughout pregnancy and for several weeks postpartum. Hypercupremia also occurs in obstructive liver disease owing to failure of the normal biliary excretory mechanisms.

Erythrocyte superoxide dismutase (ESOD), a copper dependent enzyme, has been investigated as an index of copper status and has been reported to be an early indicator of disturbed copper metabolism.[77] Recently, another copper transporter, copper chaperone for SOD1 (CCS) has been proposed to be more sensitive to changes in copper status.[52] Other potential indicators, such as leukocyte superoxide dismutase, plasma glutathione peroxidase and leukocyte cytochrome *c* oxidase, etc., require more research to draw confirm conclusions.[76]

Radiologically, separation of the epiphyses, an absence of metaphyseal fraying, and the increased density of the provisional zone of calcification may all help to distinguish copper deficiency from rickets. In contrast to scurvy, copper deficiency does not produce either a lucent line beneath the increased density of the provisional zone of calcification or a "corner sign," nor does it cause hemorrhages.

The diagnosis of copper deficiency should be considered in the presence of suggestive aetiologic circumstances, particularly when there is a hypochromic anemia unresponsive to iron therapy. One case series also documented improvement in erythropoietin-resistant anemia in adult hemodialysis patients after correction of copper deficiency.[78] If the anemia is accompanied by neutropenia and osteoporosis, together with low ceruloplasmin or plasma copper levels, the diagnosis becomes likely.

Confirmation will be provided by a prompt response to copper therapy with a reticulocytosis and increases in circulating neutrophils and in ceruloplasmin or plasma copper levels.

TREATMENT OF COPPER DEFICIENCY

Nutritional copper deficiency in infants has been treated successfully with 2–3 mg/day of copper sulfate as a 1% solution, which provides 400–600 μg of copper. Maintenance requirements for copper during intravenous nutrition are 0.5–1.0 mg/day for adults; as little as 20 μg/kg/day appears to be adequate for infants.[7] Although higher quantities may be required to achieve a positive balance, there is concern that the immature liver of the pre-mature infant may be prone to cholestasis and thus to hepatotoxicity from intravenous copper. Evidence suggests that parenteral copper supplementation (20 μg/kg/day) in cholestatic infants does not cause copper toxicity or impaired liver function.[79]

TOXICITY

Copper toxicity has resulted from the accidental or deliberate ingestion of excess copper, hemodialysis with copper-contaminated solutions, and absorption of topically administered copper salts. Acute poisoning by the oral route causes a metallic taste, nausea, epigastric pain, green-blue vomitus, and diarrhea. Jaundice and hepatomegaly may occur 2–3 days later. Laboratory parameters are indicative of hepatic injury, and there is histologic evidence of centrilobular necrosis and biliary stasis. Jaundice may also result from intravascular hemolysis caused by free copper ions, which also cause hematuria and a direct renal tubular toxic effect, leading to oliguria and anuria. Copper salts may have a cardiotoxic effect, which is responsible for the hypotonia and coma seen in severe cases. Chronic copper poisoning is a rare entity that has been associated with drinking water with a high copper content. Indian child-hood cirrhosis, a hereditary disease associated with greatly increased hepatic copper concentration, is manifest in conjunction with high copper intakes, such as with copper contaminated animal milk introduced at an early age.[80]

Acrodynia and cirrhosis have both been attributed to chronic copper poisoning. A concentration of 2 mg/L in potable water has been recommended as safe for infants without causing gastrointestinal symptoms, and this level has been provisionally endorsed by the WHO. However, higher levels (8 mg/L) in drinking water have not been

associated with apparent toxicity. The DRI's set an upper limit (UL) for copper at 10 mg/d.[6]

ABSORPTION AND METABOLISM

Approximately 35% of ingested copper is absorbed in the stomach and upper small intestine. The percentage of absorption is inversely related to the quantity ingested and has increased in copper deficiency states. The percentage of absorption also depends on the dietary form and on other dietary constituents. Studies using stable isotopes demonstrated a 40% absorption of copper in formula-fed premature infants, whereas absorption from human milk was approximately 70%. Studies in animal models have reported a range of copper absorption from infant formula, from 25% to 70%.[5] Zinc, iron, cadmium, calcium, sulfate, and molybdenum will interfere with copper absorption if given in sufficient quantities. Copper–iron interaction has been studied primarily in short terms. Iron supplementation may not affect copper absorption in infants in the longer term[81] and more research is still needed. In contrast to other trace elements, cellulose and phytate have not been found to have marked effects on copper absorption.

Absorbed copper passes through the portal circulation attached to albumin and is taken up by the hepatocytes. Copper may then be used by the hepatocytes for the synthesis of cuproproteins, especially ceruloplasmin, which is released 3 days later into the systemic circulation. Excess copper is excreted with the bile. Ceruloplasmin copper accounts for 90%–95% of the circulating copper in plasma. The highest copper concentrations are found in the liver, brain, heart, and kidneys. Because of their large mass, bone and muscle contain 50% of the body copper, whereas the liver contains only 10%. The liver of full-term infants contains 200–400 μg of copper/g of dry weight, which is 10–20 times the adult concentration (12–48 μg/g dry weight). Forty percent of neonatal hepatic copper occurs in the lysosomes attached to metallothionein. In contrast to liver copper, brain copper increases twofold from birth to adulthood. The highest concentrations are in the locus ceruleus of the brainstem and in the cortical gray matter. In erythrocytes, the copper concentration is similar to that of normal plasma (75–120 μg/dL). This copper concentration remains stable; 60% is associated with superoxide dismutase. The total copper content of an adult man is approximately 75 mg.

DIETARY REQUIREMENTS

Earlier, minimal estimates of copper requirements for older children and adults were 2 mg/day, and most diets were thought to contain at least this quantity. The most recent EAR, based on studies in normal adults under experimental depletion conditions, was set at 700 µg/day for adult men and women. The RDA was set at 900 µg/day.[6] Most recent national survey data indicate that median copper intakes for men and women are 1.0–1.6 mg/day. Six RDAs were established for children by extrapolation from the adult EAR; these are given in Appendix 2.

The young term infant is protected from copper deficiency by hepatic stores accumulated in utero. Moreover, the term infant usually achieves a positive copper balance by 1 week of age or a little later. The Food and Nutrition Board established an Adequate Intake of copper of 200 µg/day (30 µg/kg/day) for infants 0–6 months of age and 220 µg/day (24 µg/kg/day) for infants 7 to 12 months.[6] The estimated dietary requirement of the very low birth weight premature infant is approximately 100 µg/kg/day of copper.[5]

FOOD SOURCES

The richest sources of copper are oysters, followed by nuts, liver, kidney, corn oil, margarine, and dry legumes. The contribution of drinking water to the total copper intake varies with the type of piping and the hardness of the water. Information on the copper content of food items remains inadequate for optimal calculations of dietary intakes. Moreover, copper intake from diet is often overestimated. Several studies that compared calculated versus chemically analyzed dietary copper showed an average 77% higher estimation of dietary copper using food composition tables.[82] Thus, the actual copper intakes in adults from the national survey may be well below 1.0 mg/day, and more people may be consuming less than the RDA of copper.[83]

Infant formulas in North America now contain a minimum of 60 µg/100 kcal of copper, and those designed specifically for the premature infant contain substantially higher quantities, with a recommended range of 100–250 µg/100 kcal.[5] However, on a worldwide basis, there is still considerable variation in the copper content of infant formulas, and some contain higher quantities. Unprocessed cow's milk contains about 150 µg/L of copper, which is lower than that usually found in human milk (200–600 µg/L of copper) at any stage of lactation. Preterm infants have a

lower copper store and may require more copper from the diet. Preterm milk may not contain adequate copper to meet the needs of the infants.[84]

SELENIUM

Interest in the toxicity of selenium in mammals developed in the 1930s with the discovery of both acute and chronic forms of selenosis among grazing animals in Nebraska and Wyoming. The proved toxicity of selenium in animal husbandry in "natural" circumstances (in seleniferous areas) has resulted in extreme and only partially justified caution in adding selenium supplements to diets that are low in selenium. A beneficial role for selenium was not demonstrated until 1957, when selenium supplements were found to protect against liver necrosis in rats fed certain diets. The following year, selenium deficiency was shown to cause naturally occurring muscular dystrophy in lambs and calves, a problem that occurs in many areas of the world. Earlier nutritional studies indicated that there was a close association between selenium and vitamin E. In 1973, selenium was shown to be an integral component of glutathione peroxidase (GSHPx), an enzyme that destroys hydroperoxides. Although numerous other selenoproteins have been identified, the functions of many of these proteins are not well characterized. The selenoproteins iodothronine deiodinases (Types I–III) catalyze deiodination of thyroxine, triiodothyronine and reverse triiodothyronine, and as such play an active role in regulation of active hormone triiodothyronine. Experimentally, selenium restriction has been shown to cause hypothyroidism. The thioredoxin reductases, selenoprotein P, and selenoprotein W all are involved in oxidant defense systems.

Although low selenium states have been recognized in certain populations, notably in New Zealand, for many years, it was not until the 1970s, when a geochemical deficiency of selenium in a large area of China was recognized as the major etiologic factor in Keshan disease (KD), that the clinical importance of human selenium deficiency was unequivocally demonstrated. Geochemical depletion of both selenium and iodine occurs when surface soils are depleted by erosion and glacial washout, resulting in both plant and animal foods from such areas contain relatively low amounts of both trace elements. Individual cases of selenium related cardiomyopathy, as well as skeletal myopathies, have since been identified in North America and elsewhere, and less well-characterized milder selenium deficiency syndromes have also been reported.[85] Recent discovery of disease-associated polymorphisms in selenoprotein genes has

garnered attention to the broad roles of selenoproteins to health, including immune function, cancer and cognitive function. Selenium is recognized to have a U-shaped link with status, such that increased selenium intake may benefit people with low status, whereas those with adequate-to-high status might be affected adversely.[86]

CLINICAL FEATURES AND ETIOLOGY OF SELENIUM DEFICIENCY

Keshan disease (KD) is an endemic cardiomyopathy affecting children and women of childbearing age. The disease, named for a county in northeastern China, has a clear-cut geographic distribution in a broad area of China from the northeast to the southwest, an area in which the selenium content of food staples has been shown to be exceptionally low.[87] A series of controlled selenium supplementation studies was associated with an 80% reduction in the incidence of KD, whereas the mortality of identified cases was only 1% of that of untreated children.[88] Some of the etiologic circumstances of KD have not been explained clearly. The seasonal and annual fluctuations in KD have raised the possibility of an interaction between nutritional state and an infectious etiology. The recognition that selenium deficiency increases the cardiovirulence of coxsackievirus in animal models by changing the viral genome sequence is particularly intriguing.[89] Further supportive evidence is the isolation of coxsackievirus from patients with KD in the selenium-deficient area of China, although not all serotypes are equally pathogenic.[90] More studies will be required to determine whether the observations in animal models are relevant to humans with KD. However, the permissive role of selenium deficiency and the public health benefits of selenium supplementation in prevention of KD have been established convincingly.[91]

The main pathological feature of KD consists of multiple focal areas of myocardial necrosis. Presentation may be acute, with heart failure, arrhythmias, and cardiogenic shock, or chronic, with cardiomegaly with or without congestive failure. Electrocardiographic features include low-voltage ST-T wave changes, right bundle branch block, or complete atrioventricular block. Serum selenium levels in KD are extremely low, typically less than 10 μg/L. Other laboratory indices are correspondingly low. Long-term total parenteral nutrition devoid of selenium supplements can also cause severe selenium deficiency with cardiomyopathy or skeletal

myopathy.[92,93]

Kashin-Bek disease (KBD), a degenerative osteoarthropathy named for two investigators who studied patients in Siberia in the nineteenth century, has a geographic distribution similar to that of KD within China. KBD is an endemic osteoarthropathy involving children aged 5–13 years, and typically is endemic in selenium and iodine deficient geographic areas, including in China and central Africa. The disease is characterized pathologically by degeneration and necrosis of multiple articular cartilages and growth plates, causing enlargement, especially of fingers, toes, and knees and shortened extremities. Disabilities are typically permanent. Millions of people are likely to be affected with KBD. The relationship between selenium deficiency and KBD is unclear. Evidence from epidemiologic studies suggests that selenium and iodine deficiencies may interact to cause the condition. In Tibet, a comparison of those with and without KBD showed a selenium deficiency in both groups, but iodine deficiency was more severe in those with KBD. A randomized controlled trial of selenium supplementation, initiated after correction of iodine deficiency, in Tibetan children with KBD resulted in no effect on KBD, growth or thyroid function. The authors concluded that correction of iodine deficiency was more efficacious than treatment of selenium deficiency for KBD.[94]

An adequate supply of selenium is essential for normal thyroid hormone biosynthesis. For example, in goitrous children, the severity of selenium deficiency predicted the response to iodine supplementation, both with respect to reduction in thyroid size and to improved biochemical measures of thyroid function.[85] Impaired T_4 conversion to T_3 and low regulation of T_3 production have been reported in children with phenylketonuria (PKU) who were fed a phenylalanine-restricted diet that was also low in selenium,[95] but this has not been found consistently in children with PKU, even those with evidence of selenium deficiency and compromised antioxidant status.[96]

Moderately depressed levels of erythrocyte glutathione peroxidase activity, hair selenium, serum selenium, or blood selenium have been found in association with protein-energy malnutrition in developing countries and in low birth weight infants.[5] One report found significantly lower selenium levels in Malawian children with kwashiorkor who had congestive heart failure compared with those who did not develop this complication.[97] The clinical significance of these low selenium states remains unresolved. Milder degrees of selenium depletion, notably those

associated with low dietary levels in New Zealand and certain other geographic areas, have not been associated with adverse clinical consequences. There have been case reports of children on long-term parenteral nutrition or synthetic oral diets without selenium supplements who had macrocytosis and loss of hair pigment, both of which normalized following selenium supplementation.[98]

Interest in selenium in adult and pediatric patients with human immunodeficiency virus (HIV) has been prompted by observations suggesting an ameliorating role in the pathophysiologic processes of this infection. The effects may be mediated by its antioxidant effects, especially via glutathione peroxidase (GPx), and possibly via inhibition of viral replication.[99] In a large cohort study in Tanzania in children born to HIV-positive mothers, plasma selenium levels were inversely associated with risk of all-cause mortality.[100] Interpretation of these findings is complicated by the likelihood of co-existence of multiple nutritional deficiencies and by the fact that plasma selenium is impacted by acute inflammation.

BIOCHEMISTRY AND METABOLISM

Several selenium proteins have been identified; two of these have clearly established physiologic roles: glutathione peroxidase and iodothyronine deiodinase (ID). Selenium is an essential component of cellular glutathione peroxidase (GPx), its plasma homologue, and the membrane-bound phospholipid-hydroperoxide GPx. Glutathione peroxidase uses two molecules of reduced glutathione to reduce hydrogen peroxide and convert it to two molecules of water. This enzyme also catalyzes the reduction of fatty acid hydroperoxides to hydroxy acids in the tissues and thus helps to protect the lipids in cell membranes from peroxidation. GPx is present in a wide variety of tissues and accounts for 90% of the selenium in erythrocytes. Messenger RNA levels of liver GPx decrease with dietary selenium restriction.

ID has been identified as a selenoenzyme. This enzyme catalyses the conversion of T_4 to T_3 in the liver and other tissues. Selenium, as selenocysteine, is an integral component of ID, and its expression is influenced by dietary selenium. This enzyme provides the link between iodine and selenium because both are involved in thyroid hormone production.

Absorption of selenium depends to some extent on its chemical form.

Selenomethionine is better absorbed than inorganic forms of selenium. Intestinal absorption of food selenium is as high as 80%. Selenium homeostasis in the rat is controlled by the kidney, and the principal route of excretion in humans is the urine. The highest concentrations in the body are found in liver, tooth enamel, and nails. In the body, selenium is intimately associated with specific proteins, especially as selenocysteine. For example, more than 80% of the selenium in the rat is present as selenocysteine.

DIAGNOSIS AND TREATMENT OF SELENIUM DEFICIENCY

Selenium depletion is associated with low levels of selenium in whole blood, plasma, and hair and low erythrocyte GPx activity. Typical clinical assessment is achieved with plasma selenium concentrations; the 5th and 95th percentile range from the Third National Health and Nutrition Examination Survey (NHANES) was 100–154 μg/L (1.27–1.95 μmol/L). Plasma selenium concentrations less than 50 μg/L have been reported in healthy adults from low selenium areas. Selenium levels are low in young infants and gradually increase to adult values over a period of months. A strong positive correlation between erythrocyte GPx activity and whole blood selenium levels has been found in some populations. However, it is not yet clear how well these indicators may correlate with clinical features of selenium deficiency.[101]

The optimal treatment for selenium deficiency has not been determined. Currently, there are no clear-cut indications for oral selenium therapy apart from the prevention of KD, for which a weekly supplement of 500 μg in younger children and 1,000 μg in older children appears to suffice. On a daily basis, these quantities are somewhat above the RDA recommended by the Food and Nutrition Board.[101]

Selenium supplements should be added routinely to intravenous infusates, at least for those patients who receive a substantial portion of their nutrient intakes by the intravenous route for more than 2 weeks. The dose recommended is 2 μg/kg body weight/day.[7]

TOXICITY

Although excess selenium can cause undesirable consequences in agriculture, chronic selenium toxicity does not appear to be a problem in

humans. Blood selenium levels are elevated in children living in seleniferous areas of Venezuela, but the only clinical findings were the some-what poorly defined ones of nausea and pathologic nails. Loss of hair, brittleness of fingernails, garlic odor, a higher incidence of dental caries, and increased fatigue and irritability were reported to be signs of selenosis in an earlier survey of residents of South Dakota, where selenium toxicity occurred in farm animals.

Acute selenium poisoning is rare in humans but has been reported as a result of self-administration of selenium supplements. The outcome of acute toxicity appears to depend on both the amount ingested and the type of selenium compound. Acute ingestion of sodium selenite caused garlic odor on the breath and diarrhea in several cases. Evidence of mild, temporary liver damage and cardiac abnormality was seen in one case, but there were no permanent sequelae.

The highest selenium concentration observed in human milk in the United States, 60 µg/L, was used as the basis for the "no observed adverse effect level" in the 2000 DRIs,[101] and the DRI upper limit was set at 45 µg/day (7 µg/kg) for term infants 0–6 months. This amount was used parenterally in a supplementation trial of very low birth weight infants until the infants advanced to enteral feeds, at which time they received ~5µg/kg until 36 weeks postmenstrual age, with no apparent adverse effects.[102]

DIETARY REQUIREMENTS

Dietary surveys of selenium intake in endemic and adjacent nonendemic KD areas have led to the conclusion that selenium requirements for adult Chinese men and women are 19 and 13 µg/day, respectively.[132] This is the quantity calculated to be necessary to prevent KD. RDAs in this country have been set at 55 µg selenium/day for adult men and women.[101] Evidence from multiple studies suggests a link between selenium intake and an increased risk of type 2 diabetes in the US population, especially for those consuming higher than 55 µg selenium/day.

An AI was established for infants in 2000, recommending 15 µg/day (2.1 µg/kg/day) for infants up to 6 months of age, based on a mean selenium concentration of 18 µg/L in human milk and an average intake of 780 mL/day. The AI for older infants and young children (7–36 months) is 20 µg/day, for older children (4–8 years) 30 µg/day, and for adolescents 40–55 µg/day.[101] These recommendations have been extrapolated from adults with a generous addition for growth; actual requirements are

substantially less. Under conditions of illness in pediatric patients (i.e., burn injuries and sepsis), selenium requirement may be higher than the recommended level to maintain an optimal plasma glutathione peroxidase level.

FOOD SOURCES

The selenium content of human milk depends on maternal dietary selenium intake. Extremely low values, that is, less than 3 µg selenium/L, have been reported from areas where KD is endemic.[5] Concentrations between 5 and 10 µg selenium/L have been reported from other countries where maternal selenium intake is relatively low (e.g., New Zealand, Finland, and Poland).[103] In the United States, the mean value of the selenium content of human milk is approximately 18 µg selenium/L.[5]

The selenium content of cow's milk is generally lower than that of human milk in this country. The selenium content is reduced in the preparation of cow's milk–based infant formulas. The minimum for standard infant formulas was recommended to be 1.5 µg/100 kcal.[104] Whether the low plasma selenium and GPx levels in low birth weight infants are increased by providing generous selenium supplementation of formulas has been controversial, and feeding regimens that have provided amounts adequate to increase biochemical markers of selenium status in low birth weight infants have not demonstrated clear clinical benefit. Nevertheless, premature infants are born with strikingly low serum selenium levels and GSPx, and, without supplementation, these levels decline further.[102] An expert panel recently recommended a minimum concentration in formulas for preterm infants of 1.8 µg/100 kcal and a maximum of 5.0 µg/100 kcal, while acknowledging that it was unknown whether the lower amount would be adequate or optimal for preterm low birth weight infants.[5]

As noted above, concentrations of selenium in foods vary by geographic region and soil content. Generally, seafood (approximately 0.5 µg/g), kidney, liver, and meats (approximately 0.2 µg/g) are the best sources of selenium. Whole grains are also generally good sources of selenium provided that the soils in which they are grown are not low in selenium. Vegetables and fruits, with the exception of garlic, provide little. Daily intake in North America has been reported to range from 60 to 220 µg/day, but in New Zealand, intake is only 6 to 35 µg/day.

CHROMIUM

A role for chromium in mammalian physiology was indicated first in 1959, when it was reported that trace amounts of this element are necessary for normal glucose tolerance in the rat. Subsequent research suggested that chromium acted as a cofactor for insulin. These observations stimulated considerable interest in a possible role for chromium deficiency in the high incidence of impaired glucose tolerance in industrialized societies. Progress has been hampered, however, by a lack of laboratory indices of chromium status that would be of the greatest value in identifying appropriate subjects to include in clinical trials of chromium supplementation.

CLINICAL FEATURES AND ETIOLOGY OF CHROMIUM DEFICIENCY

Experimental chromium deficiency in several animal species has been reported to result in impaired glucose tolerance in the presence of normal concentrations of circulating insulin. Features of chromium deficiency have been reported to include impaired glucose tolerance with relative insulin resistance and peripheral and/or central neuropathy. Weight loss and poor childhood growth have also been reported.

In the pediatric age range, chromium supplementation studies have been undertaken in infants and young children suffering from protein-energy malnutrition. The results of these studies, which involved the use of a single oral dose of 250 μg trivalent chromium, suggested that chromium deficiency may be one factor responsible for the impaired glucose tolerance that occurs in association with severe generalized malnutrition. Chromium deficiency has been reported to complicate protein-energy malnutrition in some, but not all geographic areas. Lack of controls in some studies and limited subject numbers hamper the definitive interpretation of these data.

Several trials of chromium supplementation have been reported in adults, including elderly subjects.[105] Most of these trials have been small. Subjects have included noninsulin-dependent diabetic patients and otherwise normal subjects with evidence of impaired glucose tolerance. Supplements have always been trivalent chromium, on some occasions as an inorganic salt and on others as brewer’s yeast or in other forms that are thought to have favorable absorption. In several studies, chromium supplementation has been associated with improved glucose tolerance in

more than 50% of the chromium-supplemented subjects. Other apparent effects noted in some studies include a decrease in insulin response to an oral glucose load, a decrease in total blood lipids, and an increase in high-density lipoprotein cholesterol. A meta-analysis of chromium supplementation trials reported for healthy individuals and in those with glucose intolerance or type 2 diabetes found no effect of chromium on glucose or insulin concentrations in nondiabetic subjects, whereas the results from trials in diabetic subjects were inconclusive.[106]

Chromium deficiency has also been reported in patients receiving long-term parenteral nutrition without supplementation. Clinical features attributed to the chromium deficiency were weight loss, peripheral neuropathy, and encephalopathy. An abnormallylow removal rate of intravenous glucose and an abnormally low respiratory quotient indicating difficulty in metabolizing glucose for energy, dependence on exogenous insulin, and abnormalities of nitrogen and lipid metabolism all responded rapidly to intravenous chromium.[6]

BIOCHEMICAL CORRELATES

Although chromium may have several physiologic roles, for example, in nucleic acid metabolism, the role that has received most attention is its action as a cofactor for insulin. Experimental evidence is consistent with the hypothesis that chromium acts as a cofactor for insulin at the site of peripheral insulin receptors. Specifically, it has been hypothesized that a chromium-binding oligopeptide, termed chromodulin, facilitates the attachment of insulin to its receptors both at the cell membrane and intracellularly, and activates the insulin receptor kinase activity. Chromium may have to be in the trivalent ion form (Cr^{3+}) to be biologically active.[107] The biologic role of chromium as a cofactor for insulin requires further clarification and confirmation.

DIAGNOSIS OF CHROMIUM DEFICIENCY

The lack of established laboratory assays is especially evident for chromium, and deficiency states can be confirmed currently only by means of careful monitoring of the effects of chromium supplementation under controlled conditions. Normal values in such samples as blood plasma and urine have had a disconcerting tendency to fall as analytic techniques improve so that they remain near the detection limits of the equipment available at any particular time. Currently, normal levels for plasma

chromium, for example, are considered to be only about 0.1 parts per billion (100 pg/mL). This means that it continues to be extraordinarily difficult to measure low values accurately. An additional difficulty in interpretation results from uncertainties about the physiological meaning of low chromium levels. For example, it is thought that solitary plasma chromium levels do not reflect the body chromium status but only recent intake. However, low plasma chromium levels have been reported in chromium-deficient subjects, in pregnant women, and in association with experimental infections that cause impaired glucose tolerance.[6] There have been conflicting reports about a measurable increase in plasma chromium in response to a glucose load. At best, this is a tedious and difficult test for assessing chromium status. Absence of a detectable plasma chromium "response" has been reported in some diabetic patients, including gestational diabetic patients, and in some elderly people. An inverse correlation has been reported between the postprandial increase in plasma chromium and fasting blood glucose. Hair analyses provide only a crude index of chromium status. Theoretically, urine chromium levels, perhaps including measurement of the increase in urine excretion following a glucose load, should provide a useful index of chromium status. To date, however, this approach has not proved to have any conclusive value. Excessive urinary chromium losses have been noted in diabetic patients, and it has been suggested that the low chromium content of adult American tissues could result from excessive urine losses triggered by a diet high in sucrose. Confirmation of excessive chromium losses during the consumption of such diets is lacking. In summary, chromium measurements in tissue and body fluids are of no proven value in the diagnosis of chromium deficiency even if adequate laboratory facilities are available.

TREATMENT OF CHROMIUM DEFICIENCY

Suspected chromium deficiency states can be treated with 200 μg of trivalent chromium daily for several weeks or months in adults. In malnourished children, a single dose of Cr^{3+} 250 μg has been effective. Current recommendations for chromium during parenteral nutrition are 10–15 μg/day for adults or 0.1–0.2 μg/kg body weight/day for infants and young children. Levels considerably lower than this are probably adequate and may be preferable.

TOXICITY

Trivalent chromium has a low toxicity, and there are no reports of toxicity from oral administration. The minimum lethal dose of intravenous chromium as chromic chloride in mice is 800 mg/kg. Hexavalent chromium is more toxic, but 100 parts per million in drinking water can be tolerated by animals for many years. Chromate is a local irritant and is a cause of acute and chronic disease of the respiratory system, including bronchogenic carcinoma in workers in the chromate industry.

Plasma chromium concentrations have been reported to be elevated in patients receiving total parenteral nutrition, including standard quantities of intravenous chromium, who develop evidence of renal disease.[108] Chronic interstitial nephritis has been associated with ingestion of chromium picolinate as a dietary supplement.[109,110] It has been suggested that the renal disease is a result of chromium toxicity, although animal studies have not confirmed such toxicity.[111] It is also possible that the elevated plasma chromium levels are secondary to impaired chromium excretion via the kidneys. It appears prudent to reduce or withhold intravenous chromium supplements in the presence of renal disease.

ABSORPTION/METABOLISM

Inorganic trivalent chromium is absorbed poorly. Absorption of[51] Cr-labeled chromium chloride is limited to approximately 0.5%. A larger percentage of chromium is thought to be absorbed from organic chromium complexes found, for example, in brewer's yeast. Chromium picolinate has been marketed aggressively with claims that it is well absorbed and has some special beneficial metabolic effects, but documentation of these claims is poor. It is thought that the liver may be the site of a specific pool of biologically active chromium and that GTF chromium is released from this pool in response to a glucose load. This response may be mediated by the response of endogenous insulin. GTF has been reported to be the only form in which chromium can cross the placenta to the fetus. The major excretory route for chromium is through the kidney, and the urine contains at least 80% of excreted chromium. The total body chromium content of adults has been estimated to be about 6 mg.

DIETARY REQUIREMENTS AND FOOD SOURCES

Dietary chromium intakes for adults in the United States range from 25 µg/day for women to 50 µg chromium/day for men. The estimated AI for dietary chromium intake for adults set by the Food and Nutrition Board is 35 µg/day for men and 25 µg/day for women.[6] The AI recommended for infants 0 to 6 months is 0.2 µg/day and 5.5 µg/day for infants 7–12 months. The large increase in the second half of the first year of life reflects the contribution of complementary foods. The AIs for children and adolescents range from 11 to 35 µg/day.[6]

The mean chromium concentration of breast milk is approximately 0.25 µg/L.[112] Hence, the intake of the breast-fed infant would be about 0.2 µg/day. The bioavailability of this chromium may be high by comparison with that of other trace elements, but this has not been determined. Concentrations of chromium in cow's milk and infant formulas have been reported to be higher than those in human milk.[104]

Spices, brewer's yeast, liver, and kidney are especially good sources of chromium, but only small quantities are present in fish, vegetables, and fruit. Major losses of chromium have been reported during milling of wheat and refining of sugar, but stainless steel cooking containers may add to the chromium intake. Calculations of chromium in food have undoubtedly varied, depending on methods of sample preparation and analyses. Moreover, absolute quantities may not be as important as the form in which the chromium is present in foods.

MANGANESE

A nutritional requirement for manganese has been established in a wide variety of organisms and was first shown to be "essential" for animals in 1931. Interest was stimulated by the discovery in the 1930s that two economically important diseases of poultry, perosis and chondrodystrophy were caused by manganese deficiency. There are now extensive data on animal requirements, but knowledge of human manganese requirements and status is much more limited.[6]

One probable case of human manganese deficiency has been reported in a subject who was receiving an experimental synthetic diet that was retrospectively found to be low in manganese, providing only 350 µg/day of manganese for 3 months. Features attributed to manganese deficiency were hypocholesterolemia, depressed levels of clotting proteins in the plasma, weight loss, and slow growth of hair and nails. Low serum manganese levels have been reported in some diabetic and in epileptic children, and a negative manganese balance has been observed in children

with pancreatic insufficiency. The clinical significance of any of these observations remains obscure, and no cases of non-experimentally induced manganese deficiency have been reported. Experimental manganese depletion in animal models affects cartilage and bone structure and neurologic function and is associated with stunted growth and ataxia in newborns. The deficiency was also associated with lipid accumulation in the liver and kidneys and with hypocholesterolemia, a finding also observed in humans.

The low manganese concentrations found in blood plasma (approximately 1 ng/mL) and, until recently, the difficulty of obtaining accurate analyses has hindered progress in our understanding of manganese status in humans. Erythrocyte, plasma, and serum manganese concentrations demonstrate an age-dependent pattern, with the highest levels observed in young infants. Blood concentrations increase during pregnancy, which apparently result in high manganese concentrations in the fetus. Infants born prematurely have higher blood levels than term infants, and these relatively high levels persist for several weeks postnatally.[5]

Biochemically, manganese is required for the synthesis of mucopolysaccharides through the manganese-dependent enzymes polymerase and galactotransferase. Reduced activity of these enzymes, resulting in impaired mucopolysaccharide synthesis, accounts for the extensive skeletal abnormalities and the ataxia owing to impaired otolith synthesis that are seen in animals with manganese deficiency. Pyruvate carboxylase is a manganese metalloenzyme, and manganese is a potent, although not necessarily specific, promoter of oxidative phosphorylation. Peptidases, manganese superoxide dismutase, succinic dehydrogenase, and arginase appear to be manganese-dependent enzymes.

Adults absorb less than 5% of an ingested dose of ^{54}Mn.[113] Only half of this amount is retained 10 days later, but retention of the ingested dose at 10 days is 8% in the newborn and 16% in the premature infant. Breast-fed infants maintain positive balance on much lower manganese intakes than formula-fed infants. The higher retention of infants, especially those born prematurely, may reflect higher absorption efficiency, but may also reflect less efficient excretory mechanisms. Manganese absorption is enhanced by iron deficiency, but the long-term effects on retention are less clear. Neither the effects in infants of feeding iron-fortified formula for achieving optimal manganese status nor of iron deficiency on predisposing to manganese toxicity are well understood. The emerging understanding of shared transport of manganese and iron in the brain and the potential for

neurotoxicity highlight the potential importance of the interaction between these elements.[114] Manganese is excreted almost entirely through the bile, and urine losses are small.[113]

Chronic manganese toxicity, owing principally to inhalation from occupational exposure and from excessive parenterally administered manganese, causes extrapyramidal neurologic disease similar to Parkinson's disease, Alzheimer's disease, and Huntington's disease.[115] Such neurologic symptoms are associated with neuronal death in the globus pallidus and basal ganglia, regions which are rich in dopamine. Pilot data in children from the vicinity of a hazardous waste site indicated an inverse relationship between hair concentrations of manganese and arsenic and intelligence scores and memory tests.[116] Cholestatic liver disease, including that associated with total parenteral nutrition, has been associated with manganese accumulation in the liver and brain.[113] Manganese, as well as copper, should be reduced or withheld from parenteral nutrition patients with cholestatic liver disease, and iron deficiency should also be avoided if possible.

Adults are in positive manganese balance with an intake of 2.5 mg/day, but intakes of 0.7 mg/day result in a negative balance. Human milk contains only 3–4μg/L of manganese.[5] Hence, it appears that the requirements of young infants are extremely small. The Daily Recommended Intake (DRI) AI level for healthy 0–6-month-old infants was set at 3 μg/day (0.4 μg/kg), based on the mean manganese intake of exclusively breast-fed infants.[6] Formula-fed infants ingest much more manganese than breast-fed infants, with cow milk based formulas containing approximately a 10-fold greater content compared to human milk, and soy formulas being approximately 10-fold greater than cow milk formulas.[104,113] Although the toxicity of manganese administered by the oral route appears to be low and a wide range of intakes has appeared to tolerated without any clinical problems, recent reports in animal models have reported altered neurobehavioral measures in animals fed soy formula or given manganese supplementation.[117,118] Nuts and unrefined grains are rich sources of manganese, whereas animal products and seafood are relatively low in this trace element.

FLUORIDE

Fluoride has both beneficial (prevention of dental caries) and toxic (fluorosis) effects on teeth, with a small margin between intakes that are

beneficial and those that are toxic.

Fluoride has proved to have beneficial cariostatic properties during tooth development and, for this reason, is generally accepted as a necessary micronutrient. Other beneficial properties, for example, in ameliorating osteoporosis and protecting against arterial calcification, have not been substantiated convincingly.

PREVENTION OF DENTAL CARIES

Fluoride is effective in preventing dental caries. The principal means by which this protection is conferred is via a local effect on the tooth surface. Fluoride decreases demineralization of the enamel when the pH of the dental plaque is low owing to the action of oral bacteria on fermentable carbohydrates. Fluoride also accelerates remineralization when the pH rises, and it appears to decrease production of organic acids from fermentable carbohydrates on the teeth. The fluoride concentration in saliva and in dental plaque fluid necessary to achieve effects is only 0.1 part per million.[119] The systemic effect of fluoride on teeth prior to eruption appears to be small, although some protection may be conferred by incorporation of fluoride into enamel crystals during tooth development.

Prior to the widespread use of fluoridated dentifrices, lifelong use of a water supply containing 1 part per million fluoride resulted in a 50%–60% decrease in the prevalence of dental caries in permanent teeth. The beneficial effect on primary teeth was only slightly less. With the current wide-spread use of fluoridated dentifrices, the benefits of a fluoridated water supply have a somewhat decreased impact on the prevention of dental caries. Systematic reviews have confirmed the beneficial effects of topical fluoride (toothpaste, mouth rinses, varnishes, gels) on prevention of dental caries in children and adolescents.[120,121]

Near-maximal protective effect is achieved with a fluoride concentration of 1 part per million in the drinking water. The beneficial effects are likely to be greatest among children from low-income families, whose use of fluoridated dentifrices is more restricted.

FLUOROSIS

Dental fluorosis is characterized by undermineralization of the surface and subsurface enamel, resulting in increased porosity. This is a developmental abnormality affecting both primary and permanent teeth.[122] Although the

mechanism is not fully understood, fluoride appears to damage the ameloblasts that produce the enamel. The enamel appears opaque. Visible changes range from barely discernible fine white lines across the teeth to entirely chalky-white teeth. The outer enamel may break apart, and the exposed subsurface then becomes discolored.

The incidence of fluorosis has a linear relationship to calculated fluoride intake per unit body weight. This relationship is evident even at levels of fluoride intake that approach zero. The infant is thought to be especially susceptible to the effects of fluoride, with fluorosis resulting once the fluoride intake has reached a level of 40–100 µg/kg/day. The incidence of fluorosis, especially that of a mild degree, appears to have increased recently in communities with and without fluoridated water.[122] The teeth of greatest cosmetic concern are the permanent incisors and cuspids. Enamel formation in these teeth begins at 3 months and is completed by 7 years.

INTAKE OF FLUORIDE BY INFANTS

The fluoride content of breast milk is uniformly low whatever the maternal intake of this trace element. Remarkably, the incidence of dental caries is relatively low in children who have been breast-fed as infants. Fluorosis is uncommon in children who have been breast-fed as infants. The intake of fluoride from unmodified cow's milk is also low, although not as low as from human milk. Fluoride concentrations approximate 40 and 60 µg/L, respectively. The fluoride intake from formula tends to be higher and potentially in a range that can cause fluorosis, even though the fluoride content of water used in the manufacture of infant formulas has been restricted since 1978 and even when dried formulas are made up with water of relatively low fluoride content. For example, the calculated intake of fluoride of a young infant receiving 150 mL formula/kg body weight/day, prepared by mixing powdered milk–based formula (fluoride content = 690 µg/L) with water containing only 200 µg fluoride/L, is 41 µg/kg/day. Ready-to-feed formulas contain < 20 µg fluoride/L.[5] The fluoride content of bottled distilled water is low, but this does not apply to all bottled waters. Weaning foods may also provide significant quantities of fluoride, especially fruit juices, cereals, and poultry products.

Overall, the fluoride intake of young infants is less than it was two decades ago because of a decrease in fluoride content of formulas and because of the increased incidence of breast-feeding. On the other hand, the intake of older infants tends to be higher because of the progressive

substitution of infant formulas for whole cow's milk at this age. Older infants may also start to use fluoridated dentifrices. Small children ingest most of this dentifrice, and the fluoride is subsequently absorbed. The AI for 0–6 months is 10 μg/day (1.4 μg/kg/day).[123] The American Academy of Pediatric Dentistry and the American Academy of Pediatrics recommend no fluoride supplementation for infants under 6 months of age. For older infants and children from 6 months to 3 years for whom the community water supply is less than 0.3 parts per million, a supplement of 250 μg/day is recommended. These recommendations and a broad discussion of the use of fluoride to prevent and control dental caries have recently been published.[121]

IODINE

The clinical importance of adequate iodine intake has, like that of iron, been recognized for many years. Iodine was used in the treatment of goiter in the early years of the nineteenth century, and the major role of iodine deficiency in the etiology of endemic goiter was confirmed early in the twentieth century when the prophylactic value of iodine was demonstrated in Ohio schools. The early recognition of the nutritional role of this trace element can be attributed to the specific nature of the clinical features of iodine deficiency, the relative simplicity of measuring iodine in foods and other biologic samples, and the high concentration of iodine in one specific organ, the thyroid gland. Sixty percent of T_4 by weight is iodine, and the biologic importance of iodine is related entirely to its role in the thyroid hormones.[124]

ABSORPTION AND METABOLISM

Iodine is widely found in its negative ion (iodide, or I). Iodide is rapidly and almost completely absorbed by the human stomach and duodenum. Once enters the circulation, iodine is cleared by the thyroid gland to produce thyroid hormone. The effectiveness of iodine clearance varies by the host's iodine status and iodine intake. Once picked up by the thyroid gland, iodine is oxidized by thyroperoxidase, attaches to thyroglobulin and form T_4 and T_3.

Iodine is picked up by thyroid via active transportation by sodium/iodine synmporter. Some dietary substance found in cruciferous vegetables may compete with iodine for thyroid uptake. Flavonoids from

soy products can impair thyroperoxidase. This impairment does not reach a harmful extent in healthy adults, but may cause hypothyroidism in infants.

DEFICIENCY AND TREATMENT

Iodine deficiency disorders remain a global problem, despite aggressive prophylactic measures, and are the most prevalent cause of brain damage. WHO estimates that there may be nearly a billion people affected by iodine deficiency disorders, and as much as one-half of the world's population is at risk. Iodine deficiency is originally independent of socioeconomic status, but rather dependent on location. Places with low iodine content soil and water have iodine deficient plants and thus humans living in these regions will be iodine deficient as well. WHO recommended salt iodization as early as 1952 and over 70% of the world population now have access to iodized salt. Endemic goiter now occurs mainly in developing countries, typically mountainous areas such as the Andes and Himalayas and the mountainous chain extending through Southeast Asia and the South Pacific. Iodine deficiency also remains a problem in certain parts of Africa. Endemic goiter also persists in the Alps and in several Western and mid-European countries.[124] Iodine deficiency remains one of the four risk factors for impaired child development.[125]

Iodine deficiency causes inadequate thyroid hormone production. Thyroid hormone plays a functional role in different physiological processes, including modulating basal metabolic rate and promoting growth. The extreme result of hypothyroidism and iodine deficiency during development is cretinism. Two types of cretinism are described, neurologic and myxedematous, both of which exhibit severe mental retardation. The neurologic type prevails in most regions and is characterized by severe mental retardation, deaf mutism, spastic diplegia, and strabismus. The cretin appears normal at birth, but is obviously retarded by 6 months of age. There is a characteristic vacant face with a large protruding tongue. The head appears large, and a lordosis is usually prominent. Clinical evidence of hypothyroidism is usually absent. The neurologic damage does not appear to be attributable to maternal or fetal hypothyroidism; there has been speculation that it may be owing to the direct effects of fetal iodine deficiency or to an imbalance between serum T_4 and T_3. In iodine deficiency, T_4 (precursor of T_3) decreases, but T_3 remains normal or even elevated. The myxedematous type of cretin predominantly has the signs of congenital hypothyroidism but typically

has only modest enlargement of the thyroid gland. This type, which mayresult from a combination of a dietary goitrogen, and iodine deficiency, possibly complicated by co-existing selenium deficiency. Glutathione peroxidase is selenium dependent and selenium deficiency causes accumulation of peroxidase which damages the thyroid and impairs thyroid hormone production. Another selenium dependent enzyme, deiodinases converts T_4–T_3 (the active form) by removing one iodine atom. This type predominates in some Central African countries. Endemic cretinism is not a distinct entity in a region of endemic goiter but rather the severe end of a spectrum of neurologic damage.[124]

In mildly iodine-deficient areas, goiters (enlargement of the thyroid gland due to iodine deficiency) may not occur until adolescence or during pregnancy. These goiters disappear in adult males, but in women they become large. Degenerative changes then occur, and myxedema or, paradoxically, sometimes thyrotoxicosis, may follow. Milder cognitive and neuromuscular impairment due to chronic iodine deficiency is much more common.

Early in the 20th century, prophylaxis with iodized salt proved to be highly effective in North America. Although sporadic goiters still occur, these are apparently attributable primarily to unidentified goitrogens. Bread, water, milk, and chocolate are other vehicles that have been used to provide supplemental iodine. In areas of endemic goiter, intramuscular depot injections of 5 mL of iodized oil, providing 400 μg/mL of iodine, have also been used extensively. With the relatively high iodide concentrations now found in foods, especially milk, and the nationwide food distribution system in the United States, iodized salt is no longer considered to be necessary. In contrast, WHO and other international agencies have spearheaded national salt iodization programs in developing countries to eliminate the full spectrum of iodine deficiency disorders. In the 1990s, the number of countries with iodization programs doubled from 46 to 93, and there has been an accompanying improvement in the iodine status of these populations. The sustainability of these programs has been a challenge, however, resulting in persistence of widespread iodine deficiency.

DIAGNOSIS OF IODINE DEFICIENCY

Measurement of iodine excretion in casual or spot urine samples provides an excellent index of recent iodine intake and is a useful assay for assessing community iodide status, although it does not directly reflect

thyroid functions. Urinary iodine concentrations < 50 μg/L indicate moderate to severe deficiency; 100–199 μg/L indicates normal iodine status; > 200 μg/L indicates more than adequate; and > 300 μg/L indicates possible excess.[124,126] Once iodine deficiency is established, T_4 levels will be decreased (normal range equals 0.8–2.4 ng/dL). Thyroid size and thyroid-stimulating hormone and thyroglobulin concentrations reflect chronic iodine deficiency disorders. A urinary iodine concentration survey of school-aged children revealed almost 30% of school-aged children worldwide are iodine deficient and the majority of these children are from southeast Asia and Africa.[127]

IODINE TOXICITY

Excessive iodine consumption can also impair thyroid function. With the increasing levels of iodide in the US food supply, the risk of iodide toxicity is currently of greater concern than that of iodide deficiency. More cases of goiter in this country are currently attributable to excess rather than to a lack of iodide. The effects of excessive iodide intake include thyroiditis, goiter, hypothyroidism, and hyperthyroidism.[124] Large intakes of in adults may cause toxicity, especially in those who have previously had chronic iodine deficiency, which somewhat paradoxically predisposes to toxicity. A large prospective study of adults in China, which examined three distinct geographic areas with different levels of iodine intake, reported significantly higher risk of hypothyroidism and autoimmune thyroiditis in subjects with more than adequate or excessive iodine intake. Adverse effects were greatest in those who had previously been mildly deficient and subsequently increased iodine intake to greater than adequate intake.[128]

FOOD SOURCES

Plants grow in iodine-rich soils and animals feed on these plants have higher iodine content. Seaweed and fish are usually high in iodine. Because iodine distribution worldwide is not even, iodine fortification becomes the most effective way to prevent iodine deficiency. Cow’s milk is a major dietary source of iodide in the United States, one that has increased in recent years. This has resulted not only from use of iodized salt in the dairy industry but also from the use of iodates as sanitizers, especially in teat dips. Iodide concentrations in human milk are also

relatively high in this country (i.e., 140 to 180 µg iodide/L), much higher than the concentration in other countries.[6] The recommended range for term infant formulas is 53–230 µg iodide/L[104]; the comparable recommendation for preterm formulas is 48–280 µg iodide/L.[5] Fish is notable among other foods as naturally rich in iodide. Iodide in water does not usually contribute more than 10% of intake.

DIETARY REQUIREMENTS

The adult EAR of iodide is 95 µg/day or approximately 1 µg iodide/kg body weight/day; the RDA is 150 µg/day.[6] AIs for infants are 110 µg/day before the age of 6 months and 130 µg/day in older infants.[6] The upper limit (UL) for adults is 1,100 µg iodide/day; UL's for children are provided in the Appendix II.[6] These intake recommendations are generous. Some centers do not add iodide to intravenous nutrition because of that already present as contamination, including that derived from iodates used to clean tube connections. As centers have moved away from use of iodates for this purpose, the risk of deficiency may be increased, and routine parenteral administration may be warranted, but data are limited.[129] We recommend providing 1 µg iodide/kg body weight/day, a dose with minimal risk of toxicity.

CONCLUSION

Recognition of the practical importance of the trace elements in human nutrition continues to exponentially increase. Concurrently, there have been exciting advances in understanding of the biology, especially the molecular/subcellular biology of these micronutrients. Recent advances have been most notable for zinc, both in terms of basic biology and global public health. Identification of "new" biologic roles of selenium and increasing respect for its importance for human health serve as a reminder that knowledge of less prominent trace elements is likely far from complete. Although, globally, issues of trace element deficiencies pose major public health challenges, for example, iodine, there are also issues of overabundance owing especially to food fortification programs. The latter tend to underscore the importance of both vigilance toward and further research on interactions and other possible adverse effects.

Iron

9

Amina Khambalia, PhD, Ashley Aimone, MSc, RD, and S. H. Zlotkin, MD, PhD

INTRODUCTION

Iron is a constituent of many enzymes in the human body and is especially important to ensure the oxygen carrying capacity of hemoglobin. The most prevalent iron disorder is iron deficiency. Iron deficiency (ID) is the most common nutritional deficiency in children. While iron deficiency is far more prevalent than iron overload, both deficiency and excess are associated with significant morbidity and mortality. This chapter reviews issues related to iron metabolism, clinical manifestations, assessment, and prevention in infants, young children and pregnant women. The specific sections covered in this chapter are as follows: (1) What is iron? (2) Why is iron important? (3) How much iron does the body need? (4) Clinical case study; (4) What are dietary sources of iron? (4.1: Special topic—Iron deficiency and obesity; (5) How does the body maintain iron homeostasis? (5.1 Clinical case study); (6) How does the body regulate iron absorption? (7) How does the body transport iron? (8) What about too *little* iron in the body? (9) What about too *much* iron in the body? (10) How do we assess iron?

SECTION 1: WHAT IS IRON?

Iron is a versatile and highly reactive group-VIII transition metal with electrons distributed throughout five 3d orbitals.[1] Depending on the chemical environment iron can exist in several oxidation states (between –2 and +6). At physiological oxygen concentrations, iron exists in its stable ferric (Fe^{3+}) state for most of its biological complexes.

The only stable iron states in the aqueous environment of the human body and in food are ferric and ferrous iron. Ferrous (Fe^{2+}) iron is used in

transmembrane transport of iron, deposition of iron in the storage protein and synthesis of heme.[2] The human body contains 2–4 g of elemental iron, most of which is in the hemoglobin of erythrocytes.[3] Over 65% of body iron is present in the hemoglobin, up to 10% is found in myoglobin and approximately 1%–5% is present as part of enzymes.[4]

SECTION 2: WHY IS IRON IMPORTANT?

With the exception of certain members of the bacterial genera, iron is an essential nutrient for all living organisms. Iron is vital for metabolic processes such as oxygen transport, DNA synthesis and electron transport.

Iron's key function is tissue oxygenation. Oxygen is bound to an iron-containing porphyrin ring, either as part of the prosthetic group of hemoglobin within erythrocytes, or as part of myoglobin located within the cytoplasm of muscle cells.[5] Some critical proteins and enzymes that have iron as a component or cofactor include hemoglobin, myoglobin, catalase, xanthine oxidase, aconitase, reduced nicotinamide adenine dinucleotide, ribonucleotide reductase, peroxidases and cytochrome oxidase. Iron's role in electron transport and reversible ligand binding is accredited to its ability to interconvert between oxidation states and achieve various redox potentials during electrochemical reactions. Heme is contained in the active sites of cytochromes that serve as electron carriers within the cell, in iron–sulfur proteins (flavoproteins, heme-flavoproteins) required for the first reaction in the electron transport chain, and in hydrogen perioxidasess (e.g., catalase and perioxidase).[1] The cytochrome P450 family of enzymes located in microsomal membranes of liver and intestinal mucosal cells also contain heme. Cytochrome P450 is involved in detoxification of foreign substances in the liver and the synthesis of steroid hormones and bile acids.

SECTION 3: HOW MUCH IRON DOES THE BODY NEED?

Iron requirements are high during periods of rapid growth such as: (a) *infancy*, (b) *adolescence* and (c) *pregnancy* (Table 9-1). During infancy the amount of iron needed for growth is so great that the abundant iron stores present at birth are usually exhausted by 4–6 months of age. After the first year of life, adolescence is the second most critical period of physical growth in the life cycle. During pregnancy, iron requirements rise

significantly due to increased red cell mass, the expansion of plasma volume and growth of the fetal-placental unit.[6]

Infancy

Fetal hemoglobin (Hb) has a high affinity for oxygen; thereby, giving the fetus precedence for oxygen over the mother at the placental interface.[7] Delivery of oxygen from fetal Hb to tissues is lowered. As a consequence, the fetus needs more Hb to deliver a certain amount of oxygen to tissues (regulated by erythropoietin). Daily fetal iron accretion occurs at a rate of approximately 1.6–2.0 mg/kg.[8] Fetal iron is present in three forms: hemoglobin iron, tissue iron and storage iron, comprising 77%, 9% and 14% of total body iron, respectively. In late fetal and early postnatal life the greatest need for iron is for Hb synthesis.[9] At delivery, the production of fetal Hb is exchanged for the production of normal adult Hb, and oxygen is more readily available from the lungs.[7]

TABLE 9-1 Main Factors Negatively Influencing Iron Balance According to Life Stage

Birth	Infancy	Childhood and Adolescence
Before birth	0–6 months	Antacid therapy
Maternal iron deficiency	Low/depleted body iron stores	Low dietary iron supply
Intrauterine growth retardation	Rapid weight gain	Low dietary iron availability
At birth	Blood loss due to frequent sampling	Intense physical activity
Low body iron stores at birth	Blood loss due to cow milk feeding	Adolescent pregnancy
Early onset of postnatal erythropoiesis	6–12 months	Loss or dysfunction of absorptive enterocytes
Rapid postnatal catch-up growth	Low/depleted iron stores	Bowel resection

Low birth weight	Rapid weight gain	Celiac disease
Premature birth	Blood loss due to cow milk feeding	Intrinsic enterocyte defects
Fetal-maternal hemorrhage	Low dietary iron supply	Gastrointestinal blood loss: epistaxis, varices, gastritis, ulcer, tumor, meckel's diverticulum, parasitosis, vascular malformations, inflammatory bowel disease, diverticulosis, hemorrhoids, menorrhagia, cancer, chronic infection, pulmonary hemosiderosis, trauma, excessive phlebotomy, large vascular malformations
Perinatal hemorrhage	Low dietary iron availability	
Twin-to-twin transfusion	Prolonged exclusive breastfeeding	
Umbilical cord preclamping	Frequent infections	
Phlebotomy losses		
Restrictive RBC transfusion practice		
Recombinant erythropoietin administration (preterm infants)		

After birth, shifts in iron compartments occur; erythropoiesis falls as Hb concentration tends to return to normal levels around 120 g/L instead of neonatal levels around 170 g/L.[9] Iron derived from this physiologic process is accumulated in iron stores and successively used for Hb production. An infant is born with about 250 mg of total body iron (75 mg/kg), over two-thirds of which is accreted during the third trimester at a rate proportional to an increase in body weight.[12] The amount of iron present at birth depends on the length of gestational period and the weight of the baby.[10] At birth a normal full-term infant has iron stores to cover iron needs during the first 4–6 months of life.[11] After 6 months the assumed amount of iron stores endowed at birth have been utilized.

Exogenous sources of iron are required as erythropoiesis is more active.

During years of growth, iron absorption must exceed iron losses by approximately 0.5 mg daily.[5] From 4 to 12 months of age an infant's blood volume doubles, with each additional gram of Hb that is synthesized requiring an additional 3.5 mg of iron.[8] During the second half of infancy exogenous iron requirements rapidly increase to concentrations that are higher than any other time in life on a body weight basis.[16] It is only after approximately two years of life that iron requirements begin to be reduced.[7]

Adolescence

During adolescence iron requirements nearly double in both boys and girls as a result of the expansion of the total blood volume and the increase in lean body mass.[13] Estimates of physiological iron requirements during the adolescent period have been computed using a factorial method of iron components (basal losses, menstrual losses, and accretion).[14] Preadolescent levels of overall iron requirements (0.7–0.9 mg Fe/day) increase to as much as 2.2 mg Fe/day.[15,16]

Female adolescents require an additional amount of iron to account for iron losses during menses. Menstrual losses may increase daily requirements to as much as 2.1 mg/day in girls at the 75th percentile of blood loss.[13] Among 14 year old girls, median iron requirements can be 30% higher than for their mothers.[16] Iron requirements may increase further in heavily menstruating young women.

Pregnancy

Pregnancy is associated with an increased red cell mass, expansion of plasma volume and growth in the fetal-placental unit, all of which contribute to a significant increase in iron requirements. The additional iron requirement for pregnancy (3–4 mg/day) is substantial and it is estimated that fewer than 50% of women have adequate iron stores to meet this additional need.[6] Furthermore, iron requirements are not distributed equally over the duration of pregnancy. Requirements are low in the first trimester (due to the absence of menstrual iron losses and the negligible needs of the fetus) but rise to between 4 and 6 mg in the second and third trimesters, respectively.[17] During the last 6–8 weeks of pregnancy requirements may reach as much as 10 mg/day.[7]

By the end of pregnancy, approximately 1200 mg of iron is required,

either from body iron stores or from the diet.[18] The average requirement for a menstruating woman for the same period of time is roughly 400 mg. In order to accommodate this increased requirement of 800 mg and avoid a negative iron balance the average woman must absorb 500 mg (2 mg/day) more iron than she required while menstruating.[18] In most cases, dietary intakes alone are insufficient to meet the requirements of pregnancy, especially in the latter part of pregnancy.[18] It is, therefore, estimated that a female needs 500 mg of stored iron to cover iron requirements during pregnancy.[7] A woman who routinely eats a diet high in bioavailable iron and enters pregnancy with sufficient iron stores will likely meet her requirements.[17] However, a higher amount of stored iron is needed when the diet is less than optimal.[7]

SECTION 3.1: A STUDY OF CLINICAL CASE

There are wide variations in iron supplementation practices among neonatal units worldwide. Since at least the 1950s, the need for iron therapy in preterm infants has been debated.[*] There is indication for iron supplementation because premature infants have a propensity to develop iron deficiency. Conversely, the pro-oxidant role of non-protein bound iron and the poorly developed antioxidant measures in preterm infants cautions against aggressive iron supplementation in this population.[†] The goal of nutrient delivery to preterm infants is to mimic the intrauterine accretion rate and maintain normal serum levels. However, unlike intrauterine life, growth and erythropoiesis cease soon after birth making iron requirements lower. Well-executed, randomized controlled trials have been conducted to determine the iron requirements of preterm infants. Trials have established the beneficial effect of iron supplementation via fortification of human milk, iron-fortified formula and medicinal iron in decreasing the risk of iron deficiency.[†] Most studies have only evaluated short-term benefits on hematological parameters and a paucity of information on the long-term effects of iron supplementation.

Further discussion points:

What factors predispose premature infants to iron deficiency?

What iatrogenic factors are responsible for excessive iron accumulation in preterm infants?

What are the consequences of iron deficiency in premature infants?

What are the consequences of iron overload in premature infants?

What is the best route for supplementation (i.e., parenteral, intramuscular,

intravenous)?

† Raghavendra R, Georgieff MK. Iron therapy for preterm infants. Clin Perinatol. 2009;36:27–42.

SECTION 4: WHAT ARE DIETARY SOURCES OF IRON?

A normal diet contains approximately 13–18 mg of iron per day, of which only 1 mg of iron per day is needed in healthy persons to replace basal iron losses.[18] There are two forms of iron in the diet—inorganic iron and heme iron. While many foods are good sources of iron, some are limited by the bioavailability of iron. Iron-rich foods include cocoa, liver, kidney, dried fish, shell-fish, sesame seed, soy flour, and pulses.[20] Foods with low-iron content include milk, cheese, sugar, sweets, jams, and unfortified milled cereals (Table 9-2).

Heme iron is present in the hemoglobin and myoglobin of animal tissues and is thus mainly associated with meat, poultry and fish intake.[22] Heme iron may contribute up to 50% of the iron that actually enters the body.[9] In a single meal 5–35% of heme iron is absorbed.[23] Studies using radiolabeled heme or hemoglobin have established that the intestinal absorption of heme is far more efficient than inorganic iron.[11] Heme iron is well absorbed regardless of meal composition with the exception of meat and calcium. Meat has been shown to enhance heme iron absorption.[24] Calcium is the only dietary factor known to negatively influence the absorption of heme iron and does so to the same extent that it influences non-heme iron (Figure 9-1).[25]

TABLE 9-2 Iron Content of Various Foods[21]

Food	One Serving	Iron Content (mg)
Clam, mixed species, canned, drained solids	3 oz	23.8
Cereals, ready-to-eat, GENERAL MILLS, CHERRIOS	1 cup	10.3
Soybeans, mature cooked, boiled, without salt	1 cup	8.84

Cereals, ready-to-eat, KELLOGS, CORN FLAKES	1 cup	8.12
Infant cereals, including rice, oats, mixed cereals	15 g	7.10
Lentils, mature seeds, cooked, boiled, without salt	1 cup	6.59
Chickpeas, matured seeds, cooked, boiled, without salt	1 cup	4.74
Rice, white, long-grained, parboiled, enriched, cooked	1 cup	3.17
Peas, edible-podded, boiled, drained, without salt	1 cup	3.15
Infant formula—with iron, ready-to-feed	240 mL	2.90
Sardine, Atlantic, canned in oil, drained solids with bone	3 oz	2.48
Chicken liver, cooked, simmered	1 liver	2.28
Potatoes, baked, flesh and skin, without salt	1 potato	2.18
Beef, 75% lean/25% fat, cooked, broiled	3 oz	2.01
Almonds	1 oz (24 nuts)	1.22
Tuna, light, canned in oil, drained solids	3 oz	1.18
Bread, whole, commercially prepared	1 slice	0.93
Egg, whole, raw, fresh	1 large	0.92
Blueberries, raw	1 cup	0.89
Rice, brown, long-grained, cooked	1 cup	0.82
Spinach, raw	1 cup	0.81
Broccoli, raw	1 cup	0.64
Bread, white, commercially prepared	1 slice	0.73
Infant formula- low iron, ready-to-feed	240 mL	0.30
Cheese, cheddar	1 oz	0.19
Apples, raw, with skin	1 apple	0.17
Milk, cow, whole, 3.25% milk fat	1 cup	0.07

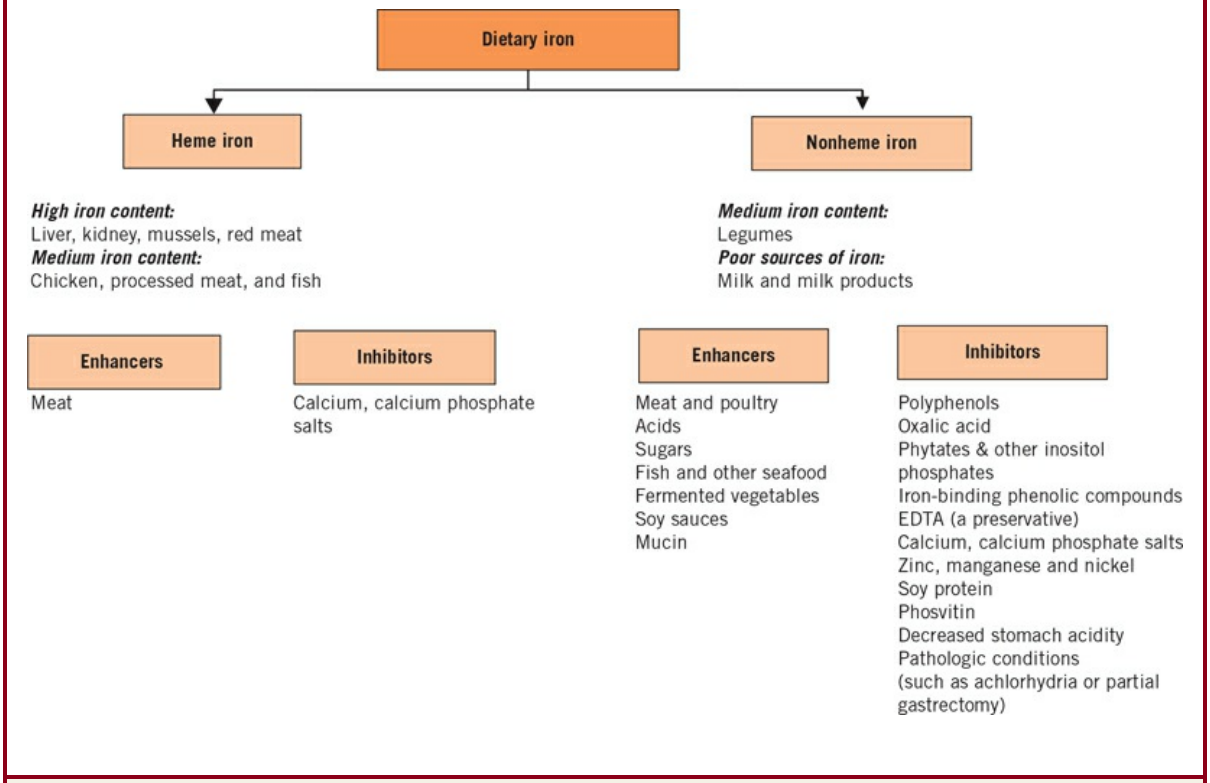

Figure 9-1 Factors affecting dietary iron absorption

Inorganic iron, predominantly found in components of plant origin, is the most prevalent form of dietary iron.[26] Inorganic iron accounts for 80–90% of the iron in a standard diet.[1] Non-heme iron is generally poorly absorbed and greatly influenced by enhancing or inhibiting substances (Figure 9-1).[20] Meat, fish amino acids and organic acids (i.e., ascorbic acid, lactic acid, citric acid, and malic acid) promote non-heme iron absorption.[26,27] These non-heme iron enhancers form soluble complexes with iron at low gastric pH levels and prevent the formation of insoluble hydroxides at the higher pH of small intestine.[9] Phenols, calcium and phytates which are present in cereals and legumes, impair non-heme iron absorption (Figure 9-1).[9] Phenolic compounds, which bear catechol or galloyl groups, have iron-binding properties.[20] Tea, coffee, cocoa, red wine, many vegetables (such as spinach), grains, herbs and spices (such as oregano and cinnamon) contain phenolic compounds. Vitamin A may be capable of preventing the inhibiting effect of polyphenols on iron absorption.[20] Phytates are a storage form of phosphates and minerals in cereals, seeds, nuts, vegetables, and fruit. Bran, oats, and fiber-rich foods are rich in phytates. The effect of phytates is counteracted by ascorbic

acid, meat, fish and poultry.[20]

SPECIAL TOPIC—IRON DEFICIENCY AND OBESITY

Results from cross-sectional studies performed in industrialized countries have consistently shown that obese individuals are at increased risk of iron deficiency.[28]

Obesity is a worldwide health problem. While large segments of the population in lower- to middle-income countries in Asia, Africa, the Middle East, and Latin America face under nutrition and poverty-related diseases, increasing proportions of the population are developing obesity and non-communicable diseases such as diabetes and coronary problems.[29] The co-occurrence of over nutrition and undernutrition is attributed to the "nutrition transition"—a term used to describe shifts in diet, physical activity, health, and nutrition.[30] The nutrition transition is characterized by a shift toward more energy-dense diets and a reduction in physical activity due to higher incomes and the influence of mass media and food marketing.[29]

Data from the American National Health and Nutrition Examination Survey III as well as data obtained in children from transition countries have suggested that among children, the prevalence of iron deficiency increases as body mass index increases from normal weight to at risk for obesity to obesity.[31,32]

The underlying mechanisms of the association between obesity and iron deficiency are not clear. The data from small studies suggest that iron deficiency in obese individuals is due to lower dietary iron intake or increased iron requirements from a larger blood volume.[28] Despite their excessive dietary and caloric intake, obese children and adolescents may be at risk of ID because they tend to consume unbalanced meals, particularly rich in carbohydrates and fat. Obesity and iron deficiency are more prevalent in lower socioeconomic groups, who consume low-cost fast foods that are low in essential nutrients and rich in fats, sugars and preservatives. It is possible that obese children have increased iron needs because of their increased growth and body surface area.[33] Higher risk of iron deficiency in obese individuals may also be related to chronic adiposity-related inflammation which increases hepcidin concentrations, which in turn, decreases intestinal iron absorption and/or increased reticuloendothelial iron sequestration.[34]

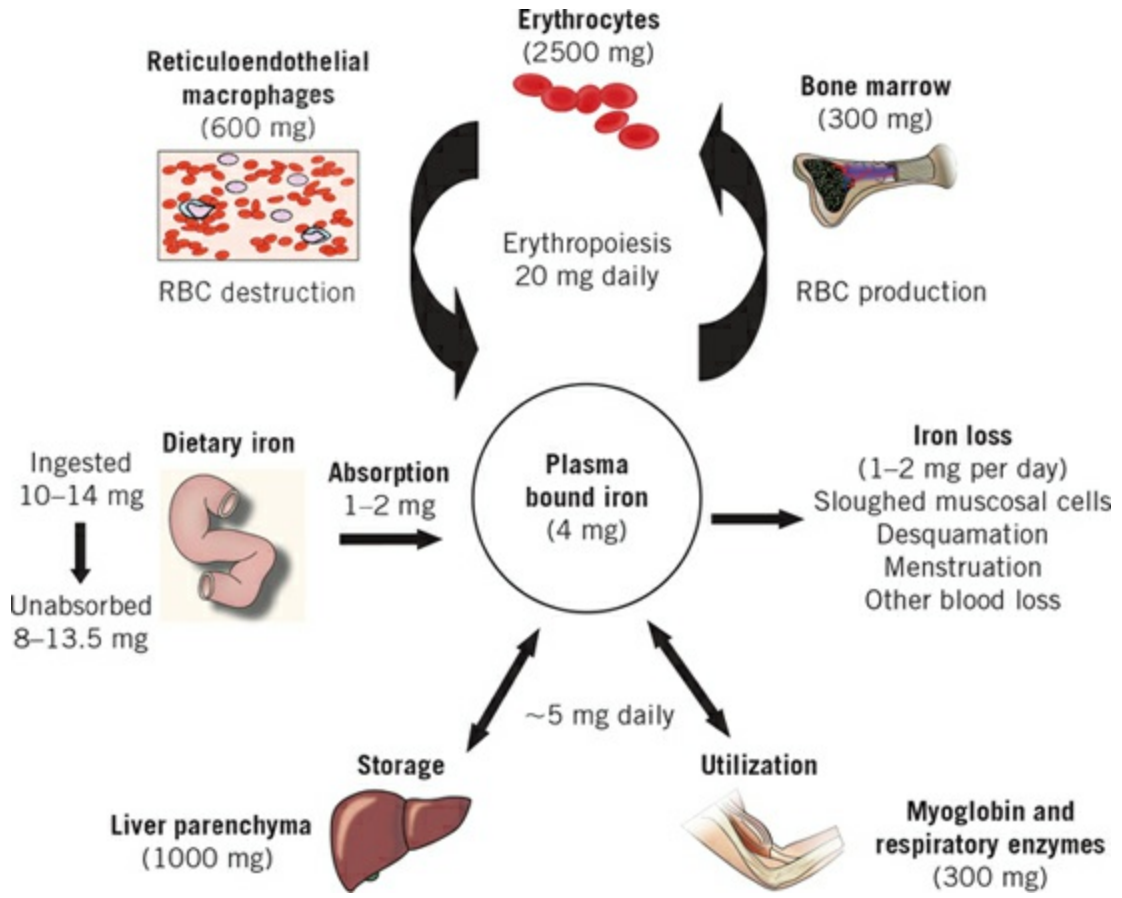

Figure 9-2 Iron distribution and exchange pools.[36–38]

SECTION 5: HOW DOES THE BODY MAINTAIN IRON HOMEOSTASIS?

Iron balance in the human body is maintained by: (a) *absorption*, (b) *turnover*, (c) *storage*, *and* (d) *excretion* (Figure 9-2).

Absorption

Humans lack a physiological pathway for iron excretion therefore, iron homeostasis in the body is determined by the regulation of iron absorption in the proximal small intestine.[7] Several processes have been found to influence the rate of iron absorption, including diet, body iron stores, marrow erythropoietic activity, blood hemoglobin concentration, blood oxygen content, and the presence of systemic inflammation.[35] Iron absorption decreases in the presence of iron overload and inflammation

and increases in response to iron deficiency, accelerated erythropoiesis, and hypoxia.[35] Some of these processes are inter-related and may occur simultaneously.

Turnover

A steady supply of iron is needed for cellular turnover. Ferroportin, a transmembrane protein exports iron from cellular storage sites into the circulation where it is rapidly bound to transferrin.[39] The export rate is closely matched to tissue requirements. Almost all functional requirements of cells located throughout the body are met from this small dynamic pool.[40] Iron is constantly being delivered from stores to maturing red blood cells to make hemoglobin and, after 4 months, returned to the stores when senescent red blood cells are catabolized by specialized macrophages in the spleen, liver, and bone marrow and the iron salvaged from the hemoglobin.[40,41]

Storage

When intracellular iron exceeds cellular requirements, excess iron is kept in storage. All cells are capable of storing iron; however, principal storage sites in humans are the liver, spleen, and bone marrow.[2] The concentration of storage iron in the body varies by gender and iron status.

Excretion

Iron in the human body is highly conserved. The majority of iron is lost in feces (derived from shed enterocytes, extravasated red blood cells, and biliary heme breakdown products that are poorly absorbed), with minimal losses from the urine, gastrointestinal tract and skin amounting to 0.08, 0.6, 0.2–0.3 mg/day, respectively.[1]

Absorption

Iron balance is highly regulated by the control of absorption in humans. Iron absorption occurs in the proximal duodenum and involves a sequence of events: (i) *reduction*; (ii) *apical uptake*; (iii) *intracellular storage or trafficking* and; (iv) *basolateral release*.

Reduction

Most inorganic iron in the diet is in the oxidized or ferric form. Before iron can be taken up by the intestinal epithelial cells or enterocytes, iron must

first be reduced from its ferric to ferrous form in the luminal brush border of the enterocyte (Figure 9-3).[35] A strong candidate for the brush border ferrireductase is duodenal cytochrome *b* (Dcytb).[42] Ferrous iron is more readily absorbed than ferric iron due to higher solubility in the proximal small intestine. Iron reduction is facilitated by the acidic milieu of the gastric content and the meal composition.[12]

Apical Uptake

In order to reach the plasma, iron must pass from the gut through the apical (lumenal) and basolateral (serosal) membranes of the enterocyte.[43] Absorptive cells located in the crypts of the duodenum are organized as finger-like villous structures to increase surface area. Beginning as stem cells, these absorptive cells proliferate and migrate out of the crypt and up to the villus over a period of several days.[44] During migration the cells differentiate and perform their functions.[45] During the intestinal phase of digestion iron is present in the lumen as either heme or non-heme iron. Non-heme iron that is liberated by gastric and pancreatic proteases becomes bound to intraluminal molecules. These iron-binding proteins prevent non-heme iron from being readily oxidized from ferrous to ferric iron in the alkaline environment and rendered insoluble and biologically unavailable.

The pathway by which heme iron is absorbed is less well defined than that of inorganic iron.[43] Heme iron is released from proteins such as hemoglobin and myoglobin in the lumen of the stomach and small intestine.[43] Luminal absorption of heme does not require binding proteins because heme iron is soluble in an alkaline environment. After binding to its receptor, heme iron is absorbed intact by the intestinal enterocytes.[11] Iron from heme is not released prior to its cellular uptake, making heme iron less susceptible than inorganic heme to variations in dietary composition.[23] The percent iron absorption from heme iron is five- to ten-fold higher than that from non-heme iron. Most studies have shown that iron deficiency is able to stimulate the absorption of both heme iron and inorganic iron.[23] The enterocyte's apical membrane transports heme and ferrous iron into the cell.[46] Iron transport is meticulously regulated by chelating compounds that are produced to detoxify extra- and intra-cellular iron.[43]

Intracellular Storage or Trafficking

Once iron has been absorbed by enterocytes it is bound by, as of yet

unidentified, chaperones. Inside the absorptive enterocyte, iron can either be stored as ferritin or transferred across the basolateral membrane into the circulation where it will be bound to apoferritin.[46] Proteins related to iron metabolism on the basolateral membrane of the precursor and mature enterocyte either sense body iron stores or facilitate regulated iron transport into the plasma. Iron that remains in the form of ferritin as the enterocyte completes its life cycle will be sloughed off with the senescent cell and exit the body through the gastrointestinal tract (Figure 9-3). This maturation process takes approximately 3–5 days.[19]

The discovery of the iron regulatory hormone hepcidin supports the liver's central role in determining the amount of iron that is absorbed by the gut and released from storage sites.[48] It has long been known that the liver is the major depot for iron; hepatocytes are the first cells in the body to have access to absorbed iron entering the portal circulation from the gut.[49] Hepcidin (also called HAMP) is a 25-amino acid peptide that is primarily produced by the liver. It is secreted into plasma, and is cleared by the kidneys.[50] Hepcidin acts as an inhibitor of iron absorption and iron release. Important cellular targets for hepcidin are the villus enterocyte, the reticuloendothelial macrophage and the hepatocyte (Figure 9-3). Hepcidin modulates the ferroportin-mediated release of cellular iron by binding to ferroportin and causing it to be degraded.[48] Decreased functional activity of ferroportin causes a decrease in basolateral iron transfer in the enterocyte and a decrease in iron export from reticoloendothelial macrophages and hepatocytes (increase in stored iron).[48]

The production of hepcidin is inversely related to iron stores, erythropoietic activity, hemoglobin, oxygen content, and inflammation.[48] Hepcidin expression is decreased when body iron requirements are high, such as when iron stores decrease, during iron deficiency, accelerated erythropoiesis, and hypoxia.[49] Increased levels of hepcidin are observed in non-genetic iron overload and inflammation.[50] While it is clear that hepcidin is a strong negative regulator of iron absorption, there is much to be learned regarding the mechanisms by which the liver senses body iron status and erythropoietic demand.[51]

Basolateral Release

The pathways by which inorganic and heme iron are taken up from the intestinal lumen by the enterocytes vary; however, it has been proposed that their basolateral export from enterocytes, that is, the step involving hepaestin and IREG1, is common to iron from both sources (Figure 9-3).

The basolateral membrane mediates the transfer of iron from the intestinal epithelial cells to the rest of the body.[45] Once inside the epithelial cell heme is either split into ferrous iron and bilirubin by heme oxygenase, or transported as the intact porphyrin ring.[23] The released ferrous iron likely enters the pool of iron in the enterocyte and exits the enterocyte via a pathway common to inorganic iron.[51] If required by the body, iron rapidly moves across the basolateral membrane and into the circulation. Once iron transverses the basolateral membrane it is bound to transferrin.[50]

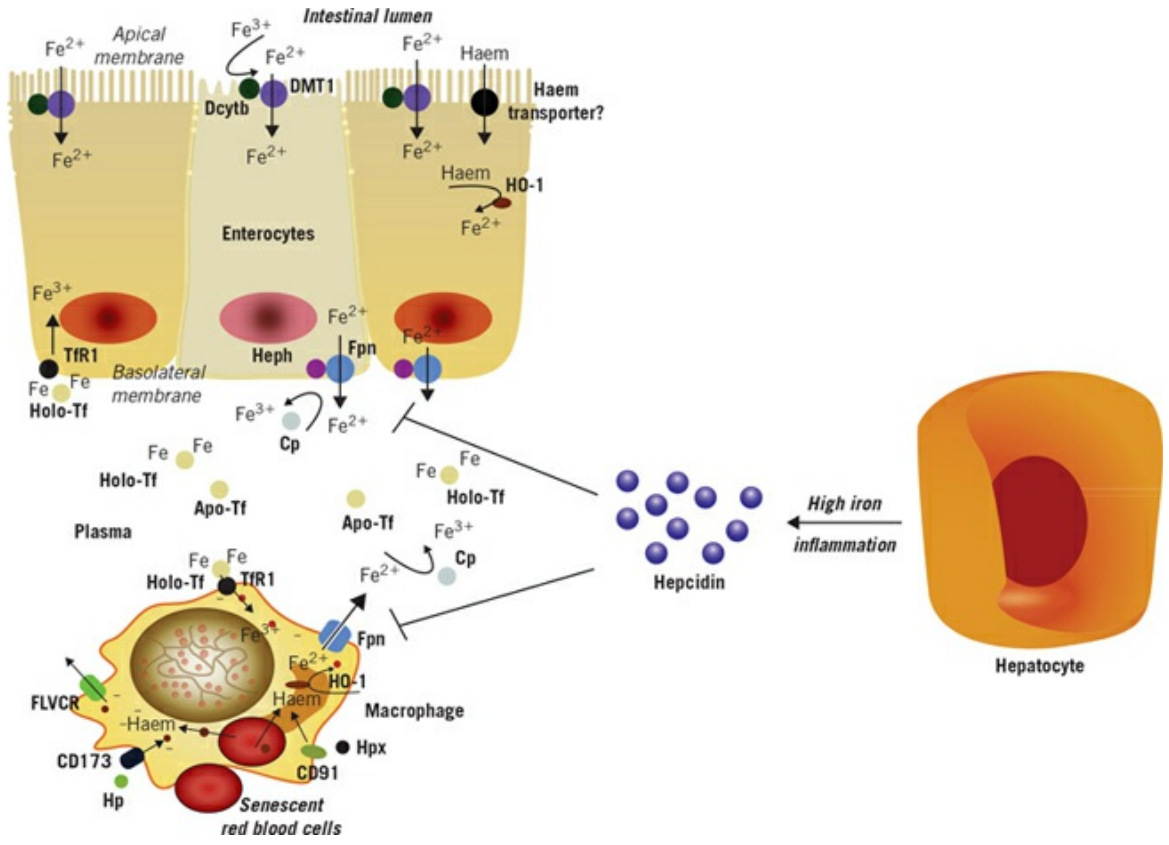

Figure 9-3 Hormonal regulation of iron efflux from duodenal enterocytes and reticuloendothelial macrophages by hepcidin.[47] Enterocytes absorb inorganic or heme iron from the diet and macrophages phagocytose iron-loaded senescent red blood cells, or acquire iron by other mechanisms. Both cell types release Fe2+ into the plasma via ferroportin (Fpn), which is incorporated into apo-Tf following oxidation to Fe3+ via hephaestin (Heph) or ceruloplasmin (Cp). Hepatocytes generate the iron-regulatory hormone hepcidin in response to high iron or inflammatory signals, which inhibits the efflux of iron via ferroportin and promotes its retention within enterocytes and

macrophages. Turnover

At the end of their functional lifetime, erythrocytes undergo changes in the structure of their membrane, causing them to be recognized as senescent cells.[1] Senescent red blood cells are taken up by macrophages and phagocytized in the spleen, bone marrow (reticuloendothelial cell macrophages) and liver (Kupffer cells) (Figure 9-2). This internal erythroid circuit removes and replaces 0.66% of the body's total iron content each day.[1] The daily requirement for the erythron alone is 20 mg of iron and yet only 1–2 mg of iron normally enters the body each day through the intestine.[36] The heme portion of hemoglobin is catabolized by hemoxygenase to biliverdin and subsequently, bilirubin.[50] Bilirubin is secreted into the bile for excretion from the body. The amount of iron that is recycled from effete red cells and returned to plasma transferrin approximates the amount of iron needed for the synthesis of new erythrocytes.[50]

Storage

Most of the iron store is located in the spleen, liver, and bone marrow in the form of ferritin.[37] Iron is stored in the form of ferritin or hemosiderin. Ferritin is comprised of 24 similar polypeptide subunits that form a cage isolating iron from the cellular milieu. Ferritin exists in at least two different isoforms (H and L).[2] The relative proportions of the two subunits vary by tissue type and development. The H form is predominant in the heart; whereas the L form is predominant in the liver. The liver contains about 60% of the ferritin in the body with the remaining amount present in muscle tissues and cells of the reticuloenthelial system. Macrophages act as a storage depot for iron recovered from effete erythrocytes or from medicinal forms of iron administered by injection. Their storage capacity is evident when tissues from patients with transfusional iron overload are stained for iron; large amounts of iron accumulate in macrophages before deposition in parenchymal cells becomes apparent.[50]

Excretion

Only a small amount of iron is lost each day (Figure 9-2). Daily basal losses of iron are limited to 0.90 to 1.02 mg/day in non-menstruating women.[37] The amount of iron lost during menstruation is variable. The mean loss is estimated to be between 0.6 and 0.7 mg/day, which translates into a loss of 17.5 mg iron per period.[52] However, basal losses have been reported to decline to about 0.5 mg/day in an iron-deficient state and increase to about 2 mg/day during iron overload.[53] Non-physiologic causes of iron losses include bleeding from gastrointestinal ulcers, intestinal parasites, cow's milk feeding to infants, aspirin, non-steroidal anti-inflammatory drugs or corticosteroid administration, or hemorrhage induced by surgery or injury.[3]

SECTION 5.1: A STUDY OF CLINICAL CASES

Since the 1970s, many studies have shown that feeding cow's milk to infants is associated with diminished iron stores and an increased probability of iron deficiency.* Several mechanisms have been postulated including: low iron content of cow's milk, which makes it difficult for infants to obtain iron requirements for growth; occult intestinal blood loss associated with cow's milk and inhibition of non-heme iron absorption by calcium and casein, which are present in high amounts in cow's milk.* There is concern that the feeding of unmodified pasteurized cow's milk also places infants at high risk of severe dehydration and may increase the risk of obesity in childhood.

Further discussion points:

What are the possible adverse effects of cow's milk owing to it high protein and electrolyte content?

Why would the feeding of unmodified pasteurized cow's milk be associated with increased risk of severe dehydration?

Why would the feeding of cow's milk be associated with increased the risk of obesity in childhood?

* Ziegler E. Consumption of cow's milk as a cause of iron deficiency in infants and toddlers. Nutr Rev. 2011;69:S37–S42.

SECTION 6: HOW DOES THE BODY REGULATE IRON ABSORPTION?

Humoral regulatory mechanisms for iron absorption include: (a) *dietary regulator*, (b) *stores regulator* and (c) *erythropoietic regulator*.

Dietary Regulator

Absorption of intestinal iron can be modulated by the amount of iron recently consumed. Absorptive enterocytes are resistant to acquiring additional iron several days after a dietary bolus.[36] This phenomenon is commonly referred to as the "mucosal block" theory. The hypothesis is that the amount of iron that is absorbed is dependent on previous exposure of the gastrointestinal tract to iron.[44] It is postulated that multipotent precursor cells in the epithelial layer of the duodenum act as sensors of body iron needs. Iron levels are programmed by enterocytes in the crypt thus modulating iron absorption at the villus.[19] Upon differentiation new proteins required for iron absorption, storage and export are expressed in the enterocyte. The lag period between injection of iron and change in iron absorption is thought to represent the time taken for cell differentiation and migration.

Stores Regulator

The store regulator senses iron levels, but instead of responding to dietary iron, appears to respond to total body iron.[36] After ingestion of foods or iron supplements, higher non-heme iron absorption occurs when stores are depleted and lower absorption occurs when stores are replete or enlarged.[44,54] An inverse linear relationship has been described between iron absorption and serum ferritin (a measure of iron stores). It has been suggested that once iron stores are replete there is a "set-point" or steady-state above which they do not further increase iron absorption. This predetermined "set-point" for iron stores is believed to vary between individuals.

Erythropoietic Regulator

The erythropoietic regulator has been postulated to modulate iron absorption in response to acute marrow iron needs.[7] It is thought that this mechanism senses ineffective erythropoiesis such as occurs in congenital disorders of red cell maturation (i.e., thalassemia, sideroblastic anemia). Anemic states that stimulate iron absorption, such as thalassemia syndromes, congenital dyserythropoietic anemias and sideroblastic anemias all involve destruction of erythroid cells near the site of their development, within the bone marrow. Anemias that are characterized by

peripheral destruction of red cells, such as sickle cell anemia, hereditary spherocytosis and autoimmune hemolytic anemia, do not cause increases in iron absorption leading to the speculation that another component of erythropoiesis other than its rate must explain the absorptive response.[40]

SECTION 7: HOW DOES THE BODY TRANSPORT IRON?

The processes that transport iron from stores in the circulating transferrin pool and out of it to supply cellular demands are both highly regulated. Iron is transported by transferrin (Tf), a plasma protein predominantly synthesized in the liver. Tranferrin can acquire iron from dietary absorption or from heme that has been degraded by the phagocytosis of senescent red blood cells. High-affinity binding of iron to Tf at physiological pH is required to prevent the toxic effect of iron ions, making it difficult to develop iron chelators that compete with transferrin for iron binding.[11]

The 80-kDa serum iron-binding protein reversibly binds to two atoms of iron.[4] The polypeptide chain is arranged in two lobes, representing the N-terminal and C-terminal halves of the molecule (Figure 9-4). When devoid of iron, a transferrin lobe takes an open conformation with the domains separated. Once iron is bound, the domains undergo a rigid rotation to enclose their iron-binding site, thereby guarding bound iron from hydrolysis and too-facile release.

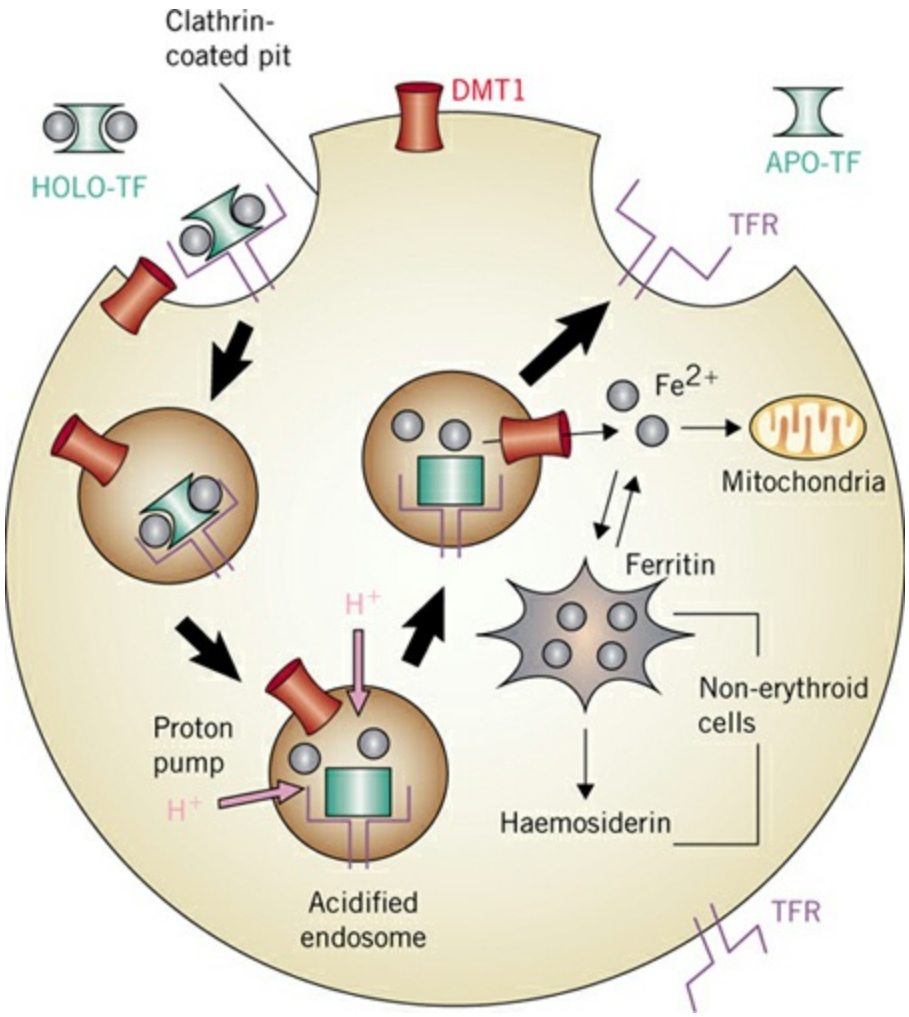

Figure 9-4 Cellular iron transport. The transferrin cycle. HOLOTRANSFERRIN (HOLOTF) binds to transferrin receptors (TFR) on the cell surface. The complexes localize to clathrin-coated pits, which invaginate to initiate endocytosis. Specialized endosomes form, and become acidified through the action of a proton pump. Acidification leads to protein conformational changes that release iron from transferrin. Acidification also enables proton-coupled iron transport out of the endosomes through the activity of the divalent metal transporter 1 protein (DMT1). Subsequently, APOTRANSFERRIN (APO-TF) and the transferrin receptor both return to the cell surface, where they dissociate at neutral pH. Both proteins participate in further rounds of iron delivery. In non-erythroid cells, iron is stored as ferritin and hemosiderin.

Normally, all non-heme iron in the circulation is bound to transferrin. However, only ~30% of transferrin binding sites are occupied, so most of the protein is free of iron. Normal individuals never have a full saturation

of all Tf iron-binding sites, thus providing a safety margin to accommodate fluctuation of iron levels from dietary and environmental changes.[2] Complete saturation is only seen in pathological states such as hemochromatosis and transfusional iron overload. Transferrin receptors are able to distinguish between iron-free and iron-loaded transferrin, ensuring cells do not waste efforts taking up the former.

Transferrin receptors are firmly anchored in cell membranes; with the major portion of the protein being external to the cell.[1] The density of surface transferrin receptors on a given cell is proportional to the cell's iron requirements. In most tissues, however, the receptor number falls sharply as the cell matures. Two exceptions are placental cells, and erythroid precursors—both rapidly dividing cells where large amounts of iron are required throughout the life span.

Transferrin-iron complexes attach to transferrin receptors (TfR) on the cell surface. The entire complex of Tf-iron and TfR are invaginated by part of the cell wall to form a vacuole. The complex is internalized by receptor-mediated endocytosis into clathrin-coated endosomes.[19] The pH in endosomal compartments is rapidly lowered through the action of an ATP-dependent proton pump.[4] The acidic milieu facilitates conformational changes in the transferrin and transferrin receptor proteins.[50] Iron is released from the complex and reduced to its ferrous form. Iron is then transported across the endosomal membrane into the cytoplasm by divalent metal transporter 1 (DMT1, previously known as Nramp2, DCT1). The TfR/Tf complex returns to the cell surface where the physiological pH causes transferrin to be released and recycled into the circulation.[43]

SECTION 8: WHAT ABOUT TOO *LITTLE* IRON IN THE BODY?

Iron deficiency disproportionately affects infants, young children, adolescents, and women of childbearing age, particularly individuals who live in developing countries because their diets provide insufficient bioavailable iron to meet their needs for growth, the replacement of menstrual losses, and pregnancy. The most important clinical clue of moderate to severe chronic iron deficiency in adults is chronic fatigue. Other features include: pallor of the skin and of the conjunctiva, stomatitis, ice eating (pagophagia), leg cramping, koilonychia, glossitis, gastric atrophy and dysphagia.[55] It is also possible that some individuals with iron

deficiency may not experience any symptoms.[1] Since clinical signs of anemia are not specific, it is recommended that biochemical tests be used to determine iron deficiency and its magnitude.[56]

Etiology

The etiology of iron deficiency can be categorized into either physiological or pathological causes.[55] Physiological causes relate to a disparity between iron requirements and the maximum absorption of iron from the diet.[57] Nutritional iron deficiency, a term that has been widely used to describe conditions where the diet cannot cover physiologic iron requirements is the most common cause of iron deficiency worldwide.[55] Segments of the population at risk for not meeting high iron requirements during periods of rapid growth include infants, adolescents and child-bearing females.[55] Impaired absorption of iron can occur in patients with achlorhydria and who have undergone gastric surgery. Gluten enteropathy is also associated with IDA, especially in young patients.[22]

Pathological iron deficiency results from excessive blood loss, which usually occurs in the GI tract.[55] In clinical practice a diagnosis of iron deficiency includes a search for pathologic causes of blood loss (e.g., tumors in the gastrointestinal tract or uterus, especially if uterine bleedings have increased or changed in regularity). Blood loss can occur from chronic use of aspirin or other non-steroidal anti-inflammatory drugs or parasitic infestations (i.e., hookworm).[22]

Epidemiology

In the World Health Report 2002 (“Reducing Risks, Promoting Healthy Life”) nutritional iron deficiency was identified as one of the 10 leading risk factors for disease, disability and death in the world today, with an impact greater than that of either zinc or vitamin A deficiency.[58] In 2008, the Copenhagen Consensus (a not-for-profit “think-tank” lead by a panel of economic experts) ranked “malnutrition and hunger” as the top ranked global challenge and iron fortification as the third highest priority for addressing this challenge.[59] Up to five billion people (80% of the world’s population) are affected by iron deficiency, most of whom live in developing countries.[60]

While it is well recognized that iron deficiency is the single most common nutritional disorder worldwide and the leading cause of anemia during infancy, childhood and pregnancy[61]; obtaining accurate estimates

of its prevalence has proven to be a challenging task. Lack of national data and a single, inexpensive and easy to use indicator of iron status, are just two of the many hurtles in assessing the prevalence of iron deficiency and its anemia.[62]

In 1991, a global Vitamin and Mineral Nutrition Information System (VMNIS) was established by the Nutrition Unit of the World Health Organization to strengthen worldwide surveillance of micronutrient deficiencies. The VMNIS supports Member States in monitoring the vitamin and mineral nutrition status of populations at the national, sub-national, regional and first-administrative level.[63] These data are compiled in a large comprehensive Micronutrients Database, which is used to monitor micronutrient status around the world, and provide global estimates of the prevalence and trends in micronutrient deficiencies over time. Currently the Micronutrients Database contains information on anemia, vitamin A and iodine deficiency.[63]

In the United States, data from the National Health and Nutrition Examination Survey (1999–2006) found the prevalence of iron deficiency to be 14.4 ± 1.9% in toddlers aged 1–2 years, 3.7 ± 0.8% in children aged 3–5 years, 9.3 ± 1.0% in adolescent females, 9.2 ± 1.6% in women,[64] and 18.0 ± 1.4% in pregnant women.[65]

Definition

Broadly defined, iron deficiency is a condition in which there is a lack of cellular iron to the tissues.[6] Iron deficiency represents a spectrum of mild to severe forms characterized by the presence or absence of physiological, biochemical, hematological and functional changes. Therefore, various definitions of iron deficiency have been formulated. The development of iron deficiency anemia is commonly thought of as a progression of *three* successive stages.[66]

The first stage—iron depletion (ID), is characterized by a mobilization of storage iron. A fall in serum iron reflects the progressive reduction of storage iron in the liver; however, the supply of iron to the functional compartment remains uncompromised. Levels of transport iron and hemoglobin remain normal.

The second stage—early functional iron deficiency (previously called iron-deficient erythropoiesis), involves a decrease in transport iron resulting in low levels of serum ferritin and low serum transferrin saturation and elevated levels of serum-transferrin receptor (TfR) and free erythrocyte protoporphyrin (FEP).[41] This stage is commonly referred to as

iron deficiency without anemia. The iron supply required for full maturation of eyrthropoietic cells is markedly reduced; however, mature red blood cells stay unaffected. Hemoglobin concentrations usually remain within in the normal range, although they may decrease slightly. Unlike iron deficiency anemia, in which iron stores are totally absent, the IDE can occur with normal or increased amounts of stored iron due to the impaired release of iron in the plasma from the storage iron compartment.[55]

The third and final stage is established functional iron deficiency, often referred to as: iron-deficiencyanemia (IDA). IDA develops when the supply of transport iron decreases to the point where hemoglobin synthesis is restricted. During this stage iron stores are exhausted, circulating levels of iron are declining and microcytic, hypochromic anemia is evident. A restricted supply of iron to the bone marrow causes a reduction in the concentration of hemoglobin in the red blood cells and an observable decline in hematocrit and red cell indices.

Risk Factors

Iron deficiency can arise from several risk factors, alone or in combination. Examples from the range of possible risk factors include: (a) inadequate iron supply, (b) increased iron requirements imposed by growth, and (c) increased iron losses.

Inadequate iron supply can be the consequence of low iron stores or low iron in the diet. At birth, low iron stores can result from low birthweight, perinatal bleeding, early clamping of umbilical cord and maternal iron deficiency. Low birthweight influences iron stores in a linear proportion; a newborn weighing 1500 has roughly half the iron content of a 3000 g well-grown term newborn.[9] Preterm infants (born before 32 weeks gestation) encounter low body iron stores because they miss out on the accretion of iron during last trimester of pregnancy.[8] In addition, preterm infants are at increased risk of iron deficiency from postnatal practices such as uncompensated phlebotomy losses, administration of recombinant human erythropoietin (rhEpo) and inadequate iron supplementation.[8] The timing of the clamping of the umbilical cord at delivery has been shown to impact the amount of blood transferred to the infant.[67] The timing of umbilical cord clamping depends on whether the cord is clamped early (less than a minute), intermediately (1–3 min), or late (after pulsations cease). For example, if the cord is not cut until pulsations cease, the infants will receive a 20–30 mL/kg body weight transfusion, which is the equivalent to approximately 30–35 mg of

additional iron.[67] To put this amount of iron into perspective, this is the equivalent to the amount of iron in 100 l of human milk.[67]

Maternal iron deficiency has been shown to affect infant iron stores and iron status. It was previously held that infants acted as parasites with respect to sequester iron from their mother in utero. However, current evidence suggests that maternal iron stores over a wide range determine iron stores in the neonate[68–73] and that even moderate degrees of maternal ID (Hb 85–100 g/L) may result in lower body iron stores during infancy in the offspring.[68] In developing countries, maternal ID (Hb < 85 g/L) affects 30%–50% of pregnancies and is arguably the most common cause of perinatal iron deficiency.[8]

Nutritional iron deficiency results from reduced dietary iron and/or low bioavailability of dietary iron. Despite the high bioavailability of the iron in human milk, human milk contains very little iron, thus iron stores in the exclusively breastfed infant will ultimately be depleted after 6 months of age.[74] If human milk remains the only food source, iron deficiency anemia will ultimately develop. The choice of complementary foods will markedly influence the risk of iron deficiency and anemia. Unfortunately, in developing countries typical home-prepared grain or rice-based complementary foods are poor sources of iron and may contain phytic acid, which is a potent inhibitor of iron absorption. For example, per 100 g, unfortified rice-based complementary foods contain 1 mg of iron and maize and wheat-based complementary foods contain 0.8 mg of iron.[75]

Adolescents at risk for nutritional iron deficiency include those on a restrictive diet, suffering from an unhealthy body image or practicing vegetarianism (restrictive intake of heme iron sources).[74] Many adolescent girls inadvertently limit iron intake by trying to control their weight or by passing through temporary period of vegetarianism because of concerns for animal warfare.[76] Vegetarians can achieve an adequate intake of iron, but have to purposely choose foods with a high concentration of non-heme iron or choose foods fortified with iron (see Table 9-2). Women who conceive during or shortly after adolescence are at increased risk for entering pregnancy with low or absent iron stores and subsequently developing iron deficiency during pregnancy.[18] The available data on iron intake in adolescents suggest that adolescent girls are unlikely to acquire substantial iron stores during this time period because intakes may average as little as 10–11 mg iron/day.[18] The bioavailability from diets in developing and industrialized countries indicates a negative iron balance is likely in many female populations.

An important and common risk factor for ID is increased iron requirements imposed by growth. During the first 2 years of life, infants require relatively large amounts of iron due to their high growth rate. On average, during the first year of life, the birth weight and blood volume of the full-term, normal birth weight infant will triple.[77] In the postnatal period preterm infants are risk of ID because of rapid growth rates, uncompensated iron losses from phlebotomy and low nascent iron stores.[30] Other periods of high iron requirements include the growth spurt during adolescence and pregnancy. Iron requirements during adolescent pregnancies are particularly high because girls in their teens may not have reached their full growth.[11]

Iron deficiency can also result from increased iron losses. In young women of child-bearing age menstrual blood loss (both "heaviness" and duration) can be a major determinant of iron status.[78] In hospitalized infants the most common cause of blood loss is frequent blood sampling.[9] Since the majority of fetal iron is present as Hb, any blood loss that lowers neonatal Hb concentration (including twin-to-twin transfusion and fetal-maternal hemorrhage, perinatal hemorrhage, considerable blood draws after birth) will have an impact on iron balance.[9] Gastrointestinal bleeding is uncommon in otherwise healthy infants, but when it does occur, it is usually due to food allergies, repeated episodes of acute diarrhea or *Helicobacter pylori* infections.[61] In tropical areas, gastrointestinal bleeding may be due to infestation with parasites such as hookworms, whipworms and round worms or hemoglobinuria may cause blood loss due to malaria.[79] Occult gastrointestinal bleeding among formula-fed infants because of cow's milk protein sensitization or among healthy infants owing to feeding with fresh cow's milk may result in negative iron balance in the first year of life.[9] The precise cause of blood loss not well understood but is likely to be an allergic-type reaction between a protein in cow's milk and enterocytes of GI tract.[14] Increased fecal blood loss in response to cow's milk is more common among infants who were breastfed early in life than in infants who were never breastfed.[9] Earlier exposure to cow's milk proteins may sensitize infants who are predisposed to allergy.[80]

Consequences of Iron Deficiency

Clinical sequelae of iron deficiency include impaired cognitive performance, anemia, poor immune function and decreased work performance (Table 9-3).[81] In children, numerous studies have consistently

demonstrated that even moderate anemia (hemoglobin < 100 g/L) is associated with depressed mental and motor development in children.[82–84] Although the mechanism whereby iron influences development is not fully understood, older research identified the role of iron in central nervous system neurotransmitter function, and more recent work has shown that brain iron is essential for normal myelination.[85–87]

TABLE 9-3 Functional Consequences of Iron Deficiency

Pregnancy	Infants and Young Children
Increased risk of anemia and maternal morbidity	Motor and cognitive developmental delays in infancy
Increased risk of prematurity and lower birth weight	Effects on emotional maturation
Higher infant mortality	Poorer academic achievement in school-age children who were iron deficient in early childhood
	Increased risk of severe morbidity from malaria in children
	Increased prevalence and duration of upper respiratory tract infections in children

It used to be presumed that iron deficiency anemia had few deleterious effects unless severe enough to compromise cardiovascular function.[88] However, over the last two decades, the negative impact of iron-deficiency anemia (IDA) in infancy on psychomotor development has been well documented in more than a dozen studies.[89] Longitudinal studies have indicated that children who were anemic in early childhood continue to have poor cognitive and motor development and depressed school achievement into middle childhood.[83] Studies in human infants with iron deficiency anemia confer findings from rodent models which document poorer performance on global assessments of cognitive, motor, and social-emotional behavior[90] and alterations in regulatory processes such as the sleep-wake cycle.[91] Iron deficiency in infancy has been associated with short- and long-term alterations related to major dopamine pathways (mesocortical, mesolimbic, nigrostriatal, tuberohypophyseal).[92] For anemic children less than 2 years of age, there is no good evidence from randomized controlled trials that iron treatment helps their cognitive and motor development.[82] For children above 2 years of age, short-term

treatment is associated with improvement in cognition but not in school achievement.

The study of cognitive function and iron status has been extended to older children and adolescents. In a randomized controlled trial, adolescent girls with depleted iron stores, who received iron supplements improved their scores on a test of memory and verbal learning compared with the placebo-treated group.[93] Another large study in preadolescents and adolescents described an association between iron status and standardized mathematics scores.[94] Those with iron deficiency anemia or iron deficiency without anemia were 2.3 and 2.4 times more likely to have low mathematics scores than those with no iron deficiency. The authors of this report suggested that screening for iron deficiency may be warranted for all children and adolescents.

During pregnancy, the negative implications of anemia caused by iron deficiency alone or in combination with other factors, e.g., folate deficiency, vitamin A deficiency, and malaria, include increased risk of preterm delivery and infant low birth weight.[95–98] There is some evidence to suggest an association between a higher risk of maternal mortality and severe anemia.[68,99] However, data were predominantly retrospective observations of maternal hemoglobin concentrations at, or close to, delivery and subsequent mortality.[68] Furthermore, the iron deficiency component of this relationship is unknown.[79] Mechanisms by which iron deficiency anemia could increase maternal mortality need to be elucidated.

Increased risk of maternal mortality has also been shown in women with severe anemia.[99] Children born to adolescent mothers are more likely to be of poor health and have a higher likelihood of infant mortality.[99] Concern for the health of young mothers and their infants has led to suggestions that adolescence may be an ideal time to optimize iron status and prevent iron deficiency during pregnancy.[100]

Rapid expansion of maternal blood volume and red cell mass during pregnancy and placental and fetal growth leave many women, even in developed countries, with low iron stores and tissue iron deficiency at parturition.[101] The consequences of poor maternal iron status postpartum are increasingly being recognized as a non-benign condition, shown to be related to maternal fatigue, depression and ability to care and nurture offspring.[102–104]

Included in an exciting surge of research in the last decade on iron's role during brain development has been recent work in the rodent model that shows that brain iron is essential for normal myelination. Regional

differences in brain iron concentration and cytochrome *c* oxidase (CytOx) activity were measured in young rats born to dams on iron-deficient or iron-sufficient diets throughout gestation and early lactation.[105] Markedly reduced neuronal metabolism in all regions of the hippocampus was found, demonstrating the vulnerability of the developing hippocampus.[105] Studies not only show that iron deficiency during gestation and lactation in the rat results in reduced brain iron, but also that the degree varies greatly by brain region.[106] New research also shows altered gene and protein profiles.[106]

Prevention

In light of accumulating evidence regarding the adverse effects of iron deficiency anemia on maternal and infant outcomes, prevention rather than treatment is highly recommended. If implemented successfully, there are three interventions that are likely to prevent anemia. These include (a) ***dietary diversification*** to foods with more bioavailable iron; (b) ***fortification*** of foods targeted to full-term infants and children; and (c) ***iron supplementation***.

Diet

For infants 0–6 months, it is assumed that iron provided by human milk is adequate to meet the iron needs of exclusively breast fed infants born at normal birth weight from mothers with good prenatal iron status.[107,108] Milk iron composition is unaffected by maternal iron intake or status.[109,110] While human milk iron content is low (0.2–0.4 mg/L) it is highly bioavailable (45–100 per cent) compared to cow's milk-based infant formula (10 per cent).[9,14] Since the average iron concentration in human milk is 0.35 mg/L, the adequate intake (AI) level is set at 0.27 mg/day (0.78 L/day × 0.35 mg/L).[14] However, even after taking a high estimate of iron absorption from human milk (50%) into consideration and assuming an iron intake of 0.075 mg/kg/day from human milk, it is estimated that term infants will absorb less than 0.04 mg/kg/day.[110] Since this iron intake is less than the amount required for growth, storage iron will utilized until dietary iron intake increases. After 6 months of age, the introduction of heme-iron containing foods or iron-fortified foods may support normal iron status; therefore, it is recommended that iron-fortified formulas and iron-containing foods be introduced once exclusive breast-feeding has stopped. The iron content of preterm human milk is approximately 0.5 mg/L.[8] Because preterm infants are at high risk for iron

deficiency because of a lack of iron accretion during the last trimester of gestation, preterm infants fed exclusively human milk are recommended to receive an iron supplement at a dose of 2–3 mg/kg per day from 1 to 12 months.[107,112]

In contrast to human milk, cow's milk has a low concentration of iron (around 0.4 mg/L) and low bioavailability because of its high calcium and phosphorus and low ascorbic acid content.[9] Cow's milk and unfortified cow's milk formulas cannot supply the infant with sufficient amounts of iron to maintain an optimal iron balance during the first 6 months of life.[9] Introduction of cow's milk is not recommended until 9–12 months of age according to the Canadian Pediatrics Society and the American Academy of Pediatrics.[107,113]

The WHO (2004) recommends introducing iron-rich complementary foods at 6 months of age to meet iron needs.[108] For infants over the age of 6 months, dietary diversification is recommended as an intervention strategy for preventing iron deficiency. Dietary diversification involves promotion of a diet with a wider variety of natural iron-containing foods, especially red meat, poultry, fish and food rich in vitamin C. The selection of weaning foods determines in large part whether an infant will be at risk of developing iron deficiency and associated anemia.[114] Typical home-made complementary foods used in developing countries are poor sources of bioavailable iron and thus, are inadequate to meet infants' high iron requirements for rapid growth and blood volume expansion.[108]

The US/Canadian recommended dietary allowance for iron (mg/day) is 11 (6–12 months), 7 (1–3 years) and 10 (4–8 years) (Table 9-4). Two major factors should be taken into consideration when determining the iron requirements of children. The first is the iron need of the individual and the second is the bioavailability of iron in the diet. Estimates of dietary iron requirements for infants over the age of 6 months have been modeled using the factorial components of absorbed iron requirements. The four major components of iron need have been assessed for infants aged 7–12 months and children aged 1–8 years: obligatory fecal, urinary, and dermal losses; the increase in hemoglobin mass; the increase in tissue iron, and the increase in storage iron. Included in the factorial model are the type of iron, heme or non-heme, and other dietary factors that may influence the iron bioavailability in the diet. The diets of infants tend to be high in cereals and vegetables with little meat, and are therefore low in heme iron. The iron in high cereal diets is considered to have a medium bioavailability of 10%.[74]

TABLE 9-4 Recommended Dietary Allowance (RDA) of Iron for Both Sexes from Birth to 18 Years[14]

Age	RDA for total iron intake, mg/day
0–6 months	0.27
6–12 months	11
1–3 years	7
4–8 years	10
9–13 years	8
14–18 years	11 for boys; 15 for girls
Pregnancy	27
Breastfeeding mothers under the age of 19 years	10

The "estimated adequate requirement" (EAR) for children and adolescents ages 9 through 18 years has been determined by factorial modeling of the median components of iron requirements.[14] The physiological processes associated with puberty that have a major impact on iron requirements are the growth spurt in both sexes, menarche in girls, and the major increase in hemoglobin concentrations in boys. Total iron requirements for adolescent boys are computed from increased iron requirements required for the expansion of the total blood volume and the increase in the lean body mass. The increase in mean total iron requirements may exceed 1.8 mg/day, or more than double those requirements of preadolescent males.[13] Iron requirements for adolescent girls include the amount of iron lost during menses in addition to the growth requirements. In female adolescents, the recommended dietary allowance (RDA) increases from 8 mg Fe/day for those 9–13 years of age to 15 mg Fe/day for those 14–18 years of age (Table 9-4).

Fortification

There are three types of fortification strategies: mass fortification; open market fortification; and targeted fortification. Mass fortification refers to the addition of micronutrients to foods consumed by all or most of the population. Mass fortification is regulated by governments. Wheat flour has been fortified in Canada, the United Kingdom and the United States since the 1940s. National fortification programs were also in place in

Denmark until 1987 and in Sweden until 1994.[115] Wheat is the cereal flour that is fortified most often, but several countries—particularly in Central and South America—also have programs for iron fortification of maize flour.[115] In developing countries mass fortification programs of fish sauce (in Thailand and Vietnam), sugar (in Guatemala), curry powder (in South Africa), and soy sauce (in China) have resulted in improved iron status of their populations.[115]

Open market fortification refers to the initiative of a food manufacturer to fortify one or more products with the aim of improving both public health and product profitability. Open market fortification of several processed foods, particularly breakfast cereals, is widely practiced, primarily in developed countries. Fortification of staple foods is likely to increase iron intake for those who eat the most (i.e., adult males). The level of fortification is purposely kept low to avoid iron overload in populations most likely to eat the most fortified foods (adult males). However, infants and children are not likely to benefit significantly from this strategy because they have a limited capacity to eat large quantities of food and the concentration of iron in fortified staples is purposely low.

Targeted fortification (e.g. infant formula and infant cereals) describes the specifically directed fortification of foods consumed by high-risk groups. Targeted fortification provides an excellent source of iron to those who need it the most. Infant cereals, for example, typically contain 7.1 mg of iron per 15-g serving, and breakfast cereals for children contain over 4 mg of iron per 30-g serving.[21] A single 30-g serving of these “ready-to-eat” cereals provides 60% of the RDA for children aged between 1 and 3 years, 45% of the Recommended Daily Allowance (RDA) for children aged 4–8 years and 75% for boys and girls aged 9–13 years. For adolescents, especially those who are restricting their total food intake or who are vegetarians, the use of iron-fortified breakfast cereals that typically contain 4–8 mg/serving is an excellent way to meet their iron requirements and to prevent anemia. In fact, ready-to-eat cereals are among the top contributors of iron, folate, vitamin A and C, and zinc intakes.[116]

The American Academy of Pediatrics (AAP) recommends that infants who are partially breastfed (receive more than half of their daily feedings as human milk) should also receive an iron-fortified formula or 1 mg/kg/day of supplemental iron beginning at 4 months of age.[107] For term formula fed infants, the AAP recommends a standard infant formula with an iron content of 10–12 mg/L for the first 12 months of life,[107] which will

provide approximately 2 mg/kg/day if the infant's energy intake from formula is adequate. Most infants, including VLBW infants should be offered formulas with iron at the time formula is introduced.

Term infants who are exclusively breast-fed do not need supplemental iron until they are 6 months of age. If solid foods are introduced earlier, they should contain an adequate amount of iron. After 6 months of age, breast-fed infants should receive extra iron in the form of iron-fortified infant cereals and other iron-rich foods. These infants should be offered an iron-fortified infant formula after they have been weaned from breast milk. Term infants who are not breast-fed should be given an iron-fortified infant formula from birth. Studies are under way to determine the optimal iron content of these formulas: and further studies are encouraged.

For premature infants, an iron supplement should be started by at least 1 month of age and continued until the first birthday.[107] Iron-fortified formula for bottle-fed infants or commercial iron drops for breast-fed infants are the recommended source of supplemental iron. Current preterm formulae available in USA fortified with 14.6 mg/L of iron provide 2.2 mg/kg per day if consumed at 150 mL/kg per day.[107] Despite the use of iron-containing formula, some preterm infants may require an additional iron supplement, although there is currently insufficient evidence to make a general recommendation in terms of the dose, route and commencement of supplementation to prevent ID in preterm infants.[107]

Iron Supplements

Another approach for preventing or treating iron deficiency is through supplementation of individuals or communities at risk. This approach would be implemented for the treatment of individuals with anemia or in situations where at-risk communities of infants and young children do not have ready access to targeted iron-fortified foods. Global guidelines for iron supplementation have been published by the Nutritional anemia Consultative Group/World Health Organization/UNICEF.[117] For children 6 to 24 months of age 12.5 mg/day of iron is recommended, in tandem with 50 μg/day of folic acid until 12 months of age. Recommendations for children and adolescents are as follows: 20–30 mg/day for children 2 to 5 years old; 30–60 mg/day for children 6 to 11 years old; 60 mg/day for adolescents and adults (plus 400 μg/day of folic acid for child-bearing aged females); 60 mg/day in addition to 400 μg/day of folic acid for pregnant women, continuing for 3 months of lactation where anemia prevalence is high (>40%).

The most common form of iron in iron supplements is ferrous sulfate;

however, fumarate and gluconate are also used. Infants are most commonly supplemented with a liquid formulation. When a soluble form of iron (such as ferrous sulfate or fumarate) is ingested in the proper dose, this intervention is efficacious. However, adherence to long-term ingestion of oral iron drops is often poor because of the unpleasant metallic taste of drops; drops can stain a baby's teeth unless wiped off immediately after use; and if the dose is high, the infant may demonstrate abdominal discomfort.

In many women, it is uncertain whether diet alone can provide the additional iron needs of pregnancy.[118] The need for iron supplementation during pregnancy is actively debated.[119–121] Most studies in pregnant women supplemented with iron show a change in total blood volume of <45%, with an increase in plasma volume of <50% and an increase in red blood cell mass of <35%.[17] While controlled trials of iron supplementation during pregnancy have consistently demonstrated positive effects on maternal iron status at delivery; the impact of iron supplementation in reducing factors that are associated with maternal anemia, that is, increased risk of preterm delivery and infant low birth weight is less clear.[95] While micronutrient deficiencies during pregnancy are thought to contribute to neonatal mortality; few trials have sufficient data or sample sizes to report on neonatal outcomes. However, two large double-blinded, placebo-controlled randomized trials conducted in Nepal have found a significant impact of early iron supplementation during pregnancy on low birth weight (LBW), as defined as < 2500 g.[122–124]

Currently, iron supplements are almost universally recommended for pregnant women. In developed countries, pregnant women are recommended to take 27 mg of iron daily.[14] For iron supplementation programs where anemia prevalence is high, the International Nutritional anemia Consultative Group (INACG) has recently changed its recommendation from 120 to 60 mg/day. However, if duration of iron supplementation during pregnancy is short, or if anemia is present, 120 mg/day is still recommended. The administration of iron supplements weekly instead of daily in humans (in which gut mucosal turnover occurs every 5–6 days) is actively being investigated as a viable means of controlling iron deficiency in populations, including pregnant women.[18]

When considering iron supplements, attention should be paid to possible interactions between iron and nutrients. Iron deficiency impairs vitamin A and iodine metabolism and may hinder the effectiveness of interventions aimed at improving these deficiencies.[125] A direct

relationship has been found between hemoglobin and serum retinol concentrations.[126] Dietary deficiencies of vitamin A and iron frequently co-exist in developing countries and vitamin A deficiency appears to affect iron transport and red blood cell production.[126] Effects have not been demonstrated in vitamin A sufficient subjects.[126] Studies in anemic children and pregnant women in regions with endemic vitamin A deficiency have shown improved iron status post vitamin A supplementation.[61] Due to the anti-infective properties of vitamin A, it has been suggested that the benefits of vitamin A on iron status may be a result of reduced level of infection.[61] Some concern has been raised regarding the potential adverse effects of food iron supplements on zinc nutrition. While reduced absorption of one of the metals may occur when solutions of inorganic iron and zinc are administered, there appears to be little support for a significant effect when the metals are given with food in doses that are considered optimal for fortification.[126]

The interaction between iron and infection has been a continuing debate, largely due to associations between iron treatment and exacerbations of infection, in particular malaria.[127] A review of 13 randomized controlled trials determined that the known benefits of iron supplementation likely outweighs the risk of adverse effects in regions where malaria is endemic.[117] However, the results of two large-scale randomized controlled trials designed to evaluate the impact of iron and zinc supplementation on mortality and morbidity in young children found that iron supplementation may be associated with adverse effects in areas where malaria transmission is high.[128,129] Following these two trials, recommendations were made to target supplementation of iron and folic acid to children who are anemic or iron deficient and to provide children with concurrent protection from malaria and other infectious diseases.[130,131] To date few studies of oral iron supplementation have shown deleterious effects in non-malaria or low transmission malaria regions.[132,134,135] A recent study by Soofie et al. reported increased rates of bloody diarrhea and signs of respiratory infections in a malnourished population of children receiving multimicronutrient supplements with iron.[132] In a malaria endemic region, the use of a similar micronutrient formulation reduced overall incidence of malaria and did not impact diarrhea or respiratory infections.[133]

SPECIAL TOPIC—IRON DEFICIENCY AND

ANEMIA IN INFANTS AND. YOUNG CHILDREN IN. MALARIA-ENDEMIC AREAS

The World Health Organization (WHO) coordinated and supported two large trials in Zanzibar, Tanzania, and in Nepal to evaluate the impact of zinc and/or iron–folic acid supplementation on the mortality and severe morbidity of preschool children.[128,129] In Zanzibar, an area of stable, perennial, and intense transmission of *Plasmodium falciparum* malaria, routine iron–folic acid supplements given with or without zinc resulted in an increased rate of severe adverse events in children (morbidity and mortality). In Nepal, the trial showed no difference in mortality or the incidence of the common infections. Results from the study in Zanzibar, Tanzania raised the issue of the safety of administering additional iron to infants and young children in areas of malaria endemicity.[134]

After the results of the trials were released, the WHO and UNICEF released a joint statement recommending that in malaria endemic areas, rather than using universal supplementation strategies, iron supplements should be targeted only to children who are anemic and at risk of iron deficiency.[135] This led to much debate among the nutrition research community on how to move forward, and country policy and program decision makers were uncertain as to how to address young child iron deficiency and anemia in their countries.[136] Since the release of the WHO/UNICEF recommendation, a systematic review has been published supporting the use of iron supplements in malaria endemic regions, when regular malaria surveillance and treatment services are also provided.[137] Thus, the WHO updated its recommendation and currently advises that in malaria-endemic areas, the provision of iron should be implemented in conjunction with measures to prevent, diagnose, and treat malaria.[138]

SECTION 9: WHAT ABOUT TOO *MUCH* IRON IN THE BODY?

There is no evidence that large iron stores provide a benefit to the individual. Although there is concern that a high daily intake of iron may cause decreased absorption of competing minerals; pro-oxidant effects; and aggravating symptoms in diseases in which iron absorption is increased,[12] there have no clinical studies that have demonstrated negative pro-oxidant effects of iron in healthy term infants. The decision to select 60 mg/day as The Lowest Observed Adverse Effect Level (LOAEL) was

based on a study that found a significantly increased risk of constipation, higher rates of gastric pain and diarrhea and more total gastrointestinal symptoms (nausea, gastric pain, constipation, and diarrhea) compared to placebo.[139]

Iron toxicity is related to the generation of free radicals. Normally enzymes such as superoxide dismutase, glutathione peroxidase and catalase metabolize and neutralize free radicals. Free iron has the ability to generate oxidative radicals that damage lipids, proteins and DNA. Normal and pathological cellular processes produce superoxide (O_2^-) and hydrogen peroxide (H_2O_2) byproducts. The redox capabilities of iron underlie its toxicity. The one-electron reduction of dioxygen by Fe^{2+} results in superoxide formation, which in turn, leads to the well-known Haber-Fenton sequence generating hydroxyl radical OH°(2):

$$Fe^{2+} + O_2 \rightarrow Fe^{3+} + O_2^{-\cdot}$$
$$2O_2^{-\cdot} + 2H+ \rightarrow H_2O_2 + O_2$$
$$Fe^{2+} + H_2O \rightarrow OH\cdot + OH^- + Fe^{3+}$$

The hydroxyl radical (HO), perhaps the most powerful oxidant encountered in biological systems, can inactivate enzymes, cause DNA strand breaks, depolymerize polysaccharides, and initiate chain-propagating lipid perioxidation.[140]

The body's innate mechanisms for preventing tissue damage from free radical formation are to keep iron chelated during most absorption and distribution phases, keep iron in a trivalent redox state and to store iron as ferritin.[5] Tissue iron loading occurs in two characteristic patterns. One type of tissue iron loading occurs when the amount of available plasma iron exceeds the iron-binding capacity of transferrin, thus requiring parenchymal cells of the liver to avidly take up iron. As iron overload progresses, iron is accumulated in cardiac myocytes, pancreatic acinar cells and other cells of the body.[36] A different pattern of tissue iron loading occurs when iron overload results from increased catabolism of erythrocytes, such as is often the case in patients with repeat blood transfusions. Iron first accumulates in reticuloendothelial macrophages and only later deposits in parenchymal cells. Parenchymal iron loading leads to tissue damage and fibrosis. The reticuloendothelial system is generally a safe sink for iron because reticuloendothelial macrophage sequester iron and attenuate its activity.

Iron Poisoning

Well-described cases of iron poisoning first appeared in publication in the 1940s and 1950s.[141] Classic animal experiments were conducted in the 1950s and 1960s and the chelator deferoxamine, used as an antidote for iron poisoning, was introduced in the 1960s. Almost all deaths from iron poisonings are in children under 3 years of age, resulting from ingestion of adult iron preparations (30–40 pills). However, deaths after exposure to as few as 5 pills has been reported.[142] Despite a vast number of exposures to iron-containing products, deaths rarely occur.[141] Hospitalization due to iron poisoning is an infrequent occurrence; the hospitalization rate among children aged 0 to 4 years has been estimated at 8.7 per 100,000 children.[143–145]

It is currently unknown how the highly regulated process of iron absorption is affected during an iron overdose.[146] Rapid absorption occurs through intact intestinal mucosa. In volunteer studies, a peak serum iron is observed within several hours of ingestion of supratherapeutic oral doses.[141] The clinical manifestations of iron poisoning occur in progressive stages (Table 9-5). Clinical management of iron poisoning includes clinical evaluation, fluid resuscitation, laboratory evaluation, abdominal imaging, chelation therapy, and gastrointestinal decontamination.[141]

Genetic Disorders of Iron Overload

Hemochromatosis refers to the accumulation of iron in tissue. Since the late 19th century hemochromatosis has been recognized as a distinct clinical syndrome.[147] In the 1930s a genetic predisposition for the disease was discovered; a single gene defect was found that leads to an inborn error of iron metabolism.[36] In 1976, a French physician named Marcel Simon and colleagues found that the genetic predisposition to hemochromatosis was closely linked to the human major histocompatibility complex.[3] This finding led to the positional cloning of the hemochromatosis gene 20 years later.[3] Since the discovery of the HFE gene, hemochromatosis conditions have been classified as primary (genetic) hemochromatosis and secondary.[19]

TABLE 9-5 Stages of Acute Iron Toxicity[141]

Stage 1: Local gastrointestinal (GI)	Usually occurs within several hours

effects	
	Nausea, vomiting, diarrhea
	GI bleeding may lead to hematemesis or blood diarrhea
Stage II: Quiescent phase	Resolution of GI symptoms
	Rarely seen today because children presenting with Stage I would receive fluid resuscitation and chelation therapy
Stage III: Systemic toxicity	Hypovolemic shock and acidosis
	Hypoperfusion- pallor, cold extremities, tachycardia and tachypnea
	Hypotension may be a late finding
	Myocardial dysfunction may be seen in severe iron poisoning
Stage IV: Recovery	Begins after initiation of fluid and antidotal therapy
Stage V: Gastrointestinal obstruction	Gastric and pyloric strictures (frequently require surgical therapy)
	May occur 2–8 weeks after initial injury

Hereditary Hemochromatosis (HH) is an autosomal recessive trait most commonly seen in people of Northern European descent.[148] Several mutations of the HFE gene have been described. Two main point mutations are either homozygotes for a gene designated C282Y (tyrosine, Y, substitution for a cysteine, C, mutation at position 282) or heterozygotes with C282Y/H63D (aspartic acid for histidine).[36]

Compared to unaffected individuals, patients with HH absorb two to three times more dietary iron.[36] The consequences of HH are severe; iron deposits first in hepatocytes, then in other parenchymal cells including heart, pancreas, and adrenals.[149] Excess iron in affected tissues catalyzes oxidative damage, resulting in cirrhosis, hepatoma, cardiomyopathy, diabetes, hypogonadism, and arthritis.[149] Because iron accumulation occurs gradually, the effects of the disease largely remain undetected until middle age or later.[36] In middle age, patients often present with diabetes from iron damage to islet cells and skin pigmentation from increased corticotrophin secretion (ATCH) secondary to adrenal insufficiency. Liver and gonadal dysfunction often accompany these features. One of the dilemmas of HH is that only half of patients with genetic mutations for HH show evidence of iron overload.[19] Population screening for hereditary hemochromatosis has not been supported because the penetrance is very

low.[147] Previous diagnosis depended on analysis of iron by liver biopsy, an expensive procedure not without risk; however, genetic testing has recently become available.[149] The most efficient approach to diagnose patients suspected to have the disease is to measure the serum transferrin saturation and ferritin levels.[147]

Not all patients with familial hemochromatosis disorders have mutations in the HFE gene. A subgroup of patients with non-HFE hemochromatosis that are genetically predisposed to severe iron loading during the first 3 decades of life are those with juvenile hemochromatosis (Table 9-6). These patients develop iron overload is the same tissue patterns as patients with classical HFE-associated hemochromatosis but at an accelerated rate.[3] Another disorder not associated with mutations in *HFE* is neonatal hemochromatosis (Table 9-6). Characterized by liver failure in newborn infants, iron overload occurs in the myocardium and in pancreatic acinar cells.[3] It is not clear whether the disease occurs as a result of iron loading or some other insult to developing hepatocytes. While medical therapies have not proven to be effective, the lives of some patients have been prolonged after liver transplantation.[3]

There is a distinct iron overload disorder in sub-Saharan African. Previously termed “Bantu siderosis,” African overload affects up to 10 per cent of some rural populations.[36] African iron overload results from a predisposition to iron loading that is exacerbated by excessive intakes of dietary iron. Iron overload was observed in Africans who drank a traditional beer brewed in non-galvanized steel drums. However, since serious iron overload does not develop in all beer drinkers and not all patients with iron overload consume excessive amounts of beer, it is postulated that a currently unidentified gene may confer susceptibility to the disorder. African overload is not due to mutations in the *HFE* gene and is not linked to the HLA locus.[36] Moreover, the pattern of iron disposition differs from that seen in HH. In African iron overload, marked iron loading occurs in hepatocytes and in hepatic Kuffer cells.

TABLE 9-6 Diseases of Iron Metabolism

Disorder	Etiology	Characterization
Neonatal hemochromatosis	Uncertain if fibrosis is from iron overload or whether fibrosis leads to iron accumulation in	Usually diagnosed at autopsy. Hepatic iron staining with variable total iron stores, liver fibrosis and bile duct proliferation. Iron deposits also found in heart, kidney, pancreas and mucosal

	remaining hepatocytes and shunting of iron to other tissues	salivary glands. The reticuloendothelial system relatively spared from iron overload. At birth liver already heavily fibrotic
Juvenille hemochromatosis	Autosomal recessive. Gene has been mapped to chromosome I; however, exact location of gene and its functional gene product are still being investigated	Phenotypically similar to HH. Onset is earlier than HH. Patients have hypgonadism, joint pain and unexplained stomach pain and die of cardiac dysfunction
African iron overload (also termed Bantu Siderosis)	Hypothesized to be related to increased dietary intake from using iron pots to dominant inheritance of an uncharacterized defect or to increased beer from non-galvanized iron brew pots	Liver macrohages and hepatocytes show increase iron loading, suggesting a defect in iron recirculation
Sideroblastic anemias	Involves first step of heme synthesis (catabolized by erythroid aminolevulinic acid-e-ALAS) and the last step of loading iron into the protoporphyrin ring	Accumulation of mitochrondrial iron, along with anemia
X-linked sideroblastic anemia	Missense mutation of the gene on the X chromosome for e-ALAS causes iron to accumulate in the mitochrondria of developing red blood cells	Prevents red blood cells from making sufficient hemoglobin. Signs and symptoms usually begin during the first three decades of life. Characteristic features include pale skin, fatigue, dizziness, and an enlarged spleen and liver. Heart disease, liver damage, and kidney failure are severe medical problems that can result from these increased levels of iron
X-linked sideroblastic anemia with ataxia	Mutation in the ATP-binding cassette 7 gene (ABC7) on the X chromosome	Distinct form of X-linked iron overload. Associated with onset of nonprogressive ataxia by early childhood. Anemia is microcytic and hypochromic
Pearson’s	Maternal	Vacuolization of marrow precursors and

syndrome	inheritance pointed to mutation in mitochrondrial DNA, with chromoral deletions commonly described	exocrine pancreatic dysfunction. Anemia is diagnosed before one year of age with macrocytic red cells and low neutrophil and platelet counts. Patients are short and have malabsorption
Friedreich ataxia	Autosomal recessive disorder	Degeneration of the central and peripheral nervous system, cardiomyopathy and diabetes. Iron accumulation has been detected in heart myocytes. Deficiency in protein fraxatin also observed. Reduced levels of fraxatin may lead to mitochrondrial respiratory failure and cellular damage and death
Hallervorden–Spatz syndrome	Family studies reveal a linkage to chromosome 20	Iron accumulation is limited to central nervous system, especially the basal ganglia. Clinical signs include dystonia, rigidity, and dementia
Aceruloplasminemia	Several mutations in the ceruloplasmin gene on the short arm of chromosome 3 have been discovered in affected families	Iron accumulation is observed in the spleen, heart, kidney, thyroid, and retina

CLINICAL CASE STUDY

Transfusion is a frequently employed therapy in sickle-cell disease (SCD). The major and unavoidable complication of transfusions in SCD is iron overload. Therefore, knowledge of iron toxicity in SCD is of paramount importance. The mechanism of end organ damage in iron overload is saturation of transferrin by excess circulating iron, which enters tissues and results in formation of reaction oxygen species (ROS).* Excess iron tends to deposit in the hepatic parenchyma, in endocrine organs, and in cardiac myocytes, causing end organ damage by ROS-mediated lipid peroxidation. Patients with SCD suffer from recurrent infections and ongoing endothelial damage by reperfusion injury that results in a chronic inflammatory-like state. The gold standard for assessing liver iron stores in the absence of cirrhosis is the hepatic iron content, determined by liver biopsy and quantitation with atomic absorption spectrophotometry. Non-invasive methods for assessing iron stores include blood tests (ferritin and iron saturation) and imaging techniques. Chelation therapy is routinely employed to prevent and treat iron overload in chronically transfused SCD patients.

Further discussion points:

Why does the role of hepcidin in the pathophysiology of iron overload in SCD remains controversial?

How do chelators work as a pharmacological therapy for treating iron overload?

What chelating agents are available and commonly used?

* Raghupathy R, Manwani D, Little JA. Iron overload in sickle cell disease. *Adv Hematol*. 010;2010:272940. doi:10.1155/2010/272940.

The aim of treatment of iron storage diseases is to remove excess iron from the body. In patients with one of the forms of primary hemochromatosis (i.e., hereditary hemochromatosis) removal of excess iron is best achieved by phlebotomy.[147] Treatment of secondary hemochromatosis consists of administration of iron chelating agents.[147]

SECTION 10: HOW DO WE ASSESS IRON STATUS?

Biomarkers for iron status were determined by physiologists who studied iron metabolism in animal models and humans. Thus, biomarkers were selected because of their specificity for identifying functional aspects of iron storage, transport and use and were focused on red blood cell production and turnover because the circulating red blood cells constitute the largest and most accessible iron containing compartment in the body.[150]

Among the wide variety of laboratory methods that are available to assess iron status (i.e., hematocrit, hemoglobin, mean cell volume, erythrocyte mean index, free erythrocyte protoporphyrin, serum iron, total iron-binding capacity, serum transferrin, transferrin saturation, serum ferritin, and serum transferrin receptor) there is no one single test that is ideal. Diminished stainable iron in a bone marrow aspirate is generally accepted to be the reference standard for iron status.[151] However, the method is invasive, costly and subject to varying interpretation.[152]

Rather than using a single measurement, a valid assessment of iron status is best characterized by multiple indices.[153] Presently, there is no consensus on the best definition of iron deficiency using multiple measures. In the United States, two combinations of multiple indices were used to assess low iron status and anemia in the National Health and Nutrition Examination Surveys II and III.[47,154] One included serum

ferritin, transferrin saturation and FEP. The other method involved MCV, transferrin saturation and FEP. Selecting the most appropriate combination of iron status indicators depends on the study objectives and the health of the study population.[151,155] Features of the more commonly accepted diagnostic indices are summarized in Tables 9-7 and 9-8. For a detailed review see Gibson.[156]

Hemoglobin

Hemoglobin (Hb) measures the presence of anemia. While it is the most widely used screening tool for iron deficiency, hemoglobin determination has serious limitations when relied upon as the only laboratory measurement because of its low specificity and sensitivity.[55] When used alone hemoglobin concentration does not distinguish between anemia due to iron deficiency and that due to infection (e.g., malaria, HIV), other micronutrient deficiencies (e.g., folate, vitamin B12, vitamin A) or other disease states (e.g., sickle cell disease, thalassemia). Furthermore, the wide range of the values in normal subjects means that Hb values overlap considerably between normal and iron deficient anemic individuals.[7] Affected by diurnal variations; Hb values in the evening tend to be lower than the values in the morning by up to 10 g/L.[156]

As with any other parameter, it is essential to interpret hemoglobin concentration according to age-specific and sex-specific reference standards. In infants, reference values for iron status variables, including hemoglobin have not been well developed and may not be accurate since they are based on extrapolation on data from older age groups.[157,158] The cut-off for anemia at sea level recommended by the WHO for infants 6 months to 5 years of age is 110 g/L. This cutoff concentration is based on studies in young children and has been extrapolated to cover infancy because of lack of more appropriate data.[156] However, several studies have indicated that this concentration may be too high.[12] Furthermore, there is growing opinion that the normative hemoglobin distribution curve is not the same throughout the world.[159]

Ferritin

Serum and erythrocyte ferritin concentrations reflect the level of storage iron.[11] Serum measurements are simpler and are the more common of the two tests.[152] Having been found to be directly proportional to the abundance of storage iron in normal subjects, serum ferritin concentration

is used as a sensitive and specific index for iron deficiency. When used in combination with the measurement of hemoglobin, serum ferritin distinguishes between the anemias of chronic disease and iron deficiency.

A low serum ferritin concentration is usually interpreted as depleted iron stores, but does not necessarily indicate systemic iron deficiency. Adequate iron for erythropoiesis can be maintained even in the presence of low stores, as occurs in frequent blood donors.[152] Once iron stores have been completely exhausted the concentration of serum ferritin no longer reflects the severity of iron deficiency. The absence of iron stores may not be associated with any adverse functional implications and should therefore only be regarded as a risk factor for the development of iron deficiency anemia.[7]

The most important limitation of ferritin is its acute phase response, which can mask an otherwise iron-depletion state in clinical conditions such as infection, inflammation, and malignancy.[152] To overcome this limitation, simultaneous measurement of a biomarker of the acute-phase response such as C-reactive protein and, where appropriate, screening for the presence of malaria parasites should be conducted.[7]

TABLE 9-7 Cutoff Points by Age Used to Identify Abnormal Values of Iron Status Measures

Iron Measure	Age (Years)	Abnormal Values
Hemoglobin (g/L)[a,b]	0.5–5	<110
	5–11	<115
	12–15 (females)	<119
	12–15 (males)	<126
	16–19 (females)	<120
	16–19 (males)	<136
	Pregnant women	<110
Hematocrit[a]	0.5–5	<0.33
	5–11	<0.34
	12–13	<0.36
	Pregnant women	<0.33
Mean cell volume (fL)[c]	1–3	<77
	3–5	<79
	6–11	<80

	11–14	<82
	15–74	<85
Serum ferritin (µg/L)[b]	1–25	<10
	6–16	<12
Transferrin saturation (%)[b]	1–2	<10
	3–5	<12
	6–11	<14
	12–15	<14
	≤16	<15
Erythrocyte protoporphrin (µmol/L RBCs)[b]	1–2	>1.42 (80 µg/dL RBCs)
	3–5	>1.24 (70 µg/dL RBCs)
	6–11	>1.24
	12–15	>1.24
	≥16	>1.24

[a] Ref. 163
[b] Ref. 154
[c] Ref. 164

The most commonly used cut-off value for serum ferritin indicating depleted iron stores is 12 µg/L, however the appropriate cut-off value that is indicative of depleted iron stores in neonates and infants, with their rapidly changing erythropoietic activity, is still under discussion.[152] Current WHO cut-offs, including those for serum ferritin, are based on populations with an unknown prevalence of infection. Research in Honduras and Sweden established cut-offs at 9 µg/L at 6 months of age and at 5 µg/L at 9 months of age to define depleted iron stores. Some authors use the cutoff of 10 µg/L for infants and young children, which is based on the distribution of serum ferritin concentrations in a large survey in the United States (NHANES III), in which the fifth percentile indicated abnormal values.[12]

TABLE 9-8 Biochemical Indices for Measuring Iron Status

Indicator	Measurement	Advantages and Disadvantages	Factors That Affect Measurement

Bone marrow examination	Performed to judge the amount of hemosiderin in the reticulum cells; absence of stainable reticular iron is characteristic of latent iron deficiency; quantity of visible hemosiderin after staining with potassium ferrocyanide correlates well with the concentration of non-heme iron	Advantages High specificity for storage iron assessment Disadvantages Invasive technique; subjective nature (result depends on the skill of the investigator); requires a sufficient amount of available marrow stroma and a meticulous staining technique. Invasive and often painful. Not appropriate for children	
Hemoglobin (Hb)	Hemoglobin is the protein molecule within red blood cells that carries oxygen; decreased concentration of Hb measures presence of anemia; most widely used test for IDA	Advantages Inexpensive; universally available Disadvantages Low sensitivity; low specificity	Diurnal variation, age, sex, race, pregnancy, high altitudes, other micronutrient deficiencies, parasitic infections, disease states
Hematocrit	Ratio of the volume of packed red blood cells to the total blood volume; indicator of the concentration of RBCs in the blood and impaired Hb formation; in presence of anemia decrease in red blood cells is observed	Advantages Inexpensive; requires a small sample volume; relatively fast analysis Disadvantages Sensitive to changes in plasma volume, as well as red cell volume; difficult to standardize because it is a calculated parameter	Measurement errors (poorly packed iron-deficient cells, improper mixing of blood because of intermittent blood flow, excessive anticoagulant in collection tube); elevated white blood cell counts; vitamin B12 deficiency, bleeding, kidney disease, cirrhosis of the liver, and malignancies; pregnancy
Mean cell volume (MCV)	Average volume of a red cell; calculated by	Advantages Inexpensive; fairly	Chronic inflammation, certain

	dividing hematocrit (volume fraction) by red blood cell count (102/L)	specific indicator of iron deficiency once thalassemia and the anemia of chronic disease have been excluded	hemoglobinopathies, lead poisoning, age, race
Mean cell hemoglobin concentration (MCHC)	The average amount of hemoglobin in the average red cell; determined by dividing hemoglobin (g/L) by hematocrit (volume fraction)	Advantages Widely available; well established Disadvantages Late indicator; low specificity	Age
Red cell distribution width (RDW)	A measurement of the variability of red cell size; calculated by multiplying the standard deviation of mean cell volume by 100 and then dividing the product by the mean cell volume	Advantages More sensitive than serum iron, transferrin saturation, or serum ferritin level Disadvantages Low specificity; worthwhile when used in combination with other parameters	Age, micronutrient deficiencies, hemoglobinopathies
Serum iron	In fasting state serum iron levels reflect transit iron going from reticulo-endothethial system to the bone marrow	Advantages Sensitive to the stage of mild iron deficiency Disadvantages Wide diurnal variations; low specificity	Diurnal variation, age, sex, inflammation, chronic neoplastic diseases, blood loss or donation, pregnancy, with chronic infections, shock, pyrexia, rheumatoid arthritis and malignancy
Total iron-binding concentration (TIBC)	Measures the extent to which iron-binding sites in the serum can be saturated; an indirect measurement of the amount of transferrin in the blood	Disadvantages Low specificity; to properly understand a value for TIBC, one also must know the serum iron, the percent transferrin saturation	Sex, age, oral contraceptives, infection, inflammation, chronic neoplastic diseases, liver disease
Transferrin saturation	Ratio of serum iron to iron-binding capacity; calculated by dividing serum iron (μmol/L) by	Advantages Most accurate indicator of iron supply to the bone	Diurnal variation; oral contraceptives, infection, inflammation,

	TIBC (μmol/L) and multiplying the product by 100 to obtain a percentage	marrow Disadvantages Wide diurnal variation and low specificity	chronic neoplastic diseases
Ferritin	Serum or plasma iron concentration reflects total amount of storage iron	Advantages Reliable and sensitive parameter for iron stores in healthy subjects; high specificity for iron deficiency Disadvantages Does not indicate the severity of the iron deficiency due to higher assay variability; acute phase reactant	Diurnal effect is minimal, age, sex, race, inflammatory diseases, infections, certain neoplastic diseases and liver disorders
Zinc protoporphyrin (ZnPP); Free erythrocyte protoporphyrin (FEP)	Zinc protoporphyrin is a product of disordered heme biosynthesis; about 90% of protoporphyrin in red blood cells is ZPP, while the remainder is present as FEP (not bound to zinc); testing method for ZPP measures both substances, and the results may be reported as either ZPP or FEP; elevated in the more advanced stage of iron deficient erythropoiesis	Advantages Stability within the individual; easily measured using a hematofluorometer (which only a couple of drops of blood and minimal technical experience) Disadvantages Skin contamination may lead to false elevations; both test and blood lead values are needed for full evaluation; fluorescent substances in plasma may interfere with hematofluorometer results	Raised levels of EP found in subjects with lead poisoning and acquired defects in hemoglobin synthesis
Serum transferrin receptor (sTfR)	Transferrin receptors are found on cell membranes and allow iron-bound transferrin to enter the cell; an increase in serum receptor levels is seen	Advantages Remains normal in patients with acute or chronic inflammation or liver disease; effective in	Hematologic disorders associated with expansion of erythroid marrow

	in patients with iron deficient erythropoiesis or iron deficiency anemia	distinguishing iron deficiency anemia from anemia of chronic disease Disadvantages Lack of standardization for assay and reference values. Expensive assay cost	

Transferrin Receptor

Soluble transferrin receptor (sTfR), a critical iron binding protein in iron metabolism, has only recently been added to the available screening tests for iron deficiency. Using sensitive immunological assays, Kohgo et al. were the first to detect small amounts of a transferrin receptor-like protein in human serum.[160] The tranferrin receptor (TfR) reflects the degree of deficiency in functional iron after iron stores have been depleted.[152] Inclusion of serum TfR in the determination of iron status is recommended because it can distinguish anemia of chronic disease from IDA in the presence of chronic infection or inflammation.[7] This noteworthy advantage contrasts with other biochemical tests for iron status, which are influenced by anemia of chronic disease. It should be emphasized that the sTfR cannot be used in isolation of other laboratory measurements to identify iron deficiency anemia (IDA) in anemic patients, because it is also elevated in hematologic disorders associated with expansion of the erythroid marrow.[161]

Certain conditions affecting erythropoiesis such as hematological disorders (e.g., sickle cell anemia, autoimmune hemolytic anemia, thalassemia) and nutritional deficiencies other than iron (e.g., folate, vitamin B12) may confound the diagnosis of iron deficiency since they have been demonstrated to raise sTfR concentration.[161] Hemolysis associated with malaria may elevate sTfR concentration and confuse the detection of iron deficiency, although the magnitude of this effect remains unknown.

A major laboratory issue that remains unsolved is the lack of proper standardization of the sTfR assay: there are several commercial assays available for sTfR, but no common reference material.[162] Over the past decade, a number of laboratories have developed different assays for measuring sTfR concentration and have explored its normal range. The

normal range for sTfR reported in the literature varies considerably.[152] To date, there are no standards for measuring sTfR. The ratio of serum transferrin receptor (sTfR) to serum ferritin (*R/F* ratio) has been shown to perform well in estimating body iron stores.[162] Further research is needed regarding age appropriate cut-offs and the standardization of laboratory techniques such as the use of anticoagulant, blood collection methods, time delay between blood collection and centrifugation, incubation time, and the extent to which samples have to be diluted.[162]

SUMMARY

The primary role of iron, an essential nutrient for living organisms, is tissue oxygenation. The amount of iron in the body is determined by the regulation of iron absorption in the proximal small intestine. The diet, body iron stores, marrow erythropoietic activity, blood hemoglobin concentration, blood oxygen content, and the presence of systemic inflammation influence the rate of iron absorption. The most prevalent iron disorder is iron deficiency. Negative iron balance can occur from consuming a diet low in bioavailable iron, during periods of rapid growth (i.e., infancy, adolescence, and pregnancy), from malabsorption secondary to pathological conditions associated with the proximal small bowel (e.g., gluten induced enteropathy) or excessive blood loss.

Iron deficiency has been identified as one of the ten leading risk factors for disease, disability and death in the world today and the leading cause of anemia during infancy, childhood and pregnancy. Consequences of iron deficiency include poor immune function and decreased work performance. In children, moderate anemia has been associated with depressed mental and motor development. Anemia during pregnancy has been associated with increased risk of preterm delivery and infant low birth weight. Preventive strategies for iron deficiency include dietary diversification of foods with more bioavailable iron; fortification (commercial or in the home) of foods targeted to full-term infants and children; and iron supplementation.

Iron deficiency remains the most prevalent nutritional disorder in the world, especially among children and pregnant women in developing countries. Further research is needed to elucidate the pathophysiological mechanisms of iron absorption and body iron homeostasis and to develop specific and sensitive measures for detecting iron deficiency in large-scale studies. In order to increase the effectiveness of public health prevention and treatment strategies further efforts need to be made towards

developing products which improve compliance, and towards improving health service delivery and partnerships between the public and private sectors.

Vitamins

10

Roland Kupka, DSc and Eduardo Villamor, MD, DrPH

INTRODUCTION

Since ancient times, dietary approaches have been used to prevent and treat ailments such as night blindness, pellagra, scurvy, and rickets. However, it was not until the end of the 19th century that specific dietary compounds other than carbohydrates, fats, and proteins began to be identified as responsible for vital functions. In 1912, the term "vitamin" was coined to denote "vital amines" deemed necessary to prevent dietary deficiency diseases. It was later shown that not all vitamins were amines, and the term, was subsequently shortened to "vitamin."

Vitamins are currently defined as organic compounds which are essential for health and are required in minute quantities in the diet because they cannot be synthesized in sufficient quantities by an organism. A total of 13 vitamins are required in humans: The fat-soluble vitamins A, D, E, and K, and the water-soluble vitamins thiamin, riboflavin, niacin, pyridoxine, folate, cobalamin, biotin, and pantothenic acid. Water-soluble vitamins are carried in the body's tissues, but are not easily stored and must therefore be consumed frequently. Fat-soluble vitamins are absorbed along with fats in the diet and in contrast to water-soluble vitamins can be stored in the body. Vitamin deficiencies are classified as "primary" when the diet provides insufficient amounts or "secondary" when absorption or utilization of the vitamin is impaired.

From its birth a century ago, the field of vitamin research remains active today. While the initial research focused on the diseases of deficiency, current research now examines a much broader role of vitamins in optimizing health. For instance, vitamin D is now considered to function not only in its traditional role in calcium absorption and bone health, but also in muscle and immune function and the prevention of

chronic diseases.

The vitamin and mineral status has improved greatly in the Western world in the past 50 years, especially among women and children, two of the most at-risk populations for deficiencies. In North America, a variety of factors can be credited for these improvements, including the introduction of fortified foods, agricultural policies leading to more equitable access to foods, and targeted programs such as the Women, Infants, and Children program.[1] Nevertheless, intakes of selected nutrients may remain inadequate among children and adults in North America and other Western countries.[2,3] Furthermore, vitamin inadequacies remain highly prevalent among elderly parts of the populations in these countries.[4]

In resource-poor settings, micronutrient deficiencies remain a major public health problem. The underlying factors are insufficient dietary intake, oftentimes due to monotonous plant-based diets, and a high prevalence of infectious diseases leading to anorexia, malabsorption, and impaired storage and metabolism of vitamins and minerals. As a result, an estimated 190 million children of preschool-aged and 19 million pregnant women are deficient in vitamin A.[5] Deficiencies in folic acid, vitamin B_{12}, and vitamin D are also of concern, but their burden is insufficiently characterized.[6] See Part V: Nutrition in Low- and Middle-Income Countries for further details.

In this chapter, we present a brief discussion on each vitamin, emphasizing the basic chemistry, physiological, and current epidemiological knowledge with a special focus on issues pertaining to child health. A summary of information on the clinical examination of nutritional deficiencies and excesses, as well as on important food sources of vitamins, is provided in Table I-8 in Appendix I. The reader is referred to Chapter 11 for a discussion on current United States Dietary Reference Intakes (DRIs) set forth by the Food and Nutrition Board of the Institute of Medicine (IOM) and to Appendix II for a listing of recommended vitamin intakes.

VITAMIN A

History, Structure, and Metabolism

The importance of a substance present in certain foods for the treatment of night blindness was already known in ancient Egypt. The Greek physician Hippocrates (460–327 B.C.) recommended the intake of “raw beef liver, soaked in honey, once or twice by mouth” for the treatment of

“nyktalopia,” or the total inability to see in darkness. However, it was only in the late 19th and early 20th centuries when the biochemistry of this compound was clarified. In 1881, Lunin reported that while mice could not survive on a purified diet of fats, carbohydrates, proteins and salts alone, their survival was drastically improved after the addition of whole milk. Similar findings led Hopkins to postulate in 1906 the existence of “unsuspected dietetic factors” required for growth and life. Three years later, a fat-soluble factor was shown to promote growth in rats and was dubbed “fat-soluble factor A.” The name was changed to “vitamin A” in 1920. In 1930, Karrer completed long-standing work on carotenoid precursors of vitamin A by identifying the structure of β-carotene, the major pro-vitamin A carotenoid.

The term vitamin A groups a number of retinoid compounds with the biological activity of all-*trans*-retinol, the alcohol form of vitamin A. Retinoids usually consist of four isoprenoid units with five conjugated carbon–carbon double bonds. 11-*cis*-Retinal is the oxidation product of retinol primarily involved in visual functions. Retinal can be further oxidized to retinoic acid, which functions in growth but not a vision or reproduction. Retinyl palmitate is the principal storage form of vitamin A. Of the more than 600 carotenoids that have been identified in nature, about 50 have can serve as vitamin A precursors. Carotenoids without vitamin A activity may still have antioxidant properties, however.

Vitamin A is usually ingested as retinyl palmitate from animal sources, and as carotenoids, mainly β-carotene, from plants. In the stomach, preformed vitamin A and carotenoids are released from protein by proteolysis, then aggregate with lipids and pass into the upper part of the small intestine. Bile salts stimulate pancreatic lipase and esterases that hydrolyze retinyl esters to retinol in enterocytes. Retinol subsequently binds to the cellular retinol-binding protein CRBP(II). Carotenoids, on the other hand, pass into the mucosal cells unaltered, and are cleaved by a 15-15´-oxygenase into retinal which also binds to the CRPB(II). Retinal reductase and lecithin-retinol acyltransferase (LRAT) recognize the CRPB(II) complexes and synthesize retinol, which is then packed into chylomicrons before entering the circulation via the lymphatic system. Triacylglycerol is hydrolyzed from circulating chylomicrons by plasma lipoprotein lipase to form chylomicron remnants. These remnants deliver retinol to the liver, where it is taken up by hepatocytes through high-affinity receptors of apolipoproteins E and B48. In hepatic lysosomes, an acidic hydrolase releases retinol to bind with apo-CRBP. At least three pathways could follow after this CRBP-retinol complex is formed: First,

synthesis of CRBP-retinal through retinol dehydrogenase (RoDH) and later retinal through retinal dehydrogenase (RALDH); second, retinol esterification mediated by LRAT; and third, rapid mobilization of retinol catalyzed by the bile salt-independent reductase (bsiREH).[7]

From the hepatocyte, vitamin A can be locally transported to fat-storing stellate cells. Plasma concentrations of unbound retinol binding protein RBP (also known as apo-RBP) regulate the mobilization of retinol from the liver. Increased concentrations of apo-RBP signal stellate cells to release retinyl esters for de-esterification to retinol. The retinol bound to RBP (also known as holo-RBP) is secreted in plasma together with transthyretin, a tetramer that minimizes the loss of RBP in urine. The complex is then distributed to peripheral tissues or recycled back to the liver in a tightly regulated system that allows retinol molecules to recirculate at least seven times before final excretion. In the retina, holo-RBP binds to membrane receptors for internalization by endocytosis. These receptors have been found also in the skin, placenta, and the blood-testes and blood-brain barriers. In the lungs, kidneys, muscle, and possibly other tissues, retinol may be taken up directly by lipid membranes in a receptor-independent fashion. Vitamin A metabolites are primarily excreted in bile. However, pathological conditions may lead to substantial losses of retinol in urine.

Bioconversion of carotenoids is inversely regulated by vitamin A status. The bioavailability of vitamin A and carotenoids is influenced by the integrity of the intestinal mucosa and the intake of other nutrients. The presence of fat in a meal as well as food processing and heat treatment improve bioavailability of β-carotene and its conversion to vitamin A in humans, while dietary fiber reduces absorption. Among genetic determinants, variant allelic polymorphisms in the BCMO1 enzyme reduce the conversion of β-carotene to retinal.[8]

Traditionally, the vitamin A activity of β-carotene has been expressed as retinol equivalents (REs). However, recent data indicate that the vitamin A activities of purified β-carotene in oil as well as dietary β-carotene are lower than what had previously been assumed. For this reason, the contribution of β-carotene, and in fact also of other provitamin A carotenoids, to dietary vitamin A intakes had been overestimated. To take into account the new data, requirements for vitamin A are now expressed as retinol activity equivalents (RAEs), rather than REs. While the RE for dietary β-carotene was 6 μg, the RAE for dietary β-carotene is 12 μg, indicating that 12 μg (instead of 6 μg) of β-carotene needs to be consumed to yield 1 μg of available retinol. The corresponding RAE is 24 μg for both

α-carotene and β-cryptoxanthin, which are other important pro-vitamin A carotenoids.[9]

Functions

Vitamin A plays a key role in gene expression of numerous physiological processes. In the form of its metabolite all-*trans* retinoic acid, vitamin A is a ligand for a family of the nuclear retinoic acid receptors (RARs), whereas 9-*cis* retinoic acid activates RARs and retinoid X receptors (RXRs). These groups of receptors form heterodimers and bind to genes in regulatory regions known as retinoic acid response elements (RAREs).

Specific physiological functions exhibited by vitamin A include vision, immunity, cell differentiation, and growth. The visual role of vitamin A occurs in the rod cells of the eye and enables sight in dim-light conditions. In this biochemical process, all-*trans*-retinol undergoes isomerization and oxidation to yield the light-sensitive 11-*cis*-retinal, which binds to opsin to form rhodopsin (Figure 10-1). As rhodopsin absorbs light, 11-*cis*-retinal changes to all-*trans*-retinal, causing it to dissociate from opsin. As all-*trans*-retinal is released, opsin undergoes a conformational change and thus alters the permeability to cations, increases membrane polarization, and generates a nerve impulse. Rhodopsin can be regenerated, which completes the vitamin A-dependent visual cycle.

The role of vitamin A in immunity is mediated mainly by the metabolites all-*trans* retinoic acid and 9-*cis* retinoic acid. At the level of mucosal immunity, vitamin A deficiency (VAD) is related to alterations in the integrity of the ocular, respiratory, gastrointestinal (GI), and genitourinary epithelia. These alterations include replacement of normal ciliated and mucus producing cells by keratinized epithelium. Keratinization and mucin production may be additionally regulated by vitamin A at the transcriptional level. Local secretion of humoral immune factors such as secretory IgA and lactoferrin may be also impaired by VAD.

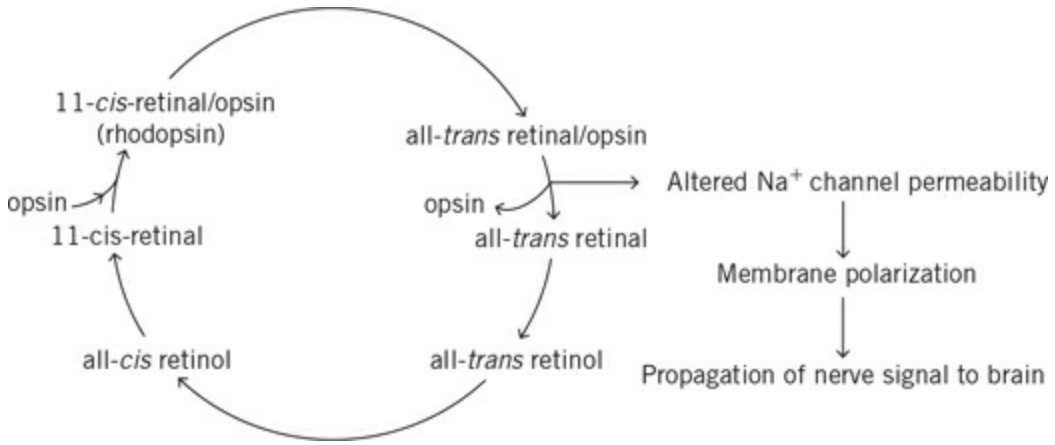

Figure 10-1 The vitamin A visual cycle.

Vitamin A influences the differentiation of white cell lines in the bone marrow, as well as the function of circulating immune cells. Phagocytosis, chemotaxis, and production of free radicals carried out by neutrophils are altered in vitamin A-deficient animals, as well as the number and cytotoxic activity of natural killer cells. Retinoic acid enhances various functions of mononuclear cells in vitro, such as phagocytic activity of macrophages, and release of tumor necrosis factor-α, interleukin 1 (IL-1), transforming growth factor-β (TGF-β), and expression of immunoglobulin receptors by monocytes that modulate proliferation of B lymphocytes. It also increases the capacity of Langerhans cells to present antigens to T lymphocytes in the skin.

Vitamin A appears to influence the antigen-specific proliferation of T lymphocytes. In animals, VAD impairs cytotoxic T lymphocyte activity. The growth and differentiation of B lymphocytes into immunoglobulin-producing cells also requires retinol, possibly through the induction of cytokine secretion by T helper lymphocytes. The antibody response against T cell-dependent antigens is usually impaired by VAD in animals, particularly during infections that would normally induce a T helper type-2 like response. In this case, instead of high production of IgG, IL-4, IL-5, and IL-10, a Th1 response consists of low antibody production and increased levels of IL-2 and interferon-γ. During the Th1 response to infections, it is thought that VAD further up-regulates such a response.

During the first 6 months of life, the most important sources of vitamin A are breast milk and hepatic stores. Breast milk levels decrease in vitamin A-deficient mothers, which may thus also compromise infant vitamin A

status.[10] After 6 months of age, complementary foods increase in importance to meet the infant's vitamin A requirements. Among US children age 2–18 years, ready-to-eat cereals and milk supply more than 40% of dietary vitamin A.[11] In poor settings, food-based approaches should ideally help meet requirements, but the poorer conversion ratios of carotenes from plant based foods may require other deficiency control mechanisms.

High-dosages of vitamin A are adequately absorbed and retained, replenish liver stores, and are released to meet tissue requirements. Even though high-dose vitamin A supplementation only transiently improves vitamin A status (as measured through serum retinol),[12] its benefits for child survival have been well documented. Summary estimates from the 17 mortality trials published to date indicate that vitamin A supplementation reduces all-cause mortality by 24% and diarrhea-related mortality by 28% among children aged 6–59 months. High-dose supplements among pregnant[13] and postpartum women[14] have no effect on maternal and infant mortality, and supplementation among neonates[15–17] and infants aged 1–5 months[15] has no consistent mortality effect. Based on these findings, WHO recommends one high-dose supplement in the form of 100,000 IU retinol to infants 6–11 months, and doses of 200,000 IU retinol every 4–6 months to children aged 12–59 months in settings where VAD is a public health problem (defined as the prevalence of night blindness is ≥1% in children 24–59 months of age or ≥20% prevalence of serum retinol ≤0.70 μmol/L among children 6–59 months of age). Vitamin A does not have any negative effect on seroconversion of childhood vaccines and supplements are recommended to be delivered during routine health system contacts such as vaccinations and integrated into the other child health and survival programs such as national immunization days and child health days.[18] Vitamin A supplementation programs among preschoolers should continue until their population serum retinol values have normalized.[12]

Among children with measles, vitamin A supplementation improves survival, reduces pneumonia incidence, and speeds recovery from diarrhea.[19–21] Based on the beneficial effects of vitamin A for recovery from measles infection, the American Academy of Pediatrics (AAP) recommends vitamin A supplementation for children aged 6 months to 2 years who are hospitalized with measles and children older than 6 months with measles and additional risk factors for VAD.[22] Children 1 year of age and older should receive 200,000 IU (60,000 μg) retinol by mouth, while

children aged 6 months to 1 year should receive 100,000 IU (30,000 μg) retinol.

Vitamin A was discovered as a growth-promoting factor in animals, but its role in growth and body composition in humans may be limited. Positive relations between vitamin A status and growth have been reported from observational studies, particularly in malnourished populations. However, these observational studies are limited by potential confounding by other nutrient deficiencies and infection. In randomized trials conducted in Asia and Africa, vitamin A supplementation generally did not improve child growth. Among children at highest risk of VAD and those with debilitating infectious diseases, including HIV, however, malaria, and persistent diarrhea, supplementation may improve growth.[23]

The industrial fortification of staple foods with vitamin A plays an increasingly important role in VAD control, but staple food consumption among young children may be too low to impact status.[24] Biofortification, that is, fortifying food by breeding crops to increase their nutritional value, either through conventional selective breeding or genetic engineering, is being evaluated as a VAD control measure. The provision of specially designed fortified complementary foods may have higher impacts but access of economically disadvantaged groups to these products may be low.[25] Increasing the amount of bioavailable nutrients through home fortification of complementary foods with low-dose lipid-based nutritional supplements or multiple micronutrient powders is promising but the impact of current formulations on vitamin A status remains unclear.[26] Until such dietary strategies reach scale, the most widely used program to alleviate the mortality effects of VAD is the twice-yearly supplementation of children aged 6–59 months.

Hepatic reserves accurately reflect vitamin A status, but cannot be measured in human studies. Serum retinol is a useful biomarker but is under homeostatic control until hepatic stores are depleted. Dose–response tests and isotope dilution assays are useful to determine marginal vitamin A status, but only dose–response tests are field friendly.[27]

Retinol dosages ≥ 150,000 μg among adults, and lower dosages among children proportional to body weight, induce transient toxic effects that include nausea, vomiting, headache, increased cerebrospinal fluid pressure, vertigo, blurred vision, and muscular incoordination. Chronic exposure to retinol at dosages of approximately 6000 μg/day or higher have also been associated with bulging fontanel among infants. Using these data and applying a large safety margin, the IOM recommends that children from 0 to 36 months should have preformed retinol intakes from

dietary and supplemental sources below 600 μg/day.[9] It has been pointed out, however, that this estimate may be overly conservative, given that 25%–30% of young children, as assessed by the Continuing Survey of Food Intakes by Individuals, have intakes above that level without evidence of adverse effects.[28] Women of childbearing age should be advised against consuming more than 2800–3000 μg/day of retinol to lower the risk of teratogenicity.[9]

VITAMIN D

History, Structure, and Metabolism

Rickets, a disorder due to vitamin D deficiency (VDD), has afflicted humanity since Neanderthal times some 200,000 years ago. Nevertheless, it was not described scientifically until the 17th century. In 1919, Mellanby linkend rickets to a nutritional deficit by inducing rickets in dogs through a synthetic diet and preventing the condition by administering cod liver or butter to diets.

This led him to propose that the dietary factor responsible for rickets was vitamin A. In 1922, McCollum distinguished antixerophthalmic factors in the diet from antirachitic factors, which he called vitamin D. Huldschinsky showed that rickets could be cured with exposure to ultraviolet (UV) rays and Hess and Weinstock demonstrated that UV irradiation induced the formation of an antirachitic factor in the skin.

Vitamin D designates a group of compounds derived from the cyclopentanoperhydrophenanthrene molecule, which have antirachitic activity. All these substances have a conjugated triene system of double bonds. The two most abundant forms of the vitamin are D_3 and D_2. Vitamin D_3 is also called cholecalciferol and is produced in the skin from 7-dehydrocholesterol, by solar radiation. Vitamin D_2, or ergocalciferol, is derived industrially from ergosterol, a plant steroid. Given that vitamin D can be produced by the human body, there is no dietary requirement for the vitamin as long as access to sunlight is available. For these reasons, vitamin D does not strictly fulfill the definition of a vitamin, and based on its various metabolic functions, the active metabolite 1,25-dihydroxycholecalciferol (1α, $25(OH)_2D_3$) is classified as a steroid hormone.

Few foods naturally contain vitamin D. The best natural sources are fatty fish such as salmon, tuna, and mackerel, and beef liver, cheese, and

egg yolks also contain small amounts. In the US, breakfast cereals and milk are commonly fortified with vitamin D. Absorption of vitamin D from the diet is relatively low, as only about 50% of dietary vitamin is absorbed. The major source of the vitamin in humans is from photochemical conversion of 7-dehydrocholesterol to previtamin D in the skin, and posterior isomerization to vitamin D (Figure 10-2). Vitamin D then passes to the systemic circulation bound to its transporter, the vitamin D-binding protein, which carries most biological forms and metabolites of the vitamin. It is taken up rapidly by the liver, but it is not preferentially stored there. The highest concentrations of vitamin D are found in blood, although adipose and muscle tissue in humans are also major storage sites for vitamin D. During deprivation, turnover from these sites is slow, and the supply of vitamin D to peripheral organs can be sustained for a period of time.

Vitamin D_3 does not have known biological functions, as it must first be hydroxylated to $25(OH)D_3$ in the liver. $25(OH)D_3$ is the most abundant circulating form of the vitamin, and is a good proxy of vitamin D_3 status. It is transported to the proximal tubules of the kidney, where a 1-hydroxylase converts it into $1\alpha,25(OH)_2D_3$. This hydroxylase is considered the most important regulatory mechanism of the vitamin D endocrine system. Its activity is regulated by the concentration of $1\alpha,25(OH)_2D_3$, parathyroid hormone (PTH), calcium, and phosphate. The second hydroxylated metabolite of D_3 produced in the kidney is $24R,25(OH)_2D_3$. Although this metabolite may play unique roles in vitamin D functions such as regulating PTH and bone mineralization, it is likely that both $25(OH)_2D_3$ and $24R,25(OH)_2D_3$ may be required. Vitamin D is mostly excreted in bile through catabolic pathways that are not well understood yet. Only small amounts of the vitamin are recovered during enterohepatic circulation. Some water-soluble metabolites of vitamin D, especially calcitroic acid (1α-hydroxy-23 carboxy-24,25,26,27-tetranorvitamin D_3), are also excreted in urine.

Functions

Vitamin D has a well-described role in bone health and calcium and phosphorous homeostasis. It also regulates genes that function in immune responses as well as cellular growth, differentiation, and apoptosis. As part of its steroid form $1\alpha,25(OH)_2D_3$, vitamin D is biologically active by rapidly activating several signal transduction pathways through the

membrane receptor VDR_{mem} as well as by regulating gene transcription through its nuclear receptor VDR_{nuc}.[29]

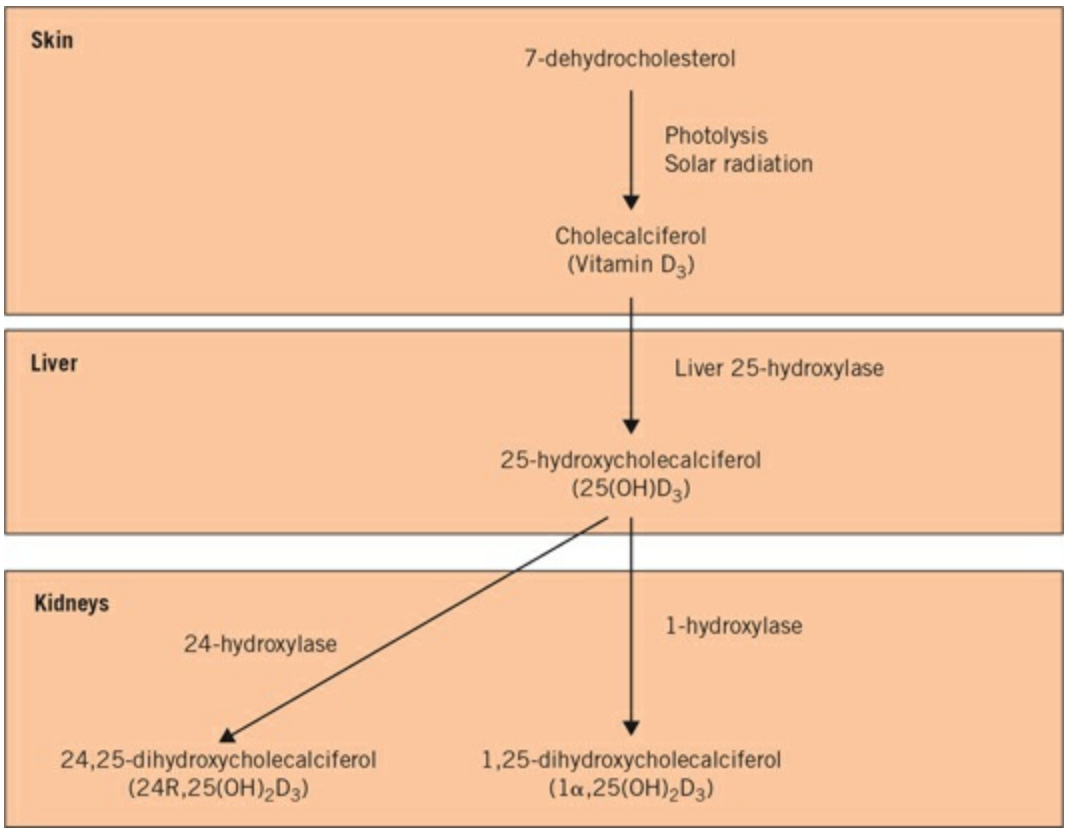

Figure 10-2 Overview of vitamin D metabolism (R).

The rapid, non-genomic physiological responses triggered by the interaction of $1\alpha,25(OH)_2D_3$ with the membrane receptor VDR_{mem} include the stimulation of Ca^{2+} absorption in the intestine (transcaltachia), opening of Ca^{2+} and Cl^- channels, activation of protein kinase C and mitogen-activated kinase, Ca^{2+} entry in skeletal muscle cells, and uptake of Ca^{2+} by osteoblasts.[29]

The mechanisms involving gene transcription are initiated when $1\alpha,25(OH)_2D_3$ binds in target organs to its nuclear receptor, VDR_{nuc}, which has domains also found in other steroid hormone receptors. After binding, VDR forms a heterodimer with RXR and later, the complex interacts with the vitamin D response element in the transcription control region of target genes. These activated promoter genes may also bind to coactivator proteins such as TATA, TBP, and TFIIB, and the resulting

transcriptional complex is then able to modulate DNA transcription.[30] Of the more than 60 genes regulated by 1α,25$(OH)_2D_3$, the gene linkend to the induction of the calcium binding protein calbindin D is one of the most important ones because it is directly related to many of the known physiological functions of vitamin D.

Regulation of mineral homeostasis is the classical function attributed to vitamin D. This process occurs at various target organs. In the intestine, 1α,25$(OH)_2D_3$ induces the transport of calcium and phosphate from lumen to plasma, possibly by activating calbindin, and also through changes in the membrane composition of the brush border cells. In the kidney, 1α,25$(OH)_2D_3$ downregulates 25$(OH)D_3$-1α-hydroxylase, thus controlling its own production. 1αx,25$(OH)_2D_3$ also stimulates the activity of 25$(OH)D_3$-24-hydroxylase. In bone, 1α,25$(OH)_2D_3$ and PTH mobilize monocytic stem cells to become mature osteoclasts. 1α,25$(OH)_2D_3$ may promote bone growth and mineralization through its effect on increasing intestinal calcium absorption, and possibly also by promoting differentiation of growth plate cells via chondrocyte membrane receptors and augmenting osteoblast proliferation and calcium uptake.

In skeletal muscle, vitamin D may be an important stimulant of calcium release during hypocalcemia. Myopathy frequently accompanies bone diseases related to VDD. In the skin, 1α,25$(OH)_2D_3$ appears to foster differentiation of keratinocytes, and protects them from UV stress. Some types of psoriasis can improve with the topical application of vitamin D analogs. Pancreatic β-cells respond to vitamin D with insulin secretion and VDD is accompanied with impaired insulin production. High doses of vitamin D may decrease the risk of type 1-diabetes in children.[31]

Various actions of vitamin D on the immune system have been reported. Immune cells, such as T and B lymphocytes, monocytes, and dendritic cells may be dependent on vitamin D as they contain VDR_{nuc} and some exert hydroxylase activity. Children with low serum 25(OH)D concentrations may be at increased risk of respiratory and GI infections[32] and supplemental vitamin D may reduce the incidence of influenza A[33] and acute respiratory infections[34] in this group. VDD in adults may be related to reactivation of latent tuberculosis, but more research is needed. The immune effects of vitamin D are explained by upregulation of Th2-immune responses that protect against extracellular pathogens[35] and induction of the antimicrobial peptide cathelicidin in the innate response against intracellular bacteria.[36] Vitamin D may also down regulate Th1-

immune responses, which may explain why vitamin D suppresses various autoimmune diseases and prolongs allograft survival.

In observational epidemiologic studies, VDD is related to early sexual maturation[37] and increased risks of obesity[38] and asthma.[39] Randomized trials are needed to demonstrate whether these relations are causal.

Recognition is growing that VDD may be a major public health problem worldwide, even in equatorial regions where it had not been suspected before. In the US, up to 20% of children ages 6–11 years are vitamin D-deficient (serum levels of 25-hydroxyvitamin D [25(OH)D] <50 nmol/L), while 52% have vitamin D insufficiency (25(OH)D ≥50 to <75 nmol/L).[40] Hispanic and black children are at the highest risk for VDD. Poor maternal vitamin D status impairs fetal vitamin D accretion during pregnancy and further compromises child vitamin D status due to reduced breastmilk vitamin D concentrations.

Even though regular brief exposure to sunlight can theoretically offset low dietary intakes, skin production of vitamin D is variable and depends on many factors, including skin color, time of the day and season of the year, geographical latitude, and age. The optimal amount of vitamin D intake is a matter of debate. In 2008, the AAP recommended a minimal intake of 400 IU/day for infants and children.[41] By contrast, in 2010, the Institute of Medicine set a recommended dietary allowance of 600 IU/day for children 1 to 18 years of age with maximum intakes of 2500 IU, 3000 IU, and 4000 IU for age groups 1–3 years, 4–8 years, and 9–18 years, respectively.[42] For infants <1 year of age, adequate intake was set at 400 IU/day. Some prominent vitamin D researchers argue that a higher recommendation is needed to decrease the prevalence of deficiency and improve vitamin D-related health outcomes considering that tolerable upper intake level is likely much higher than currently established. Nevertheless, additional evidence from randomized trials will be needed before a new revision of recommended intake takes place.

VITAMIN E

History, Structure, and Metabolism

Vitamin E was discovered by Bishop and Evans in 1922 as a fat-soluble compound in wheat and lettuce that was necessary to avoid fetal death in rats. The vitamin was shown to be essential among humans, not until the late 1960s, when its deficiency was linked to hemolytic anemia among premature infants. The potential protective role of vitamin E as an

antioxidant against chronic and degenerative illness is currently an active field of research.

Natural vitamin E occurs in the form of eight different isomers, four tocopherols and four tocotrienols. A chromanol ring is common to all isomers, but while tocopherols have a saturated phytyl tail, tocotrienols have an unsaturated tail. Based on the number of methyl groups on the chromanol ring, the isomers are grouped into α-, β-, γ-, and δ forms of tocopherol and tocotrienol. The various isomers of vitamin E are not interconvertible in humans and that they have different metabolic functions. Only certain forms of α-tocopherol are maintained in the plasma and are thus considered to be the active form that is relevant to establish nutritional requirements. These active forms are the *2R*-stereoisomers of α-tocopherol (classified as *RRR*-, *RSR*-, *RRS*-, and *RSS*-α-tocopherol), while the *2S*-stereoisomeric form (SRR-, SSR-, SRS-, and SSS-α-tocopherol) are not maintained in plasma and are thus not considered to be active. Synthetic forms of vitamin E are a mixture of all eight α-tocopherol steroisomers (prefixed "*all-rac-*," for *all-racemic*), while only the *RRR*-stereoisomer occurs in food.

After ingestion, all forms of vitamin E combine with bile salts and pancreatic secretions in the intestinal lumen, form micelles, and are taken up into enterocytes. Absorption of all forms of vitamin E is low, but appears to be inversely related to intake. It is also reduced by long-chain polyunsaturated fatty acids (PUFAs), but increased by medium-chain triglycerides. At the enterocyte, all forms of vitamin E are incorporated into chylomicrons and enter the circulation via the lymphatic system. As a result of chylomicron catabolism, vitamin E is distributed to tissues by means of circulating lipoproteins. Chylomicron remnants that contain the remainders of newly absorbed vitamin E are taken up by the liver. A selection process occurs in the liver, as RRR-α-tocopherol, the active form of-tocopherol, is preferentially resecreted into nascent VLDLs by-tocopherol transfer protein and recirculated through the body. During the conversion of VLDL to form LDL, some α-tocopherol is transferred to HDLs, which transport it to all of the circulating lipoproteins. The α-tocopherol remaining in LDL enters the cells of peripheral tissues through the LDL receptor pathway. The metabolic products of α-tocopherol after oxidation are dimers and trimers, as well as tocopheryl chromanoxy radicals that can be reverted to tocopherol by reducing agents such as vitamin C and glutathione. Subsequent oxidation of the tocopheroxyl radical produces tocopheryl quinone that, after reduction, can be excreted in the feces, or converted into tocopheronic acid by side chain oxidation

and excreted in urine as glucuronate conjugates. Other non-oxidation metabolites of the tocopherol phytyl tail are excreted in urine. These include 2,5,7,8-tetramethyl-2-(2′-carboxyethyl)-6-hydroxychroman, or α-CEHC, and γ-CEHC. High amounts of supplemental vitamin E result in increases in urinary α-CEHC concentrations. Due to the low bioavailability of ingested vitamin E, large amounts of the vitamin are excreted in feces. Absorbed forms of the vitamin that are in excess of requirements are excreted unchanged in the bile.

Functions

Vitamin E deficiency in animal models results most commonly in necrotizing myopathy, but may also lead to encephalomalacia, exudative diathesis, and embryonic degeneration. Deficiency symptoms also appear to depend on the status of other nutrients such as selenium and certain amino acids. In humans, vitamin E deficiency due to a poor diet is rare. However, it may occur among premature infants and secondary to pathologies causing fat malabsorption, such as abetalipoproteinemia, cystic fibrosis, and cholestatic disease. Neurological alterations are the most common manifestation of vitamin E deficiency in humans.

The specific mechanisms of vitamin E deficiency syndromes are not clearly understood. However, it is accepted that the most important function of vitamin E is protection against tissue damage caused by lipid peroxidation. Primordial free radicals (e.g., superoxide) can be originated in normal metabolism and through the effect of toxins. These free radicals may contribute to the formation of lipid free radicals when conjugated with PUFAs. The lipid radicals undergo a propagation sequence whose final products are lipid hydroperoxides (LOOH), which enter an autooxidative chain sequence until two radicals combine in a 2-electron bond. Vitamin E prevents auto-oxidation in at least two steps: (a) it traps peroxyl radicals; thus, a stable LOOH molecule is formed with a vitamin E radical subproduct; and (b) this vitamin E radical can still bind to other lipid radical. It is estimated that one tocopherol molecule is enough to protect 100 PUFA molecules from auto-oxidation. Some functions of vitamin E are strongly dependent on interactions with other nutrients. The antioxidant efficacy of tocopherol is enhanced by the presence of other antioxidant systems. The glutathione peroxidase system is selenium-dependent, and may explain the fact that selenium reduces the severity of vitamin E deficiency and that both may act synergistically against oxidative stress. Vitamin C (ascorbic acid) appears to reduce the vitamin E requirement by regenerating tocopherol after oxidation. β-Carotene also

may be a co-adjuvant of vitamin E in its membrane antioxidant functions; on the other hand, vitamin E increases the lymphatic uptake of β-carotene and its conversion to retinol. High intakes of PUFAs increase vitamin E requirements, but the extent remains unclear.

Vitamin E may improve immune function at various levels. In addition to its ability to scavenge lipid soluble free radicals generated during the immune response, vitamin E improves T-cell function by decreasing macrophage PGE-2 production and supports lymphocyte maturation by stabilizing membranes and facilitating the binding of antigen-presenting cells to immature T cells.[43] Other vitamin E-related functions include the regulation of xanthine oxidase, an important enzyme in the conversion of purine bases to uric acid, and the modulation of the activity of microsomal oxidases, protein kinases, and proliferation of smooth-muscle and endothelial cells.

Whether vitamin E supplementation has positive effects on health outcomes is controversial. Supplementation with vitamin E decreased the incidence of upper, but not lower, respiratory infection in elderly nursing home residents.[44] Evidence from other trials does not clearly support a preventive role against chronic disease, including cardiovascular [45] or Alzheimer's disease,[46] and some studies, in fact, suggest a potential deleterious role on certain cancers.[47] Information is scant on the effects of vitamin E supplementation alone on pediatric health. Gestational vitamin E supplementation has no effect on the offspring's risk of asthma[48] and supplementation in preterm infants increased the risk of sepsis.[49]

There is no evidence that toxic amounts of vitamin E can be ingested from food alone. However, supplemental intakes of vitamin E should not exceed 1000 mg among adults to prevent hemorrhagic toxicity and diminished blood coagulation among individuals who are on anticoagulant therapy or who are vitamin K deficient. Lower ULs have been defined for children older than one year to safeguard against potential toxic effects. For infants, the IOM has not determined a UL, given that there is a paucity of data and considering that food should be the only source of the vitamin for infants. While supplemental vitamin E may lower the risk of retinopathy of prematurity, there are no convincing data to suggest that supplemental vitamin E reduces the occurrence of bronchopulmonary dysplasia or intraventricular hemorrhage. According to the AAP, large parenteral doses of vitamin E in preterm infants, which elevate serum levels >40 μg/mL, are contraindicated as they may increase the risk of bacterial and fungal sepsis.[50] The IOM recommends that premature infants

should not ingest more than 21 mg of α-tocopherol to prevent hemorrhagic toxicity.[51]

VITAMIN K

History, Structure, and Metabolism

In 1929, Dam described a bleeding condition in chicks fed diets formulated to investigate cholesterol metabolism. He suggested the existence of a new vitamin in 1935 after this fat-soluble compound effectively prevented the bleeding condition in chicks. In 1939, a research group led by Doisy attributed its chemical and physical properties to a substituted 1,4-naphthoquinone. Dam and Doisy jointly received the Nobel Prize for medicine in 1943 for the discovery of the vitamin and for the elucidation of the chemical structure.

Vitamin K is a fat-soluble vitamin that consists of a family of compounds with a common 2-methyl-1,4-naphthoquinone ring structure. Vitamin K_1, or phylloquinone, is synthesized by plants and has a phytyl side chain. Vitamin K_2, is synthesized by bacteria as multiple homologs called menaquinones, which are characterized by unsaturated isoprenyl side chains of varying lengths. Menaquinone-4 is the most common homolog because animal enzymes can generate it from plant phylloquinone.

Excellent sources of phylloquinone are green vegetables such as kale, spinach, collards, parsley and broccoli, and plant oils such as soybean and canola account for large quantities in the diet. Menaquinone is found in meat, eggs, and dairy products. Vitamin K is absorbed from the first half of the small intestine alongside dietary fat. Absorption of pharmacological preparations of phylloquinone in adult humans is about 80%, but may only be about 20% from food sources.[52] After incorporation into chylomicrons in the intestinal mucosa, the vitamin is secreted into lymph and is taken up by the liver from chylomicron remnants through apolipoprotein E receptors. There is no known carrier protein and phylloquinone is principally transported with triacylglycerol-rich lipoproteins. Vitamin K is principally stored in the liver, albeit at lower levels than other fat-soluble vitamins. Menaquinones account for a higher proportion than phylloquinone, possible because of their slower hepatic turnover. Menaquinones are produced in the large intestine, but they may have very limited bioavailability and therefore may only contribute little to satisfying human vitamin K requirements. Phylloquinone, generally in the form of a

metabolite, is excreted in the feces via bile and to a lesser degree in urine. Little is known on the degradative metabolism of menaquinones.

Functions

Vitamin K serves as a cofactor in the carboxylation of the amino acid glutamic acid to form γ-carboxyglutamic acid (Gla), which is critical to the calcium-binding function of a number of proteins. After carboxylation, vitamin K is oxidized to vitamin K 2,3-epoxide, which can be successively recycled to quinine and hydroquinone in reactions catalyzed by dithiol-dependent reductases. These reductases can be inhibited by coumarinic, anticoagulant drugs such as warfarin. Undercarboxylated proteins have historically been referred to as proteins induced by vitamin K absence or antagonism, or PIVKAs. Undercarboxylated prothrombin, also known as PIVKA-II, is a sensitive marker of subclinical vitamin K deficiency after infancy.[53]

In the blood coagulation cascade, seven vitamin K-dependent factors and proteins play a major regulatory role (Figure 10-3). Factors IX and VII activate factor X through the intrinsic and extrinsic pathways, respectively, while factor X activates the synthesis of prothrombin from thrombin. The vitamin K-dependent proteins C, S, and Z function as anticoagulants in hemostasis.

Vitamin K also functions in bone health and calcification of tissues as a cofactor for the bone Gla proteins osteocalcin, matrix Gla protein (MGP), and protein S. Osteocalcin, also known as bone Gla protein, is produced in osteoblasts and odontoblasts and binds to hydroxyapatite crystals through its three Gla residues. Its synthesis is regulated by the active form of vitamin D (calcitriol). The percentage of undercarboxylated osteocalcin (%ucOC) is a sensitive marker of vitamin K deficiency and is related to lower bone resorption and formation in growing children.[54] In turn, supplementation with vitamin K_2 may maintain bone mineral density and prevent fractures among osteoporotic patients.[55] Vitamin K activates the calcification inhibitor MGP, which is expressed in various soft tissues and cell types, and may therefore prevent vascular calcification.[56] Protein S deficiency has been associated with osteopenia and osteonecrosis, as well as impaired vascular repair relevant for cardiovascular health, but its exact role in bone metabolism remains unclear.[57]

Recent research on vitamin K has identified the vitamin K dependent protein Gas6, which is a growth factor with mitogenic and antiapoptotic properties that helps maintain cells in the rest phase of the cell cycle.[58]

This research also helped identify that vitamin K_2 serves as a mitochondrial electron carrier, helping to maintain normal ATP production, which may make it a target for the treatment of mitochondrial pathologies.[59]

High intake of natural sources menaquinones, generally through cheese, is associated with a reduced risk of cancer[60] and coronary heart disease.[61] Oral phylloquinone and menaquinone supplementation is related to reduced bone loss.[62] More research is needed on the role of vitamin K in these conditions, however.

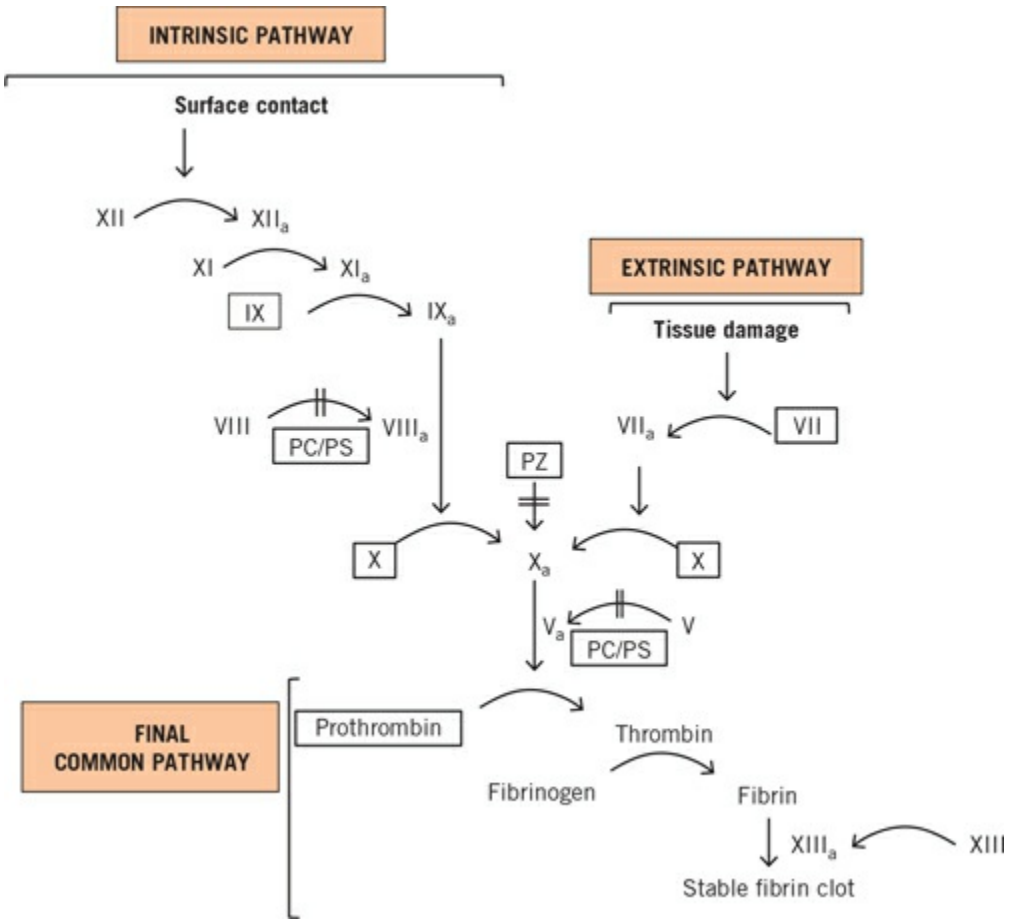

Figure 10-3 Role of Vitamin K in the blood coagulation cascade. Proteins C, S, and Z are shown as PC, PS, and PZ, respectively. Active proteins are shown with the subscript "a". Boxed factors and proteins are vitamin K-dependent.

Among adults without fat malabsorption, abnormal hemostatic control and other signs of vitamin K deficiency are extremely uncommon. In

contrast, liver menaquinone levels are either absent or extremely low at birth because of poor placental transfer and therefore place newborns at high risk of vitamin K deficiency bleeding (VKDB). Breast milk contains 2 μg/L of phylloquinone in colostrum and 1 μg/L in mature milk, and MK-4 levels at about half those levels. These low levels make exclusive breastfeeding a risk factor for VKDB, but exclusive breastfeeding should still be promoted for the early months of life given its other benefits and while other vitamin K deficiency control strategies are employed. Infant formulas are typically fortified to contain 55 μg/L of phylloquinone and are therefore a better source than breast milk.[53]

VKDB among infants is due to an insufficient production of clotting factors in the liver and presents in several forms. The earliest form of the disorder (occurring within the first 24 hours of life) is rare, but may be fatal due to bleeding from intracranial, intrathoracic, intra-abdominal and GI sites. It is generally caused by maternal use of drugs that inhibit vitamin K metabolism. Classical VKDB (occurring between days 2 and 7 of life) is typically restricted to the GI tract, umbilicus, skin, nose, or site of circumcision and is generally not lethal. It is considered as idiopathic but may be related to poor feeding practices and low intakes of breast milk or formula. Late VKDB peaks between weeks 3 and 8, but may occur as late as 6 months. It generally occurs among exclusively breast-fed infants and among infants malabsorption of vitamin K caused by undiagnosed cholestasis. It is the form with the most severe public health consequences and is often marked by acute intracranial hemorrhage and therefore higher rates of neurological handicaps or death.[53]

Without vitamin K prophylaxis, the incidence of late VKDB is an estimated 7 per 100,000 in the Europe but may be higher in less developed countries.[53] VKDB is effectively prevented by administering a single intramuscular dose of 0.5–1 mg to all newborns, as currently recommended by the AAP.[63] Weekly oral vitamin K supplementation during the first 3 months of life is effective among most children but not those with latent cholestasis. Research conducted in the1990s implicated intramuscular vitamin K with an increased risk of childhood cancer, but these findings have not been replicated in other studies.

High dietary intakes of vitamin K decrease the therapeutic effectiveness of anticoagulant medications such as warfarin. Therefore, dietary and supplementation habits should not be altered once the anticoagulant dose has been established. There is no evidence that high intakes of phylloquinone or menaquinones from food or supplements lead to adverse effects among persons who are not on anticoagulant therapy.

VITAMIN C

History, Structure, and Metabolism

Medical writings from ancient Egyptians, Greeks and Romans were the first to describe a syndrome akin to scurvy, the disease associated with vitamin C deficiency. The first modern accounts of scurvy appear in the sailing logs of the Portuguese and Spanish marine expeditions of the early 16th century. In 1747, Lind conducted his famous clinical experiments on board of the British vessel Salisbury in which he cured scurvy with oranges and lemons. In 1932, research groups led by Szent-Györgyi and King isolated and identified vitamin C. Haworth subsequently determined the structure of ascorbic acid and synthesized the vitamin. For their groundbreaking work on vitamin C, Szent-Györgyi and Haworth received the Nobel Prize in 1937.

The term vitamin C, a six-carbon lactone, encompasses a redox system composed of L-ascorbic acid, monodehydro-L-ascorbic acid (a free radical), and oxidized ascorbate (dehydro-L-ascorbic acid, or DHA). Vitamin C is synthesized from glucose by many animals. Humans lack L-gluconolactone oxidase, an enzyme necessary for the synthesis of ascorbic acid, and therefore require dietary supply of the vitamin. Vitamin C is widely distributed in fruits and vegetables. Excellent sources include citrus fruits and their juices, kiwis, and red and green peppers. Other good sources include broccoli, baked potatoes, and tomatoes. After ingestion, the vitamin is absorbed in the small intestine, preferentially in the distal segment, through the sodium-ascorbate co-transporters (SVCTs) and hexose transporters (GLUTs). At higher GI concentrations, it is also absorbed by passive diffusion. Absorption is 70%–90% of usual intake levels, but decreases to below 50% at intakes exceeding 1 g/day. The bioavailability from foods is similar to that from synthetic sources. The vitamin enters cells as DHA, where it is reduced to ascorbate by glutathione-dependent mechanisms. Relatively low amounts of the vitamin are lost through catabolism. The vitamin is excreted as unmetabolized ascorbic acid and oxalate. Renal excretion of vitamin C increases proportionally with higher intake levels and reaches up to 80% after intravenous dosages of approximately 100 g.[64]

Functions

Vitamin C plays important antioxidant roles and serves as a cofactor for enzyme-mediated hydroxylation reactions. The vitamin C-dependent enzymes prolyl 4-hydroxylase, prolyl 3-hydroxylase are required for the

hydroxylation of proline and lysyl-hydroxylase for the hydroxylation of lysine residues in the synthesis of collagen. Without this hydroxylation, precursor molecules of collagen are unable to fold into their final triple helical structure. Non-folding collagen explains many of the symptoms of scurvy, such as gum bleeding, bruising, and inadequate repair of damaged tissue. In carnitine synthesis, Vitamin C is a cofactor for 6-*N*-trimethyl-L-lysine hydroxylase and γ-butyrobetaine. Carnitine deficiency and decreased oxidation of fatty acids in muscle may be responsible for the muscular weakness characteristic of scurvy. Vitamin C is a cofactor of dopamine-β hydroxylase in the synthesis of norepinephrine and epinephrine, and peptidylglycine α-amidating monooxygenase in the activation of hormones and neurotransmitters. Ongoing work is examining the role of vitamin C in cell differentiation and intracellular signaling cascades.[65]

Ascorbic acid has strong antioxidant properties by scavenging reactive oxygen species. It thus neutralizes phagocyte-derived oxidants and protects plasma lipids, lipid membranes, and ocular tissue from oxidative damage. The antioxidant properties of ascorbic acid suggest that the vitamin may have protective properties against degenerative diseases such as atherosclerosis and cancer.

In observational studies, consumption of vitamin C-rich diets is related to a lower cancer risk, but there is concern that vitamin C is merely a marker of better diets or healthier general lifestyles in these studies. In line with this evidence, there are no clear benefits of oral vitamin C supplementation for cancer risk.[66] Vitamin C-rich diets and intakes of >700 mg supplemental vitamin C/day relate to a lower risk of coronary heart disease.[67] However, evidence on the benefits of supplemental vitamin C from randomized, controlled trials are inconclusive.[68]

For decades, vitamin C has been implicated in preventing and treating the common cold. However, a review of all studies administering oral dosages of 0.2 g/day of vitamin C did not reduce the incidence and severity of colds in the general population; however, supplemental vitamin C may reduce incidence among subgroups engaging in heavy physical exercise or living in cold environments.[69] There is evidence to suggest that vitamin C is related to several aspects of the immune function. Ascorbic acid supplementation improves neutrophil chemotaxis.

Vitamin C interacts with other nutrients in vivo. Ascorbic acid positively interacts with the endogenous antioxidant glutathione, and may contribute to antioxidant protection by maintaining glutathione in its reduced form. In iron absorption, vitamin C reduces ferric iron found in

dietary nonheme iron in the more absorbable ferrous iron form, and may impair the formation of unavailable iron complexes with ligands normally present in the GI lumen. Dietary vitamin C of about 25–50 mg/meal improves nonheme iron absorption and may improve iron status.[70]

Vitamin C deficiency among infants manifests itself as infantile scurvy, in the form of bone abnormalities, hemorrhage symptoms, and anemia. However, vitamin C deficiency is unlikely to occur when infants are exclusively breastfed during the first 6 months of life or when fortified infant formulas are used.

High vitamin C intakes from food are unlikely to lead to adverse effects; however, intakes should be limited to the RDA levels among those with hemochromatosis, glucose-6-phosphate dehydrogenase deficiency, and renal disorders. Among healthy adults, excess intake through supplements (>3000 mg/d) has been associated with mild adverse effects, such as osmotic diarrhea and intestinal discomfort. To prevent vitamin C-related adverse effects, healthy adults should not consume vitamin C at levels above the UL set at 2000 mg/d; taking into account their lower body weight, ULs are lower for children.

THIAMIN

History, Structure, and Metabolism

Descriptions of beriberi or *kakke*, the disease caused by dietary thiamin deficiency, appeared in Chinese medical manuscripts more than 4 millennia ago. It became a major public health problem in Eastern and Southern Asia and Europe when polished rice, devoid of the thiamin-rich aleurone layer between the germ and the endosperm, became a major staple food. The first reference to a potential nutritional cause of beriberi appeared in 1884 when a Japanese surgeon, Takaki, showed that the prevalence of the disease in the navy could be reduced by feeding sailors meat, wheat and milk instead of their usual diet, which consisted of polished rice and dried fish. In 1890, Eijkman documented that a diet of polished rice caused polyneuritis in chicken. In 1901, Grijns found that the antineuritic factor in rice bran was water-soluble, and Funk first referred to the factor as “vitamine” in 1911. Frazier and Stanton successfully used extracts of rice polishing to cure beriberi in humans in 1909–1915, and Williams published its structure in 1936.

Thiamin, also called vitamin B_1, vitamin F, and aneurin, consists of a pyrimidine nucleus and a thiazole ring linkend by a methylene bridge. The

natural form of the vitamin is a base, and the commercial form is usually a chloride hydrochloride salt. Bacteria, fungi, and plans can synthesize thiamin, but humans and animals depend on dietary intakes.

After ingestion, dietary thiamin phosphate esters are hydrolyzed to thiamin or thiamin monophosphate (ThMP) by an intestinal alkaline phosphatase and transported across the brush-border membrane to the portal system. The vitamin is absorbed in the proximal small intestine by an active, saturable, and energy-dependent transport. At high luminal concentrations, passive diffusion also becomes important. The liver, and to a lesser extent erythrocytes, capture and phosphorylate most of the thiamin entering the bloodstream.[71] Even though urinary thiamin excretion is downregulated when tissue levels decrease, tissue thiamin depletion occurs relatively rapidly under low dietary intake.

Functions

In the form of thiamin diphosphate (ThDP) (also known as thiamin pyrophosphate), the coenzymatic and most abundant form of the vitamin in tissues, thiamin is an indispensable cofactor in key metabolic pathways. In eukaryotes, ThDP accounts for 80%–90% of cellular thiamin, ThMP and free thiamin for less than 15%, and thiamin triphosphate (ThTP) for less than 1%.

One major ThDP-dependent biochemical reaction is the oxidative decarboxylation of α-keto acids. It involves the oxidative decarboxylation of pyruvic acid, the first step in the conversion of pyruvate to acetyl CoA in the mitochondria; the oxidative decarboxylation of α-ketoglutaric acid, a step within the tricarboxylic acid cycle in which α-ketoglutarate is converted into succinyl CoA; and the oxidative decarboxylation of the branched-chain α-keto acids α-ketoisocaproate, α-keto-β-methylvalerate, and α-ketoisovalerate, to produce isovaleryl CoA, α-methylbutyryl CoA, and isobutyryl CoA, respectively, in high energy-generating pathways.

ThDP is also required in the transketolase reaction occurs in the cytosol, an essential reaction for the synthesis of ribose and oxidation of glucose by the pentose phosphate pathway. In the peroxisome, ThDP functions in the α-oxidation of 3-methyl-branched fatty acids, primarily phytanic acid, a degradation product of chlorophyll ingested through the diet, in order to produce long-chain aldehydes. The failure of this α-oxidation reaction and concomitant accumulation of phytanic acid leads to Refsum disease, an autosomal recessive neurological disease.

Thiamin deficiency impairs numerous enzymes and cellular processes. Animal studies suggest that maternal thiamin deficiency impairs brain

lipogenesis[72] and energy metabolism.[73] In humans, maternal thiamin deficiency may increase the risk of intrauterine growth retardation[74] and in conjunction with niacin and pyridoxine deficiencies increase the risk of oral facial clefts.[75] Thiamin deficiency has also been linkend to increased risk of Alzheimer's disease. Oral and parenteral thiamin may improve cognitive function in patients with Alzheimer's disease, but more research is needed in this field.[76] High intakes of milled grains, a poor source of thiamin, increase thiamin needs owing to thiamin's role in carbohydrate metabolism. Consumption of thiaminases, which destroy thiamin, in fermented raw fish, betel nuts, and fermented tea leaves also contributes to thiamin deficiency. Thiamin deficiency used to be an important nutritional problem in emergency settings such as refugee camps, but can now be controlled through fortified blended foods used in these camps. Beriberi, the classical thiamin deficiency disease, generally manifests itself as the so-called dry form of the disease, a chronic, generally non-fatal condition characterized by peripheral neuropathy with sensory, motor, and autonomic compromises, predominantly of the distal segments of the limbs. Wet beriberi is less common and is characterized by edema, lactic acidosis, pulmonary hypertension and may lead to heart failure. Thiamin deficiency may also be common, but often unrecognized among critically ill patients and appropriate supplementation necessary.[77] Infantile beriberi may be found in children 2–3 months of age whose mothers have low thiamin concentrations in breast milk. In 2003, a defective soy-based infant formula caused an outbreak of thiamin deficiency among Israeli infants.[78] Cases were effectively treated with intramuscular doses of thiamin (50 mg/day) for two weeks.

Chronic, excessive alcohol consumption is linkend to low thiamin intake and impaired absorption and storage of the vitamin, and therefore predisposes to the thiamin deficiency disorder Wernicke–Korsakoff syndrome. The syndrome generally starts with Wernicke's encephalopathy, characterized by ataxia of gait and paralysis of eye movements, which at an early stage is responsive to intravenous thiamin. Prolonged deficiency may result in Korsakoff psychosis, which consists of mental alterations, including amnesia and irreversible brain lesions. Genetic factors, AIDS, or cancers may also predispose to Wernicke–Korsakoff syndrome.

There are no reports of toxicity from excess thiamin intake from food or supplements, presumably due to the low absorption efficiency of intakes >5 mg and rapid urinary excretion when tissue levels are elevated.[9]

RIBOFLAVIN

History, Structure, and Metabolism

Riboflavin, or vitamin B_2, was discovered as a fluorescent "yellow growth factor" in the heat-stable fraction of anti-pellagra extracts found by McCollum and collaborators. It was synthesized by Kuhn and Karrer in 1935, and its structure was elucidated by Warburg and Christian in 1938.

All riboflavin-related compounds have an isoalloxazine ring. Riboflavin itself does not have significant physiological functions, but is converted to the coenzymes flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD) in reactions catalyzed by riboflavin kinase and FAD synthetase, respectively (Figure 10-4). Hydrolysis reactions catalyzed by phosphatases can reverse this process. About two-thirds of the riboflavin in food is present as FAD, and smaller amounts as FMN and the free form. Riboflavin is very sensitive to UV radiation and can be destroyed during phototherapy of neonatal jaundice.[79]

The most common dietary sources of riboflavin are milk, eggs, meat, green leafy vegetables and enriched breakfast cereals. After ingestion, the riboflavin coenzyme derivatives are hydrolyzed to riboflavin in the brush border of enterocytes and absorbed mainly in the proximal small intestine by an active, saturable, carrier-mediated transport system. Two intestinal riboflavin transporters have recently been identified.[80,81] In enterocytes, free riboflavin is converted to FMN, most of which is further converted to FAD. After the action of nonspecific phosphatases, riboflavin enters the blood as FMN alongside the free form of the vitamin.

The liver captures large parts of the vitamin after absorption. In the blood, riboflavin is transported mainly bound to immunoglobulins and to a lesser degree to albumin. The vitamin is converted to its coenzymatic forms in the cytoplasm of many tissues, especially in the small intestine, liver, heart, and kidney. About 90% of the vitamin form in cells are FAD and the remainder FMN. Riboflavin is excreted in urine, predominantly in its free form.

Functions

Riboflavin functions via the cofactors FMN and FAD, which are used by more than 150 proteins involved in energetic metabolism, redox homeostasis and numerous regulatory events.

In the respiratory chain, FAD plays a key role in energy production. FAD helps protect tissues against lipid peroxidation by regenerating glutathione in the glutathione peroxidase antioxidant system. The role of

FAD in the activation of NADPH oxidase, needed for cell defense and production of signaling molecules related to innate immunity and other cellular responses, has recently been identified.[82]

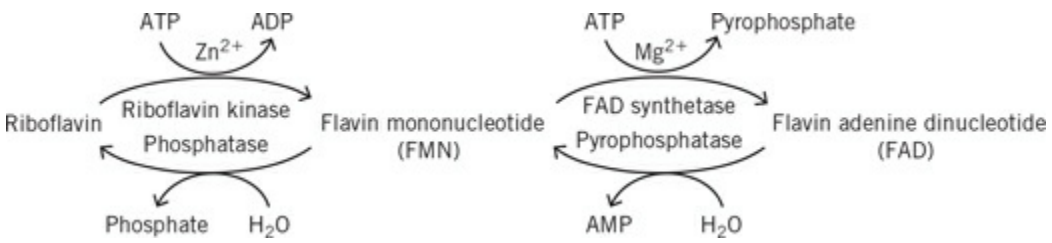

Figure 10-4 Interconversions of riboflavin and its cofactors.

Riboflavin enzymes are also involved in the metabolism of drugs, lipids, and several nutrients. FAD is important for folate and vitamin B_{12} metabolism. It is a cofactor for the enzyme 5,10-methylenetetrahydrofolate reductase, which catalyzes the conversion of methylene tetrahydrofolate to methyl tetrahydrofolate. The latter is required for the remethylation of homocysteine to methionine. In the metabolism of vitamin B_6, FMN is required for the conversion of pyridoxal-5-phosphate, while in niacin metabolism, the FAD-dependent kynurenine hydroxylase is needed for the conversion of tryptophan to niacin. Riboflavin deficiency may also impair iron absorption.

Inadequate food intake is a major cause of riboflavin deficiency, especially among those consuming dairy-free diets and the poor. High consumption of alcohol and certain psychotropic, chemotherapeutic, and antimalarial medications are related to poor riboflavin status. Poor riboflavin status may be common among critically ill patients[83] and translates into poor riboflavin levels in breast milk.[84] Among the several types of riboflavin-responsive genetic disorders that have been identified recently, the most common one is multiple acyl-CoA dehydrogenase deficiency, an autosomal recessive disease caused by defects in the mitochondrial electron transfer system and fatty acid metabolism.[85]

Riboflavin deficiency generally coexists with other vitamin deficiencies. Clinical deficiency symptoms in humans include stomatitis, glossitis, dermatitis, keratitis, anemia, and neurological dysfunction. Riboflavin deficiency may also impair cardiovascular health by increasing homocysteine concentrations and blood pressure[86] and possibly increase

cancer risk.[87] Recently, high-dose riboflavin supplements were identified as a potential prophylactic treatment in children and adolescents suffering from migraine.[88]

High riboflavin is not thought to lead to adverse effects, presumably due to limited GI absorption and rapid urinary excretion of the vitamin, but more information is needed on effects related to the use of pharmacological dosages over extended periods of time.

NIACIN

History, Structure, and Metabolism

Pellagra, the manifestation of niacin deficiency in humans, was first described in Spain in 1735. The disorder was soon recognized throughout large parts of Europe and Northern Africa when corn became the major food crop. The disease was also common in the United States in the early twentieth century, where it affected hundreds of thousands of people, with up to 7000 reported annual deaths.[89] In 1914, Goldberger began to demonstrate the nutritional origins of pellagra and in 1937, niacin was shown to cure the manifestation of pellagra in dogs and humans.

Niacin is found in a variety of foods, including beef, chicken, fish, liver, peanuts, and legumes. It is absorbed at physiological concentrations in the stomach and intestine by pH-dependent facilitated diffusion, while at higher concentrations passive diffusion predominates. NAD and NAD phosphate (NADP), the major forms of niacin in food, are converted by enzymatic action in the gut mucosa to nicotinamide. In the blood, nicotinamide constitutes the major form of vitamin and serves in the tissue synthesis of NAD when needed. However, both NAD and NADP can be synthesized in all tissues from nicotinic acid or nicotinamide. NAD is produced in different metabolic pathways that all involve the enzyme nicotinamide mononucleotide phosphoribosyltransferase.

Humans cannot synthesize nicotinic acid or nicotinamide endogenously and are therefore reliant on dietary intakes. However, niacin is unique among the B-vitamins in that it can be synthesized from a precursor molecule. The essential amino acid tryptophan can be converted to NAD via the formation of quinolinic acid and nicotinic acid ribonucleotide. An estimated 60 mg of dietary tryptophan yields 1 mg niacin,[90] but the conversion may be inhibited by deficiencies in other nutrients and by certain disease states, as explained in the next section. In typical Western adult diets, tryptophan contributes as much as two thirds

of the required niacin activity.

Excess niacin is excreted in the urine, mainly in the forms of N^1-methylnicotinamide (NMN) and 2-pyridone.

Functions

The metabolically active forms of niacin are NAD and NADP, whose nicotinamide moiety serves as an electron carrier or hydrogen donor in numerous redox reactions that are essential in carbohydrate, lipid, and amino acid metabolism. The NAD coenzyme generally functions as an electron acceptor in catabolic reactions that produce energy (e.g., the citric acid cycle). It also serves as the substrate for enzymes in non-redox pathways that cleave the β-*N*-glycosylic bond of NAD to free nicotinamide and catalyze the transfer of ADP-ribose. These non-redox pathways may modulate or regulate DNA and genome fidelity, and inflammatory and immune responses. NADP participates in reductive biosynthetic pathways involving fatty acid and cholesterol synthesis. It functions with NAD as a cohydrogenase in the pentose phosphate pathway to oxidize glucose 6-phosphate to ribose 5-phosphate. A novel area of research examines the role of NAD as a substrate for sirtuins (SIRTs), NAD-dependent protein deacetylases, of which seven members have been identified in humans. SIRTs have diverse cellular locations and functions, including epigenetic gene silencing, DNA repair and recombination, cell cycle regulation, apoptosis, and regulation of metabolism.[91]

The classical symptoms of the niacin-deficiency disease pellagra can be summarized as dermatitis, diarrhea, dementia, and potentially death (often called “the four Ds”). Pellagra develops when dietary niacin and tryptophan are insufficient to meet niacin requirements. Human experiments indicate that pellagra could develop after 50–60 days on a corn diet, which is low in both bioavailable niacin and tryptophan. The conversion of tryptophan to niacin is augmented among pregnant women and women taking oral contraceptives.[92] On the other hand, excessive intake of the amino acid leucine and inadequate intakes of iron, riboflavin, or vitamin B_6 may inhibit the conversion of tryptophan to niacin. In humans, prolonged isoniazid treatment, malignant carcinoid syndrome, chronic alcoholism, and Hartnup’s disease may result in pellagra-like symptoms.

Pharmacological levels of niacin are used to treat lipid disorders and prevent cardiovascular disease. They lower VLDL, LDL, and triglyceride levels while increasing beneficial HDL levels through mechanisms remain

incompletely understood.[93] Pharmacologic doses of nicotinic acid (but not nicotinamide) in the range of 1.5–4 g/day have proven effective at reducing the risk of atherosclerotic heart disease.[94] Several lines of evidence support niacin as a potential protective agent against skin cancer[95] and niacin's role in colon cancer is under investigation.[96] Low dietary niacin intakes may increase risk of Alzheimer's disease[97] and possibly multiple sclerosis and other neurodegenerative diseases.[98]

High niacin intakes from food are not known to cause adverse effects. Excess pharmacological dosages may lead first lead to flushing and subsequently to liver toxicity, impaired glucose tolerance, and nausea and vomiting. For children younger than one year, no UL has been defined due to a lack of data and suggestions that intakes should occur from food alone. For older children, ULs were defined based on adult data on flushing and subsequent adjustments based on body weight.[9] However, it has been argued that data on flushing is not relevant for children, and that there are therefore insufficient data to define a UL for children.[28]

VITAMIN B_6

History, Structure, and Metabolism

Vitamin B_6 was discovered by Gyoergy in 1934 during investigations on the etiology of the niacin deficiency disease pellagra. In 1939, Harris and Folkers elucidated the structure and achieved the synthesis of pyridoxine.

The term vitamin B_6 encompasses a group of compounds that are metabolically interchangeable and that, in their free form, are named pyridoxine (an alcohol), pyridoxal (an aldehyde), and pyridoxamine (an amine). These forms also exist in their respective 5´-phosphate ester forms pyridoxine phosphate (PNP), pyridoxal phosphate (PLP), and pyridoxamine phosphate (PMP).

The major forms of vitamin B_6 in animal foods are PLP and PMP, and pyridoxine and PNP in plant-derived foods. Rich sources of vitamin B_6 in U.S. diets are beef, poultry, and fortified cereals; other excellent sources are chickpeas, fish, beef liver, and other organ meats.

In the jejunum, phosphate ester forms of the vitamin are dephosphorylated, and free vitamin B_6 is absorbed by passive diffusion. The bioavailability of vitamin B_6 obtained from a mixed diet is approximately 75%. Vitamin B_6 is also synthesized by bacterial sources in

the colon and taken up by a regulatable carrier-mediated process, but its contribution to the human nutritional status remains to be defined.[99]

The free forms of vitamin B_6 are taken up by the liver and converted to PLP. Bound to albumin, PLP is also the major transport form carried to organs and tissues. About 75% of the body's vitamin B_6 pool is present in muscle. This pool is resistant to depletion even after prolonged intake of a vitamin B_6-deficient diet, which indicates that muscle vitamin B_6 is not a storage form of the vitamin that can be drawn upon in times of inadequate vitamin B_6 intakes. Catabolism of vitamin B_6 occurs mostly in the liver and excretion of the vitamin occurs in the urine, predominantly as 4-pyridoxic acid.

Functions

PLP facilitates the transfer of amino groups and is thus critical for the production of nonessential amino acids. For example, PLP is a cofactor for the enzyme glutamate-oxaloacetate aminotransferase, which catalyzes the formation of aspartic acid from glutamate. As a cofactor for kynureninase, PLP facilitates the conversion of the amino acid tryptophan to active niacin and the decarboxylation of precursor amino acids to generate several neurotransmitters, such as serotonin, taurine, dopamine, norepinephrine, histamine, and γ-aminobutyric acid.

In cellular one-carbon metabolism, the PLP-dependent enzyme serine hydroxymethyltransferase catalyzes the reversible transfer of the three-carbon of serine to tetrahydrofolate (THF) in the production of 5,10-methylene THF and glycine, which can be converted back to THF by the PLP-dependent glycine decarboxylase multienzyme system (Figure 10-5). With cystathione synthase, PLP converts homocysteine to cystathione, and with cystathione γ-lyase cystathione to cysteine. In carbohydrate metabolism, PLP functions in the production of glucose 1-phosphate from glycogen, in lipid metabolism in the production of carnitine and phospholipids, and in heme synthesis in the rate-limiting formation of γ-aminolevulinate.

Vitamin B_6 deficiency is first evidenced by decreases in plasma PLP levels and lowered amounts of the excretory product 4-pyridoxic acid in the urine. Continued vitamin B_6 deficiency leads to seborrheic dermatitis and decreased synthesis of neurotransmitters, resulting in depression, confusion, and abnormal brain wave patterns as indicated by abnormal electroencephalograms. Infants fed vitamin B_6-deficient formula are also

at risk of developing convulsions.[100] Vitamin B_6 deficiency may depress humoral and cell-mediated immunity by impairing the production of one-carbon units necessary nucleic acid synthesis. It may also impair heme synthesis and thus cause hypochromic microcytic anemia.

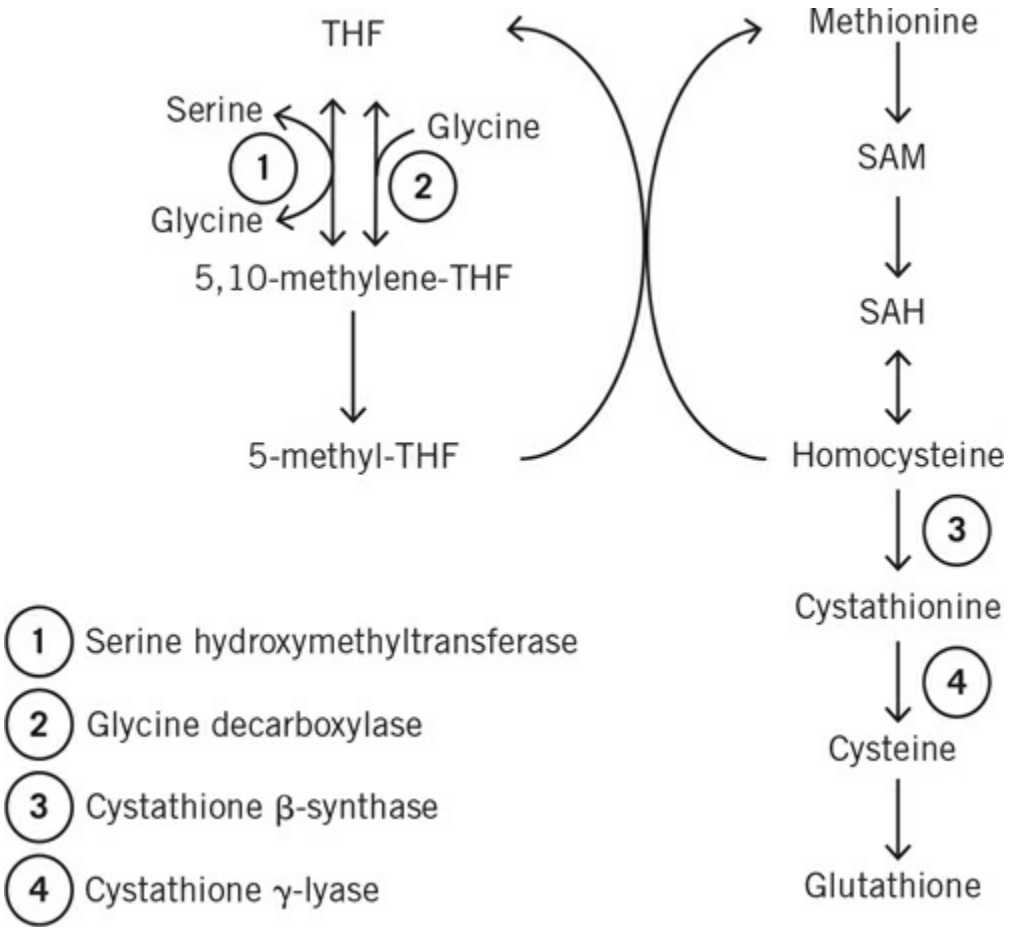

Figure 10-5 Vitamin B_6-dependent enzymes in one-carbon metabolism.

In observational epidemiologic studies, plasma PLP concentrations are inversely related to risk of colorectal cancer,[101] lung cancer,[102] coronary artery disease,[103] cerebrovascular disease,[104] and inflammatory conditions.[103] However, the biologic mechanisms are unclear. In fact, supplemental vitamin B_6 did not lower cardiovascular events or mortality in a high-risk populations either alone or when administered with other B vitamins.[105,106]

Levels of vitamin B_6 in breast milk are dependent on maternal intakes

of the vitamin and there is evidence that lactating mothers who consume inadequate levels of vitamin B_6 pass on deficient amounts of the vitamin to the infant.[84] Risk factors for human vitamin B_6 deficiency are old age, alcoholism, and use of penicillamine, isoniazid, and L-DOPA. Lower PLP levels have also been documented among oral contraceptive users.[107] High doses of vitamin B_6 may be beneficial in special conditions that elevate PLP requirements, such as intractable epilepsy among infants and inborn errors of vitamin B_6 metabolism. However, peripheral neuropathy and other adverse side effects must be considered.[108]

To safeguard against toxic effects of vitamin B_6, it is recommended that adults should not consume >100 mg/day. ULs have been set for children aged 1–18 years that are based on extrapolations from the adult UL.[9]

FOLATE

History, Structure, and Metabolism

In 1931, Wills described clinical folate deficiency as a tropical "macrocytic anemia" curable by a yeast extract. Ten years later, folate was isolated and extracted from spinach leaves in 1941 by Mitchell and others.

Folate is a generic term for a family of compounds that have nutritional properties of folic acid, the simplest form of the vitamin. Folate and folic acid derive their names from the Latin word for "leaf" (*folium*). Folic acid (pteroylglutamic acid) consists of a pteridine bicyclic ring system linkend to *p*-aminobenzoic acid, which is connected by a peptide bond to glutamic acid. Folic acid is the chemical form used in synthetic folate supplements, but does not occur in appreciable amounts in foods. Most folates exist in nature as polyglutamates, with five to eight glutamate residues joined to the first glutamate. The vitamin may be modified by reduction of the pteridine ring system to generate dihydrofolic acid and tetrahydrofolic acid (THF). The N-5 and N-10 positions of THF, either individually or in concert, can carry 1-C units, including methyl ($–CH_3$), formyl (–HCO), methylene ($–CH_2$), formyl (–CH=O), or formimino (–CH=NH) groups.

Good dietary sources of folate are liver, green leafy vegetables, citrus fruits, beans, and peas. Since 1998, folic acid has been added to enriched grain products includes breads, cereals, flours, and rice in the United States, and these products have become important contributors to dietary folate intakes. Currently, 75 countries mandate the addition of folic acid

(alongside iron) to grain products, most commonly wheat flour.[109]

Food folate occurs mostly as polyglutamates, which undergo hydrolysis in the jejunum by glutamate carboxypeptidase II in a pH-dependent mechanism. Transport into the intestinal cell is mediated by protein-coupled folate transporter (PCFT) and to a lesser degree by the reduced folate carrier. At high luminal levels, absorption can also occur by non-saturable passive diffusion. The monoglutamate from 5-methyl-THF is the predominant form in the portal circulation and in plasma. In tissue, most of folate is converted to polyglutamate forms by the enzymes methionine synthase and folylpolyglutamate synthetase to increase enzyme affinity and to retain and concentrate folate intracellularly.

Excess folate is excreted in the form of cleavage products in the urine. Fecal losses of folate are difficult to quantify because of the presence of folate-producing microbes in the colon.

Functions

Folate, in the form of its primary coenzyme THF, serves in the transfer of 1-C compounds needed in cycles for methionine, thymidylate, and purine synthesis. In these interconnected cycles, folate coenzymes are interconverted by C1-THF synthase in reactions producing 10-formyl THF, 5,10-methenyl THF and 5,10-methylene THF (Figure 10-6).

In the metabolism of amino acids, serine can transfer a methylene group to THF, to form glycine and 5,10-methylene-THF, which in turn can be reduced to 5-methyl-THF, followed by the transfer for the methyl group to homocysteine in a reaction catalyzed by the vitamin B_{12}-dependent enzyme methionine synthase to produce methionine and regenerate THF. This reaction is important in sustaining sufficient methionine pools for *S*-adenosylmethionine (SAM), which is involved in more than a hundred physiological reactions, including the methylation of DNA, RNA, and membrane phospholipids.

In a reaction catalyzed by thymidylate synthase, 5-10-methylene-THF donates a methyl group for the formation of the thymidylate, a necessary precursor of DNA synthesis and erythrocyte formation. THF is subsequently regenerated from DHF. The trifunctional enzyme C1-THF synthase converts 5,10-methylene-THF to 10-formyl THF, which is necessary for the *de novo* synthesis of the purines adenine and guanine. However, 5,10-methylene-THF may not be a major precursor in the production of 10-formyl-THF because the cellular environment favors the conversion of 10-formyl THF to 5,10-methylene-THF. A more important

reaction of the entry of 1-C units for folate-dependent biosynthetic reactions is the formulation of THF catalyzed by C1-THF synthase.

The first manifestation of folate deficiency is a decline in serum folate levels, occurring after approximately two weeks of consuming a folate-deficient diet. Deficiencies may also occur due to impaired absorption of the vitamin and after intake of a range of medications, including methotrexate, anticonvulsants, and anticancer drugs with anti-folate activity. An increasing number of folate-related polymorphisms resulting in impaired folate metabolism are being discovered.[110]

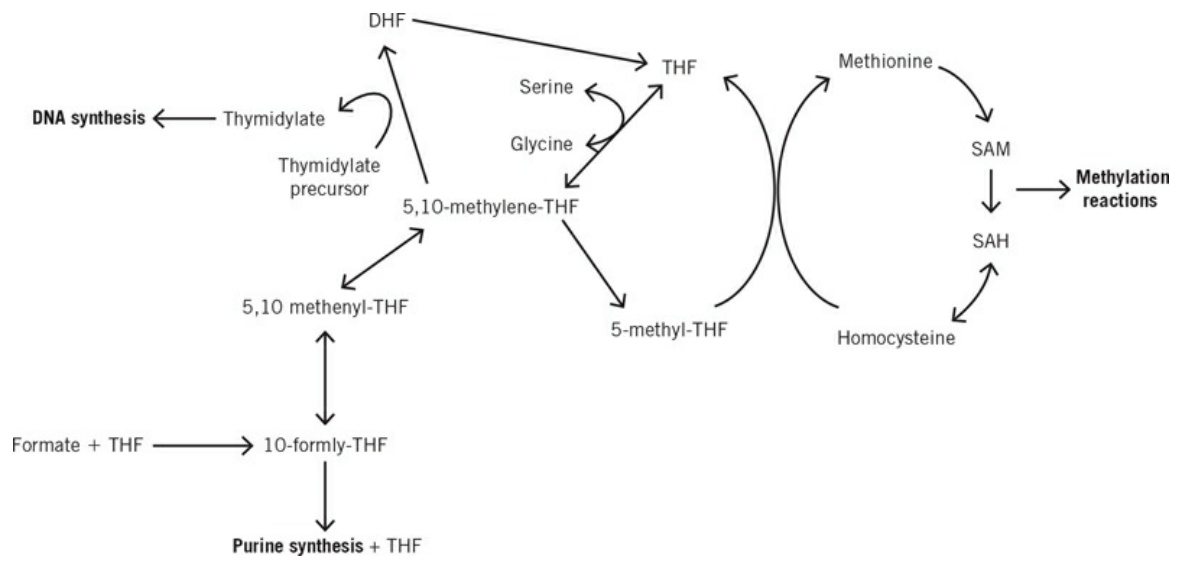

Figure 10-6 Summary of folate metabolism.

Folate deficiency leads to hyperpigmentation of neutrophils and a rise in homocysteine levels and abnormally nucleated erythrocytes in the bone marrow. Continued folate deficiency may lead to megaloblastic anemia. In the rapidly dividing cells of the GI tract, folate deficiency may impair cell division and lead to GI symptoms.

Increased folate consumption is related to lower plasma homocysteine levels and may therefore reduce vascular disease. However, folic acid therapy tested in randomized controlled trials had no effect on the incidence of major cardiovascular events.[111]

Owing to its role in DNA methylation, synthesis, and repair, dietary folate deficiency has been implicated in enhanced carcinogenesis, particularly in rapidly proliferative tissues such as the colorectal mucosa. In observational studies, higher dietary folate intakes are related to lower

risk of colorectal and other types of cancers.[112] However, high-dose folic acid does not reduce colorectal cancer risk.[111] There are concerns that folic acid supplementation may increase the growth of pre-existing tumors but more research is needed in this area.

Adequate folate status early in pregnancy greatly decreases the risk of NTDs, the most common major congenital abnormality in many countries,[113] and possibly congenital heart disease as well.[114] For this reason, folic acid has been added to enriched grains and mixed food items containing these grains in the United States since 1998 at levels of 0.14 mg/100 g flour.[115] This program has been credited with reducing the prevalence of low serum folate (<3 ng/mL) in the general population from 21% to <1% and with reducing NTD prevalence from 10.8 to 6.9 per 10,000 population.[116,117]

Deficiencies in either folate or vitamin B_{12} impair DNA synthesis in erythrocyte formation and thus lead to megaloblastic anemia. Deficiency in vitamin B_{12}, but not folate, also leads to neurological complications. There is concern that high intakes of folate may obscure or delay the diagnosis of vitamin B_{12} deficiency and associated neurological complications, especially among older adults with atrophic gastritis and those who follow a vegan diet or who suffer from pernicious anemia and bacterial overgrowth in the gut. The recommended ULs for folate proposed by the IOM attempt to safeguard against the masking of vitamin B_{12}.[118]

VITAMIN B_{12}

History, Structure, and Metabolism

The symptoms of the main vitamin B_{12} deficiency disorder, pernicious anemia, were first described in the mid-19th century by Addison. In 1926, Minot and Murphy showed that large quantities of liver normalized the hematological symptoms of pernicious anemia and in 1948, Folkers and Smith isolated the vitamin in the crystalline form from liver.

Vitamin B_{12} (cobalamin) is a large molecule with a complex corrin ring structure and a cobalt molecule at its center. Vitamin B_{12} is produced exclusively by microbes. Good dietary sources are meats (especially organ meats), fish, shellfish, eggs, fortified cereals and to a lesser extent dairy products. The vitamin is not generally present in plant products or yeast,

although high levels are present in dried green and purple lavers (seaweed). About 50% of dietary vitamin B_{12} is absorbed from mixed diets.[119]

Dietary vitamin B_{12} is mostly bound to proteins and released by pepsin in the acidic gastric environment. Free vitamin B_{12} binds to R protein (haptocorrin) and in the alkaline environment of the duodenum, R protein is degraded by pancreatic enzymes and the vitamin B_{12} binds to intrinsic factor (IF). In the ileum, the IF-B_{12} complex is taken up by the cubam receptor and is released as transcobalamin (TC). Absorption via passive diffusion may also occur, but only accounts for about 1% of absorbed vitamin B_{12}. After absorption, vitamin B_{12} is transported as part of TC to the liver and other tissues, where the TC-B_{12} complex is taken up by receptor-mediated endocytosis.[120]

Vitamin B_{12} is readily converted to its coenzyme forms after release from lysosomes. Among healthy omnivores, body vitamin B_{12} stores amount to about 2–3 mg, of which 50% is stored in the liver.

The main form of vitamin B_{12} excretion is bile, but daily losses are minimized to 0.1%–0.2% of the body pool due to effective reabsorption during enteropathic circulation. At very high plasma concentrations, such as after injections of the vitamin, urinary excretion also occurs.

Functions

In humans, vitamin B_{12} functions as part of the coenzyme methylcobalamin for methionine synthase and as part of 5-deoxyadenosylcobalamin for L-methylmalonyl-CoA mutase. Methylcobalamin is required by methionine synthase for the methyl transfer from 5-methyl-THF to homocysteine, to yield the end products methionine and THF. Methionine is required for the synthesis of the methyl donor SAM used in numerous methylation reactions.[121] In the absence of vitamin B_{12}, folate becomes trapped in its inactive form 5-methyl-THF, DNA synthesis is impaired, and megaloblastic anemia develops.

As part of 5-deoxyadenosylcobalamin, vitamin B_{12} is required for the enzyme L-methylmalonyl-CoA mutase to convert L-methylmalonyl-CoA to succinyl-CoA in an isomerization reaction. Lack of production of succinyl-CoA due to vitamin B_{12} deficiency is unlikely to have serious

metabolic consequences as succinyl-CoA is abundantly derived from fats and carbohydrates. However, accumulation of L-methylmalonyl-CoA in the cell can lead to increased production of odd-chain and branched-chain fatty acids. These fatty acids may be abnormally incorporated into nerve cell membranes and may account for neurological symptoms due to degenerated myelin nerve sheaths.[122] Vitamin B_{12} deficiency generally increases levels of methylmalonic acid, a marker for vitamin B_{12} deficiency, and of homocysteine, a less specific marker.

Foods of animal origin are the best naturally occurring sources of vitamin B_{12} and those who follow a vegan diet are therefore at risk for vitamin B_{12} deficiency. Vegan mothers may pass on inadequate levels of vitamin B_{12} through their breast milk are thus advised to supplement their infants from birth with vitamin B_{12} at the level of the adequate intake. Vitamin B_{12} deficiency may be a common public health problem in South Asia, selected parts of Africa and the Americas, but more data are needed to characterize the magnitude of the problem.[123,124]

In the United States, dietary intakes of vitamin B_{12} in the general, non-vegan population generally meet dietary needs. Vitamin B_{12} deficiency is therefore more commonly due to poor absorption rather than inadequate intakes. The most common cause of severe vitamin B_{12} absorption is pernicious anemia, a chronic atrophic gastritis in which autoantibodies are formed to IF producing parietal cells or to IF directly. In children, pernicious anemia is generally the result of a genetically determined defect in secretion of IF or the secretion of a defective IF. The prevalence of pernicious anemia increases with age and undiagnosed pernicious anemia may affect 2% of individuals over 60 years of age in the United States.[125] The vitamin deficiency can be corrected by large weekly injections of vitamin B_{12}, but simpler oral regimens using pharmacological dosages may also be effective.[126]

In atrophic gastritis, a chronic inflammation of the stomach mucosa, there is loss of gastric glandular cells with resultant reduced secretion of hydrochloric acid, pepsin, and IF, which in turn lowers the absorption of vitamin B_{12} from food proteins. The gastric levels may also result in an overgrowth of bacteria in the stomach and small intestine that bind the vitamin for their own use. Atrophic gastritis is the major cause of vitamin B_{12} deficiency among the 10%–15% of people over the age of 60 years.[127]

The neurological symptoms associated with vitamin B_{12} deficiency

may include tingling and numbness sensations in the extremities, motor disturbances, and cognitive changes such as loss of concentration and dementia. In extreme cases, the degeneration of peripheral nerves may progress to irreversible paralysis. Neurological complications may in some cases present without hematological symptoms. In fact, there is evidence of an inverse association between the prominence of neurological complications and the severity of anemia.

GI impairments due to vitamin B_{12} deficiency include atrophic glossitis, papillary atrophy of the tongue, appetite loss, flatulence, and constipation. Among children, severe vitamin B_{12} deficiency is related to irritability, failure to thrive, apathy, anorexia, and developmental regression and can often be reversed with supplementation.[128]

There is no evidence of adverse effects of vitamin B_{12} obtained from foods or supplements. As a result, ULs have not been defined for vitamin B_{12}.[118]

BIOTIN

History, Structure, and Metabolism

Using feeding studies with dried eggwhite, Boas described in 1927 that mammals require the water-soluble vitamin biotin. Koegl and Toennis isolated the vitamin from egg yolk in 1932 and the chemical structure was elucidated by du Vigneaud and colleagues in 1942. One year later, Harris and colleagues first synthesized biotin.

Biotin is an imidazole derivative that is widely distributed in foods and generally bound to protein. Digestion of dietary protein releases biotinyl peptides and intestinal biotinidases further hydrolyze biotinyl peptides to biotin. At low luminal concentrations, the vitamin is absorbed via the SMVT, which binds biotin, pantothenic acid, and lipoic acid with similar affinity. At high luminal concentrations, a nonsaturable process dominates. The bioavailability of biotin from food and supplements is nearly complete, but is impaired by the heat labile protein avidin contained in raw eggs. Biotin is bound non-specifically by albumin, α-globulin, and β-globulin and taken up into the liver and peripheral tissues via SMVT. The vitamin is stored in the liver and is excreted mainly in urine and to a lesser degree in bile.

Functions

Biotin serves as a coenzyme for carboxylases active in energy metabolism, fatty acid synthesis, and amino acid metabolism. It also binds to DNA binding proteins called histones and functions in cell signaling pathways.

Biotin is attached to the active site of five mammalian carboxylases: Acetyl-CoA carboxylases I and II catalyze the binding of bicarbonate to acetyl-CoA to form malonyl-CoA, required for the synthesis of fatty acids; pyruvate carboxylase is a key enzyme in gluconeogenesis; propionyl-CoA carboxylase catalyzes essential steps in the metabolism of several amino acids, cholesterol, and odd chain fatty acids; and methylcrotonyl-CoA carboxylase catalyzes an essential step in leucine catabolism.

Histones are essential for the folding of DNA into chromatin. The five major classes of histones H1, H2A, H2B, H3, and H4 have been identified in mammals. The covalent binding of biotin to lysine residues in histones, mediated by biotinidase and holocarboxylase synthetase, regulates posttranslational modifications of histones important for processes such as transcription, replication, and repair of DNA.[129]

Biotin functions in the expression of genes for enzymes involved in biotin utilization in human cells. In these reactions, biotin is transformed into biotinyl-5'-AMP by holocarboxylase synthetase and activated by soluble guanylate cyclase and a cGMP-dependent protein kinase.[130]

Even though symptomatic human biotin deficiency is rare, it has been manifested among persons on biotin-free total parenteral nutrition and among persons who consume large amounts of raw eggs over extended periods of time. The first manifestation of biotin deficiency is a depressed biotin level in urine. Signs of frank biotin deficiency include hair loss and a scaly red rash around the eyes, nose, mouth, and genital area. Neurologic symptoms in adults have included hallucination, depression, lethargy, and numbness and tingling of the extremities. Among infants, deficiency symptoms occur after three to six months on biotin-free total parenteral nutrition, which is earlier than among adults, possibly because of increased biotin requirements due to growth. Biotin deficiency has also been related to impaired cellular and humoral immunity, cell proliferation, and fatty acid metabolism.

Biotin deficiency may also be due to genetic defects. Infants with a genetic defect in the enzyme biotidinase fail to recycle biotin and lose large amounts of biotin metabolites in urine. Symptoms generally occur between 1 week and 1 year of age and include poor feeding, vomiting, rash around eyes, nose, and mouth, and neurological symptoms such as muscle pain, lethargy, and numbness. Genetic defects may also induce deficiencies in individual and multiple carboxylases or biotin transporters.

Pharmacological biotin supplementation generally improves symptoms related to these genetic defects and must be maintained throughout the lifetime.

There are no reports of adverse effects due to high doses of biotin. Even doses as high as 200 mg given orally and 20 mg given intravenously are not related to toxicity symptoms.[118]

PANTOTHENIC ACID

History, Structure, and Metabolism

Pantothenic acid was discovered as a growth factor for yeast and certain bacteria by Williams in 1933. Elvehjem and Jukes showed in 1939 that pantothenic acid was required for growth and prevented dermatitis in chicken. Williams established the chemical structure of the vitamin in 1940.

Pantothenic acid consists of a β-alanine molecule and a dihydroxy acid called pantoic acid joined by an amide link. There is little data on the pantothenic acid content of food, but the vitamin is thought to be widely distributed in both plant and animal based foods. Major known sources include chicken, beef, egg yolk, milk, potatoes, oat cereals, broccoli, and avocado. However, up to 75% of the vitamin may be lost during food processing, such as freezing and canning and refining of whole grains. In food, the vitamin is present as CoA or as 4´-phosphopantetheine, and dephosphorylation and hydrolysis reactions produce pantothenic acid, which is readily absorbable. The vitamin is taken up into the enterocyte at low concentrations by the SMVT, and passive transport at higher concentrations. After absorption, the vitamin is taken up from the plasma into the brain by facilitated diffusions and into other organs by the SMVT. The vitamin is excreted in urine, primarily as pantothenic acid.

Functions

Pantothenic acid serves as the substrate for the synthesis of CoA and Acyl Carrier Protein (ACP), which play important roles in the metabolism of carbohydrates, proteins, and fats. There are five enzymatic steps in the conversion of pantothenic acid to CoA, which then serves as the 4´-phosphopantetheine substrate in the formation of ACP (Figure 10-7).

As part of CoA, pantothenic acid functions in the transfer of acetyl and acyl groups in many vital reactions. These include reactions in oxidative metabolism and catabolism that generate energy from carbohydrates,

lipids, and proteins. In carbohydrate metabolism, CoA functions in reactions such as in the citric acid cycle and the acetylation of sugars; in lipid metabolism, CoA is required to synthesize essential fats, cholesterol, and steroid hormones. ACP is central to the synthesis of fatty acids through its role as a carrier of acyl intermediates.[131]

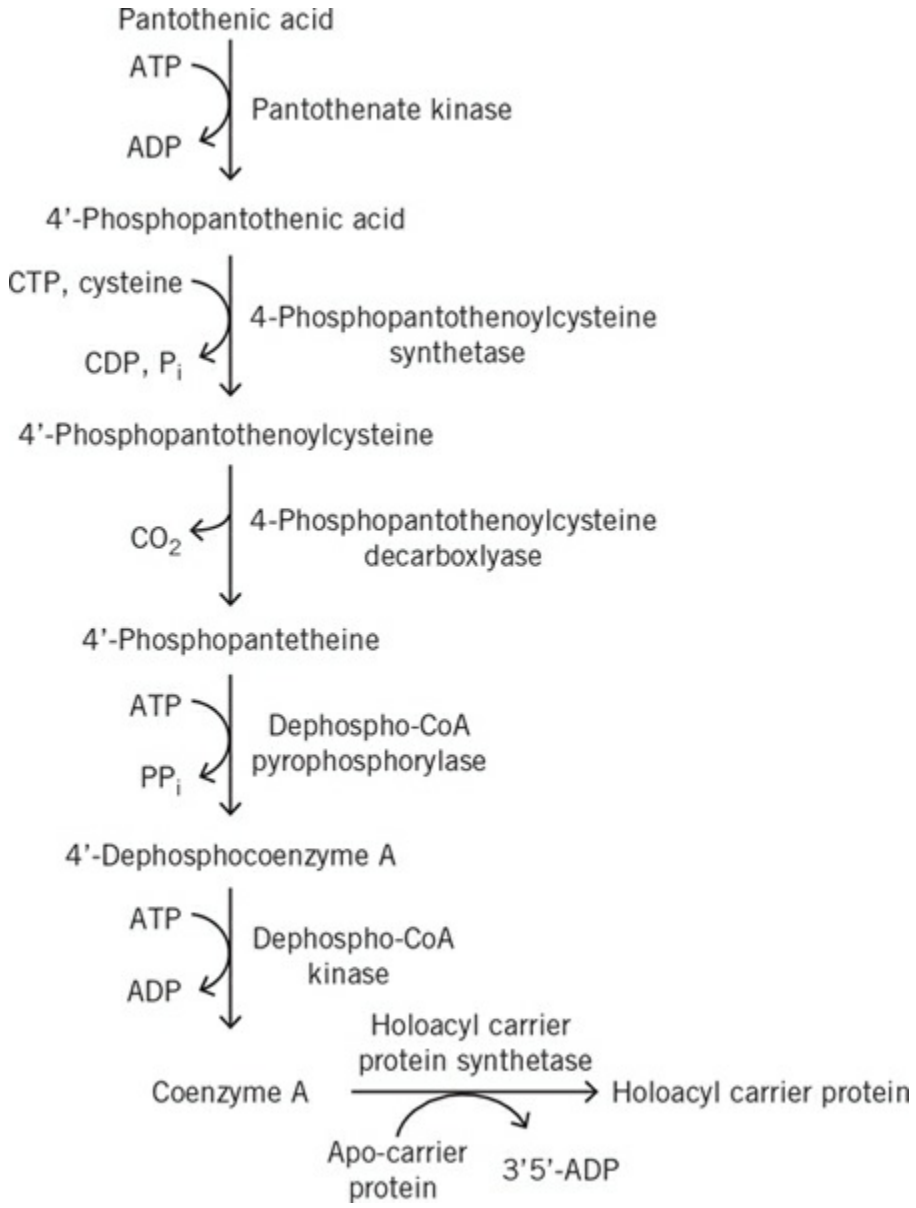

Figure 10-7 Conversion of pantothenic acid to Coenzyme A.

Pantothenic acid deficiency in humans is rare. Among severely malnourished prisoners of war during World War II, suffering from multiple deficiency diseases, the "burning feet" syndrome, a new condition

of paresthesia and severe pain in the feet and toes, was thought to be due to pantothenic acid deficiency. In experimental states of pantothenic acid deficiency induced by feeding volunteers synthetic diets devoid of pantothenic acid or by administering pantothenic acid antagonists, neuromotor disorders, mental depression, GI symptoms, and increased insulin sensitivity have been noted.

A variety of health claims have been made for pantothenic acid and its derivatives.

Pantethine, a metabolite of pantothenic acid, may have a hypocholesterolemic effect and raise high-density lipoprotein levels in individuals with dyslipidemia and hypercholesterolemia.[132] Oral pantothenic acid has been implicated in improved wound healing, but epidemiologic studies do not support this claim.[133] High dosages of the vitamin may have therapeutic benefits during rheumatoid arthritis[134] and lupus erythematosus[135] and are not related to adverse effects.

SUMMARY

We have reviewed the history, structure, function, and metabolism of the 13 water- and fat-soluble vitamins. Although the “golden age” of vitamin discovery and biochemical identification was 100 years ago, modern medical and public health advances continue to be made in the field, and both population and genetic approaches to determine optimal vitamin intake are being undertaken.

Dietary Reference Intakes in the United States

11

Alice H. Lichtenstein, DSc and Stephen R. Daniels, MD, PhD

INTRODUCTION

The dietary reference intakes (DRIs) are a set of recommendations intended to provide guidance in evaluating nutrient intakes and planning meals on the basis of nutrient adequacy.[1] In contrast to their predecessor, recommended dietary allowances (RDAs) last published in 1989, the DRIs differ in two ways: the emphasis has shifted from preventing nutrient deficiencies to reducing chronic disease risk and in addition to providing guidance for daily intakes, it also includes recommendations for maximum upper levels at which no adverse health outcomes would be expected, termed tolerable upper intake levels (ULs).

The DRIs were established during the mid-1990s through the mid-2000s with a series of committees that included both American and Canadian members under the auspices of the Food and Nutrition Board, Institute of Medicine of the National Academies of Science, in collaboration with Heath Canada. Separate committees were established for the following subcategories of nutrients: calcium, phosphorus, magnesium, vitamin D, and fluoride[2]; thiamin, riboflavin, niacin, vitamin B_6, folate, vitamin B_{12}, pantothenic acid, biotin, and choline[3]; vitamin C, vitamin E, selenium, and carotenoids[4]; vitamin A, vitamin K, arsenic, boron, chromium, copper, iodine, iron, manganese, molybdenum, nickel,

silicon, vanadium, and zinc[5]; energy, carbohydrate, fiber, fat, fatty acids, cholesterol, protein, and amino acids[1]; and water, potassium, sodium, chloride, and sulfate.[6]

Depending on the available data for each nutrient, their DRIs are comprised of estimated average requirements (EARs), RDA or adequate intakes (AIs), and UL value.[7] In the case of macronutrients, there is an alternate category of recommendations, the acceptable macronutrient distribution ranges (AMDRs).[1] This latter category was established because evidence indicated that for energy containing nutrients optimal health outcomes were observed over a range of intakes.

When it appears an adequate body of new data is available for a specific nutrient or group of nutrients to warrant a reassessment of the DRI values, the data are reviewed and updated if necessary. Most recently, in 2010 a committee was convened to review the data for vitamin D and calcium. To facilitate this process, a systematic review was commissioned by the IOM for their use.[8] On the basis of the committee's deliberations, a modification was made to the DRIs for these nutrients.[9]

Table 11-1 provides summary definitions for these terms as established by the Food and Nutrition Board, including EAR, RDA, AI, UL, and AMDR.[10]

TABLE 11-1 Dietary Reference Intakes

Estimated Average Requirements (EAR): the average daily nutrient intake level estimated to meet the requirements of half the healthy individuals in a particular life stage and gender group.

Recommended Dietary Allowance (RDA): the average daily nutrient intake level sufficient to meet the nutrient requirements of nearly all (97–98%) healthy individuals in a particular life stage and gender group.

Adequate Intake (AI): a recommended average daily nutrient intake level based on observed or experimentally determined approximations or estimates of nutrient intake by a group (or groups) of apparently healthy people that are assumed to be adequate—used when an RDA cannot be determined.

Tolerable Upper Intake Level (UL): the highest average daily nutrient intake level likely to pose no risk of adverse health effects to almost all individuals in the general population. As intake increases above the UL, the potential risk of adverse effects increases.

Acceptable Macronutrient Distribution Ranges (AMDR): the intakes that are associated with reduced risk of chronic disease, intakes at which essential dietary nutrients can be consumed at sufficient levels and intakes based on adequate energy intake and physical activity to maintain energy balance.

Source: Adapted from IOM.[10]

BASIS FOR ESTABLISHING DRI VALUES

In formulating the DRIs, data were drawn primarily from peer reviewed publications. In some cases, the basis on which the reference values were derived was scanty, particularly for the younger age categories. In those cases, with the exception of birth through 1 year of age, the reference values were extrapolated from adult data. The actual criteria on which nutrient adequacy was based varies among nutrients and age groups. This information is documented, in detail, in each of the DRI committee reports.[1–6]

The DRI values are presented for the following age categories: 0 through 6 months, 7 through 12 months, 1 through 3 years, 4 through 8 years, 9 through 13 years, 14 through 18 years, 19 through 30 years, 31 through 50 years, and greater than 70 years. This chapter will be restricted to recommendations for categories up to and including age 18 years.

In general, the recommendations for infants aged 0 through 6 months are based on average consumption of human milk. Recommendations for individuals 7 through 12 months are based on average consumption of human milk and complementary foods. For subsequent age groups, sources of data, depending on the specific nutrient, include mean national intake data (Continuing Survey of Food Intake by Individuals) and amounts shown to provide the greatest protection against a specified chronic disease or deficiency state. Further taken into consideration was whether the recommendations provided for adequate levels of energy meet expenditure plus energy deposition and maintenance of nitrogen equilibrium plus protein deposition. The criteria used to assess adequacy can differ for individuals at different stages in the life cycle.

DIETARY REFERENCE INTAKES

Estimated Average Requirement

EAR is the daily value that is estimated to meet the requirement, defined by a predetermined indicator or criterion of adequacy, of half the healthy population of individuals represented by each age and sex group. The underlying assumption is that the distribution of actual requirements in a population is normally distributed. The EAR value is dependent on the indicator used to assess nutrient adequacy. The primary use of EAR values is to establish RDA values.

Recommended Dietary Allowance

RDA is the daily value that is estimated to meet the requirement, defined by a predetermined indicator or criterion of adequacy, by 97%–98% or nearly all of the healthy population of individuals represented by each age and sex group. By definition, the RDA value is calculated by summing the EAR and two standard deviations of the EAR if there are adequate data on which to calculate the variance. In cases where there are inadequate data with which to calculate the standard deviation of the EAR, the variance is assumed to be 10% of the EAR and the RDA is calculated by summing the EAR and two times 10% of the EAR. The primary use of RDA values is as a daily intake goal. For nutrients, where there were inadequate data on which to calculate EAR and RDA values for children, the numbers were extrapolations from adult data.

Adequate Intake

AI is the daily value that is estimated from the actual intake data of healthy people when there are inadequate data with which to calculate an EAR. The AI values are expected to meet or exceed the amounts needed to maintain a defined nutritional state or criterion of adequacy in essentially all members of a specific age and sex group. Hence, the AI values may exceed the EAR values in the range of individuals covered. The AI values are intended to be used similarly to the RDAs. Nonetheless, the level of certainty for AI values is less than that for RDA values. Both the RDA and AI values are used as goals for nutrient adequacy.

Acceptable Macronutrient Distribution Range

AMDR values were established for the macronutrients (fat, carbohydrate and protein) and *n*-6 and *n*-3 fatty acids (Table 11-2). The subcategory for fatty acids was created because they are essential nutrients—humans cannot make them in adequate amounts to support growth, development, and maintenance. The AMDR values provide a recommended range of intakes that are associated with optimal health outcomes and fulfill the RDAs for essential nutrients based on adequate energy intake and physical activity to maintain energy balance. Ranges were established after reviewing the available data and superimposing information about the interrelated metabolic fates of the macronutrients. The recommendations are expressed as percent of dietary energy because their absolute intakes are dependent on total energy needs. For the most part, the criteria used to establish AMDRs are the levels associated with low chronic disease risk and levels necessary to ensure sufficient intakes of other essential

nutrients. In some cases, for subclasses of the macronutrients, for which specific, unique functions were identified, additional criteria were used to establish either ERA or AI values. Examples include omega-3 fatty acids and indispensable amino acids.

Tolerable Upper Limit

The UL is the daily value that is estimated to be the highest level likely to pose no risk of adverse health effects for most people. The word "tolerable" was chosen as a qualifier for "upper levels" specifically to avoid implying that the upper levels are preferable or beneficial, especially compared to the RDAs or AIs. UL values were determined using a risk assessment methodology. ULs are a new category of recommendations and were added because of the concern that widespread fortification of foods and common use of dietary supplements can result in intake levels considerably higher than that attainable with mixed diets and may result in adverse health outcomes.

TABLE 11-2 Uses of DRIs for Assessing Intakes by Individuals and Groups

For an Individual	For a Group
EAR: Use to examine the probability that usual intake is inadequate.	**EAR:** Use to estimate the prevalence of inadequate intakes within a group.
RDA: Usual intake this level has a low probability of inadequacy.	**RDA:** Do not use to assess intakes of groups.
AI: Usual intake at or above this level has a low probability of inadequacy.	**AI:** Mean usual intake at or above this level implies a low prevalence of inadequate intakes.[a]
UL: Usual intake above this level may place an individual at risk of adverse effects from excessive nutrient intake.	**UL:** Use to estimate the percentage of the population at potential risk of adverse effects from excessive nutrient intake.

Abbreviations: AI, adequate intake; EAR, estimated average requirement; RDA, recommended dietary allowance; UL, tolerable upper intake level.

[a]When the AI for a nutrient is not based on mean intakes of healthy populations, this assessment is made with less confidence.

Source: Adapted from IOM.[10]

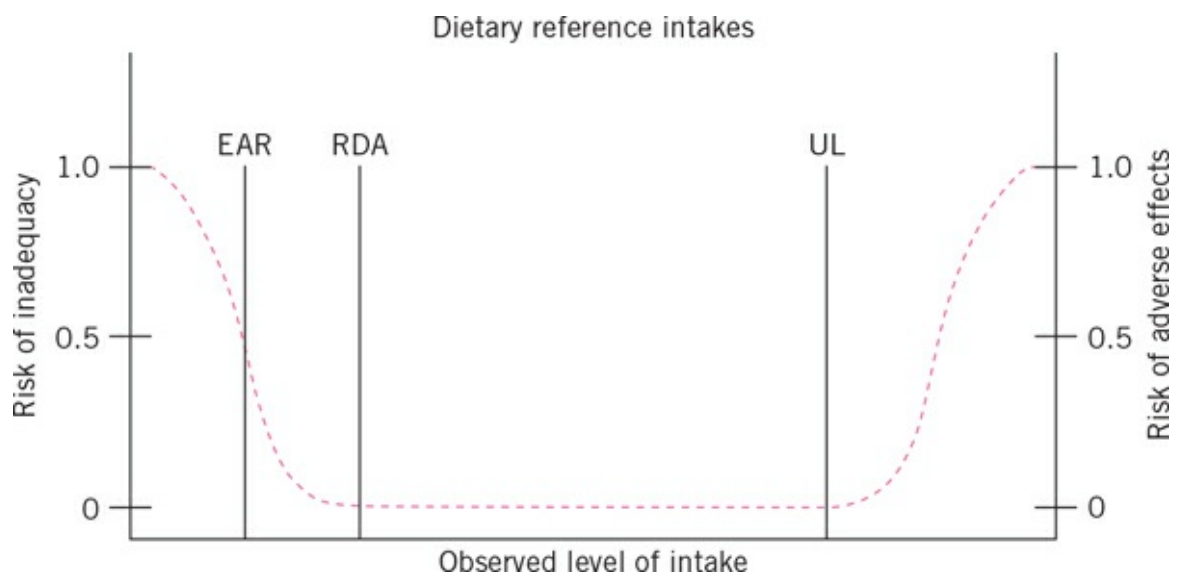

Figure 11-1 The relationship between the estimated average requirement (EAR), recommended dietary allowance (RDA), and tolerable upper intake level (UL). The risk of inadequate intake is 50% at the EAR, 2%–3% of the RDA, and close to 0% at the UL. Risks of adverse effects are close to 0% at the UL but increase with increasing intake. (Reproduced with permission from the Institute of Medicine.[2])

The relationship among the EAR, RDA, and UL values is depicted in Figure 11-1. Intakes between the RDA and UL values are assumed to be optimal because the risk of inadequacy and excess are both estimated to be close to zero.

INTENDED USES OF THE DRI

The major uses of DRIs as defined by the Food and Nutrition Board include determining the nutrient adequacy and for the purpose of planning diets for both individuals and groups of individuals (Table 11-3). They serve as the basis for all federal feeding programs, food assistance programs, and nutrition education programs, and are used to set Dietary Values (DV) for Food and Drug Administration's mandatory Nutrient Facts Panel. The DRIs, Dietary Guidelines for Americans and MyPlate are internally consistent.

DRI LIFE STAGE GROUPS RELEVANT TO THE

PEDIATRIC POPULATION

Infancy

DRI values are provided for two 6-month age groups during the first year of life, 0 through 6 months and 7 months through 1 year. Recommendations are based on the assumption that the infants are full-term, born to healthy and well nourished women, and exclusively fed human milk. Ethical considerations preclude the experimental determination of EAR values for infants. For this reason all the recommended values for these age categories are AIs. They are derived from the mean composition of an average volume of milk consumed by the specific age group. The recommendations are based on AI values, hence, may exceed the EAR values. It is important to note the decision of the Food and Nutrition Board committees to base the AIs on human milk is consistent with the recommendation of the American Academy of Pediatrics and the Canadian Paediatric Society, both of which state that exclusive breastfeeding is the preferred method of feeding for normal full-term infants for the first 4–6 months of life.

TABLE 11-3 Dietary Reference Intakes (DRIs): Acceptable Macronutrient Distribution Ranges[a]

	Range (Percent of Energy)	
Macronutrient	**Children, 1–3 y**	**Children, 4–18 y**
Fat	30–40	25–35
n-6 polyunsaturated fatty acidsb (linoleic acid)[a,b]	5–10	5–10
n-3 polyunsaturated fatty acidsb (α-linoleic acid)	0.6–1.2	0.6–1.2
Carbohydrate	45–65	45–65
Protein	5–20	10–30

[a]Food and Nutrition Board, Institute of Medicine, National Academies

[b]Approximately 10% of the total can come from longer-chain n-3 or n-6 fatty acids.

0 Through 6 Months

For the first 6 months of life, food intake relative to body weight is for the most part constant. As an infant grows, their food intake will increase. The mean intake of a nutrient is calculated based on the average concentration

of the nutrient from 2 through 6 months of lactation and an average volume of milk (780 mL/day). It is assumed that infants will have adequate access to human milk and can thus increase their intake to meet their requirements for growth and maintenance.

7 Through 12 Months

For the second 6 months of life, growth velocity slows and daily nutrient needs, on a body weight basis, are lower than during the first 6 months. This 6-month period is characterized by a gradual weaning from milk and transitioning to a mixed diet including solid foods. It was assumed on the basis of available data that nutrient needs have not changed markedly during this time period.

Toddlers: Age 1 Through 3 Years

For ages 1 through 3 years, growth velocity in height has been greater than other age periods after infancy. From a practical perspective the Food and Nutrition Board committees also took into consideration that after age 4 years children enter into daycare and school systems and that hence, the source and exposure to food frequently changes. It is noteworthy that data for individual nutrients are relatively scarce for this age category and many values were extrapolated.

Early Childhood: Ages 4 Through 8 Years

For ages 4 through 8 years there are continued changes in growth velocity and endocrine status. These changes separate this group from the younger and older age categories. Although limited, the Food and Nutrition Board committees determined there were more data to define EAR's and AIs for this than the prior age categories. The DRIs for ages 4 through 8 years form the basis of many school feeding programs.

Puberty/Adolescence: Ages 9 Through 13 Years and Ages 14 Through 18 Years

The distinction between ages 9 through 13 years and 14 through 18 years was made on the basis of multiple developmental criteria. For girls, the criteria were increased estrogen secretion physically marked by breast development and onset of the growth spurt. For boys, the criteria were initiation of testicular development and onset of the growth spurt. In general, the growth spurt in boys begins about 2 years later than in girls. For this reason sex specific recommendations are made starting with these

age categories.

TYPES OF DATA USED TO FORMULATE THE DRIs

The type of data used to formulate the DRIs varies from age group to age group and nutrient to nutrient, especially between energy containing and non-energy containing nutrients. Nevertheless, there are certain common features. The primary source of the data used to formulate the DRI values is clinical, dose–response, balance, depletion–repletion, and observational and case-controlled studies.

On the basis of a review of the available data, the possible criteria of nutrient adequacy were identified by each committee for each individual nutrient. The collective scientific judgment of the committee members was then used to select the indicator criterion to determine whether the available data would allow for the establishment of an EAR or AI value. The criterion differed among nutrients and in many cases differed by life stage group. The evaluation and decision were documented for each nutrient by the committee members and was included in the individual reports. Factors that went into the decisions were the strength of the data, consistency and preponderance of the data, and the degree of concordance among epidemiological, and clinical and laboratory findings.

The following factors were taken into consideration when assessing the available data: strength of association (usually expressed as relative risk), dose–response relationship, temporally correct association (with exposure preceding the onset of disease), consistency of association; specificity of association, and biological plausibility.

RDA's AND AI's FOR INFANTS, CHILDREN, AND ADOLESCENTS

The current RDA, AI, and AMDR values for infants, children, and adolescents can be found on the Food and Nutrition Board's website.[11] Noteworthy, these numbers should be used as targets on a daily basis. Actual intakes should be averaged over a number of days to assess adequacy.

For individuals below 18 years, there are few age-specific categories of nutrients that have AMDR values than have RDAs and IAs values; the categories include children aged 1 through 3 years and 4 through 18 years.

The collapsing of categories was necessary due to limited data for the potentially unique needs of each of the original age grouping.

Summarized in Table 11-4 are additional macronutrient recommendations for non-essential dietary components: cholesterol, *trans* fatty acids, saturated fatty acids, and added sugars. These non-essential dietary components are ubiquitous in the food supply and intakes, specifically with respect to the lipid soluble compounds, and have been associated with increased risk of chronic diseases.[12] These are general recommendations across all age and sex categories.

TABLE 11-4 Dietary Reference Intakes (DRIs): Additional Macronutrient Recommendations[a]

Macronutrient	Recommendation
Dietary cholesterol	As low as possible while consuming a nutritionally adequate diet
Trans fatty acids	As low as possible while consuming a nutritionally adequate diet
Saturated fatty acids	As low as possible while consuming a nutritionally adequate diet
Added sugars	Limit to no more than 25% of total energy

[a]Food and Nutrition Board, Institute of Medicine, National Academies.

Source: Adapted from IOM.[1]

TOLERABLE UPPER INTAKE LEVELS

Current ULs for those nutrients for which values have been established can be found on the Food and Nutrition Board's website.[11] The dearth of data for some nutrients precluded establishing UL values and does not indicate that intake at any level is without risk. It is important to note that UL values can only be used to assess the likelihood that an individual may be at risk for adverse effects, not that they actually will be at risk. As indicated, these values represent upper limits at which no adverse effects are likely to occur, not optimal intakes.

SELECTED NUTRIENT FUNCTIONS AND MAJOR FOOD SOURCES FOR VITAMINS AND

ELEMENTS

Summarized in Table 11-5 are nutrient functions and their major sources in the U.S. food supply. The wide range of foods noted among the nutrients is reflective of both natural occurrence and mandatory federal guidelines for fortification. For example, there are a limited number of foods that are good sources of vitamin D. For this reason, the federal government has mandated that all fluid milk be fortified with vitamin D. Fluid milk was chosen because of the unique needs of growing children and adolescents for this nutrient and historically the habitual food intake patterns of these age groups. As the intake of milk declines in these age groups, alternate approaches may be needed to ensure AI of this essential nutrient.[13]

TABLE 11-5 Dietary Reference Intakes: Macronutrients (Continued)

Nutrient	Function	Selected Food Sources
Carbohydrate-total digestible	RDA based on its role as the primary energy source for the brain; AMDR based on its role as a source of kilocalories to maintain body weight.	Starch and sugar are the major types of carbohydrates. Grains and vegetables (corn, pasta, rice, potatoes, breads) are sources of starch. Natural sugars are found in fruits and juices. Sources of added sugars are soft drinks, candy, fruit drinks, and desserts.
Total fiber	Improves laxation, reduces risk of coronary heart disease, assists in maintaining normal blood glucose level.	Includes dietary fiber naturally present in grains (such as found in oats, wheat, or unmilled rice) and functional fiber synthesized or isolated from plants or animals and shown to be of benefit to health.
Total Fat	Energy source and when found in foods, is a source of *n*-6 and *n*-3 polyunsaturated fatty acids. Its presence in the diet increases absorption of fat soluble vitamins and precursors	Butter, margarine, vegetable oils, whole milk, visible fat on meat and poultry products, invisible fat in fish, shellfish, some plant

	such as vitamin A and pro-vitamin A carotenoids	products such as seeds and nuts, and bakery products.
n-6 polyunsaturated fatty acids (linoleic acid)	An essential component of structural membrane lipids, involved with cell signaling, and precursor of eicosanoids. Required for normal skin function.	Nuts, seeds, and vegetable oils such as soybean, safflower, and corn oil.
n-3 polyunsaturated fatty acids (α-linoleic acid)	Involved with neurological development and growth. Precursor of eicosanoids.	Vegetable oils such as soybean, canola, and flax seed oil, fish oils, fatty fish, with smaller amounts in meats and eggs.
Saturated and *trans* fatty acids, and cholesterol	No required role for these nutrients other than as energy sources was identified; the body can synthesize its needs for saturated fatty acids and cholesterol from other sources.	Saturated fatty acids are present in animal fats (meat fats and butter fat), and coconut and palm kernel oils. Sources of cholesterol include liver, eggs, and foods that contain eggs such as cheesecake and custard pies. Sources of *trans* fatty acids include sticking margarines and foods containing hydrogenated or partially hydrogenated vegetable shortenings.
Protein and amino acids	Serves as the major structural component of all cells in the body, and functions as enzymes, in membranes, as transport carriers, and as some hormones. During digestions and absorption dietary proteins are broken down to amino acids, which become the building blocks of these structural compounds. Nine of the amino acids must be provided in the diet; these are termed indispensable amino acids. The body can make the other amino acids needed to synthesize structures from other amino acids.	Proteins from animal sources, such as meat, poultry, fish, eggs, milk, cheese, and yogurt, provide all nine indispensable amino acids in adequate amounts, and for this reason are considered “complete proteins”. Proteins from plants, legumes, grains, nuts, seeds, and vegetables tend to be deficient in one or more of the indispensable amino acids and are called “incomplete proteins”. Vegan diets adequate in

	total protein content can be “complete” by combining sources of incomplete proteins which lack different indispensable amino acids.

Source: Dietary Reference Intakes for Energy, Carbohydrates, Fiber, Fat, Fatty Acids, Cholesterol, Protein, and Amino Acids (2002/2005). This report may be accessed via www.nap.edu. Adapted from IOM.[10]

With the increasing trend for widespread fortification of the food supply, issues related to potential intakes approaching the UL values need to be monitored.[14] In some cases, the consumption of fortified foods can be passive and in some cases intentional. In both cases, non-traditional sources of vitamins and elements will alter total intake. This general issue came to light when it was reported that long-term intake of a diet high in retinol, independent of dietary supplements, was associated with the risk of osteoporotic hip fractures in women.[15] Recent concern has been raised about the potential for high intakes of folate and risk of developing colon cancer.[16] Better nationwide monitoring tools, especially for children, are necessary.

DIETARY GUIDELINES FOR AMERICANS

In addition to the DRIs, the U.S. Departments of Health and Human Services and Agriculture jointly issue Dietary Guidelines for Americans.[17] “Key Recommendations” are provided to summarize and focus the information in terms of actionable items. The U.S. Dietary Guidelines are reviewed and revised on the basis of the most recent scientific evidence every five years.

The intent of the Dietary Guidelines is to summarize and synthesize current knowledge in the area of nutrition with the intent of providing straight forward food based recommendations that promote health and decrease chronic disease risk. The Dietary Guidelines are intended for the entire U.S. population. The current recommendations are summarized in Table 11-6.

PRACTICAL ASPECTS OF ADEQUATE DIETARY INTAKE IN CHILDREN AND ADOLESCENTS

The DRI values are a helpful tool in evaluating whether individuals or groups are taking in adequate levels of nutrients to ensure appropriate growth and development throughout childhood and adolescence. An understanding of DRI values and the Dietary Guidelines can help pediatricians and other pediatric health professionals guide families in developing appropriate dietary patterns. Unfortunately, this may not be enough as parents, caregivers, and children are making dietary choices in a challenging food environment where some types of foods are highly promoted and advertised while other foods more consistent with the guidance provided by the Dietary Guidelines are not. Additional concerns include the cost of more nutrient dense foods relative to less dense foods,[18] the availability of foods in schools and after school programs, and difficulty with portion sizes and packaging which are not designed to meet dietary requirements of children.

The DRI values and Dietary Guidelines were designed in part to recognize issues with regard to growth and development as well as the contribution of diet to the development of chronic disease risk. This relationship is increasingly true in the pediatric age range where the prevalence of obesity is increasing along with the more frequent development of type 2 diabetes and other risk factors for future cardiovascular disease.[19] Thus, the practical implementation of developing dietary patterns in children that will meet the age appropriate DRI intake levels without exceeding energy requirements is critical. There are age-specific issues regarding the implementation of DRIs that must be considered.

Newborns

The American Academy of Pediatrics has recommended breastfeeding as the best strategy for feeding newborns. Human breast milk is the reference against which other forms of infant feedings must be judged.[20] Human milk is relatively high in saturated fat and cholesterol and is low in sodium. The American Academy of Pediatrics has encouraged breastfeeding exclusively, if possible, for the first 4 to 6 months of life.[21] Human milk appears to be uniquely tailored to meet nutritional needs over the first 6 months of life. The composition of human milk changes over time to meet these needs.[20] Babies appear to digest human milk more easily than formula[22] and babies who were breast fed appear to adapt more readily to new foods based on the diet of the mother when solids are introduced.[23] Nevertheless, some mothers find exclusive breastfeeding for

the first 6 months difficult. For these mothers, commercial formula or a combination of breast milk and the gradual introduction of solid foods provides an appropriate alternative.

Age 1–6 Years

This age range is when children adopt eating patterns that are more similar to adults. The transition period toward solid foods provides a unique and important opportunity for parents to develop healthful eating patterns in their children. However, in the later part of this period, it is also a time when children begin to be influenced by other aspects of the food environment such as eating patterns in peers, food advertising, and the availability of foods at home. Food consumption data indicate that infants and young children are exposed to a wide variety of foods that are high in saturated fat and added sugars.[24] These foods and beverages include fruit juice, sugar-sweetened drinks, snack foods, and French fries. For children 1–4 years of age, current intakes may exceed calorie and other requirements by 30% or more.[25] The excess calorie intake is especially true for children who are sedentary.

TABLE 11-6 US Dietary Guidelines for Americans, 2010—Key Recommendations

Balancing Calories to Manage Weight

- Prevent and/or reduce overweight and obesity through improved eating and physical activity behaviors.
- Control total calorie intake to manage body weight. For people who are overweight or obese, this will mean consuming fewer calories from foods and beverages.
- Increase physical activity and reduce time spent in sedentary behaviors.
- Maintain appropriate calorie balance during each stage of life—childhood, adolescence, adulthood, pregnancy and breastfeeding, and older age.

Foods and Food Components to Reduce

- Reduce daily sodium intake to less than 2300 mg and further reduce intake to 1500 mg among persons who are 51 and older and those of any age who are African American or have hypertension, diabetes, or chronic kidney disease. The 1500 mg recommendation applies to about half of the U.S. population, including children, and the majority of adults.
- Consume less than 10% of calories from saturated fatty acids by

replacing them with monounsaturated and polyunsaturated fatty acids.
- Consume less than 300 mg per day of dietary cholesterol.
- Keep *trans* fatty acid consumption as low as possible by limiting foods that contain synthetic sources of *trans* fats, such as partially hydrogenated oils, and by limiting other solid fats.
- Reduce the intake of calories from solid fats and added sugars.
- Limit the consumption of foods that contain refined grains, especially refined grain foods that contain solid fats, added sugars, and sodium.
- If alcohol is consumed, it should be consumed in moderation—up to one drink per day for women and two drinks per day for men—and only by adults of legal drinking age.

Foods and Nutrients to Increase

Individuals should meet the following recommendations as part of a healthy eating pattern while staying within their calorie needs.

- Increase vegetable and fruit intake.
- Eat a variety of vegetables, especially dark-green and red and orange vegetables and beans and peas
- Consume at least half of all grains as whole grains. Increase whole-grain intake by replacing refined grains with whole grains.
- Increase intake of fat-free or low-fat milk and milk products, such as milk, yogurt, cheese, or fortified soy beverages.6
- Choose a variety of protein foods, which include seafood, lean meat and poultry, eggs, beans and peas, soy products, and unsalted nuts and seeds.
- Increase the amount and variety of seafood consumed by choosing seafood in place of some meat and poultry.
- Replace protein foods that are higher in solid fats with choices that are lower in solid fats and calories and/or are sources of oils.
- Use oils to replace solid fats where possible.
- Choose foods that provide more potassium, dietary fiber, calcium, and vitamin D, which are nutrients of concern in American diets. These foods include vegetables, fruits, whole grains, and milk and milk products.

Building Healthy Eating Patterns

- Select an eating pattern that meets nutrient needs over time at an appropriate calorie level.
- Account for all foods and beverages consumed and assess how they fit within a total healthy eating pattern.
- Follow food safety recommendations when preparing and eating foods to reduce the risk of foodborne illnesses.

It is important that parents introduce more healthful foods during this age period. This includes the introduction of fruits and vegetables, whole grain products, fish and after age 2 years, low-fat dairy products. Parents should avoid introducing foods with lower nutritional value and should recognize that new foods may need to be introduced repeatedly before their ultimate acceptance by young children. This may require as many as 10 repetitions to establish acceptance and taste preference.[26,27] During this period of time, as with older children, parents should be mindful of their attitudes and behavior toward food and eating because in many cases they will be reflected in their children.[28,29]

Parents should use this time to establish healthy eating patterns and as much as possible should choose and maintain on a regular basis consistent time for meals. Self-regulation of the amount of food a child consumes serves to allow them to develop appropriate cues for satiety, a behavior that should be encouraged.[30] Parents can help to manage this by providing appropriate portion sizes for the age of the child. Likewise, it is important for parents to recognize that the amount of food eaten at any one time will vary from meal to meal and day to day, and to allow their children to adapt to internal clues. In addition, parents should to aware of and, when appropriate, limit snacking and other food intake that may be related to boredom or other cues rather than hunger.[28] It is important to establish healthy eating patterns early in young children.

Age 7–12 Years

During this age range eating outside the home, at school, aftercare programs, friends‘ houses, and quick-serve establishments, becomes a greater part of the daily pattern. Schools and other venues have become an increasingly difficult part of the food environment for children due to the availability of competitive foods and drinks which are high in calories and have low nutrient diversity. Fortunately, there are strong and consistent efforts to improve school menus, especially those available to children.

Although establishing good habits for food choices prior to the onset of school can be challenging, maintaining these habits as children get older and more independent is ever more complex due to peer pressure, advertising and other factors. Other issues during this age range include the introduction of fad diets.

Parents must serve as positive role models and continue to equip children and early adolescents with strategies to maintain healthful dietary

patterns. Pediatricians and other pediatric health professionals can also help by emphasizing these issues as part of routine health maintenance. Parents and health professionals can also be important advocates for children and for appropriate diet at their schools and other organized programs (e.g., sports teams and after school activities). Parents can work with those involved in providing meals and snacks to assess and improve the food environment. They can also encourage school systems to include more age-appropriate educational programs regarding food and nutrition for children. The objective should be to make more healthful foods and drinks available and to adopt local marketing strategies to encourage students to make more appropriate food choices.

Adolescents

Adolescence may be a particularly vulnerable period with regard to food choices. Because of accelerated growth and maturation, nutritional needs change during adolescence. The increased caloric need may stimulate appetite. These factors combined with a difficult food environment and peer factors may lead to less healthful choices.

In this age range, food choices and purchases are increasingly made outside of parental control. Current data suggest that adolescents have increased intake of fast food including pizza, hamburgers, and French fries, as well as increased consumption of sugar-sweetened beverages.[31] Of primary concern these foods and beverages can lead to excessive energy intake and weight gain. In addition, they tend to displace the recommended fruits, vegetables, low fat dairy, whole grains, lean meats, and fish. This dietary pattern leads to excess intake of saturated fat, *trans* fatty acids, sugar and insufficient intake of some micronutrients such as calcium, iron, zinc and potassium. In addition, intake of vitamins A, D, C and folic acid may be low.[31,32]

Parents and pediatric health professionals can have an important impact on the dietary intake of adolescents. Interactions with adolescents must take into account their increasing independence and must recognize that they will ultimately be making their food choices with less and less outside influence. Recommendations and counseling must be individualized to account for different cultural, household, and lifestyle situations. In addition, the food environment at home and the role-modeling of parents' choices is critical. The family remains an important influence for many adolescents. Pediatric health professionals should also discuss the potential impact of food marketing and provide behavioral tools to minimize the influence of marketing on food choices of

adolescents.

It is clear that many factors influence the food selection of children and their families. These issues must be recognized and considered in attempts to get children and adolescents to make appropriate food choices which then result in meeting the DRIs for energy, macronutrients, and micronutrients. Better strategies need to be developed to accomplish this goal.

CONCLUSIONS

The DRIs are a set of recommendations intended to provide guidance in evaluating nutrient intakes and planning meals on the basis of nutrient adequacy. They are nutrient, not food based recommendations. The emphasis in the development of the most recent DRI values was on reducing chronic disease risk. Depending on the available data for each nutrient, their DRIs are comprised of the EAR and RDA or when inadequate data are available AI and UL. In the case of macronutrients, there is an additional category of recommendations, AMDR. Within the category of infants to adolescents, DRI values have been established for the following age categories; 0 through 6 months, 7 through 12 months, 1 through 3 years, 4 through 8 years, 9 through 13 years, and 14 through 18 years. When assessing the available data the following were taken into consideration: strength of association (usually expressed as relative risk), dose–response relationship, temporally correct association (with exposure preceding the onset of disease), consistency of association, specificity of association, and biological plausibility. For full-term infants born to healthy mothers, it is expected that all nutrient needs will be met with exclusive breastfeeding for the first 4 to 6 months of life. For the second 6 months of life, the expectation is that nutrient needs will be met by a transition from breast milk to a mixed diet which includes solid foods. As children get older, the assumption was made that an increasing amount of food will be consumed outside the home, and as the child becomes more independent, that they will be determined more and more of these food choices. Inherent in the ability of children and adults to meet their nutrient requirements is the need to make wise food choices. It is important for parents, health care professionals, daycare providers and schools to educate children in the area of food and nutrition. This includes making healthy food choices available and encouraging children to take advantage of these options. In addition, it is important for adults to serve as positive role models for children in terms of behavior and attitudes about food and

nut.

Functional Food Ingredients: Probiotics, Prebiotics, Nutraceuticals, and Phytochemicals

Mandana Amir Shaghaghi, MSc, RD, Peter J.H. Jones, PhD, and Philip M. Sherman, MD, FRCPC

PROBIOTICS AND PREBIOTICS

Introduction

The intestinal **epithelial surface** comes into contact with a continuous flux of a vast variety of antigens. The primary function of the intestinal mucosa is the absorption of nutrients. This function necessitates the transport of molecules across a single layer of epithelial cells (enterocytes in the small bowel and colonocytes in the large intestine) and distinguishes the lining of the gut mucosa functionally from that of the respiratory or genitourinary

tracts.

Epithelial cells lining the surface of the body form a protective physical barrier against the external environment. The intestinal epithelium, however, must simultaneously be able to selectively absorb nutrients. Therefore, the epithelium in the alimentary tract (with the exception of the oral cavity, esophagus, and rectum) consists of a single layer of cells. The majority of the cells in the epithelial monolayer consist of polarized absorptive cells referred to as enterocytes. The apical surface of enterocytes is covered with microvilli, with the lipid bilayer of the microvillus membrane and an overlying glycocalyx formed by membrane-bound glycoproteins constituting a significant barrier to antigen entry. Paracellular antigen penetration is prevented by apical junctional complexes (including intercellular tight junctions) creating a physical barrier between enterocytes. The permeability of tight junctions can be modified by cytokines, such as tumor necrosis factor (TNF)-α and transforming growth factor (TGF)-β, and by substances elaborated by microbial pathogens.

The intestinal **immune system** must be able to recognize potential pathogens and inhibit their adherence and invasion by protective immune exclusion or inflammatory responsiveness while still allowing for the uptake and transport of dietary nutrients and certain intact macromolecules, such as growth factors and maternal immune globulins present in breast milk, without inappropriate and detrimental immune reactions.[1] The intestinal immune system has unique structural and functional characteristics which have evolved to fulfill the dual task of immune defense and tolerance (Table 12-1).

TABLE 12-1 Components of the Intestinal Mucosal Barrier

1. External Barrier
   - Gastric `acid
   - Digestive enzymes
   - Non-specific antimicrobial factors (e.g. lysozyme, lactoferrin, peroxidase, defensins)
   - Secretory IgA
   - Intestinal mucus
   - Peristalsis
2. Epithelial Layer
   - Microvilli
   - Plasma membrane
   - Tight junctions

- Innate immune receptors
- Intraepithelial immune cells

3. Intestinal Lymphoid Tissue
   - Uptake and presentation of antigens
   - Induction of secretory IgA production
   - Local and systemic inflammatory responses
   - Maintenance of tolerance
4. Indigenous Intestinal Microbiota
   - Degradation of luminal antigens
   - Inhibition of colonization and adherence of pathogens
   - Stimulation of the intestinal immune system

The indigenous **intestinal microbiota** is established during the first years of life, with commensal bacteria having a profound impact on the structural and functional maturation of the gut.[2] Indeed, the intestinal microbiota is considered an essential component of the intestinal immune system (Figure 12-1). Intestinal epithelial cells express a number of pattern recognition receptors (PRRs), which recognize microorganism-associated molecular patterns (MAMPs). MAMPs, present on both commensal and pathogenic microbes, are required for their survival and, therefore, are evolutionarily highly conserved.[3] These conserved microbial structures include unmethylated CpG motifs characteristic of bacterial DNA, virus-derived single-stranded RNA, bacterial cell wall compounds such as lipoteichoic acid, peptidoglycan, and lipopolysaccharide (LPS, present on Gram-negative bacteria) and bacterial flagellin.[4] Intestinal PRRs and their ligands are summarized in Table 12-2.

Normally, the human intestinal tract harbors an enormous quantity and diversity of indigenous microbes. The number of prokaryotic cells in the intestine is ~10^{14}, the vast majority of which are found in the lumen and outer mucus layers of the colon. In health, the microorganisms are not adherent to the inner mucus layer or to surface epithelial cells,[5] but intimately adherent organisms are seen with the presence of pathogenic infections (such as enteropathogenic *Escherichia coli*) and adherent commensal organisms in active Crohn's disease involving the large intestine.

With the emergence of culture-independent molecular identification techniques, the number of microbial species constituting the healthy gut microbiota is between 500 and 1000.[6] Colonization of a sterile intestinal tract commences at birth and proceeds in a step-wise and systematic fashion. Maternal intestinal and vaginal microbes provide the first bacterial

inoculum to the newborn. Consequently, the microbiota composition of infants born by cesarean section differs significantly from that of vaginally born infants.[7] Early nutrition also has a profound impact on the composition of the infant gut microbiota. In particular, breastfeeding promotes the growth of bifidobacteria and lactobacilli, which become the predominant microbiota species in breast-fed infants. After weaning, and by about 1–2 years of age, the gut microbiome composition comes to resemble that seen in older children and adults.[8]

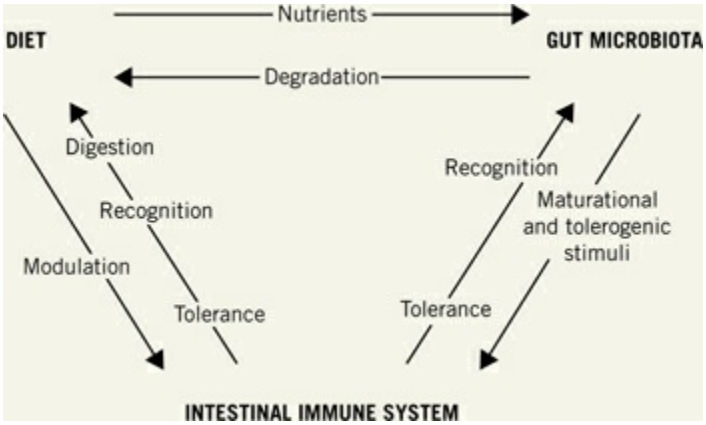

Figure 12-1 Potential for interactions between the indigenous intestinal microbiota, and the intestinal immune system.

TABLE 12-2 Intestinal Pattern Recognition Receptors and Their Known Ligands

Receptor	Ligand
TLR1	Lipopeptides
TLR2	Lipopeptides and lipoteichoic acid
TLR3	Viral dsRNA and viral sense ssRNA
TLR4	Lipopolysaccharide
TLR5	Bacterial flagellin
TLR6	Lipoteichoic acid
TLR8	Viral antisense ssRNA
TLR9	CpG DNA
TLR11 (mice, not humans)	Bacterial flagellin
NLR1 (Nod1)	Diaminopimelic acid of bacterial peptidoglycan
NLR2 (Nod2)	Muramyl dipeptide of bacterial peptidoglycan

Abbreviations: CpGDNA, unmethylated cytosine-guanine rich deoxyribonucleic acid; dsRNA, double-

stranded ribonucleic acid; NOD, nucleotide-binding oligomerization domain; ssRNA, single-stranded ribonucleic acid; TLR, toll-like receptor.

The composition of the diet appears to impact the composition and functions of the gut microbiome. For instance, there are differences described in the fecal microbial composition of children living in Florence, Italy and those growing up in a rural village in Burkino Faso.[9] Gut microbial communities of herbivores differs from carniverous mammals, with adult humans having an intestinal microbial composition that is characteristic of omniverous primates.[10] In murine studies, feeding of high saturated fats drive changes in the composition of the intestinal microbiome which impacts on disease susceptibility, using the development of colitis in genetically susceptible (IL-10 gene knockout) mice as the measured outcome variable.[11]

Intestinal microbes are necessary for normal morphological and immunological maturation of the gut.[12] For instance, germ-free mice exhibit impaired sIgA production. Moreover, specific strains of the intestinal microbiota modulate the expression of host genes involved in a variety of intestinal functions, including nutrient absorption, metabolism, mucosal barrier function, and intestinal maturation. Defective immune maturation in germ-free mice can be corrected by colonization with *Bacteroides fragilis*, a member of murine indigenous intestinal microbiota.[13]

Indigenous microbes contribute to intestinal barrier function by degrading intraluminal antigens and by inhibiting the adherence and subsequent internalization of pathogenic microbes. Antigen transport across the intestinal epithelium is increased in the absence of intestinal microbes in experimental animals.

The host is tolerant to its indigenous gut microbiota.[14] Abrogation of oral tolerance to dietary antigens results in food allergy, whereas inappropriate inflammatory immune response against the gut microbiota is described in chronic inflammatory bowel disease (IBD). Several studies indicate that oral tolerance cannot be induced in germ-free animals. Reconstitution of the intestinal microbiota, with bifidobacteria, in such animals restores the ability to establish oral tolerance in the neonatal period, but interestingly not at a later age.

The importance of enteral nutrition and antigenic stimulation to both intestinal microbiota and gut immunophysiology is demonstrated by studies showing that total parenteral nutrition results in a reduction of both aerobic and anaerobic gut bacteria and decreased intestinal concentrations

of polymeric IgA and anti-inflammatory cytokines, such as interleukin (IL)-4 and IL-10. Studies in both mice and humans indicate that three way cross-talk between the gut luminal microbiota, intestinal epithelial cells, and the adaptive immune system (in particular, B cells and the production of sIgA) affects nutritional function as measured by dietary fat absorption.[15]

In a variety of disease states (necrotizing enterocolitis (NEC), irritable bowel syndrome (IBS), IBDs, celiac disease, obesity, and diabetes), there is a loss of the diversity of the gut microbiome. The studies to date in humans are associative in nature, but experimental models indicate the potential for a cause-and-effect relationship.[16]

Probiotics are live micro-organisms, which when administered in adequate amounts confer a health benefit to the host. Probiotics taken orally transiently alter the composition of the gut microbiota, especially in settings with reduced diversity.[17] They are marketed in both single-bacteria and multiple-bacteria preparations, with some of the more common strains being *Lactobacillus casei*, *Lactobacillus acidophilus*, and *Bifidobacterium bifidum.* In older children and adults, intestinal colonization of probiotics is transient unless taken on a regular basis, because shedding of the orally ingested microbe in the feces stops soon after cessation of the supplementation.

In children, multiple meta-analyses of randomized controlled trials report that a variety of probiotic strains taken by pre-schoolers living in the developed world shortens the duration of acute infectious diarrhea by about 1 day and reduces the duration of virus shedding in rotavirus-infected children. Systematic reviews also demonstrate that probiotics can reduce the frequency of *Clostridium difficile*- and antibiotic-associated diarrhea in a strain- and dose-dependent fashion both in children and in adults.[18] There is also evidence that probiotics reduce dietary lactose intolerance when live bacterial cultures are present in fermented dairy products, resulting in decreased abdominal cramping and bloating as well as a decrease in concentrations of exhaled hydrogen. Probiotics have also been reviewed for their roles in immune modulation, lowering cholesterol levels, reducing eczema and atopy in high risk infants, eradication of *Helicobacter pylori* infection, and maintaining chronic IBDs in remission.[19] Data on the beneficial effects of probiotics with regards to either upper or lower respiratory tract infections are more limited.

Probiotic effects include degradation of dietary antigens, promotion of mucosal barrier functions, inhibition of mucosal pathogen adherence and

interaction with the innate and adaptive immune systems of the host.[20] Alterations in the intestinal microbiota composition in infancy precede the development of atopic disease, suggesting a causal link between indigenous gut bacteria and the atopic phenotype. Some probiotic bacterial strains have immunological effects that could contribute to reducing the risk of allergic diseases. In experimental studies, probiotics suppress IgE responses, inhibit Th2 (allergy promoting) cytokine production and induce the production and activity of regulatory (anti-inflammatory) T cells.[21]

Supplementation with *Lactobacillus rhamnosus* GG during late pregnancy and lactation induces anti-inflammatory mucosal immune responses, as indicated by an increase in the concentration of TGF-β2 in breast milk, and reduces the frequency of atopic eczema for up to 5 years in at least some study populations.[22] *Lactobacillus* GG has shown promising potential in reducing the risk of atopic dermatitis in infants at high hereditary risk for atopic disease. In a double-blind, placebo-controlled clinical trial of 159 pregnant women *Lactobacillus* GG was administered 2–4 weeks prior to expected delivery and the probiotics subsequently administered to either the breastfeeding mother or the infant until the age of 6 months. Probiotic supplementation reduced the risk of atopic dermatitis in these high risk infants from 46% to 23% during the first two years of life and this protective effect has subsequently been reported, at least in some studies, to extend out to the age of 4 years.

The pathogenesis of NEC in premature newborns, albeit not yet completely clarified, involves increased gut permeability combined with enteral feeding in the setting of an altered intestinal microbiota characterized by reducing gut diversity.[23] Consequently, probiotics have been used in prospective randomized controlled trials. The findings suggest a reduced risk of developing NEC in premature infants entered into the probiotic arm of the study trials compared to the babies given placebo. The probiotics may act to reduce NEC by promoting gut barrier function, by inhibiting colonization of potentially pathogenic bacteria, or by controlling innate immune responses in immature gut epithelia.[24] Subsequently, multiple randomized, placebo-controlled trials using different probiotic combinations and the results of several meta-analyses have also described significantly reduced incidence of NEC compared to placebo.[25] The findings now have to be extended to other settings around the world and the active ingredient(s) mediating the biological effects should be identified and well characterized, since regulators in some parts of the world remain reluctant to provide high doses of viable microbes to

vulnerable premature babies.[26]

IBS is increasingly recognized to be a long-term complication of acute infectious enteritis. Reduced microbial diversity has been described in the fecal microbiota of both adults and children with IBS.[27] Visceral hyperalgesia is a feature of post-infectious IBS and treatment with selected probiotic strains reduces clinical symptoms in a dose-dependent manner. In a meta-analysis of studies undertaken in adults, the number needed to treat was just 4; equivalent to or even better than any other described therapies in IBS which have also been subjected to the rigors of a randomized controlled trial. What is needed now are head-to-head comparisons of various treatment options in well defined populations employing clearly define and widely accepted outcome parameters.[28]

The chronic IBDs, Crohn's disease and ulcerative colitis, are characterized by mucosal inflammation as a result of detrimental immune reactivity towards indigenous intestinal microbes. Thus, modulating either the composition of intestinal microbiota or mucosal immune responses by probiotics provides a means to either treat or maintain remission of IBD symptoms.[29] *Lactobacillus* GG enhances intestinal IgA production in patients with Crohn's disease. A probiotic *E. coli*, strain Nissle 1917 is effective in maintaining remission in patients with ulcerative colitis. The probiotic combination VSL#3 (containing *Lactobacillus casei*, *Lactobacillus plantarum*, *Lactobacillus. acidophilus*, *Lactobacillus delbrueckii* subsp. *bulgaricus*, *Bifidobacterium longum*, *Bifidobacterium breve*, *Bifidobacterium infantis*, and *Streptococcus salivarius* subsp. *thermophilus*) induces remission in mild to moderate ulcerative colitis. The multi-strain probiotic mixture is also effective in preventing acute pouchitis, a non-specific inflammation of an ileal reservoir surgically fashioned following sub-total colectomy, and in reducing the risk of recurrence of chronic pouchitis. These beneficial effects might be the result of inducing tolerogenic immune responses by increasing levels of the anti-inflammatory cytokine IL-10.

Prebiotics are defined as non-digestible food ingredients (generally complex, non-digestible, but fermentable galacto-oligosaccharides (GOS) and fructo-oligosaccharides (FOS)) that beneficially affect the host by selectively stimulating the growth or activity of intestinal bacteria and thereby promote host health.[30] The commensal microbiome (in particular, Bacteroides species) contains carbohydrate-active enzymes that serve to extract energy from complex polysaccharides and provide short-chain fatty acids as substrate for colonocytes.[31] Prebiotics are preferentially utilized as

substrates by Bifidobacteria, that also generate butyrate, and by certain lactic acid-producing bacteria.

Breast milk contains substantial amounts (5–8 g/L) of GOS, a complex group of substances derived from lactose. These oligosaccharides share similarities with epithelial cell surface carbohydrates and adhesion molecules. They exert a number of important functions, from blocking the adhesion of bacteria to intestinal cell surfaces to being responsible for the predominance of the Bifidobacteria and lactic acid-producing bacteria (Lactobacilli) in the fecal microflora of the breast-fed infant.[32] The complex milk oligosaccharides are only minimally digested in the upper gastrointestinal tract and then undergo fermentation in the colon, thereby accounting for much of the hydrogen gas that is exhaled by breast-fed infants.

Breast milk provides the newborn infant with optimal nutrition for growth and development and immune protection during a critical period when neonatal immune defenses are still immature. Infectious disease is a major threat to the neonate and a leading cause of infant mortality in many areas of the world. It is well-established that breastfeeding protects the infant from infectious diseases. This protective effect is mediated by a number of passive antimicrobial factors, including lysozyme, lactoferrin, peroxidase, defensins, cathelicidin, sIgA, TLRs with soluble CD14 and oligosaccharides.

The protection afforded by breast milk is particularly crucial in developing countries, where breastfeeding reduces the need for infants to consume potentially contaminated water. In addition to passive immune protection, breast milk contains factors which contribute to immune maturation by stimulating the intestinal immune system either directly or via modulating the indigenous intestinal microbiota.33 The role of breast milk in reducing the risk of NEC in premature neonates is well-established. This effect may be mediated, at least in part by TGF-β, which is present in colostrum in large amounts. TGF-β attenuates intestinal epithelial cell inflammatory responses associated with the development of NEC. Increased gut permeability during the first days of life is associated with an increase in the risk of developing NEC. Breastfeeding improves the integrity of the intestinal barrier during the neonatal period, as assessed by the absorption of macromolecules in a rabbit model. TGF-β is known to enhance intestinal repair and promote barrier integrity.34.[34]

After weaning, the most common prebiotics include lactulose, inulin, FOS, and GOS. The effects of prebiotic oligosaccharides in promoting bifidobacteria in the intestinal microbiota of infants have been

demonstrated in a number of double-blind, placebo-controlled trials.[35] Prebiotics may also modulate micronutrient intake, as demonstrated by a study in which administration of an inulin-type fructan significantly increased calcium absorption and bone mineralization in adolescents.

Given an epidemiological link between intestinal microbiota composition and the development of atopic disease, prebiotics have been tested in reducing the risk of developing atopic disorders. In a randomized, placebo-controlled trial of 259 infants a hypoallergic formula supplemented with a GOS/FOS mixture reduced the frequency of atopic dermatitis in at-risk infants.[36]

Conclusions

Nutrients affect mucosal and systemic immune functions and the gut microbiota. General malnutrition or lack of certain nutrients may result in immunodeficiency predisposing to infectious disease. Indigenous intestinal microbes process dietary antigens and contribute to gut immune homeostasis by excluding pathogens and providing maturational and modulatory stimuli. The intestinal immune system constantly monitors intestinal antigens. Protective immune defenses are launched against potential pathogens whilst a number of active processes ensure tolerance towards dietary antigens and the microbiota.

Recent advances in understanding the mechanistic basis of these interactions provide the means to design specific interventions to restore intestinal homeostasis by supplementation of the diet with probiotics, prebiotics, immunomodulatory micronutrients and selected phytochemicals. Such novel dietary constituents are considered to promote overall health and are now being evaluated both as therapeutic and preventive modalities. The evidence required for changing current clinical practices will be defined by advances in basic research related to more a detailed understanding of underlying mechanisms and then applied to the clinical setting by coordinated and rigorously conducted clinical trials in a variety of settings including across the life-span continuum.

NUTRACEUTICALS WITH PEDIATRIC CONSIDERATIONS

Introduction

Nutraceuticals are foods or food products which provide health benefits and/or prevent chronic disease. Nutraceuticals range from isolated

nutrients and dietary supplements to herbal products. More individuals in developed countries than ever are now using dietary supplements, expecting to either enhance their overall health and well being or improve their physical and mental performance.

Supplement use is common across all population segments, including young children and adolescents. It is estimated that approximately half of children living in the United States receive some form of vitamin and mineral supplements.[37,38] There are a myriad of reasons for supplement use by children. Parents give dietary supplements to their children to enhance health, as a substitute for good nutrition, to be a good parent, because of personal positive experiences, or at the recommendation of alternative medicine health specialists.[39] Indeed, children whose parents use dietary supplements themselves are more likely to give them to their offspring.[40] In one birth cohort, nearly a third of participating two-year-old children receive nutrient supplements.[41] Many older children and adolescents also continue to obtain vitamin and minerals from dietary supplements.[42] Teenagers often use additional supplements that are touted as appearance, energy and athletic performance enhancers.

Many children also ingest dietary supplements with herbal and other non-nutrient ingredients either occasionally or on a regular basis. Use of both nutrient and herbal supplements is most common in children with long-term health problems.[43] Given insufficient safety data on the potential impact of these supplements on the developing fetus, they cannot be recommended for use by pregnant women. Supplement use has been studied specifically in children with chronic diseases, such as IBDs,[44] cancers,[45,46] and in some conditions, such as cystic fibrosis, that limit nutrient absorption from foods or increase requirements, which makes nutrient supplementation a critical component of treatment.[47]

Appropriately dosed dietary supplements are an important source of essential nutrients for some children and adolescents, ensuring adequate intakes for optimal growth and development. Dietary supplements that provide higher than adequate amounts of nutrients, or contain non-essential ingredients, on the other hand, can cause concern because of potential health risks and questionable benefits, particularly during pregnancy. Interactions of supplement ingredients with prescription or over-the-counter medications also must be considered. The growth of the industry and a lack of product regulation raise concerns for the health and safety of children. Because so many children use them, each visit to the pediatric health care provider should include a review of current

supplement use. A careful evaluation of individual dietary patterns and specific medical circumstances should then guide the selection of dietary supplements for use, if any are needed.

NON-PHYTOCHEMICAL SOURCES

Long-Chain *n*-3 Polyunsaturated Fatty Acids

Dietary changes are concerned at the recent increase in prevalence of chronic disease, such as obesity and type 2 diabetes. Indeed, increased intake of highly processed modern diets in developed countries has resulted in declining intake of a number of essential nutrients required for optimizing physical health and brain function in children. Included are decreases in the intake of two crucial long chain *n*-3 polyunsaturated fatty acids (PUFAs) eicosapentaenoic acid and decosahexaenoic acid (DHA) (derived mainly from oily fish), which serve critical roles in membrane fluidity, neurotransmission, neurogenesis, signal transduction, and ion channel activation and protection.[48] As a result, *n*-3 PUFA supplementation during infancy and childhood has received a great deal of interest for its potential protective effects on diseases ranging from allergy to learning and behavioral problems as well as for beneficial effects on optimal growth velocity, visual acuity and neurodevelopment. There may also be reduced rates of prematurity when PUFAs are taken as supplements during pregnancy.

Infants, including premature infants, have the ability to synthesize DHA from precursors, but the synthetic capacity appears insufficient to keep up with high demands required for growth. DHA is needed for incorporation into the cortical gray matter and the retina. The long-chain *n*-3 PUFA, DHA, is highly concentrated in gray brain matter (15%–20% of all lipids in the brain) and plays an essential role in normal brain structure and function.[49] In infants fed formulas devoid of DHA concentrations in the gray matter and retina are substantially lower than the levels observed in breast fed infants. The same is true for DHA concentrations present in plasma and erythrocyte membrane lipids.[50]

Infants fed DHA-free formulas show evidence of impaired retinal function during the early months of life.[50] However, this effect appears to be transient and may not be demonstrable in older infants. The presence of DHA in infant formula is considered desirable, because these fatty acids are present in breast milk and their absence from the diet produces low concentrations in the brain, retina, erythrocytes and plasma of human

infants.

There is evidence for beneficial effects of supplementation of *n*-3 PUFAs in subgroups of children with behavioral problems, learning difficulties, and developmental disorders.[51–53] In clinical studies, the protective effect of supplementation of *n*-3 PUFA on subsequent disease outcomes, including attention deficit hyperactivity disorder (ADHD) and autism spectrum disorders (ASD), has been assessed. Existing studies evaluating the effects of supplementation of *n*-3 PUFAs on children with ADHD have not shown conclusive results.[54] Moreover, to date there is no high quality evidence indicating that supplementation of omega-3 fatty acids improves core and associated symptoms in children with ASD including social interactions, communication and stereotypes.[55]

Fish oil supplementation during pregnancy exclusively[56–58] and postnatally alters cellular immune responses and function in the offspring, including a decrease in allergen-specific Th2 responses, an increase in polyclonal Th1 responses[57,58] and potential allergy-protection by modestly reducing the risk of sensitization in the infant.[56,57,59] Fish oil supplementation after 6 months of age, however, has not proven effective in reducing allergies later during childhood.[60,61]

Supplementation of *n*-3 PUFA also appears to have beneficial effects for primary and secondary prevention of cardiovascular disease. Effects of *n*-3 PUFA on cardiovascular health results from a multifaceted synergistic process involving anti-inflammation, reduction of very-low-density lipoprotein, reduction of triglycerides (TG), regulation of transcription factors and gene expression and both anti-arrhythmic and anti-thrombotic effects.[62]

Supplementation of DHA in children with hyperlipidemia is associated with restoration of brachial artery endothelial function, a decrease in serum TG level and a shift in lipoprotein subclasses towards large, buoyant low-density lipoprotein particles.[63–65]

PHYTOCHEMICAL SOURCES

Phytosterols

Plant sterols and stanols (collectively referred to as phytosterols) represent a cluster of vegetable sterols which are chemically analogous to cholesterol. This cluster includes a series of structurally specific compounds, including sitosterol, campesterol, and stigmasterol as the major plant sterols. Plant stanols, which are a hydrogenated form of plant

sterols, are found much less abundantly than plant sterols. Plant sterols and stanols occur naturally in the diet at various levels, generally below 450 mg/dL, although both vegetarian diets and our ancestors' food intake patterns suggest that intakes were considerable higher in less industrialized lifestyles. In general, only 5%–10% of the ingested major plant sterols are absorbed, while cholesterol absorption can exceed 50%.

For over 40 years, phytosterols have been known to have cholesterol lowering properties. Along with rising interest in functional foods and nutraceuticals during the last two decades, phytosterols have gained much attention and are increasingly being used for the prevention and management of hypercholesterolemia. Numerous studies have examined the cholesterol lowering effects and mechanism of actions of phytosterols. As a result, scientific and regulatory bodies[66–68] support the efficacy of phytosterols and recommend a typical intake of 2 g/d of phytosterols to optimize blood lipid concentrations in adult populations. Cholesterol lowering efficacy of phytosterols has also been examined in children with familial hypercholesterolemia.[69,70] However, the numbers of studies evaluating children still are quite limited.

Increases in serum plant sterol concentrations (from 19 to 30 μM) are described in people taking plant sterols either as functional foods or supplements.[71] High serum phytosterols concentrations are also reported in children consuming diets high in phytosterols.[72] Considering the possible atherogenic effect of phytosterols, concerns have been raised with regards to the safety of increased serum phytosterols concentrations from the high intake of phytosterols in functional foods and supplements.

Herbal Supplements

Herbal products exist as both crude (roots, leaves, seeds, or teas) and commercial (tablets or capsules) preparations. While crude herbal products are more often ingested in less developed countries, commercial herbal products are more commonly used in developed countries.[73] Children and adolescents are increasingly using herbal supplements, often reflecting the use patterns of their parents and other family members. Very little, if any, information is available about age-specific pharmacodynamics, clinical benefits, or potential risks.

Echinacea (*Echinacea purpurea*)

Fresh or dried root of *Echinacea purpurea* and its preparations contain caffeic acid derivatives, alkamides, polyacetylene derivatives,

polysaccharides, glycoproteins, and essential oils. The German Commission E has approved Echinacea for the treatment of symptoms of upper respiratory infections associated with colds.

Ephedra/Ma huang (*Ephedra sinica*)

Dried, young branchlets, harvested in the fall, of *Ephedra* sinica or equivalent *Ephedra* species contains alkaloids (ephedrine and pseudoephedrine). In the United States, ephedra is regulated under the Dietary Supplement Health and Education Act (DSHEA) in aqueous infusion, alcoholic tincture, and dry extract available as either capsules or tablets. The alkaloids of ephedra (ephedrine and pseudoephedrine) are approved by the Food and Drug Administration (FDA) as over-the-counter ingredients in remedies used for managing the common cold, flu and allergies.

The use of ephedra in products for weight loss, athletic performance enhancement, and central nervous system stimulation has raised concerns, with questions about the safety of these products. As a result, its use in dietary supplements is now banned. The FDA has received reports of 80 deaths and 1400 adverse effects associated with ephedra in dietary supplements; ephedra has been linked to heart attack, stroke, seizures, and psychosis.

St. John's Wort (*Hypericum perforatum*)

Dried parts above ground are gathered during the flowering season of the *H. perforatum*. The German Commission E approved the use of St. John's Wort internally for the treatment of psycho-vegetative disturbances, depressive moods, anxiety, and nervous unrest. Oily preparations are approved for external use in the treatment of acute and contused injuries, myalgia and first-degree burns.

Ginkgo Biloba (*Ginkgo biloba*)

Dry extract, which is pharmaceutically prepared (in a 35–67:1 ratio of dried leaves to final extract), contains flavonone glycosides (quercetin and kaempferol), terpene lactones (ginkgolides A, B and C), and ginkgolic acids. Ginkgo Biloba is approved by the German Commission E for symptomatic treatment of disturbed performance in organic brain syndrome within a therapeutic regimen, improvement in pain free walking in peripheral arterial occlusive disease, vertigo and tinnitus.

Garlic (*Allium sativum*)

Fresh or dried compound bulbs of *Allium sativum* with no less than 0.5% alliin have active compounds that include thiosulfinates (allicin). In clinical trials, garlic has been effective in lowering cholesterol in patients with hyperlipidemia and in treating hypertension. Garlic has antibacterial, antimycotic, lipid-lowering, inhibiting of platelet aggregation, prolonging of bleeding and clotting time, tumor inhibition and fibrinolytic activity enhancing properties. Commission E approved the use of garlic as a support to dietary measures for lowering elevated levels of blood lipids and in the prevention of age-dependent vascular changes. However, there are only limited results related to the use of garlic for pediatric patients with hyperlipidemia.

Chamomile (*Chamomilla recutita*)

Fresh or dried flower-head of *Matricaria recutita* is a popular ingredient in herbal teas. It is prepared for topical use in rinses, creams, ointments, and vapor baths. In Germany, chamomile is widely used in caring for sensitive skin in infants and children and for inflammatory skin conditions. The Commission E has approved chamomile for intestinal spasms and inflammatory diseases of the gut.

Ginger (*Zingiber officinale*)

Peeled, fresh or dried rhizome of *Zingiber officinale* contains oleoresin, volatile oil, carbohydrates, lipids, vitamin A and niacin, minerals, and amino acids. Ginger is used alone and as a component in digestive, anti-nausea, and cold and flu dietary supplements in the United States. The Commission E has approved ginger for dyspepsia and the prevention of motion sickness.

Valerian Root (*Valeriana officinalis*)

Fresh underground plant parts or carefully dried parts of *V. officinalis* and its preparations in effective dosages contain essential oil with monoterpenes and sesquiterpenes. The Commission E approves the product for restlessness and sleeping disorders based on nervous conditions. Clinical data support its action as a mild sedative and sleep-promoting agent. However, the U.S. Pharmacopoeia does not support the use of valerian due to inadequate evidence provided by high quality clinical studies.

It should be noted that many herbal products used as food supplements can be associated with a spectrum of liver injury ranging from asymptomatic elevations in serum liver enzyme tests to fulminant liver

failure and death.[73] Since children are more susceptible for hepatotoxicity, special considerations are needed for herbal supplements in this population.

Other Plant-derived Bioactives

Phytoestrogens are not nutritionally important, but they have biologically active effects, exerting estrogenic as well as anti-estrogenic activities. Three types of dietary phytoestrogens include isoflavones, lignans, and coumestans. Isoflavones, the major class of dietary phytoestrogens, are abundant in soy products and have a similar structure and function to endogenous estrogen.[74] Lignans are present in flaxseeds, grains, nuts, fruits, vegetables, tea, and coffee. Coumestans contribute very minimally to dietary phytoestrogen intake.[75] Soy protein-based infant formula provides phytoestrogens that are not present in human breast milk. Phytoestrogens are readily absorbed by the infant gut, but produce no clinically recognizable effects. However, when followed into adulthood, young women who had been exposed to soy formula as infants have greater menstrual flow and experience more discomfort with menstruation.[76] These effects are biologically significant, because they demonstrate that even a relatively brief exposure during a susceptible period of the life-span have effects that can last for decades. Higher prepubertal phytoestrogen intake in girls is associated with later breast development and later pubertal onset.[74,77] Several experimental studies show that intake of soy and isoflavones can have protective effects against hormone-related cancers. Higher exposure to phytoestrogens (both isoflavones and lignans) during childhood and adolescence is associated with a reduced risk of breast cancer.[78] Isoflavone and lignan intake in adolescence may decline breast cancer risk through a number of biologic mechanisms including: decreasing the sensitivity of developing adolescent breast tissue and mammary glands to chemical carcinogens and decreases tumor incidence, promoting mammary cell differentiation through increasing mammary duct branching and decreasing the number of highly proliferative terminal end buds which are more susceptible to carcinogens in adulthood, influencing the expression of proteins in breast tissue that are involved in malignant tumor progression including estrogen and progesterone receptors, and eliminating carcinogenic free radicals through the anti-oxidant properties of isoflavones.[72]

Special Considerations in Pediatrics

Much of the knowledge about important aspects of dietary supplements comes from studies in adults that have then been extrapolated to children. Considerable uncertainty still exists with regard to estimates about appropriate dosing, clinical effectiveness and potential risks for pregnant women, newborns, infants and young children. Growing tissues, including the brain and bones, may be more susceptible to the effects of a supplement than is the case in adults, but firm evidence in this regard is lacking. Infants under 4 months of age have not yet fully developed the hepatic drug metabolizing enzymes and, as a result, are likely to be more sensitive to herbal phytochemical exposures. Thus, caution is warranted in recommending these products for use in young children.

When assessing the safety and efficacy of a dietary supplement for a child, several considerations must be made. For example, a high dose of phytosterols can compete for absorption of cholesterol and fat soluble vitamins and make it potentially dangerous. A further reason to regulate the preparation of dietary supplements, nutraceuticals, and functional foods is that some plants contain a wide variety of toxic chemicals that promote survival in their environmental niche and defend against bacteria, insects, and herbivores. Manufacturers may inadvertently include toxic constituents during the manufacturing process. Natural ingredients stored improperly can be substrates for molds that make highly dangerous mycotoxins. For instance, mold on peanuts forms the potent carcinogen aflatoxin.[79] Taken together, there is as much reason for having oversight of natural supplements as there is for oversight of synthetic drugs and foods. On the other hand, the increased review and regulation of dietary supplements could decrease access of the public to some products. For supplements administered at doses that are found in foods, the adoption of Good Manufacturing Practices should not alter availability to the consumer. For nutraceuticals that expose humans to ingredients at the doses they would normally not be exposed to, demonstration of safety should be mandated, even if this means a more prolonged period of time to introduce a new product to the marketplace. On balance, this seems a reasonable cost to protect the public health.

ACKNOWLEDGMENTS

The authors thank the authors of chapters from the 4th Edition of this textbook portion of which have been incorporated into this chapter (Chapter 22: Drs. Samuli Rautuva & W. Allan Walker; Chapter 35: Drs. Ekhard E. Ziegler, Samuel Fomon, & Susan J. Carlson; and Chapter 70:

Drs. Steven H. Zeisel & Martin Kohlmeier). Work in the authors' laboratories is supported by operating grants from the Canadian Institutes of Health Research. PJHJ is the recipient of a Canada Research Chair in Nutrition and Functional Foods and PMS the recipient of a Canada Research Chair in Gastrointestinal Disease.

Energy Requirements in Health and Disease

13

Jean L. Bresson, MD, PhD

The interpretation of the changes in metabolic rate resulting from either malnutrition or disease finds its roots in the physiologic determinants of daily energy expenditure. The technical aspects of the measurement of energy expenditure and its obligate correlate, body composition, extend beyond the scope of this chapter and have been thoroughly reviewed in the literature.[1,2] Once raw data are available, many factors may confuse cross-sectional and, even more, age-related comparisons. The influence of body components, whether fat-free mass (FFM), fat mass (FM), or organ weight, should be considered first in an attempt to account for the wide differences in metabolic rate among infants, children, and adults. This is also relevant to a better understanding of the responses to underfeeding and malnutrition. Conversely, recent advances in the field of minor contributors to energy expenditure, such as the thermic effect of feeding or the thermic response to cold, may help us to understand how physiologic mechanisms may be turned into energy-losing machinery.

One of the most common findings in the sick child is a reduced food intake, which is widely accepted as the main, if not the only, cause of malnutrition. However, evidence accumulates suggesting that metabolic dysregulations may also participate and, in some instances, be primarily responsible for the nutritional deficit. This may be particularly true for proteins which, unless fat, are not stored but make up functional or structural tissues. Nitrogen balance in the adult or net protein deposition in the growing child results from protein synthesis rates equal to or higher

than protein breakdown, respectively. This equilibrium may be disrupted by the overproduction of peptides, otherwise playing a pivotal role in the regulation of the immune system. It results in a protracted increase in protein breakdown over protein synthesis. This mechanism is found in acute as well as in chronic inflammatory syndromes and may lead to severe protein malnutrition, despite apparently normal nutrient intakes. Consequently, underfeeding is clearly not the only factor in malnutrition. Furthermore, these protein losses are not easily controlled by classic dietary treatment and represent a pressing case for developing a specific pharmacologic approach.

PHYSIOLOGIC DETERMINANTS OF ENERGY EXPENDITURE

Basal Metabolic Rate

Comparisons between the rates of energy expended, or heat produced, by individual subjects require that the measurements should be free of the effects of any factor known to increase it. Failure to control for the effects of activity, feeding, and physical environment on metabolic rate would obviously result in spurious interindividual differences. Benedict proposed a set of standard conditions required to perform accurate measurements of the basal metabolic rate (BMR) in adults[3]: the subject should be awake, but in complete muscular repose both before and during the measurement, ideally performed in the morning before the patient rises; the subject should be in the postabsorptive state, normally accepted as 12 or more hours after the last meal, and should have received prior to the measurement a maintenance diet ensuring the stability of body weight; the subject should be in emotional repose and familiar with the measurement devices; in women, the measurement should not be made immediately before or during the menses; ambient temperature should be set in the range of the subject's thermal neutrality to avoid any thermoregulatory effect on heat production.

Obviously, these requirements may be impractical in infants and young children or in clinical settings. Metabolic rate measurement not performed in the postabsorptive state, but complying with the remaining conditions, and usually termed resting metabolic rate (RMR), is about 15% higher than true BMR.[4] It should be pointed out that, even in adults, the conventional period of 12 hours after the last meal may not be a sufficient interval to guarantee that the continuing effects of its metabolism are

negligible.[5] Hence, BMR should not be viewed as a measure of the absolute minimal metabolism. Indeed, energy expenditure is about 8%–12% lower during sleep than under basal conditions. As it is difficult to quantify the amount of work performed during spontaneous physical activity,[4] measurement of the sleeping metabolic rate (SMR) may be a convenient way to minimize its consequences on energy expenditure in young children. Thus, rather than defining a specific physiologic event, the set of standardized conditions chosen for metabolic rate measurements is primarily aimed at reducing the variance related to uncontrolled factors, to increase the power of interindividual or intergroup comparisons. When the rigorous conditions listed by Benedict are fulfilled, repeated measures display a remarkably low level of intraindividual variations. For example, the coefficient of variation (σ/m) of replicate indirect calorimetry measurements amounts to about 2%–4%, of which 2% could be accounted for by the variability related to the technique.[4]

The reproducibility of such measurements is high, even over a prolonged investigation. Thus, the range of intraindividual variations in BMR becomes much narrower than the range of interindividual variations that one may observe in cross-sectional studies of normal adult populations. A threefold difference is usually found between the lower and higher BMR individual values, expressed in kcal or kJ/d.[6] Repeated measures confirm that these are true between-subject differences. Furthermore, BMR is about 15% lower in adult females than in adult males. Much of these interindividual differences may be related to body build, as suggested by the significant correlations between BMR and body weight or height, or Quételet index (P/T^2).[7] Multiple regression analysis indicates that FFM accounts for about 65%–75% of BMR variance between subjects[8] and that FM, age, and sex together account for another 5%.[8] It is noteworthy that—exclusive of pregnancy—the contribution of FM to BMR variance is limited,[8,9] or even negligible.[4] This may be related to the low metabolic rate of adipose tissue, estimated to 3–4.5 kcal/kg fat/d. Thus, large differences in FM would not be expected to contribute greatly to differences in basal energy expenditure. Indeed, BMR becomes comparable in males and females after adjusting for FFM. Thus, FFM, FM, age, and sex account for about 80% of the interindividual variability in BMR, and nearly all the effect of these covariates is attributable to FFM (Figure 13-1).[10] However, differences between lower and higher individual metabolic rates still amount to about 600 kcal/d even after adjustment for these factors.[8] Further studies showed that family

membership is another significant determinant of BMR.[11] In the Pima Indians, metabolic rate among families may vary by nearly 600 kcal/d, whereas the mean variation within families is only about 60 kcal/d.[10] In this population, FFM, age, sex, and family membership account for 94% of the variability in metabolic rate, family membership contributing about 11%. Actually, a metabolic rate lower than that predicted by FFM, age, and sex at the beginning of the study turned out to be a major risk factor for body weight gain during the subsequent follow-up,[8] implying that obesity may also result from an economy in energy expenses. These results emphasize the necessity to express metabolic rate in relation to FFM, its major contributor, rather than in relation to any other parameter such as crude body weight or body area.

However, this mode of expression may still hamper interindividual comparisons in the pediatric population. During growth, RMR expressed either as kcal/kg body weight/d[12] or as kcal/kg FFM/d[13] follows a nonlinear increase, with slopes substantially higher in infants and young children than in adolescents and adults (Figure 13-2). After a steep increase in the days following birth,[14] RMR falls disproportionately to the rise in body weight[15] or FFM,[13] being about 67 kcal/kg FFM/d at 3 months, 46 kcal/kg FFM/d at 11 years, and 37 kcal/kg FFM/d at 13 years, 15 as compared to adult values of 28 kcal/kg FFM/d (Figure 13-3). This suggests that the metabolic activity of FFM is changing as a whole[16] or that the relative contribution of tissues with different metabolic rates to the composition of FFM is changing,[17] or both.

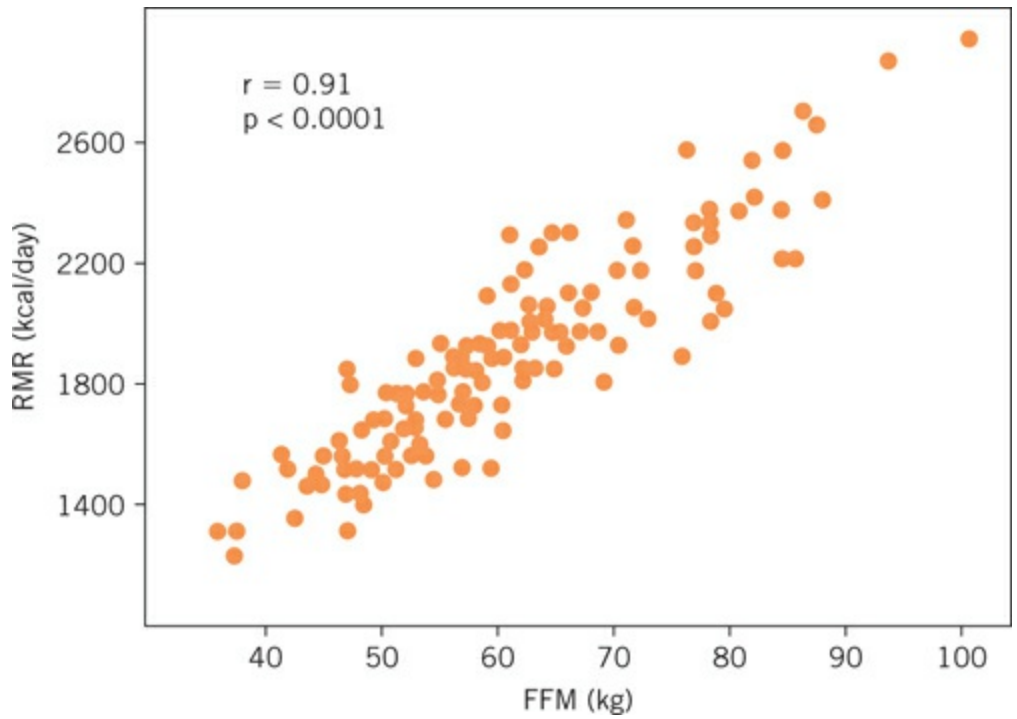

Figure 13-1 Relationship between resting metabolic rate (RMR) and fat-free mass (FFM) in 130 subjects. (From Bogardus et al.[10] With permission from the *New England Journal of Medicine*.)

Holliday pointed out that the brain, heart, liver, and kidney together make up only 5%–6% of the body weight, but account for 60%–70% of the BMR in the adult. Conversely, muscle mass, which makes up about 44% of the body weight, accounts for only 15%–30% of BMR.[12] In contrast, the FFM of infants and young children comprises about 30% muscle and 20% other organs, and that of adolescents averages 42% muscle and 8% other organs.[12] Therefore, the higher metabolic rate of infants and children in relation to FFM could be ascribed to a greater proportion of metabolically active non-muscle organ mass and to a lesser proportion of less metabolically active muscle mass than in adults (Table 13-1).[12,13] This is exemplified by experiments carried out on pigs with different nutritional background.[18] A first group was fed to gain steadily 14 kg over 70 days. A second group was fed to gain 19 kg during the first 35 days (high-energy period) and to lose 5 kg during the second 35 days (low-energy period; group HL), and this pattern was reversed (low-energy period first) in a third group (LH). At the end of the 70-day experiment, all animals had achieved the same body weight, but the fasting metabolic rate

of the LH group was 25%–50% higher than that of the HL group and 13%–40% higher than that of the first one. Furthermore, there was a significant correlation between fasting metabolic rate and organ weights.[18] The consequences of these observations are twofold. First, comparing the BMR/FFM ratio between two groups of subjects may be misleading, when values of FFM are markedly different,[13] mainly because the ratio of the weight of organs (heart, liver, brain, spleen, and kidneys) to total FFM decreases as FFM increases.[19] Second, this raises the possibility that abnormal metabolic rates in disease states may be related to a change in the proportion of metabolically active organs to less active muscles. For example, a reduction in muscle mass could account for the inverse relationship between RMR per kilogram of body weight and per cent ideal body weight observed in patients with Crohn's disease.[20]

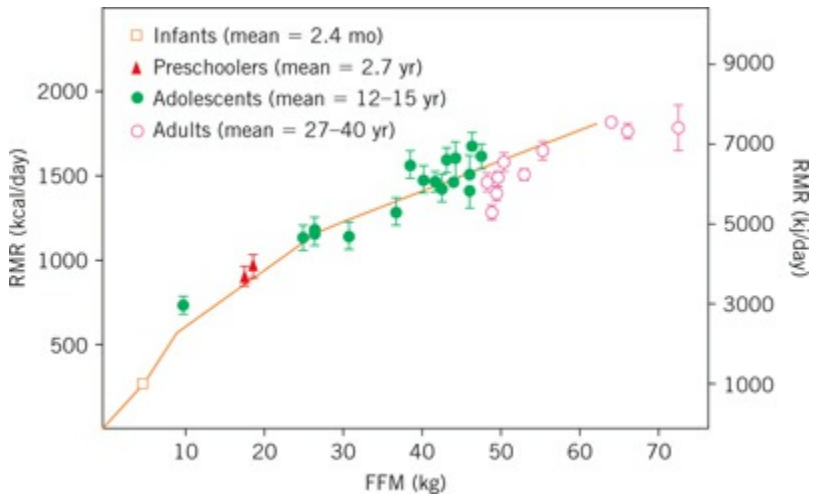

Figure 13-2 Relationship between resting metabolic rate (RMR) and fat-free mass (FFM) among different age groups. (Adapted from Weinsier et al.[13] With permission from the American Society for Clinical Nutrition.)

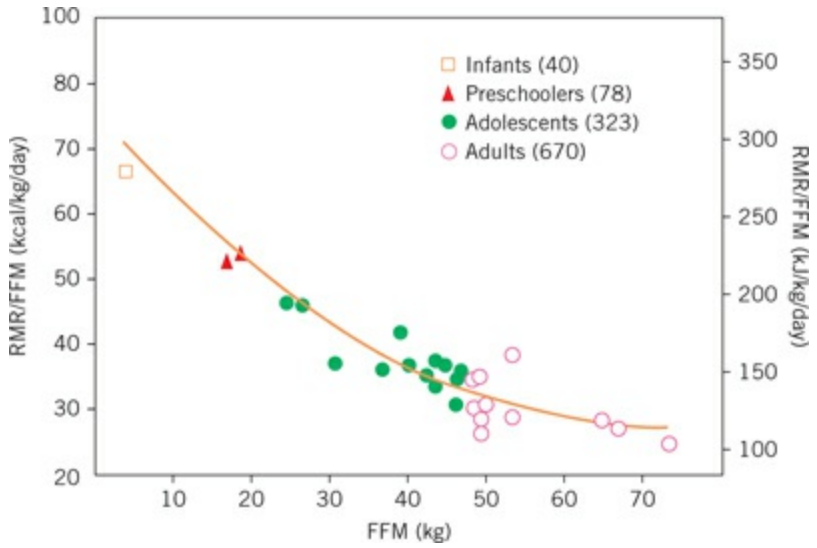

Figure 13-3 Relationship between resting metabolic rate (RMR) per unit fat-free mass (FFM) (RMR/FFM) to FFM among different age groups. (Adapted from Weinsier et al.[13] With permission from the American Society for Clinical Nutrition.)

Differences in metabolic rate between young and mature animals have also been found in other mammalian species. These weight-related differences further extend to comparisons between mature animals of different species. For example, mouse metabolic rate is about 5 times greater than man's and about 10 times that of the elephant.[21] Kleiber, and Brody and Proctor proposed a generalization according to which RMR follows a metabolic power function corresponding to weight 0.75.[21,22] However, the mass coefficient is not the same in various species, ranging from 0.48 to 0.91, the mean value being 0.67 ± 0.03. As there is no definite value for either the intraspecific or interspecific mass exponents, any attempt to explain the Brody–Kleiber empiric relationship by a general physical principle is most likely to fail.[22] Actually, this loose statistical relationship may obscure rather than reveal biologically important changes. The relative proportion of metabolically active tissue may contribute to these differences as large mammals have a greater proportion of tissues with low metabolic activity, whereas smaller ones have a greater proportion of tissues with higher metabolic activity. However, Krebs showed that the rates of respiration of homologous tissues are affected by the size of the animal, although there is no strict parallelism between measured tissue oxygen consumption and the BMR of the animals.[23] A

comparison between homeo- and poikilotherms might give a hint about a possible cause for this difference. The standard metabolic rate is sevenfold greater in the rat (a typical mammal) than in an ectothermic vertebrate (bearded dragon) of the same body size and at the same body temperature.[24]

TABLE 13-1 Relation Between Basal Metabolic Rate (BMR) and Muscle and Organ Metabolic Rates with Age

Height (cm)	Weight (kg)	BMR (kcal/d)	Muscle MR (kcal/d)	Organ MR (kcal/d)	B/A (%)
		A	B	C	
60	5.5	300	21	279	7
80	11.0	590	45	545	7.6
110	19.0	830	117	713	14
140	31.0	1160	204	956	17.6
160	50.0	1480	373	1107	25.2
180	70.0	1800	500	1300	27.7

Source: From Blaxter.[21]

This large difference in metabolism is also manifest at the cellular level and may be related to membrane properties.[25] Rat hepatocytes respire fourfold faster than do hepatocytes from the lizard. The inner membrane of isolated rat liver mitochondria has a permeability that is four- to fivefold greater than the proton permeability of the lizard liver mitochondrial membrane.[24] Thus, the greater proton permeability of the mitochondrial inner membrane contributes to the greater metabolic rate of mammals. Actually, this is a major source of heat production (see below), the variations of which might impinge on lifespan.[26] Similarly, plasma membrane permeability to Na^+ and K^+ is higher in mammals than in ectothermic vertebrates, increasing the amount of energy devoted to active Na^+–K^+ exchange.[27] Thus, the activity of the Na^+–K^+-ATPase accounts for about 20% of the total in vitro energy expenditure by mammalian tissues.[28] The use of ouabain to inhibit Na^+–K^+-ATPase in vivo leads to a 20%–30% inhibition of resting oxygen consumption in guinea pigs.[29] and to a 20%–25% inhibition in mice,[30] supporting the idea that active Na^+–K^+ exchange is a significant determinant of resting energy expenditure. In

humans, Na^+–K^+-ATPase activity may contribute 20%–25% to BMR.[31] As in animals, Na^+–K^+-ATPase is subject to chronic control by thyroid hormones, and slight interindividual variations in free T_3 index among healthy adults would account for a between-subject difference in SMR of 142 kcal/d.[32] Furthermore, the magnitude of Na^+–K^+-ATPase-dependent energy expenditure in tissues appears to be related to the physiologic status, and particularly to age. Muscle preparations from 7- to 21-day-old calves expend 26% more total aerobic energy in support of Na^+–K^+ transport than do the same muscles from 7-month-old calves.[28] Similarly, the Na^+–K^+-ATPase-dependent respiration of skeletal muscle preparations from 4-week-old lambs accounts for a 48% greater amount of energy than similar muscles from adult ewes. Also, energy consumption in support of active Na^+–K^+ exchange by the intercostal muscle from young lambs is 119% greater than for similar preparations taken from adults.[33] Comparable differences exist between hepatocytes obtained from 1- to 8-week-old lambs and from mature sheep.[34] In this latter case, the lower oxygen consumption of hepatocytes isolated from mature sheep is largely attributable (70%–90%) to the decrease in the Na^+–K^+-ATPase-dependent component of respiration. Thus, membrane-associated processes appear to be significant components of BMR.

It is striking that in quiescent-cultured animal cells exposed to mitogens, one of the first events to take place is a rapid, very large increase in the rate of Na^+ flow into the cells,[35] which in turn induces increased Na^+–K^+ pumping. Activation of Na^+–K^+-ATPase appears to be an early growth-related event, and it is tempting to speculate that increased energy expended on active Na^+–K^+ transport by young mammals is also related to their higher growth rate.[33] Active ion transport is probably not the sole cause of this difference. Measurement of whole-body protein synthesis shows that the smaller mammals display the higher protein synthesis rates in relation to their body weight. Within-species comparisons also indicate that immature animals have higher protein turnover rates than adults. For example, protein synthesis amounts to 6.7 ± 1.1 g/kg/d in term infants as compared to 3.5 ± 0.6 g/kg/d in adult humans. Simultaneously, basal energy expenditure is 45.1 ± 4.6 and 23.6 ± 3.8 kcal/kg/d in newborns and adults, respectively.[36] Thus, a similar ratio of BMR to whole-body protein synthesis (6.7–6.9 kcal/g) applies to both healthy newborn and young adults, suggesting that the turnover of cellular constituents, including proteins, and energy expenditure change in parallel with maturation.

Therefore, differences in BMR in relation to body weight or FFM during growth is not merely a matter of proportion between tissues with high or low metabolic rates, but is also related to differences in the amount of work done by the cells to ensure the turnover of their constituents and maintain the membrane electrochemical gradients.[37]

Energy Cost of Growth

An estimate of the energy cost of growth can be obtained in groups of rapidly growing infants from the relationship between growth rate and metabolizable energy intake.[38] The slope of this linear relationship provides an estimate of the total amount of energy stored and expended for synthesis, and its intercept at zero growth indicates the amount of energy required for maintenance. It should be pointed out that maintenance requirement may be higher than BMR by 10% in premature infants[39] and 50% in children,[40] as maintenance includes expenses for limited activity and feeding.[41] The energy cost of growth can also be estimated from the independent measurement of stored energy and energy expended for synthesis.[39] An indirect method for calculating the cost of tissue synthesis is to relate weight gain to energy expenditure, assuming that an increase in expenditure is directly related to the increase in cost of synthesis. Unfortunately, the result may be obscured by activity. A direct measurement of the cost of synthesis rests on the assumption that the thermic effect of feeding (i.e., the increase in metabolic rate after the meal over the resting value in the postabsorptive state; thermic effect of feeding [TEF]) is largely accounted for by synthesis. This is supported by the positive correlation observed between weight gain and TEF in rapidly growing individuals.[41] However, the TEF may be grossly underestimated unless the interval between feeds is long enough to allow metabolic rate to return to postabsorptive levels.

Various estimates of the total cost of growth are in the range of 3–6 kcal/g of new tissue. A widely accepted figure in normal infants is 5 kcal/g.[39,40] Metabolic balance and body composition studies indicate that the average composition of weight gain is 28% fat and 16% protein during the first year of life.[42] Assuming crude energy contents of 9.25 and 5.65 kcal/g for fat and protein, respectively, it is possible to estimate the amount of energy stored to about 3.5 kcal/g of body weight gain. In contrast, the cost of synthesis is about 1.5 kcal/g of body weight gain. Direct estimates of the amount of energy expended for synthesis usually provide figures in the range of 0.55–0.7 kcal/g.[39,43] This discrepancy may be related to an

underestimation of the TEF, as it is measured only two to three hours after the last meal. The so-called fasting metabolic rate used as a baseline is likely to be falsely high due to the lasting effect of feeding. As the energy stored in weight gain represents about 70% of the total energy cost of growth, one can expect wide differences according to the composition of tissues laid down. For example, it is possible to calculate that the total amount of energy required to deposit 1 g of protein is about 13.4 kcal/g and is 10.8 kcal/g for fat.[44] Thus, a weight gain comprising 16% protein and no fat would cost about 2.2 kcal/g. Conversely, a weight gain consisting of fat with no protein would cost about 9.7 kcal/g, assuming that adipocytes may contain up to 90% lipids. These differences may account for the high cost of weight gain found in overfed adults. In these conditions, weight gain consists of about 70% fat and 30% fat-free tissue,[45] the theoretic cost of growth then amounting to approximately 7 kcal/g. Similarly, the average cost of weight gain in patients with anorexia nervosa ranges from 5 to more than 7 kcal/g, suggesting either important changes in the composition of body weight gain during rehabilitation,[46] or an important confounding effect of activity.[47]

The daily energy cost of growth will depend obviously on growth rate as well as on the composition of new tissue. Growth rate is highest during the first three months of life, reaching 30–35 g/d between birth and 8 weeks of age, or a fractional growth rate of about 1% per day.[42] It decreases rapidly thereafter to 7–10 g/d at 1 year of age, or 0.07% per day to 0.09% per day, and to about 5 g/d (less than 0.03% per day) by 5 years of age. Thus, the cost of growth represents a significant part of daily energy needs (approximately 33%) from birth to 4 months of age. Later on, it decreases to about 7% between the ages of 4 and 12 months, 1.6% between 12 and 24 months, and 1% between 24 and 36 months. Thereafter, it is negligible compared to daily energy expenditure. Thus, on the basis of nutrient partition between growth and nongrowth, the 1- to 2-year-old child appears more like the adult than the small, rapidly growing infant.[48]

Thermic Effect of Feeding

It was recognized long ago that fed animals have substantially higher metabolic rates than fasted ones.[49] The effect of specific nutrients was investigated during the 19th century showing that the ingestion of proteins induces a greater increase in energy expenditure than carbohydrates or fat. The ingestion of a mixed meal also results in an increased metabolic rate

above BMR. Energy expenditure may increase by up to 30% over BMR in response to large energy challenges, a sizable change equivalent to 6% to 10% of the energy intake.[50] Unlike BMR, the TEF appears to be independent of weight, FFM, FM, and Quételet index.[50] In contrast, its duration and magnitude are linearly related to the energy intake,[50] which explains the greater effect of large meals.[51] Duration and magnitude of TEF do not appear to be significantly different when the same meal is ingested or directly delivered into the stomach.[52] However, the magnitude of the thermic effect is significantly greater if the same energy load is delivered in a short time rather than over several hours.[51,53] The route of administration of the nutrients, either intragastric or intravenous, does not seem to affect the magnitude of the response,[54] suggesting that the energy expended on luminal digestion, fermentation, mechanical mixing, and nutrient absorption makes only a modest contribution to the TEF in normal subjects. Energy expenditure may still be significantly higher than postabsorptive levels by five to eight hours after a large energy challenge.[50] Furthermore, the effect of the antecedent diet may significantly affect both SMR and RMRs. For example, RMR remains elevated by 12% 14 hours after the last meal during short-term overfeeding.[5] In these conditions, the TEF lasts not only for the whole day, but also throughout the night until the following morning, when the effect is still apparent. There is also strong indication that the TEF of one meal merges into the thermic effect of the next meal. Thus, the duration of the TEF should be carefully considered before attempting to determine either BMR or the effect of feeding, particularly in infants.

The composition of the meal bears some importance. In accordance with earlier work, the thermic response to a high-protein meal is greater than that to a high-carbohydrate one.[55] Similarly, the TEF is greater after a high-carbohydrate meal when compared to a high-fat[56] or a mixed diet.[57] Thus, high-fat meals could be a risk factor for obesity in children.[58] However, the ingestion of a mixed meal elicits many simultaneous and complex events, and an experimental account of the thermic response to feeding could only come from a simplified model. The euglycemic-hyperinsulinemic clamp offers several advantages in this regard.[59] It involves a single nutrient and bypasses absorption, allowing one to know precisely the rate of glucose appearance within the milieu intérieur at any time. Combined with indirect calorimetry, it allows one to assess the effect of glucose infusion on glucose oxidation and storage as well as on energy expenditure. When different plasma insulin concentrations are achieved,

together with glucose infusion rates appropriate for maintaining euglycemia, it is readily apparent that the increase in energy expenditure secondary to glucose administration is not related to an increase in its oxidation rate. In contrast, the increase in energy expenditure is closely related to the rate of glucose storage.[60] This is supported by studies in insulin-resistant patients showing that their blunted thermic response to glucose infusion is restored when glucose storage rate is matched to controls by further increasing insulin concentration.[61] Thus, in agreement with Flatt's proposal,[62] the TEF is primarily related to the cost of storage of the nutrients. According to the stoichiometry of these reactions, it is possible to calculate that the synthesis of glycogen costs about 4% of the energy of the glucose stored (0.15 kcal/g), and that this cost increases to 28% (1.05 kcal/g) when glucose is converted to fat. Conversely, the cost of triglyceride synthesis from absorbed fats amounts to about 2% of their energy content. Because of the many ATP-consuming steps involved in the synthesis and breakdown of proteins, the cost of amino acid incorporation into proteins is estimated to about 25%, but might be as high as 55% of their energy content.[62] Indeed, comparing the thermic effect of high-protein and high-carbohydrate diets shows that the former results in a greater thermic response (+45%) than the later. Simultaneously, the increase in protein turnover is twice as much with the high-protein diet as with the high-carbohydrate diet. The metabolic cost of protein synthesis would thus accounts for about 68% and 36% of the thermic effect of each diet, respectively, and the combined effect of increased protein synthesis and nitrogen excretion would account for 96% of the thermic effect of the high-protein diet.[55]

The cost of storage may not be the only component of the TEF. Indeed, the increase in energy expenditure related to glucose infusion is substantially higher than predicted from the amount of glucose stored.[60] The fact that overfeeding or the ingestion of a glucose-rich meal elicits an increase in sympathetic nervous system (SNS) outflow,[63] or in plasma noradrenaline concentration and turnover,[64] a known thermogenic hormone, suggests that the stimulation of the SNS is involved in the thermic response to feeding. This is supported by the blunting of the glucose-induced increase in energy expenditure by β-adrenergic blockade during insulin clamps. As a result, the residual variation in metabolic rate becomes almost identical to the value predicted from the amount of glucose stored.[65] This implies that the TEF has two components. One is an obligatory component directly related to the storage of nutrients and

accounts for about 60% of the response to feeding. The other is related to the stimulation of the SNS and represents about 30% of the increase in energy expenditure.[66] This partition is confirmed by the use of clonidine, a centrally acting α_2-adrenergic receptor agonist that inhibits SNS outflow. In association with the decreased SNS response to a carbohydrate-rich meal, TEF is blunted by 33%, a value similar to that obtained from peripheral β-adrenergic blockade during insulin clamps.[67] The effect of SNS activity on energy expenditure is not restricted to the hours following meals. Its inhibition by clonidine also decreases RMR. Although the reduction in RMR does not reach significance because of the small number of subjects, it should be stressed that a 6% decrease in baseline metabolic rate over a whole day might account for a greater overall diminution in energy expenditure than the larger 33% blunting of TEF over a few hours.[67] The contribution of SNS activity to energy expenditure in the postabsorptive state is further confirmed by the 8% reduction in BMR observed in response to a β-adrenergic antagonist that does not affect T_3 production, nadolol.[68] Furthermore, urinary noradrenaline excretion and muscle sympathetic nerve activity are significantly correlated to RMR adjusted for FFM, FM, and age in normal adults, implying that SNS activity is a physiologic determinant of energy expenditure.[69,70] A similar correlation between urinary noradrenaline excretion and oxygen consumption is observed in infants,[71] suggesting that the effects of SNS activity on energy expenditure extend to this age.

Therefore, the thermic effect of feeding involves a short-term meal-related component lasting for several hours, and is accounted for by both nutrient storage (obligatory) and acute stimulation of the SNS (facultative). In rapidly growing infants, this short-term effect also reflects the cost of synthesis of new tissues, as its magnitude is significantly correlated to growth rate.[41] However, the response to feeding also involves a longer term component, which may affect BMR and SMR.

Thermogenesis

Heat production by living organisms is associated with respiration and concomitant oxidation of nutrients. According to the chemiosmotic theory,[72] the enthalpy of oxidation is transduced by the respiratory chain of the mitochondria into an electrochemical gradient (or proton-motive force), which powers the ATP synthase. However, the efficiency of the system, characterized by the ratio of the amount of energy recovered as ATP to that liberated during substrate oxidation, is far from one, even if it

is higher than previously estimated from the standard-free energy of ATP, ΔG^0.[1] Attempts to directly evaluate this efficiency in man indicate that about 65% of the energy liberated may be recovered under the form of ATP.[73] Thus, a minimum of 35% is lost as heat, and oxidation at the level of mitochondrial respiration appears as the primary heat-releasing process. This is consistent with the significant relationship existing between body temperature and BMR or SMR.[74] However, basal heat production may be insufficient to maintain the core temperature within a narrow range of variation, particularly when heat exchange is increased by a low ambient temperature. Extra heat production can be generated by recruiting metabolic processes that do not produce any net work. Isometric muscular contraction, as it may occur during malignant hyperthermia, is a major heat-generating process. Similarly, shivering increases oxygen consumption,[75] and because no external work is performed, the energy appears as heat.

There is some evidence in adult humans that heat production may be increased by other means. For example, BMR or 24-hour energy expenditure (24hEE) increases significantly (6%–11%) in response to an ambient temperature drop from 28°C to 20°C–22°C, without any overt sign of shivering or any correlation with activity.[76] Similarly, the metabolic rate of full-term infants increases in response to an ambient temperature lowering from 32°C to 23°C. This increase is not correlated with activity and occurs in the absence of shivering. In these conditions, the infants' response is dramatic, amounting to a 100% increase in energy expenditure,[77,78] which suggests that a nonshivering thermogenesis is operative. In the rat, the early stage of cold adaptation is associated with shivering. However, shivering disappears with acclimatization, and a nonshivering heat source eventually takes over all the duties of heat production. It is now well established that cold exposure results in a marked increase in sympathetic activity, largely responsible for the elevated metabolic rate of the rats.[79] The dominant role in nonshivering thermogenesis has been ascribed to brown adipose tissue (BAT), even in adult animals.[80] BAT stimulation is achieved through β-adrenergic receptors, among which is a new type of receptor with pharmacologic properties differing from either β_1 or β_2, thus termed β_3.[81] BAT's prominent characteristic is the synthesis of a specific, 32,000 Mr protein, known as uncoupling protein-1 (UCP-1; review in Himss-Hagen[82]), located in the inner mitochondrial membrane and acting as a proton conductance pathway. UCP-1 dissipates the proton gradient created by

respiration, thus bypassing ATP synthase. In turn, the dissipation of the proton gradient causes a dramatic increase in the mitochondrial respiratory rate. Upon β-adrenergic stimulation, BAT substantially increases its respiration. As mitochondrial respiration and phosphorylation are uncoupled, ATP generation accounts for much less than 10% of oxygen consumption, and the enthalpy of oxidation of the nutrients is essentially dissipated as heat, making BAT a tissue specialized in thermogenesis. Acute cold exposure leads to a rapid and pronounced elevation of the level of the mRNA coding for UCP-1, and UCP-1 synthesis is evident within 15 minutes.[83] In contrast, hypothyroid rats are unable to maintain a normal body temperature when placed at 4°C, despite increased noradrenaline turnover rates. The response of UCP mRNA to adrenergic stimulation in hypothyroid brown adipocytes is readily restored by T_4 through mechanisms requiring its intracellular conversion to T_3. For a full UCP-1 response to cold, near saturation of the nuclear T_3 receptor is required. BAT contains a type II 5'deiodinase (5'D-II), which locally generates T_3 and allows it to reach a very high level of receptor occupancy despite the low physiologic plasma T_3 levels. Indeed, T_4 appears to be a much more efficient source of T_3 for BAT than plasma T_3 when the 5'D-II is activated. Conversely, iopanoic acid, an inhibitor of 5'D-II, abolishes the T_4-induced restoration of both UCP-1 response and normothermia in hypothyroid rats. In turn, 5'D-II activity is stimulated by SNS, and nuclear T_3 receptors are nearly saturated within four hours of cold exposure. Thus, SNS, through cAMP generation, and thyroid hormones act synergistically on BAT. T_3 affects the UCP-1 gene expression at a transcriptional and posttranscriptional level.[84] However, this effect of T_3 is not sufficient to elevate UCP-1 mRNA cellular content in the absence of significant levels of transcription, explaining why T_3 cannot increase UCP-1 mRNA in vivo in the absence of adrenergic stimulation.[85] Thus, T_3 amplifies the effects of the adrenergic stimulation on UCP-1 gene expression, allowing BAT to reach its full thermogenic capacity. Conversely, pretreatment of rats with corticosterone abolishes the UCP-1 mRNA response to noradrenaline and cold by inhibiting UCP-1 gene expression.[86] Interestingly, this effect is antagonized by the action of the corticotropin-releasing hormone (CRH; under feedback control by glucocorticoid) on the central nervous system, stimulating SNS outflow and leading to an increased expression of UCP-1.[87] The simultaneous expression of several proteins (UCP, 5'D-II, and β_3-

adrenoreceptors) appears to characterize functionally active BAT, although only UCP-1 is tissue specific.

The search for BAT in humans implied the characterization of UCP-1. This protein was first reported in fat depots from patients with pheochromocytoma.[88] It was subsequently isolated from newborn fat.[89] Later on, UCP-1 was found in humans at all ages, but its content was highest in children.[90] Since then, human UCP-1 gene has been cloned. Its sequence is 80% homologous to rat UCP-1, both at the nucleotidic and amino acid levels. Both UCP-1 and UCP-1 mRNA are present in infants and in adult patients, UCP-1 mRNA being detected in the periadrenal adipose tissue of all the subjects studied.[91] UCP-1 transcripts are abundant in an infant's perirenal fat, but are in low quantity in subcutaneous depots.[92] Full-term newborn interscapular UCP-1 content is equal to, or even higher than, the level found in 3-week-old mice acclimatized at 20°C (a temperature below thermal neutrality). In contrast, ATPase content is low in infant BAT, similar to that found in animal BAT mitochondria, compared with heart and liver mitochondria.[93] The specific content of UCP-1 in infant BAT increases twofold between 25 and 32 weeks of gestation and remains nearly constant thereafter.[93] Infant BAT also expresses a 5'D-II. Strikingly, 5'D-II content follows the same pattern as UCP-1 and achieves levels comparable to 5'D-II activities found in animals stimulated during the neonatal period by exposure to cold or increased cAMP levels.[93] Moreover, β_3-adrenoreceptor mRNA is expressed in children and adults.[92] This coexpression of UCP-1, 5'D-II, and β_3-adrenoreceptor suggests that functional BAT exists in humans from birth to old age. Measurements performed in vitro on isolated cell preparations as well as in vivo suggest that the heat-dissipating capacity of BAT is in the range of 300 W/kg of tissue.[94] Thus, 16 g of BAT would be sufficient to account for the 25–30 W/m^2 increase in energy expenditure observed in newborns exposed at 23°C.[78] This would represent about 3% of the adipose tissue mass of newborns, or a figure similar to the amount of BAT found in adult rats acclimated to cold.[80] It is radiologists, not physiologists, who rediscovered active BAT in human adults. Indeed, the infusion of 2-deoxy-2-[^{18}F]fluoro-d-glucose to cancer patients, to identify metastases by positron emission tomography, resulted in many "false positive" signals (particularly in the neck, supra-, subclavicular, and paravertebral areas) which could be completely quenched by one-hour exposure to a warm environment.[95] It was soon confirmed that this highly

active, cold-sensitive glucose uptake was due to fully functional BAT,[96] which contributes to energy expenditure and to the control of adiposity.[97,98]

Adrenaline-mediated thermogenesis also occurs in human muscle,[99] even if its mechanism is still uncertain. Adrenaline infusion causes a 25% increase in whole-body energy expenditure and stimulates forearm muscle oxygen consumption by as much as 90%. Assuming that forearm muscle is representative of total body musculature, skeletal muscle would then account for up to 40% of the adrenaline-infusion-induced thermogenesis in humans.[100] More recently, it was shown that T_3 administration to normal adults results in a significant increase in the activity of muscle tricarboxylic acid (TCA) cycle, without any change in the rate of ATP synthesis.[101] The disproportionate increase in TCA cycle flux compared with ATP synthesis suggests that T_3 induces an increase in muscle thermogenesis by promoting mitochondrial energy uncoupling. Indeed, human muscle has the intrinsic capacity for cold-induced adaptative thermogenesis via mitochondrial uncoupling under physiologic conditions.[102] In this regard, it is noteworthy that intraindividual variations in BMR are tightly correlated to small, spontaneous changes in thyroid hormone concentrations in healthy adults,[32,103] a mechanism which could contribute to cold adaptation.

Besides mitochondrial uncoupling, the thermogenic potential for Ca^{2+} cycling is exemplified by the pathological syndrome of malignant hyperthermia, a dominant pharmacogenetic myopathy that occurs in humans and several other mammalian species. Ca^{2+} cycling-mediated thermogenesis in skeletal muscle cells is a well-characterized mechanism for nonshivering thermogenesis in fish and recently in birds. It could prove to be an important source of heat in mammals lacking large amounts of BAT. In any cases, the biochemical properties of muscle (i.e., fast-twitch versus slow oxidative fibers) do contribute to the interindividual variability in SMR and 24hEE in the adult.[104] However, the respective contributions of BAT and muscle to the overall thermogenic response remain difficult to ascertain. Some studies in adults suggest that approximately 700 g BAT would contribute 25% to adrenaline-induced thermogenesis, whereas the approximately 34 kg muscle mass would account for 50% of the thermic response.[105] Despite the uncertainties about the respective contribution of its effectors, the reality of nonshivering thermogenesis in humans is now well established and its impact on energy expenditure and body FM recognized.

24-Hour Energy Expenditure

The measurement of 24hEE in free-living conditions over relatively long time intervals can be assessed by determining the turnover rates of isotopes of hydrogen (^{2}H) and oxygen (^{18}O) in total body water.[106] Despite its cost and its methodological limits, the doubly labeled water technique is quite suited for studies in infants and children. Actually, it led to recognize that recommended dietary allowances overestimated energy requirements by a significant extent in these age groups.[107]

BMR represents a major determinant of 24hEE. For example, it amounts to about 60% of 24hEE in sedentary adults.[108] The difference between BMR and 24hEE comprises thermogenesis, the thermic effect of feeding and the amount of energy expended on physical activity, be it exercise or nonexercise activity. Obviously, this is the most variable component of total energy expenditure.

In 1985, the FAO/WHO/UNU expert committee on energy requirements expressed the energy needs as multiple of BMR. The 24hEE to BMR ratio was subsequently referred to as physical activity level (PAL). Although not entirely satisfactory, PAL offers a convenient means of assessing and comparing physical activity, which is its main source of variance. Extreme PAL range from about 1.2 in the completely chair- or bed-bound subjects to about 4.7 in Tour de France cyclists.[109] PAL > 4 represents levels of expenditure which are not sustainable on a permanent way of life. On the contrary, PAL range of 1.2–2.5 corresponds to sustainable lifestyles, where 2.5 represents a very physically active one. Actually, a PAL of 1.35 is now considered as the lowest value compatible with long-term maintenance in normal adults and a PAL range of 1.55–1.65 represents the average of the so-called sedentary lifestyle.[110] Data suggest that activities do not have to be obviously strenuous for relatively high PAL values to be achieved. In adults, the time spent at activities with low and moderate intensity determines the activity level, whereas high-intensity activities do not have much impact.[111] In other words, the cumulative impact of low to moderate activities of prolonged duration is of greater energetic significance than short bursts of high-intensity activities. In children, PAL show an inverse relation with the time spent on low-intensity activities[112] and, as in adults, engagement in vigorous-intensity activities does not influence significantly 24hEE.[113] It is noteworthy that the fraction of time spent on low-intensity activities appears lower in 8-year-old children than in young adults and elderly persons.[112] PAL values vary from about 1.4–1.5 to 1.7–1.9 in boys and girls between 1 year of age

and adolescence.[114] Indirect estimates suggest that the energy cost of spontaneous activity represents only 5%–10% of 24hEE in premature infants,[43] but amounts to 20%–26% of 24hEE between 1 and 4 months of age[115] and up to 50% in 8- to 12-year-old children. A mean PAL value of 1.5 was reported in 10- to 13- year-old boys and girls. In this latter case, the variability of the 24hEE to BMR ratio is quite large, reflecting important individual differences in the amount of energy expended for activity (1.20–1.87).[116]

Of note, PAL is negatively associated with body fat in 5- to 10.5-year-old[117] or 6- to 8-year-old children.[118] This suggests that the amount of energy expended on physical activity may significantly affect energy balance, a potential asset in the prevention and treatment of obesity. Although most cross-sectional studies support a relationship between body fat and activity in children,[119] the results of interventions aimed at preventing childhood obesity through the implementation of physical activity programs remain inconclusive.[120] This is intriguing, as obesity may develop from a remarkably small daily net imbalance between energy intake and expenditure (median of estimated energy accumulation: 15 kcal/d),[121] a difference well within the range of moderate-intensity physical activity expenses. However, this discrepancy could be accounted for by the lack of effect of physical activity interventions on the overall activity level of children.[122]

On the contrary, it is not quite unexpected that most studies in obese adults demonstrate that participating in routine endurance exercise activities for up to a year does not induce a significant weight loss in the absence of an energy-restricted diet. Obesity represents the storage of a large energy surplus (over 100 Mcal in adults) and any attempt to reduce this imbalance, even by a small amount, would require a very significant increase in energy expenditure. Indeed, diminishing such reserves by 1% would imply a net negative balance of ≥1000 kcal. For a 100 kg-overweight individual, this would translate into more than 2 hours of brisk walking (4 mph) or light jogging every day to expend about 700 kcal/d.[123] Thus, a negative outcome with exercise alone is likely related to a failure to achieve an adequate level of physical activity.

Nonexercise, spontaneous physical activity, also known as nonexercise activity thermogenesis (NEAT), encompasses the daily expenditure of living activities (mainly ambulation) and the energy cost of all nonvolitional muscle activity, such as muscle tone, posture maintenance, and fidgeting. NEAT may play a significant role in the maintenance of

energy balance. Spontaneous physical activity measured within the confines of a respiratory chamber accounts for an average 348 kcal/d, with individual extremes of 100–800 kcal/d.[4] NEAT appears to be a familial trait, amounting to as much as 13% of 24hEE. Thus, NEAT may be—independently of volitional exercise—an important mediator of resistance to fat gain. Changes in NEAT account for differences in fat storage between individuals and failure to activate NEAT in the face of excess energy may lead to weight gain.[124] The comparison of mildly obese and control adults suggests that obese individuals may save up to 352 kcal/d (269–477 kcal/d) by staying seated 164 minutes longer per day than their lean counterparts, an economy not matched by a similar reduction in energy intake.[125] The contribution of NEAT to 24hEE in childhood is unknown, but might be quite significant. The regulation of NEAT is also unknown. However, familial resemblance in twin pairs' physical activity is predominantly explained by shared environmental factors rather than by genetic variability.[126]

Thus, components other than BMR and the energy cost of activity contribute modestly to the 24hEE of normal infants and children. However, an increase in the energy expended by these minor components (SNS activity and thermogenesis) may significantly alter energy balance in disease states. Conversely, the activation of nonshivering thermogenesis by activation/recruitment of BAT could have a positive effect: increasing energy expenditure would result in a decrease in body fat, an exciting prospect for the prevention of obesity.[127]

EFFECTS OF UNDERFEEDING AND MALNUTRITION

Effects on Energy Expenditure

Underfeeding healthy or obese adults result in a consistent 20%–30% reduction in BMR and 24hEE expressed either in absolute terms or related to body weight, body surface area, body weight to the 0.73 power,[128] or FFM.[129] It should be pointed out that this effect has important implications for the clinical management of obesity, as this compensatory change opposes the maintenance of a body weight that is different from the usual weight.[129] The decrease in BMR is rapid during the first weeks, then proceeds at a slower rate.[128,130] Thus, the initial, rapid decrease in BMR is not entirely accounted for by a corresponding loss of metabolically

active tissue.[128,131] (See also Refs. 142 and 145.) An analysis of fasting and semi-starvation studies suggests that about 25%–30% of the short-term decrease in BMR may be independent of the loss in lean body mass, indicating either a change in the composition of FFM or an alteration of cellular metabolism.[130] The dramatic effect of refeeding on BMR, which returns to normal within a few days without a parallel increase in body weight,[128] further supports the hypothesis that the decrease in metabolic rate during acute dietary restriction is of larger magnitude than what could be expected from tissue losses. A downregulation of BMR might be related to the decrease in noradrenaline appearance rate,[64,132] and in thyroid hormones[64,133,134] in response to fasting or semi-starvation. This possibility is supported by the prevention or the reversal of the metabolic response to acute energy restriction by replacement with either levodopa or T_3.[133,134] The enhancement of the thermic response to adrenaline infusion by prior starvation is consistent with a reduction in SNS activity.[135] A decrease in SNS outflow might also explain the significant reduction in the energy cost of glucose storage observed after underfeeding normal adults for seven days.[136] Similarly, it might account for the absence of any increase in the metabolic rate of undernourished patients exposed to mild cold. As their thermic response to adrenaline is conserved, the defect in cold-induced thermogenesis following weight loss cannot be ascribed to a decrease in tissue responsiveness. In these patients, the thermic response to mild cold is fully restored after weight gain.[137] Similar functional defects are apparent in children. Malnourished infants switched from 28°C to 24°C respond with a progressive fall in central temperature. When recovered, these infants increase their BMR by 20% in response to temperature lowering, and are able to maintain their body temperature within the normal range without shivering.[138] A decrease in skeletal muscle respiration proportional to the change in BMR in malnourished infants further supports a decrease in cellular metabolism.[139] However, metabolic rate measurements in chronically undernourished children may provide results that apparently conflict with those observed during acute energy restriction in adults.

Surprisingly, BMR may be approximately normal relative to body weight, and may even appear higher in those infants who are the most wasted.[140] Similar results are obtained in chronically undernourished adults. BMR related to body weight appears higher in the undernourished than in the controls, although in absolute terms it is significantly lower.[141] Total body cell mass (BCM) is reduced even in moderate deficiency, but

muscle mass seems to decrease linearly with the increasing severity of undernutrition, whereas visceral cell mass shows limited changes. For example, body fat and BCM are reduced by 29%, whereas muscle mass is decreased by 41% in severe undernutrition.[142] This is in general agreement with animal experiments, although a larger range in the weight change of some organs in response to nutritional manipulations may be observed.[143] Thus, taking into account the respective metabolic rate of tissues,[14] it is not surprising that BMR related to BCM or FFM may appear falsely high in some cases of severe malnutrition. This increase in metabolic rate related to FFM or body weight does not preclude an overall depression of tissue metabolism.[140,144] In infants, protein turnover, synthesis, and breakdown rates are significantly lower (approximately 40%) before than after recovery from malnutrition. Diminished substrate cycling is observed in adults during short-term underfeeding, and the resulting decrease in both protein turnover and glucose cycling may account for about 35% of the reduction in 24hEE.[145] Conversely, the malnourished infants' increase in energy expenditure in response to dietary treatment is an early event,[140] concurrent with a dramatic increase in growth rate[41] and in protein turnover,[146] suggesting that it is not entirely accounted for by the change in body composition. Fasting metabolic rate (related to body weight) during rapid growth is equal to, or even higher than,[140,144] the recovered values, a fact that further strengthens this possibility. Another way to look at the reality of metabolic rate downregulation would be to measure the cost of growth, which might be decreased by a higher metabolic efficiency. Although an overall increase in food efficiency may exist during the early period of catch-up growth,[41] the cost of growth during recovery from malnutrition generally appears similar to that of the normal infant.[146] However, longitudinal studies may easily overlook any enhancement in metabolic efficiency if it is short lived.[147]

Effects on Substrate Use

The classic studies of starvation showed that endogenous glucose production amounts to about 180 g/d after a few days' fast, of which 80% is oxidized by the brain.[148] The bulk of gluconeogenic precursor is provided by body proteins.[148] After five or six weeks of starvation, ketone bodies have replaced glucose as the predominant fuel for brain metabolism,[149] and glucose production has decreased to about 86 g/d, of which about 50% comes from recycled lactate and pyruvate.[150] Thus,

fasting endogenous glucose production relies on gluconeogenesis much earlier than previously expected[151] and both decrease as peripheral glucose uptake diminishes. The reduced demand in gluconeogenic precursors is paralleled by a significant reduction in protein breakdown, which favors sparing of tissue proteins.[152] In parallel, there is a state of insulin resistance at both the hepatic and peripheral levels, and normal insulin sensitivity is restored after refeeding.[153] From the beginning, fat is the predominant fuel, the respiratory quotient falling to 0.70 by the fourth day of fasting.[148] Observations made in malnourished children are consistent with these results. Protein contributes little to total energy expenses.[154] The average daily amount of glucose oxidized is also lower, and glucose oxidation decreases more rapidly in response to fasting before recovery than after recovery,[154] which does not demonstrate, but is suggestive of, a reduction in glucose production.[148] It is striking that the reduction in urinary nitrogen output, which occurs in lean, starving adults, is proportionate to the simultaneous decrease in metabolic rate, suggesting that protein sparing might result from the general reduction in fuel use rather than from a specific fat-related mechanism.[155] However, the protein-conserving effect of growth hormone under fasting conditions has been ascribed to the stimulation of lipolysis,[156] thus demonstrating that free fatty acids are important protein-sparing agents.

Therefore, underfeeding results in a significant decrease in metabolic rate related to tissue loss and, to a lesser extent, to a reduction in the activity of the remaining tissues. This reduction in metabolic rate can be viewed as an attempt to save energy in the face of reduced intakes. However, such an economy goes far beyond the physiologic range of adaptation, as it is obtained at the expense of growth and body composition. Furthermore, its only flexibility depends on the use of functional tissues as a source of substrates. Thus, any interfering increase in energy demand may entirely jeopardize this precarious balance.

EFFECTS OF DISEASE STATES

The compromise achieved by malnourished infants may be imperiled in two obvious ways. The first one would be to increase energy expenditure, for example, through fever. The other one would be to disrupt the adaptation of protein metabolism by a selective increase in protein breakdown, leading to a rapid net loss of nitrogen.

Effects on Protein Metabolism

It has been known for a long time that urinary nitrogen output is dramatically increased during infection and trauma, in sharp contrast with what is observed during malnutrition. In vivo studies reveal that this is accounted for by a disproportionate increase in protein breakdown over synthesis. However, infusion of counterregulatory hormones to healthy adults falls short of reproducing the massive 20- to 40-g/d nitrogen losses observed after trauma or thermal injury, although it does induce plasma hormone elevations typical of severe stress.[157] In contrast, peptides isolated from the plasma of patients with sepsis or trauma are able to specifically induce a dramatic increase in protein breakdown, without affecting synthesis.[158,159] This specific effect on protein breakdown is reproduced in vitro by incubating muscle biopsies with the culture medium of activated macrophages, suggesting that cytokines are involved. Cytokines are a large family of cellular regulators that include interleukins (ILs), tumor necrosis factors (TNFs), interferons (IFNs), and others. They play a pivotal role in the immune system, but their effects extend far beyond the immune cells. Each cytokine may interact with different cell types, thus exhibiting pleiotropic functions in different target cells.[160] Conversely, many different cytokines may exert the same biological actions—a property known as redundancy. Administration of recombinant tumor necrosis factor (rTNF) or recombinant interleukin-1α (rIL-1α) to animals results in accelerated muscle proteolysis.[161] Chronic administration of either rTNF or rIL-1α induces muscle wasting.[161,162] Furthermore, there is a synergistic effect between TNF and IL-1 on the stimulation of proteolysis.[161] In contrast with earlier expectations, the effect of cytokines on protein breakdown is only partially abolished by inhibitors of prostaglandin (PG) E_2 synthesis.[163] Moreover, proteolysis in response to rIL-1α is not mediated by glucocorticoids. In humans, administration of rTNF also results in a dose-dependent rise in the amino acid efflux from muscle,[164] confirming the central role of cytokines in the protein losses associated with various acute and chronic diseases. In muscle, the underlying mechanism involves the induction of E3 ubiquitin ligases gene (Atrogin-1 and muscle-specific ring finger protein 1 or MuRF1) leading to muscle atrophy through the selective action of the ubiquitin-dependent proteasome on muscle cell gene products. The induction of these ubiquitin ligases can be down regulated by insulin-like growth factor I (IGF-I).[165] As in adults, the rates of protein synthesis and breakdown increase markedly in response to infection in children.

However, breakdown increases more than synthesis, leading to a net loss of nitrogen.[166] Although malnutrition blunts the response to infection, infected malnourished children have protein turnover rates twice as high as uninfected ones, the relative increase in protein breakdown resulting in a negative protein balance.[166] Increased protein breakdown was first noted in sepsis or trauma patients, but a significant change may also be observed in response to much less severe conditions, such as vaccinations,[167,168] suggesting that even mild infections are likely to offset the fragile equilibrium of undernourished children.

It should be pointed out that protein metabolism imbalance per se (i.e., protein breakdown rates greater than synthesis) results in a net protein loss and thus may lead to protein deficiency. Growth failure in Crohn's disease might be accounted for by such a mechanism. Growth failure is often associated with Crohn's disease and may even precede symptoms. These patients have a short stature, but in most cases their body weight is close to the expected weight for height, but their FFM is significantly lower than in age-matched controls. As growth hormone (GH) secretion is normal,[169] a search for nutritional deficiencies was undertaken. A reduction in energy intakes is noted in some reports, but not all, whereas protein intakes appear consistently within the ranges of recommended dietary allowances. Furthermore, energy losses in the feces are not different from those of normal children, and intestinal protein losses are only slightly increased over control values. When measured, energy expenditure related to FFM is comparable to results in matched controls[170] and the preserved FM argues against a significant energy deficit.[171] Despite the lack of evidence in favor of nutritional deficiencies, energy supplements do result in a significant increase in growth rate, suggesting that a nutritional deficiency is indeed responsible for growth failure in Crohn's disease. That such a deficiency could not be ascribed to an overt imbalance between intakes and needs suggests that it might result from an abnormal utilization of available substrates. Indeed, abnormal protein turnover rates are consistently found in these patients.[172,173] Moreover, alterations in protein metabolism are correlated with the intensity of the inflammatory syndrome[172,173] and are consistent with an increased production of TNF-α and IL-1.[174] Besides the dramatic effect of energy supplements, another line of evidence points toward a nutritional deficiency in Crohn's disease. The plasma concentration of IGF-I is significantly decreased in these patients and further correlates with growth rates.[175] Reduced plasma IGF-I concentrations, despite normal or increased circulating GH levels, is a trait

of malnutrition and measurements of IGF-I levels have been proposed as a highly efficient way of monitoring nutritional rehabilitation.[176] Of particular interest is the fact that plasma IGF-I concentration is closely correlated with protein balance in both animal and man.[176,177] In the rat, IGF-I level is also correlated with protein intake.[178] Furthermore, low fasting IGF-I concentrations cannot be restored to normal levels by refeeding protein-free diets.[177] This is related to the direct modulation of IGF-I expression by essential amino acid availability, independently of insulin and glucocorticoid contributions.[179] Likewise, IGF-I levels in infected malnourished children are sensitive to dietary protein alterations.[180] High-protein diets result in higher IGF-I levels and in improved growth rates, 180 despite the possible direct effect of some cytokines on IGF-1 expression.[181] Therefore, the decrease in IGF-I levels in Crohn's disease pinpoints the critical importance of protein metabolism in growth failure. Indeed, nutritional supplementation results in elevated IGF-I concentrations and increased growth rates.[175] Food supplements induce a significant increase in protein synthesis which results in an increase in protein balance. In contrast, nutritional support does not seem to affect the elevated breakdown rates.[172] The favorable effect of the nutritional supplements could then be accounted for by the specific induction of protein synthesis by amino acids. Therefore, growth failure in Crohn's disease may be related to an abnormal utilization of substrates, due to an imbalance between protein synthesis and breakdown rates, the latter being specifically increased by the associated inflammatory syndrome. This may be exaggerated by direct effects of cytokines on the GH-IGF-1 axis,[182] not to mention the deleterious effects of steroid treatment on protein metabolism. Reduction in food intake would only exaggerate the protein debt by further reducing the synthesis-to-breakdown ratio, whereas nutritional support compensates for the increased breakdown rates by promoting protein synthesis.

Findings in rheumatoid arthritis (RA) are also consistent with a dominant effect of inflammatory syndromes on protein metabolism. RA is associated with a chronic inflammatory syndrome involving local cytokine production. The immunologic response occurs in affected joints and can also be observed and monitored in peripheral blood. The circulating level of some cytokines (IL-6) is significantly correlated with the commonly used markers of inflammatory syndromes, indicating that it is related to disease activity.[183] The measurement of ^{40}K and total body water in RA patients shows that their BCM is decreased, as compared to controls. In

addition, there is a strong dose–response between RA severity and the amount of BCM adjusted for stature: the more severe the RA, the lower the BCM.[184] BCM is also inversely associated with TNF-α production.[185] This decrease in BCM is important in two regards: it amounts to about one-third of what is thought to be a survivable loss and it occurs in patients with energy and protein intakes comparable to those of controls. Surprisingly, the FM measured by dual-energy x-ray absorptiometry is not very different in RA adult patients and in controls.[186] This last observation suggests that the covert nutritional deficiency responsible for the decrease in BCM in adults is not primarily related to energy imbalance. Alternatively, the increase in protein breakdown rates observed in these situations might account for the preferential loss in FFM,[187] particularly in muscle.[188]

A comparable increase in protein breakdown may be induced by ammonium chloride infusion to healthy volunteers, an effect also found in chronic renal failure (CRF). For example, proteolysis may be increased in children with CRF by up to threefold in relation to metabolic acidosis.[189] In contrast with cytokine-mediated protein breakdown, net proteolysis is related to changes in plasma cortisol levels, suggesting that it plays an important role in protein metabolism during metabolic acidosis. It should be pointed out that the acidosis-induced increase in net proteolysis may be quite deleterious to infants and children with inherited diseases of amino acid metabolism.

Therefore, the disruption of protein metabolism regulation in favor of breakdown, by cytokines overproduction during chronic inflammatory syndromes or by some glucocorticoid-mediated mechanisms during chronic renal failure, might well constitute an entry into severe malnutrition, independent of decreased food consumption.

Effects on Energy Expenditure and Energy Substrate Utilization

Fever is a common event in children. It is also an efficient way to increase energy expenditure. DuBois emphasized the striking similarity between fevers of greatly different origins by showing that metabolic rate has a much closer relationship with body temperature than with the nature of diseases. This relationship indicates that metabolic rate increases by an average 13% for each 1°C above normal temperature.[75] A comparable relationship is found in children, resting energy expenditure increasing by about 12% for each 1°C above normal temperature.[190] For example,

during acute malaria the mean increment in RMR is about 30%.[191] This would amount to 1200 kcal/d expenditure in a 5-year-old child, or to a 250–300 g/d weight loss, should the child not eat.[190] It is noteworthy that the increase in RMR for each degree of increase in temperature is positively correlated to the ratio of actual weight to the expected weight for height, suggesting that undernutrition blunts the RMR response to fever.[190] Although the rise in metabolic rate was first related to shivering,[75] there is some evidence that other mechanisms are operative. An endotoxin bolus delivered to healthy volunteers induces a significant pyrogenic response (+2°C in body temperature) within 90 minutes, maximal at 180 minutes, and sustained for more than six hours. Total body oxygen consumption is increased by 28% at two hours, when body temperature is about half-maximal, and remains elevated at six hours. Coordinately, splanchnic oxygen consumption is increased by 64% at two hours and is still increased by 47% at four hours.[192] The increase in splanchnic oxygen extraction represents approximately 80% of the increase in whole-body oxygen consumption at two hours, suggesting that shivering is not the major source of heat production at this time, although body temperature is still rising. This interpretation is consistent with the absence of increase in leg oxygen extraction at two hours.[192]

Both the pharmacological approach and the gene knockout technology stress the importance of cytokines in the development of this thermic response. However, some discrepancies persist, which may be related to cytokine redundancy and to the models used. For example, IL-1β and IL-1 type-1-receptor knockout mice challenged with low or high dose of lipopolysaccharide (LPS) display a thermic response similar to wild-type mice, whereas fever, anorexia, and weight loss resulting from turpentine injection are completely abolished.[193] Similarly, the significant increase in plasma IL-6 levels observed in wild-type mice injected with turpentine is virtually absent in the IL-1β knockout mice.[194] Injection of turpentine into IL-6 knockout mice also fails to induce fever, anorexia, and weight loss.[195] All these data support the direct implication of IL-1β and IL-6, but also TNF-α, in the induction of fever and sickness behaviors. The thermic response to LPS is dependent upon PG synthesis, as it is blocked by indometacin, as well as by cyclooxygenase 2 (COX2) or PG receptor gene disruption. PG receptor (subtype EP3) knockout mice fail to mount a febrile response to LPS, IL-1β, and PGE2. The pyrogenic effect of IL-1β may also be inhibited by pretreatment with either a receptor antagonist or a monoclonal antibody to CRH.

In parallel to their effects on energy expenditure, cytokines affect food intake in both animals[196] and humans.[197] Chronic administration of IL-1 to rats causes persistent inhibition of feeding.[196] Strikingly, this effect is not obtained in fish oil–fed rats.[198] Anorexia induced by IL-1 is mediated by CRF,[198] melanocortin-3/4 receptors[199] and, to a lesser extent, by PGs.[200] Other cytokines including IL-2, IL-6, and IFN-α also stimulate hypothalamic CRF expression and/or release.[201] Thus, CRF seems to modulate both aspects of energy balance regulation in the rat, that is, food intake and energy expenditure. CRF effect on energy expenditure is mediated by a stimulation of SNS outflow, as reflected by a dramatic increase in the secretion of both adrenaline and noradrenaline,[99,202] explaining that the increase in body temperature and oxygen consumption induced by experimental inflammatory syndromes may be significantly reduced by β-adrenoreceptor blockade.[203,204] The chronic administration of IL-1β induces a sustained rise in body temperature and a reduction in food intake. The simultaneous increase in energy expenditure and decrease in energy intake result in a significant reduction in body weight gain of the experimental rats compared to controls, indicating that low levels of IL-1β release, maintained over periods of several days, could be responsible for changes in energy balance during chronic infection or inflammation.[205]

Chronic cytokine overproduction also affects energy expenditure in humans. In RA, for example, RMR adjusted for BCM is about 12% higher than in adult controls. Furthermore, there is a positive correlation between cytokine production and the increase in RMR, cytokine production and BCM accounting for about 20% and 50% of RMR variability, respectively.[184] RMR adjusted for FFM is increased by about 20% in children with systemic juvenile rheumatoid arthritis (JRA) as compared to controls. As a result, they are stunted and their FFM is reduced. Oligo and polyarticular JRA children still display an 8% increase in RMR over controls.[206] Similarly, RMR is increased in stable, cystic fibrosis (CF) patients by 10%–25% above control values,[207,208] a change which is not accounted for by the increase in the oxygen cost of breathing.[207] There is a positive relationship between RMR and TNF-α levels,[209] and adrenaline levels, TNF-α accounting for about 27% of RMR variability. Contrary to RA patients who have a significant reduction in FFM but a relatively conserved FM, both FFM and FM are significantly reduced in CF patients.[210] Thus, besides the dramatic thermic response to infectious disease or injury, cytokines may also mediate lower-magnitude increases in metabolic rate, which might lead to a progressive depletion of energy

stores if sustained for weeks or month.

Infection also induces important changes in the production or utilization of energy substrates. Infected patients present glucose intolerance, irrespective of the severity of the infection and of the infective agent.[211] There is a significant increase in endogenous glucose production, which is not suppressible by glucose infusion and partially accounts for the increase in plasma glucose concentration. The stimulation of hepatic glucose production is principally mediated by increased levels of catecholamines and an increased glucagon-to-insulin ratio.[212] Although whole-body glucose turnover is increased, insulin ability to stimulate glucose uptake is reduced. Indeed, peripheral glucose utilization is impaired when compared to controls.[213] It is noteworthy that marked insulin resistance is present in previously healthy individuals with uncomplicated viral infections.[214] Insulin resistance is readily apparent four hours after the administration of LPS to healthy volunteers. The increase in glucose turnover and the peripheral insulin resistance may be partially accounted for by a sustained β_2 stimulation[215] and by the increase in free fatty acid appearance rate in infected humans and animals,[204,212] an increase related to adrenergic stimulation.[212] Cytokines, particularly TNF-α, also contribute to insulin resistance by a direct effect on the insulin signaling cascade[216] and by increasing free fatty acid appearance rate by a stimulation of adipose tissue lipolysis.[217] Similarly, IL-6 is a potent modulator of fat metabolism in humans, increasing lipolysis and fatty acid oxidation.[218] This might be related to the suppression of adipocyte glyceroneogenesis, through the inhibition of cytosolic phosphoenolpyruvate carboxykinase (PEPCK-C) gene expression, which results in a dramatic increase in free fatty acid release by adipose tissue.[219]

When compared to healthy controls, fat oxidation is increased in septic patients and falls by a much lesser percentage in response to glucose and insulin.[220] Indeed, at the end of an insulin clamp, fat oxidation still contributes about 58% to metabolic rate in the septic patients, whereas it amounts to only 23% in controls.[220] Moreover, fat oxidation rate appears to be positively related to the severity of sepsis. Despite an increase in glucose turnover, fat thus appears as a preferred calorie source during sepsis.[221] Endotoxin administration to humans induces an increase in adrenaline and cortisol levels, whereas glucagon and insulin do not change.[192] Simultaneously, there is a significant rise in free fatty acid levels. Splanchnic glucose output is also increased and a progressive

hyperglycemia ensues. The reduction in glucose utilization, like that observed in sepsis, is related to impaired nonoxidative glucose disposal and not to abnormal glucose oxidation. Increases in plasma glucose, free fatty acid turnover (126%), and fat oxidation (60%), and similar variations in hormone concentrations follow the injection of rTNF to human volunteers, further supporting the role of cytokines in the development of the metabolic response to acute infection or injury.[222] It is interesting that an increase in both free fatty acid and glycerol concentrations is also observed in CF patients despite a reduction in FM, suggesting that chronic inflammatory syndromes may result in changes in the pattern of substrate utilization qualitatively comparable to those observed during acute infection.

ENERGY REQUIREMENTS IN DISEASE

Energy

The Food and Agricultural Organization of the World Health Organization (FAO/WHO) has published detailed estimates for energy requirements in infants and children of various ages.[223] In the adult, baseline energy needs, that is, energy needed to cover the metabolic response to food and the energy cost of minor activities, are assumed to be equal to 1.35 × BMR, and the time spent sleeping equal to BMR. This is considered as a survival requirement and is of practical value only for estimating the short-term needs of inactive and dependent individuals. Otherwise, estimates should include the energy cost of various occupational activities. However, it is not possible to specify with any confidence the allowance that should be made for a desirable level of physical activity in infants and children. Thus, energy requirements from birth to 10 years have been derived from the observed intakes of healthy children growing normally. Beyond 10 years, calculations are based on published BMR measurements, incremented for the cost of growth and for a cost of activity assumed to be about 1.6 × BMR. Free-living measurements of 24hEE corrected for the energy deposited during growth show that estimated energy requirements are substantially higher than total energy expenditure.[224] Furthermore, calculated energy expenditure also exceeds the energy intakes of 10- to 17-year-old children and adolescents.[224] Clearly, the difficulties encountered in achieving an accurate prediction of the energy needs in healthy infants and children would make unrealistic any such attempt in sick children, as the issue is further confused by the opposing effects of underfeeding and

disease on energy expenditure. Then the only option left is to try to identify some agreement about the range of variations in metabolic rate induced by diseases.

Studies in 13–60 month children with acute measles-associated underfeeding suggest that negative energy balance is related to a dramatic reduction in gross energy intake concomitant with a sustained level of energy expenditure. Metabolic rate after recovery is not significantly different from the values obtained during acute infection, although an average 20% increase would have been expected from the presence of fever.[225] The surprising stability of metabolic rate during acute infection might be accounted for by the balanced effects of underfeeding and infection. In any case, maintenance energy requirement (MER) determined at zero energy balance is 64 kcal/kg/d,[225] a figure similar to the MER of thriving infants.[42] In these infants, the safe level of energy intake is estimated to be between 91 and 100 kcal/kg/d,[225] as compared to the 81–87 kcal/kg/d free-living 24hEE of normal infants, 224 or the average 103 kcal/kg/d estimated energy requirements in the toddler group. It is further possible to evaluate the consequences of sepsis and trauma on energy expenditure. Earlier measurements in adults indicated 20%–50% increases in metabolic rate in response to severe infection or multiple trauma. Studies performed in critically ill patients without malnutrition indicate that the mean increase in fasting metabolic rate ranges between 5%[226] and 14% to 18% over predicted values.[227] This is consistent with reports comparing septic patients to matched controls and showing a 15%–19% increase in fasting metabolic rate over normal values.[228] Comparable estimates are obtained in traumatized children. RMR peaks at three days after injury, representing an 8% increase over predicted values or a 14% increase over replicate measurements obtained after discharge.[229] After surgery, the mean increase in RMR over baseline reaches about 15%. In these conditions, RMR peaks at four hours postoperatively and returns to baseline levels by 12 hours, thus resulting in a modest overall change in metabolic rate. Furthermore, the increase in RMR is related to the nature of the surgical procedure, the maximal rise being about 5% for minor surgery and 19% for major operations.[230] A similar trend toward decreasing estimates is observed regarding the energy expenses following burn injury. RMR in burned infants is independent of burn size and of the time elapsed between burn injury and measurements. Indeed, these two factors only account for 24% and 21% of the variation in RMR above predicted values, which is primarily dependent on body size.[231]

Furthermore, β-adrenergic blockade induces a substantial decrease in RMR in severely burned children.[231] As a result, the amount of energy required to achieve energy balance may be much lower than previously estimated. Actually, caloric delivery in excess of 1.2 × RMR might only result in increased FM without changes in lean body mass.[232] A comparable reevaluation of the change in metabolic rate resulting from severe head injury suggests that patients who are properly taken care of have a lower than expected increase in RMR.[233] Therefore, it is likely that an energy intake equivalent to 1.5 × BMR would meet the requirements of most septic, traumatized, or burned infants and children. That increases in RMR after trauma, sepsis, or burn injuries are somewhat comparable is consistent with the existence of common mediators. Although the increase in energy expenditure resulting from disease appears to be substantially lower than previously estimated, applying equations that were originally developed for healthy, nonhospitalized individuals to predict the energy requirements of critically ill children could result in significant errors and may lead to provision of inappropriate nutritional support.[234]

Energy Substrates and Amino Acids

Energy intake should provide glucose and fat in amounts adapted to insulin resistance and to the preferential oxidation of lipids. Physiologic considerations also suggest that the amount of glucose infused to malnourished, uninfected patients be limited. In adults, glucose oxidation levels off at about 4 mg/kg/min in response to increasing glucose infusion rates.[235] A similar limitation exists in 6-month-old infants, with a maximal oxidative glucose disposal rate of 12 mg/kg/min.[15] Furthermore, this maximal oxidative disposal decreases in parallel to energy expenditure with age, amounting to about 9 mg/kg/min at 6 years and about 6 mg/kg/min at 10 years.[15] In the uninfected infant, glucose infusion in excess of the maximal oxidative glucose disposal rate only results in inhibiting fat oxidation whether of endogenous or exogenous origin,[15] and may adversely affect protein metabolism and net protein deposition.[236] Thus, expecting some benefit from high glucose intakes in infected infants seems hazardous. On the contrary, glucose intakes should be lower because of the glucose intolerance. Glucose intakes in the range of the physiologic endogenous glucose production of the corresponding age range[237] are sufficient to meet the needs of glucose-requiring tissues. In these conditions, the clearance of intravenous emulsions as well as their oxidation are enhanced in septic patients. The other goal is to equilibrate

the increased proteolysis by promoting protein synthesis. In the healthy adult, protein synthesis is primarily regulated by amino acid inflow. Similarly, amino acid infusion decreases net nitrogen losses in septic patients; the higher the amino acid intake, the more rapid the effect. In burned infants and toddlers, amino acid intakes in the range of 2.5–3 g/kg/d efficiently support recovery.[238]

The Inflammatory Syndrome: A Case for a Pharmacologic Approach

Providing nutrients may not be enough in many of these situations. Nutritional support should be aimed at avoiding unnecessary increases in metabolic rate or, better, at controlling the disease-induced increase in energy expenditure. Obviously, attention should be given to ambient temperature and humidity, particularly in infants and burn patients. Furthermore, the use of inhibitors of either cytokine expression or COX, as well as of blockers of SNS peripheral effects, should be considered. As glucocorticoids suppress the production and the action of several cytokines as well as the production of PGs, it appeared warranted to test their effects in vivo in septic patients. The results are disappointing and do not support their use in sepsis, probably because corticoids could be administered only after cytokine release.[239] The use of molecules (antibodies or receptor analogs) directed against cytokines[240] or modulating inflammation[241] offers very interesting possibilities. Another way to curb the inflammatory response is to interfere with signal transduction in target cells through inhibitors of the COX. Indeed, pretreatment with ibuprofen results in the complete suppression of fever, tachycardia, and increase in stress hormones after endotoxin injection, as compared to the subjects who were not pretreated, despite an identical rise in TNF in both groups.[242] Similarly, the use of β-adrenergic receptor antagonists may substantially diminish energy expenditure.[204] If these dispositions may reduce metabolic rate, in many cases they will have little effect on the accelerated protein breakdown.

A pharmacologic intervention would be even more pressing when nutrition support fails to prevent protein losses, as it is the case in sepsis or during cancer cachexia. Animal models confirm that protein wasting is not accounted for by the effects of underfeeding in these situations,[182] thus requiring an approach other than dietary therapy. Besides their effect boosting proteolysis, glucocorticoids have an inhibitory effect on protein synthesis, which could further exaggerate cytokine-induced protein losses.

Unfortunately, COX inhibitors seem to have only a partial and transient effect.[182] One remaining possibility is to directly inhibit cytokine production by new agents. Pretreatment with pentoxifylline inhibits TNF secretion and partially suppresses anorexia, weight loss, and muscle protein wasting in septic rats,[243] although fever, myalgia, and increased cortisol levels are unaffected in pretreated, endotoxin-injected humans.[244] However, these molecules are effective when administered prior to endotoxin or TNF injection, but little is known about their efficacy as therapeutic agents.

The other possibility is to antagonize the effects of cytokines on protein metabolism. Recombinant growth hormone (rGH) administered to postoperative patients induces a dramatic change in nitrogen balance, despite low energy intakes. Furthermore, rGH treatment is able to reverse net whole-body and skeletal muscle protein catabolism in cancer patients.[245] This positive effect has been confirmed in severe sepsis and in patients with HIV-related wasting. Similarly, recombinant insulin-like growth factor I (rIGF-I) infusion to rTNF-treated animals preserves its anabolic action and induces a significant reduction in net protein losses in the face of high TNF levels.[246] It is noteworthy that decreased IGF-I levels, a common finding in acutely ill patients, may enhance protein catabolism. The protein anabolic effects of both rGH and rIGF-I may be substantially increased by using both agents simultaneously,[247] a synergy that might prevent GH resistance. Although recombinant hormones are not the only agents favoring net protein synthesis, available evidence suggests that they are the best candidates to date for improving the nutritional therapy of protein-wasting inflammatory syndromes through direct pharmacologic intervention. Indeed, data suggest that rGH treatment improves growth and clinical conditions of CF patients,[248] in children with chronic renal failure[249] or juvenile arthritis,[250] increases linear growth and lean body mass in patients with Crohn's disease[251] and, by and large, has substantial anabolic effects on whole-body protein and bone metabolisms in children on chronic steroid therapy.[252]

Severe Acute Malnutrition: 14 Pathophysiology, Clinical Consequences, and Treatment

Mary E. Penny, MBChB

The number of children affected and long-term consequences of malnutrition place it among the greatest public health problems facing the world today. An estimated 19.3 million children (3.5%) under 5 years in developing countries are severely wasted, that is, they are less than 3 SD below the median of weight-for-height.[1] The majority, 12.9 million, live in Asia and 5.6 million in Africa. These children are at an increased risk of dying. Even mild degrees of malnutrition increase the risk of mortality by 50%, but this risk greatly increases with the severity of wasting.[2] An analysis of eight low-income countries reported that children with severe wasting had nine times higher risk of dying of any cause (OR 9.4 [95% CI 5.3–16.8] with the greatest risk for pneumonia deaths (OR 8.7 [95% 4.-15.6]).[4,3,4]

Severe wasting or severe acute malnutrition (SAM), which used to be called protein energy malnutrition, is eminently treatable, but sadly the treatment of SAM is an area where the gap between existing knowledge of

successful practice and the reality of the management of most malnourished children is abysmal. Several reports document how the adoption of improved treatment following the World Health Organization (WHO) guidelines[5] can greatly reduce mortality even in resource-restricted circumstances (and with optimum management mortality can be as low as 5%[6–9], but the reality in many areas is mortality rates of 20% or more, with even higher rates for children with kwashiorkor.[4,10–12]

The global importance of malnutrition and its long-term consequences are dealt with in Chapters 15, 40, and 41. The public health significance, as discussed in Chapters 15 and 16, emphasizes the necessity for the combination of policies designed to prevent malnutrition with programs to treat children with malnutrition. Malnutrition is not only a problem of developing countries. Failure to recognize malnutrition may also contribute to increased morbidity and mortality in other conditions such as congenital heart disease and cystic fibrosis in developed countries.[13,14] This chapter deals with the clinical management of severe malnutrition and attempts to show how an understanding of the pathophysiology provides a basis for the treatment of the severely malnourished children; it is principally concerned with severe SAM as a clinical entity because the failure to recognize the special needs of these children contributes to high mortality.[5]

DEFINITIONS AND DIAGNOSIS OF SEVERE ACUTE MALNUTRITION

Malnutrition has many causes. In any individual, inadequate food intake, infections, psychosocial deprivation, the environment, and perhaps genetic variability contribute. The clinical manifestations in the child depend on the duration and degree of shortfall in dietary intake, the quality of the diet, host factors such as ageand the interplay with infection. Recently, the role of the microflora (microbiome) of the intestine has been demonstrated.[15]

The first step in the diagnosis of SAM is nutrition assessment. This is an essential part of any clinical pediatric evaluation and is discussed in detail in Chapter 2, “Clinical Assessment of Nutritional Status.” Repeated nutritional assessments of all ill children are important to prevent the insidious onset of malnutrition, which may hinder recovery. Adequate growth is an indication of health and recovery. For an individual child, the most important information is gained from serial measurements of the

child‘s growth, and this provides essential information for diagnosing cause and guiding treatment. The importance of using this often available, but overlooked information cannot be overstated.

Although measurements of height (or length in children under 2 years) and weight are the usual mainstays of diagnosis, the mid-upper arm circumference (MUAC) has also been shown to be useful in identifying children with SAM who are at increased risk of dying and need treatment in hospital or specialized facility care.[5] Nutritional survey data from 31 countries show that applying a cutoff of less than –3 SD weight-for-height (WHO standards) and a MUAC cutoff of less than 115 mm identifies a similar number of children, 3.22% and 3.27%, respectively.[16] This new cut off identifies more children at a greatly increased risk, about nine times the risk of dying. The former cut off criteria of –3SD weight for height using the NCHS reference standards only identified 1.48% and a similar percentage, 1.48%, were identified by a MUAC cut off of 110 mm.[6]

The two criteria identify different children so WHO has recommended that both criteria be used, together with the presence of edema to diagnose SAM (WHO combined statement) (Table 14-1).[6] MUAC is more sensitive for younger aged children, an age when malnutrition is particularly critical for future development.[17] It is an easy and cheap test and does not require looking up values in chart. Sole reliance on weight and length or height or MUAC can lead to failure to recognize kwashiorkor and an under estimation of the severity of the malnutrition in these children. The scheme recommended by WHO Table 14-1. has the merit of distinguishing these two entities. Some authorities report that MUAC <115 mm is better than weight-for-height at identifying children at high risk of mortality and recommend using only MUAC[18] plus an examination for edema.

Biochemical and hematologic tests are useful for specific diagnoses and for monitoring progress but are rarely necessary for starting treatment. SAM is often associated with micronutrient deficiencies, and examination should include a specific search for Bitot‘s spots or xerophthalmia, manifestations of vitamin A deficiency and examination for signs of other micronutrient deficiencies.[19]

(Figure 14-1) illustrates a child with marasmus and shows the characteristic muscle wasting particularly evident in the buttocks, the pinched face, and anxious demeanor. (Figure 14-2) shows the same child on recovery.

Figure 14-3 illustrates a child with kwashiorkor. Symmetric edema is evident, especially in the lower limbs. The hair is sparse, and the flaky

paint rash is seen on the buttocks, legs, and arms. Figure 14-4 shows the typical bilateral symmetric edema of the legs.

Marasmus is generally believed to be the result of a cumulative, usually slow, inadequate energy, and protein intake. The child's metabolism has adapted, producing changes that prolong survival and protect essential visceral and brain function. This is the type of SAM traditionally seen in famine, food restriction, or anorexia. Kwashiorkor is also a severe form of malnutrition. The etiology is not yet well understood, but the long-held view that protein deficiency in the face of adequate energy intake causes kwashiorkor is now untenable. Observed findings are more in keeping with an interaction between nutritional deficits and the response to injury, infection, and oxidative stress.[20,21] The intestinal microflora appears to play an important role.[15] Marasmus and kwashiorkor commonly coexist, and although a simple unified approach to clinical management can be applied successfully to both conditions,[5] both are clinically distinct entities. When the conditions coexist, the child should be treated as having kwashiorkor.

TABLE 14-1 Criteria for Diagnosis of Severe Acute Malnutrition

Result (Indicator)	Measure	Cut-off for Diagnosis
Severe wasting (marasmus)	Weight-for-height[a]	<–3SD
Severe wasting (marasmus)	MUAC	<115 mm
Bilateral Edema (kwashiorkor)	Clinical examination	Any edema

[a]Based on WHO Standards (www.who.int/childgrowth/standards).

PATHOPHYSIOLOGY

Metabolic Responses to Inadequate Energy Intake

SAM is the result of a chronic and cumulative failure to meet physiologic energy and nutrient requirements.[22] The manifestations of this process depend on different factors: age, concomitant infection, the intestinal microflora, prior nutritional state, and the nature of the dietary restriction. Both the early classic experimental studies of food energy deprivation and starvation in animals and humans and studies of severely malnourished children on admission and during recovery have contributed to our understanding of the physiological responses to severe undernutrition.[23,24]

In the absence of infection, fasting results in an initial depletion of fat stores and then glycogen stores mediated by metabolic and endocrine changes that have the common goal of preserving vital functions, allowing the animal or human to survive until dietary energy can be restored. Early changes include a reduction in activity that conserves energy expenditure.[25] Growth is slowed, reducing the energy need to maintain this, and changes occur in body composition. Metabolic rate expressed in relation to height or lean body mass decreases.[23] Brain and viscera are relatively preserved Figure 14-5, resulting in the body composition typical of marasmic children.[26–28] There is an increase in total-body water, which

is mainly extracellular but may also be intracellular.[28]

These metabolic adjustments to starvation are mediated, at least in part, by hormones. Cortisol concentration rises but remains responsive to stress.[27] Insulin secretion falls, and there is a reduction in plasma insulin levels, a reduced response to glucose, and peripheral insulin resistance.[29,30] Growth hormone is generally high, and the normal suppression by glucose load is lost, although exceptions occur in marasmus.[31] There is low activity of insulin-like growth factor, the metabolic effector of the growth-promoting effect of growth hormone.[27] The net effects of these hormonal changes are mobilization of fat, degradation of muscle protein, and reduction in basal metabolic rate. Increased aldosterone contributes to potassium loss already compromised by the effects of energy restriction and reduced adenosine triphosphate synthesis on the sodium pump.[32]

Adaptation to Reduced Protein Intake

During energy and protein deprivation, especially in marasmus, skeletal muscle is lost as structural protein is recycled to conserve essential enzymes and provide energy for metabolic processes.[27] There is both a fall in muscle protein synthesis and an increase in breakdown, which provides essential amino acids to the liver for protein synthesis and gluconeogenesis.[27]

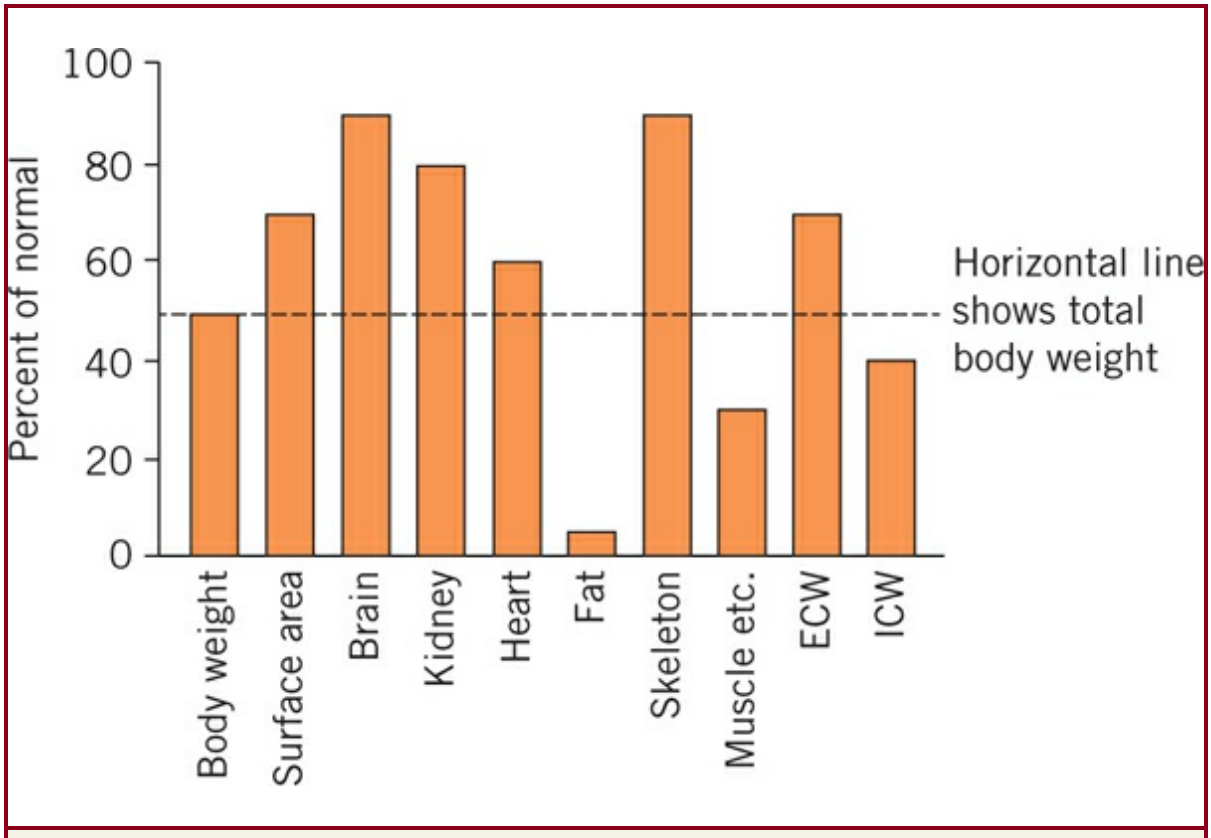

Figure 14-5 Weights of organs at death in atrophic children as percentages of normal age controls. ECW, extracellular water; ICW, intracellular water. (Adapted from Kerpal-Fronius and Frank)[16]

In kwashiorkor, whole-body protein breakdown is slower than in marasmus.[33] Within the liver, there is a shift in the rates of synthesis of different proteins; synthesis of albumin, transferrin, and apolipoprotein B are decreased, but synthesis of other proteins is maintained.[34]

Loss of skeletal muscle tissue in SAM may result in a relative shift in protein turnover from skeletal muscle to organs such as liver which have a different amino acid composition. This together with inadequate intake of sulfur amino acids may lead to a reduced availability of the essential amino acid methionine. It is suggested that one effect of these metabolic changes is a deficiency of methionine, which is manifested in the skin and hair changes of kwashiorkor.[35] Methionine is the sulfur donor for cysteine synthesis. All children with SAM have reduced cysteine synthesis, but this is much more marked in kwashiorkor.[35] Reduced availability of cysteine means that GSH synthesis is reduced and there is less glutathione and thus decreased antioxidant activity, a consistent finding in kwashiorkor.[36–38] This explanation is supported by studies showed faster reduction in edema

and improved outcome in children with kwashiorkor who received N-acetylcysteine supplements.[39] These findings need to be considered in establishing guidelines for dietary rehabilitation of children with SAM, especially kwashiorkor.[40]

Of relevance, cysteine is essential for maintenance of intestinal structure and function. Children with SAM and especially those with kwashiorkor typically have enteropathy[41] with intestinal mucosal damage, and in these circumstances, there is a high requirement for cysteine. The potentially important role of sulfur amino acids in kwashiorkor may provide the key to understanding the mechanisms where by certain patterns of gut microbiome predispose to kwashiorkor in the presence of diets that are characteristically deficient in cysteine and methionine since mice transplanted with fecal material from kwashiorkor children had lower concentrations of methionine and cysteine in their feces compared with mice transplanted with feces of healthy children.

Changes in Electrolytes

Changes in chemical composition of the body that occur during malnutrition have important consequences for treatment. Sodium, potassium, and phosphate merit special mention, but changes in other electrolytes, such as magnesium and calcium, are also important.[20]

The vast proportion of total-body potassium is intracellular, in contrast to sodium, which is actively removed from cells by the sodium pump. In both marasmus and kwashiorkor, sodium retention occurs, resulting in an increase in whole-body sodium, even though serum levels may be low, reflecting an increase in extracellular water. There is a decrease in total-body potassium, although serum potassium may remain normal.[42] Alleyne and colleagues described how potassium kinetics are altered during recovery.[43] There was an initial acute repletion of potassium when hypokalemia and whole-body deficiency improved, followed by a longer phase of cell membrane recovery and reestablishment of the normal Na/K gradients. A third phase occurred when rapid growth of skeletal muscle increased potassium requirements.[44,45] Nichols and colleagues calculated from balance studies that 7.0 mmol/kg of potassium was needed in the first week or acute phase of recovery, an amount similar to the level of supplement giving best results in a clinical trial in Malawi.[46,47]

The inconsistencies between serum and total-body potassium are explained by events at the cell membrane. In marasmus, there is a decrease in the activity of the ouabain-sensitive energy-dependent sodium pump,

resulting in increased intracellular sodium and reduced potassium.[48] These cell membrane changes are associated with intracellular changes, with relatively low intracellular K and relatively high sodium.

Different mechanisms operate in kwashiorkor, in which there is an increase in cell membrane leakiness. Sodium, responding to the electrolyte gradient, enters the cell, stimulating increased activity of the sodium pump but not enough to prevent Na increase and K loss.[48,49] Similar differences between marasmus and kwashiorkor were reported by Kaplay in India.[50] Forrester and colleagues found that these electrolyte changes could be reproduced in the in vitro erythrocytes if glutathione was artificially reduced, resembling the situation in kwashiorkor.[40] Increased intracellular sodium is accompanied by increased cell water, which may be one of the explanations for edema in kwashiorkor.[51] Hypoinsulinemia is implicated in this process.[52] These electrolyte changes are the basis for the recommendations of potassium supplementation in all severely malnourished children; dietary restriction of sodium, and the use of oral rehydration solution (ORS) with less sodium than the standard 75 mmol/L solution. As will be discussed, a balance is needed to avoid too little sodium that can result in severe hyponatremia.[41]

Hypophosphatemia has been shown to occur in malnourished children and is associated with high mortality. In a South African study, 10 of 60 patients died, all but one with very low serum phosphate.[53] The lowest levels of serum phosphate were associated with diarrhea and dehydration. A study from Malawi supports the association of hypophosphatemia and increased mortality.[54] However, it is difficult to distinguish the effects of low phosphate from hypokalemia, which also causes hypotonia and sudden death. In Jamaica, serum phosphate levels were generally higher than those recorded in Africa and although these correlated with edema, hypophosphatemia was not associated with mortality.[55] Repletion, even on a milk diet, took two to three weeks. The advantage of milk-based diets is relatively high phosphate content.

Interaction With Infection

Infection and nutrition are mutually interlocked in a vicious cycle that operates at many levels, from social cultural interrelations to intracellular metabolism. Environmental conditions that give rise to inadequate energy and protein intakes are also associated with conditions in which bacterial and other microbial contamination are often rife[56] affecting the microbial milieu of the intestine. In addition, in famine or poverty, children‘s diets

tend to consist largely of carbohydrate staples with little or no animal products or fat.[57] Animal products such as red meat, poultry, offal, fish, milk, and eggs are important bio available sources of minerals and other micronutrients that have an essential role in combating infections.[58] Fat, needed to provide essential fatty acid (EFA) and facilitate the absorption of fat-soluble vitamins such as E, D, and A, which also protect against infections, is also often low in these diets.

During infection, there are metabolic changes that concentrate body energy resources on production of acute-phase proteins in the liver and are often the opposite of those seen in starvation.[59] The production of acute-phase proteins and the metabolic consequences of infection are mediated by protein cytokines, lipid-derived factors that include prostaglandins, leukotrienes, and platelet activation factor. Endocrine changes also play a role; the concentration of catabolic hormones such as glucocorticoids, glucagons, and epinephrine increases. The cytokine interleukin (IL) 6 increases norepinephrine, cortisol, and glucagon and is the main stimulus for the mobilization of acute-phase proteins in the liver. Cytokines also enhance the effect of stress-related hormones on the production of acute-phase proteins.[60] Because of the interaction between food restriction and infection in the pathogenesis of malnutrition, any integrated approach to explaining the pathophysiology has to take both into account. The differences between kwashiorkor and marasmus may be partially explained by an increased shift toward the metabolic consequences of infection in children with kwashiorkor. In addition, preceding nutritional status may modify the metabolic effects of infection. A review of children presenting with kwashiorkor indicated that they had higher birth weights than those presenting with marasmus supporting the concept that intrauterine factors and preceding nutritional status influence the development of kwashiorkor.[61] Recent findings that the pattern of the gut microbiome is a determinate of kwashiorkor also support this concept.[15]

CYTOKINES

Cytokines and Response to Infection

Because of the fundamental role of cytokines in infection and the interaction with malnutrition, a brief summary of their action is necessary. For more detail, readers are referred to more complete reviews.[60,62] Cytokines are small, nonstructural proteins that can be produced by nearly all nucleated cells in very small amounts, have local and systemic effects,

and are involved in the primary response to infection. Synthesis of cytokines is rapidly induced in response to infection, trauma, ischemia, and other events. Cytokines are also involved in mediating the changes in protein metabolism and muscle function that accompany infections, fasting, and cancer cachexia. The family of tumor necrosis factors (TNFs), IL-1, and IL-6 are all pro-inflammatory cytokines. The pro-inflammatory cytokines mediate the local inflammatory response, which includes local heat, redness, pain, swelling, and systemic effects such as fever and anorexia. To avoid self-injury during the inflammatory response, the induction and synthesis of cytokines are controlled in a complex interactive process full of checks and balances. This tightly controlled system is disturbed in malnutrition. Clinically, children with severe malnutrition often have a reduced inflammatory reaction and blunted febrile response,[63] and some studies have reported reduced levels of in vitro production of IL-1 and TNF by circulating monocytes in malnutrition.[64,65] Other studies suggest that, in a similar way to well-nourished children, the immune cells of marasmic children are able to mount a cytokine response involving IL-6 and TNF?, and this occurs in response to acute infection.[63,66,67] It is less clear to what extent this occurs in vivo and how to interpret these results in the context of the malnourished child‘s reduced acute-phase response and the blunted clinical expression of the inflammatory response.

Acute-Phase Proteins

Cytokines modulate the production of acute-phase proteins. C-reactive protein, α-1-antitrypsin, x03B1-macroglobulin, and fibrinogen are examples of positive acute-phase proteins, so-called because their synthesis by the liver increases in response to stresses, including infection.[68] Serum concentration of the so-called negative acute-phase proteins (albumin, prealbumin, fibronectin, retinol-binding protein) is reduced in children with malnutrition.[65,68] Low levels of fibronectin have been reported to be a useful early indicator of malnutrion.[69] Positive acute-phase proteins are an essential part of the defense against infections, but uncontrolled inflammation has been linked to adverse consequences, for instance, in inflammatory bowel disease, rheumatoid arthritis, and perhaps kwashiorkor. Studies are complicated by the coexistence of infection and malnutrition and the limitations of interpreting serum levels, which represent a balance between synthesis and catabolism. Studies in Ghana on children without sign of infection found raised concentrations of C-

reactive protein in kwashiorkor and to a lesser extent in marasmus.[70] α-1 Acid glycoprotein levels were raised in kwashiorkor in Thai children.[68] On the other hand, Ekanem and colleagues,[71] studying children, 75% of whom had kwashiorkor, documented only slight increases in C-reactive protein in children without infection and large increases in infected children, indicating apparent preservation of the acute-phase response to infection in this population of children. This is in contrast to findings in Jamaica of normal levels of C-reactive protein and serum amyloid A with a blunted response in the expected acute-phase response to diphtheria-pertussis-tetanus vaccination.[72] Elegant studies in Jamaica and in Malawi using stable isotope labeled leucine, in marasmic children, with infections showed that there was an increase in some acute-phase proteins (C-reactive protein, haptoglobin, α-1 acid glycoprotein, α-1 antitrypsin) in response to infection but this response was attenuated despite preservation of the cytokine response.[73] The increase in plasma levels of acute-phase proteins was attributable to a reduction in catabolism rather than an increase in the synthesis of proteins, in contrast to the situation in normally nourished infected children.[73] Plasma fibrinogen, which is normally increased in response to infection, showed no response in these children. A study from Malawi suggests that the reduced acute-phase protein response might be modulated by the protein content of the diet. A diet with higher protein from egg white and additional trytophan, the rate limiting amino acid for acute-phase protein synthesis, resulted in an increase in serum concentrations of six acute-phase proteins.[74]

The consequence of a reduced inflammatory response to infections has important clinical repercussions both because the usual manifestations of infection may be absent in SAM making diagnosis difficult and because the mortality from infection is greatly increased. Further studies are needed to understand the different changes that occur in response to infection and most importantly the way in which dietary management may counteract these changes.

Kwashiorkor

Kwashiorkor has historically been attributed to a diet lacking in protein, and the edema was believed to be explained by low albumin. In consequence, children were treated with high-protein diets. However, several observations have long cast doubt on this hypothesis.[75] Kwashiorkor often follows infections such as measles and dysentery and has been reported in breast-fed babies, who presumably are ensured

adequate protein intake, and children in the same community on very similar diets may develop kwashiorkor or marasmus. Edema has been shown to improve independently of albumin. Golden demonstrated that recovery was possible with relatively low-protein diets and was dependent on energy intake and not on protein.[76] The latest findings of the importance of prior gut microbiome confirm that kwashiorkor is not due to overall protein deficiency although the amino acid composition of the diet might possibly have a role in the interplay between diet, infection, and factors that determine what is going on in the child‘s gut.[15]

Free Radicals

While progress is being made in understanding the causes of kwashiorkor, full understanding of the pathophysiology will need to account for the well–established, decreased antioxidant response that allows unabated free radical damage to cells and explains some of the clinical findings in kwashiorkor.[36]

The acute inflammatory cells that form the first line of defense against infections respond with a respiratory burst during which free radicals are produced. This response to infection or cell injury relies on these free radicals for the destruction of bacteria. The free radicals are characterized by one or more unpaired electrons, which make them highly reactive and unstable. Reactive oxygen species include oxygen radicals such as singlet oxygen and nonradicals such as hydrogen peroxide; reactive nitrogen species include nitric oxide. The most potent free radicals include the hydroxyl radical and iron free radicals, which occur when unbound iron is present during free radical production. Free radicals are produced in normal metabolism, and a certain level of these radicals is required for normal functioning. However, this amount is kept to a minimum by a number of scavenging mechanisms, which detoxify the radicals. Free radical production is increased by stresses, which include inflammation, infections, and environmental stresses.[77] Oxidative stress is a process in which the normal balance between pro-oxidants and antioxidants is shifted toward the oxidant side, resulting in an increase in free radicals that cause biologic damage.[78] Increased oxidative stress has been demonstrated in kwashiorkor.[79] The damage caused by free radicals includes disrupting enzymes and nucleic acids and the peroxidation of lipoproteins and EFAs in cell membranes by hydrogen peroxide. Dietary antioxidants protect from oxidant damage either directly by scavenging free radicals or because they are required for enzymes that neutralize free radicals. Examples

include the copper and zinc-dependent enzyme superoxide dismutase, the selenium-dependent enzyme glutathione peroxidaseand catalase. The sulfur amino acids methionine and cysteine are precursors involved in the production of glutathione, which reduces oxidative stress and protects against free radicals damage.

Many studies show low concentrations of antioxidants in the serum and red cells of children with malnutrition, especially kwashiorkor.[40,80] Blood cell concentrations of glutathione, vitamin E, and the vitamin E-to-cholesterol ratio are reduced, resulting in diminished resistance to oxidative stress.[66] It seems that the balance between production and quenching of free radicals is perturbed in kwashiorkor, resulting in oxidative stress. This has been attributed to low levels of dietary antioxidants, with increased free radicals as a consequence of the disturbance in the acute-phase response to infections and other environmental stresses.

In keeping with this concept, a randomized trial of a supplement of N-acetyl cysteine given to children with kwashiorkor improved clearance of edema and shortened time to recovery in children.[39] However, a placebo controlled trial designed to test the dietary antioxidant deficiency hypothesis gave daily supplementation of an antioxidant mixture of riboflavin, vitamin E, selenium, and N-acetylcysteine for 20 weeks to children in Malawi but failed to prevent the occurrence of kwashiorkor.[81] EFAs were not included in the supplement. In this context, simply giving dietary supplements of these antioxidants was not enough to prevent kwashiorkor, but it may well be that this is only part of the story and we need to understand more about the interplay between diet and other determinants of kwashiorkor.

Lipid Metabolism, Polyunsaturated Fatty Acids, and Free Radicals

Recent research investigating the role of lipids in malnutrition lends support to the theory of oxidant stress as a cause of kwashiorkor. It has long been known that there are changes in the lipid profile of red cell membranes and plasma in malnutrition.[82–84] Recent interest has focused on these EFAs and their metabolites as these have protean functions, which include maintaining the integrity of cell membranes and involvement in the synthesis of immunologically active elements such as prostaglandins and leukotrienes.[85] A low proportion of arachidonic acid, one of the EFAs, in the lipid profile of cell membranes and low

concentrations in the plasma of children with severe malnutrition have been reported.[86] These changes in EFAs are not due to dietary deficiency alone and are more likely a result of shifts in the metabolism of these EFAs. In particular, desaturation, which is subject to endocrine influence, is reduced, and low desaturase activity has been reported in SAM.[87] There may also be peroxidative degradation of EFAs in cell membranes. Levels of antioxidants are consistently reduced in SAM, and this increases the peroxidation of membrane long-chain polyunsaturated fatty acids (PUFAs).[88,89]

Leukotrienes are a family of mediators involved in the inflammatory response. The EFA arachidonic acid mentioned above is a precursor of the leukotrienes. Glutathione is also needed for the synthesis of leukotrienes from arachidonic acids, and several studies have documented low levels of whole-blood glutathione and low urinary excretion in kwashiorkor and marasmus patients,[40,90,91] suggesting that synthesis of the leukotrienes might be compromised in severe malnutrition. However, it seems that different leukotrienes are affected in different ways because concentrations of the cysteinyl leukotrienes LTE4 and LTC4, which mediate vascular damage and edema, have been found to be increased in the red cells of children with kwashiorkor but not marasmus, whereas LTB4, which stimulates chemotaxis, was much reduced.[38] Cysteine supplementation improved the erythrocyte synthesis rate in children with kwashiorkor.[39]

The changes in sodium and potassium fluxes across cell membranes characteristic of kwashiorkor may also be explained in this model of reduced antioxidants. In an in vitro model, red cells depleted of glutathione showed increased leakiness to sodium and potassium, mimicking the findings seen in kwashiorkor.[40] The active transport of sodium out of the cell was increased but could not compensate for the increased permeability, resulting in the low K, high Na typical of malnutrition.

In summary, some of the pathology of kwashiorkor can be explained by low antioxidants and increased oxidative stress, resulting in changes of free radical damage, increased sodium/K flux across membranes, triglyceride accumulation in the liver, low albumin, changes in n-6 PUFAs, and altered leukotriene production. Until recently, the determinants of this interplay of nutrient deprivation and infectious or environmental stresses, leading to a disturbed balance in the normal physiologic response to these insults, were not understood.

Exciting results from recent studies in Malawi have been a major break through in understanding of the pathogenesis of Kwashiorkor.[15] These

studies have produced evidence that the gut microbiome in conjunction with a diet high in carbohydrates and deficient in other nutrients predisposes to kwashiorkor. The researchers followed 371 twin pairs from birth collecting monthly fecal samples. During the study,[19] same gender twin pairs became discordant for kwashiorkor and gut microbiome of serial fecal samples from 13 of these were examined. The age-related progression in one of the principal coordinates that describes variability in these fecal microbiomes was absent in the kwashiorkor twin compared to the healthy twin suggesting that some aspect of the microbiome might predispose to kwashiorkor.[15]

Fecal samples from healthy and kwashiorkor children were transplanted into gnotobiotic mice fed either regular chow or a staple-based nutrient deficient "Malawi type diet". The mice receiving the Malawi diet and the kwashiorkor transplant showed marked weight loss where as the other mice did not.[15] When these mice were fed "Ready to Feed Therapeutic food" (RUTF), there was marked weight gain, but the microbiome profile remained unchanged. This provided clear evidence that the combination of the deficient diet and the microbiome was responsible for the weight loss. Further work will no doubt clarify many of the mechanisms involved but of interest, given earlier findings of a possible role for methionine and cysteine, the mice harboring the kwashiorkor microbiomes had significantly lower methionine and cysteine concentrations in feces, amino acids that are deficient in the "Malawi-type diet."[15] They also described urinary metabolite changes suggesting a selective inhibition of some of the enzymes of the tricarboxylic acid cycle involved in energy metabolism and the authors suggest that children with this pattern of gut microbiome might have "difficulty with energy metabolism when exposed to a micro-and macronutrient-deficient low-calorie diet" such as the "Malawi-type" diet.[15]

Changes in Organs and Systems in Malnutrition

In addition to the myriad cellular manifestations of SAM, widespread alterations in organ and system function occur, many of which are relevant to clinical management.

Endocrine System

Endocrine changes mediate the metabolic adaptation to starvation and have been mentioned above. Pancreatic atrophy is a common finding in marasmus.[92] Glucose clearance is reduced in both marasmus and

kwashiorkor due to pancreatic α cell dysfunction rather than insulin resistance.[93] These changes have important consequences on the clinical management of severely malnourished child children are potentially at risk of hyperglycemia when fed high carbohydrate diets or if given intravenous infusions of glucose especially as a bolus[93] yet at the same time vulnerable to hypoglycemia if subjected to periods without food.

Studies in malnutrition have generally reported raised concentrations of growth hormone on admission,[31] but these concentrations reduce in those gaining weight on dietary treatment. Cortisol concentrations rise, especially in kwashiorkor, and the circadian rhythm is abolished, but the response to adrenocorticotropic hormone is preserved.[22] Cortisol levels also rise with infection; 80% of children with kwashiorkor showed a rise in cortisol in response to infection compared with only 50% of those with marasmus[22] This reduced response in marasmus may explain why these children are so susceptible to hypoglycemia. High levels of adrenaline are reported early in hospitalization, especially in kwashiorkor.[22] Both the plasma concentration and the secretion rate of aldosterone are high.[32]

Thyroid gland function is altered in malnutrition.[94,95] During nutrition deprivation, at first thyroxine (T4) increases, but as malnutrition becomes more severe, and especially if kwashiorkor develops, total T4 decreases. There is also a decrease in thyroid binding proteins, but this does not account for all of the reduction in T4 and suggests a primary effect on synthesis.[96] Increased thyroid stimulating hormone secretion heralds recovery.[97] There is also a reduction in deiodination of T4 to triiodothyronine (T3), resulting in reduced T3.

Immune System

Children with severe malnutrition are very susceptible to infection, especially with gram-negative organisms, and deaths are often attributable to sepsis. The subject has been extensively reviewed[70,98,99] and is it is well documented that there are profound changes in cell-mediated immunity, the complement system, and function of polymorphonu clear cells and fewer reported effects on humoral immunity.

Cell-Mediated Immunity

Cell-mediated immunity is altered in severe malnutrition.[70] The thymus, necessary for normal differentiation of T cells, is consistently reduced in size,[100] and the production of thymic hormones is reduced.[98,99] Evidence of T-cell functional impairment also comes from the observation of

reduced cutaneous tests to the recalled antigens, for instance, the tuberculin test[101]; however, studies differ in reports of numbers of circulating T cells and the ratio and effect on T-cell subsets. In general, it appears that T4 cells are relatively reduced, and T8 cells are affected to a lesser degree.

Humoral Immunity

Immune globulin production by B cells has been reported to be normal or raised70 and immunoglobulin (Ig)G seroconversion in response to several vaccines is preserved.[102] Increased IgA has been reported but children with severe malnutrition in Brazil were found to have lower secretory IgA in urine, which increased on rehabilitation.[103] The complement system shows consistent abnormalities with decreased C3 level.[104] Some studies report particularly low concentrations of C3 in kwashiorkor. However, Ekanem and colleagues found that C3 levels, although low, rose significantly in the presence of infection.[71] C4 levels seem to be increased or unaffected by nutritional status. The consequence of these various effects is a reduced capacity of the malnourished child to respond to and combat infections, leading to an increased risk of sepsis, one of the main reasons for mortality in malnourished children.

Liver

In the liver, there is a shift away from the production of carrier proteins and a relative increase in the production of acute inflammatory proteins, indices of response to injury or infection. This is particularly marked in kwashiorkor. The liver in kwashiorkor is often enlarged and shows a fatty infiltrate owing to accumulation of triglycerides.[105] These changes improve on clinical recovery, and there is no evidence that kwashiorkor per se results in long-term liver damage or cirrhosis.[106]

Cardiac System

Cardiac output is reduced in children with acute SAM compared with cardiac output on recovery.[23] There is a reduction in left ventricular mass and impaired function.[107] Sinus bradycardia may be present, as well as mild hypotension. Concomitant deficiencies such as hypokalemia, anemia, and vitamin deficiencies may affect the heart. Pericardial effusion may be present in edematous malnutrition. During recovery, the heart size increases rapidly owing to chamber enlargement, and left ventricle musculature increases in proportion to increasing weight.[108] Heart failure

is a risk in these children and fluid management of children with SAM requires care.[107]

Unnecessary intravenous transfusions including blood transfusions are associated with higher mortality. Bachou analyzed deaths of children admitted to a Ugandan teaching hospital and reported mortality rate of 24%, despite following WHO management criteria. Most deaths occurred in the first week (70%) and 29% in the first 48 hours. Mortality was not associated with HIV status or signs of infection. Mortality was increased almost five times (OR 4.8 95% CI 1.5–7.2) in children with hemoglobin >5g/dL and three times (OR 3.2 95% CI 1.6–4.3) if they received an intravenous infusion in the absence of signs of severe dehydration.[10] Deaths were attributed to fluid overload. These findings led to retraining of hospital staff and a comparison of mortality before and after adherence to the WHO guidelines for IV infusions and blood transfusions. They documented a reduction in inappropriate transfusions and IV infusions and significant reduction in the mortality of children who were transfused and/or infused although overall case mortality in this setting was not reduced.[109]

WHO guidelines advise blood transfusions only when hemoglobin is <5 g/dL and intravenous infusion for children with severe acute dehydration. Under these circumstances, intravenous fluids are essential and should not be withheld from children with severe acute dehydration. Brewster recommends delayed capillary refill time as a useful indicator for dehydration and the need for IV fluids.[110]

Respiratory System

The reduction in muscle mass that occurs in severe malnutrition affects respiratory muscle, including the diaphragm; this leads to reduced muscular function, which influences vital capacity and maximal inspiration and inspiratory pressures.[111] This weakness may be exacerbated by electrolyte abnormalities such as low phosphate[112]and hypokalemia. The ventilatory response to hypoxia is blunted, but not the response to hypercapnia.[113] Despite these alterations, tachypnea and sub costal retraction remain useful signs in diagnosing pneumonia in malnutrition.[114]

Gastrointestinal Tract

Diarrhea and malnutrition often occur together and in circumstances where there is a lack of hygiene and constant exposure to bacterial contamination

of food and water. Children and adults living in tropical unhygienic areas tend to have abnormal intestinal mucosal structure and function, tropical enteropathy, which may or may not be asymptomatic.[41,115] Small bowel bacterial overgrowth may also occur and it is estimated that lack of hygiene contributes to overall malnutrition.[3] The interaction among the environment, microflora of the intestine, nutrition, and growth is not limited to the small intestine. Remarkable advances in the ability to study the pattern of gut microflora, the microbiome and its metabolic activity based on fecal samples suggest that there are complex interactions between the environment, host genome, and diet that determine nutritional outcomes from malnutrition to obesity.[15]

Malnutrition increases the risk of more prolonged episodes of diarrhea,[116] and the combination of persistent diarrhea (more than 14 days of diarrhea) and malnutrition carries an especially high mortality.[117] Any concurrent diarrhea is associated with increased mortality in hospitalized children with SAM, 21% of children with diarrhea on admission to hospital in Kenya with SAM died compared with 12% of those with no diarrhea.[118]

Diarrhea and malnutrition so often coexist that it is difficult to determine the extent to which each contributes to pathology. Nevertheless, both animal and human studies suggest that severe malnutrition per se affects the intestinal tract with reduced gastric acid production, thinning of the small intestinal mucosa, and flattening or disappearance of the villi with relative sparing of the crypts.[23,119] There is increased cellularity of the lamina propria, especially in children with kwashiorkor.[119] This enteropathy is reflected in impaired mucosal function, increased permeability as demonstrated by the double sugar technique, and malabsorption as shown by nutrient absorption studies.[120–122] The mucosa seems to be particularly affected in kwashiorkor. In children with SAM in Malawi, kwashiorkor was associated with abnormal intestinal permeability results, and persistent diarrhea was not an independent risk factor for altered permeability.[121] Loss of the villous architecture of the small intestine for any reason reduces disaccharide activity because the disaccharides, especially lactase, are found at the villous tips. Thus, lactose malabsorption is a common finding in SAM.[41]

Fat malabsorption is also seen in both persistent diarrhea[123] and SAM[124] as well as the mucosal changes; bacterial overgrowth in the upper small intestine has been described in SAM and may lead to bile salt deconjugation, further impairing fat absorption[125], but in contrast to

carbohydrate, fractional fat absorption remains constant over a wide range of intake,[126] so more fat in the diet results in more fat absorbed, and in practice, the increased fat loss is of little clinical consequence. This is of considerable practical importance because the high energy density of fat means that more calories can be given in smaller volume, which is essential when feeding SAM children, who are usually anorexic. RUTF, which is a fat-based food, has been successfully used for the treatment of uncomplicated SAM.[127] Certain nutrients including amino acids, zinc and vitamin A are especially important for mucosal health.[128,129] and additional advantage of RUTF is the ability to sustain fortification with different micronutrients including the fat soluble vitamins.

However, while RUTF represents a significant advance in feeding options for uncomplicated SAM, there is still controversy over the use of F75 and F100 liquid diets especially in children with SAM and diarrhea,[41] and further research is needed to design and test fluid diets that maximize nutrients for gut health, avoid carbohydrate intolerance and address the need for adequate phosphate, magnesium, zinc, and other micronutrients in practical and palatable combinations.

Diets including F75 and F100 that are milk based and fluid provide quality protein and essential elements such as phosphate and magnesium as well as the added micronutrients but the presence of lactose may exacerbate diarrhea.[41] Carbohydrates are well absorbed in the small intestine until disaccharidase capacity is overwhelmed, at which point, the unabsorbed sugars cause osmotic diarrhea and the risk of dehydration. Therefore presenting a mixture of different carbohydrates in small frequent feeds in presentations with relatively slow gastric emptying can help allow even lactose to be tolerated.[130] Studies in children with persistent diarrhea, many of whom were malnourished, demonstrated that locally prepared diets with less than 3 g/kg body weight/day as lactose were well tolerated and led to prompt recovery.[131] Nevertheless in some situations, for instance in Southern Africa where HIV is common, milk-containing foods even in small frequent doses is a problem produce clinically lactose intolerance.[41] As lactose intolerance can cause life-threatening severe diarrhea and dehydration, any suggestion of worsening diarrhea with fecal reducing substances should be taken seriously and the diet changed. It is important not to discontinue food but to seek a low osmolar lactose-free alternative.

Hematology: Anemia

Anemia is common in severe malnutrition and may be attributable either to iron deficiency and/or reduced red cell production in adaptation to a smaller lean body mass.[132] Despite the fact that most children will have been consuming a diet deficient in bioavailable iron, in kwashiorkor, there is elevated hepatic iron, and bone marrow iron shows stainable iron in half of children. This is an unusual finding in marasmus.[132] Iron is normally tightly bound to proteins during storage and transport to prevent free iron forming the extremely damaging hydroxyl radical. In kwashiorkor, the reduced plasma levels of transferrin mean that iron-binding capacity is reduced and the concentration of free iron may increase.[133] Low serum transferrin has been associated with an increased risk of mortality in hospitalized children with SAM.[134] It has been suggested that free iron causes or contributes to the etiology of kwashiorkor,[134] although not all children with kwashiorkor have raised indices of free iron. The homeostatic control of intestinal iron absorption is maintained in children with kwashiorkor.[135] Those with high serum ferritin and percent saturation of transferrin were found to absorb less oral iron than those with low serum ferritins.[135] The iron issue is important not only because of its possible role in the etiology of kwashiorkor but also because iron supplements might actually increase mortality in acute SAM. Smith and colleagues, in a small non randomized study in Nigeria, found higher mortality; 10 of 31 children given iron supplements at admission or day 3 died compared with 2 of 12 non supplemented children.[136]

In contrast, additional iron is required during recovery, as the accompanying increase in lean body and red cell mass quickly depletes iron stores and classic iron deficiency features can occur.[137] Iron supplements should be given during this stage.

Little is known about the relative role of other micronutrient deficiencies in contributing to the anemia of malnutrition. In early studies in South Africa and Egypt, there was no evidence of vitamin B12 deficiency, but serum folic acid levels were low.[138,139] In Cairo, low serum folate levels correlated with megaloblastic findings on bone marrow and with improvement in these parameters following treatment with injected folic acid, but in South Africa, serum folate was unrelated to hemoglobin levels, which improved without folic acid supplements. Copper, riboflavin, and vitamin E deficiencies may contribute to the anemia of SAM.

Skin, Hair, and Teeth

In marasmus, the dry wrinkled loose skin is a result of almost total loss of

subcutaneous fat. This leads to a relative increase in surface area, reduced protection from ambient temperature, and therefore increased susceptibility to hypothermia. Hair is thin, grows slowly, and falls out readily, and on microscopy, there is a lack of hair root bulbs and a shift to the resting state of hair growth.[140] In kwashiorkor, skin changes may be florid and show the characteristic signs described earlier, or they may be absent. Some changes are similar to those seen in acrodermatitis enteropathica, and improvement may occur with zinc ointments, suggesting that concomitant zinc deficiency may be implicated.[141] Other nutrient deficiencies, such as EFA deficiency, the B vitamins, and amino acid deficiencies, especially methionine, also cause skin changes and may contribute. Hair is also affected; depigmentation is a classic sign. Hair follicles show fewer and abnormal growing bulbs, showing atrophy and shaft constriction with depletion of pigment.[142] Even a single episode of prolonged malnutrition in the first year of life delays primary dentition and is associated with higher prevalence of primary dentition caries and possibly also permanent dentition caries.[143,144]

Brain Function and Development

Most child malnutrition occurs at a time of rapid development, so any insult at this time may have far-reaching consequences and SAM has been shown to prejudice the long-term development of children.[145] In addition to primary effects on neuronal tissue, there may be secondary effects owing to anemia, micronutrient deficiencies, apathy, and reduced activity. The environment in which most malnourished children live often fails to provide the stimulation and support that the developing child needs to realize his/her potential. The clinically recovered child usually returns to this same environment, thus making it more difficult to determine the impact of malnutrition per se on long-term development. Early studies comparing the outcome of children recovered from severe malnutrition who either returned home or were adopted into families with more resources suggested that environmental influences outweighed the sequelae of the malnutrition.[146] The randomized trials conducted by Grantham-McGregor in Jamaica[147], and in Bangladesh[148] and others in India[149] have contributed greatly to our understanding of the importance of stimulation independent of dietary therapy in mitigating the effect of severe malnutrition on developmental delay. The benefits of such early stimulation last into adulthood.[150] This important subject is further addressed in Chapter 25, “Neuropsychological Development, Nutrition

and Behavior".

Bones

Children with severe malnutrition often remain stunted after recovery. Branca and colleagues used pyridinoline and deoxypyridinoline, cross-linking amino acids of collagen that are excreted in the urine in proportion to skeletal turnover, to study bone turnover in severe malnutrition.[151] They found low rates of bone turnover during the acute phase of malnutrition and much higher levels during recovery. Age, severity of wasting on admission, and crosslink excretion accounted for 44% of the variability in height velocity during recovery.[151–153]. Bone demineralization has also been reported and may be attributable to phosphate deficiency.[154] Bone changes typical of copper deficiency may also be present, as well as scurvy caused by vitamin C deficiency. Vitamin D deficiency which causes rickets and osteomalacia, deserves special mention. Once a common condition, rickets almost disappeared with the widespread consumption of vitamin D fortified milk, but it is now being reported more frequently and subclinical vitamin D deficiency is thought to be common[155] and Vitamin D is known to be essential for B and T cell function, especially phagocytosis.[156,157] Children with rickets are at greater risk of pneumonia[158] and studies have shown an association between asymptomatic low concentrations of serum 25-hydroxy vitamin D3 (25OHD3) and lower respiratory tract infections.[159] Low concentrations of 25OHD3 have also reported to increase risk of tuberculosis especially in those with certain polymorphisms of the Vitamin D receptor.[160] In addition, there is evidence that vitamin D deficiency in childhood is associated with increased risk of chronic diseases such as type 1 diabetes and some cancers in adults.[155] Although little studied, malnourished children may be at increased risk of vitamin D deficiency because of low dietary calcium and vitamin D intakes, including insufficient vitamin D in breastmilk, low dietary fat and perhaps less sun exposure if they are frequently ill and more likely to be indoors.

CLINICAL MANAGEMENT

In 1999, the WHO published "Guidelines for the Management of Severe Malnutrition: A Manual for Physicians and Other Senior Health Workers".[5] These guidelines were a seminal step forward in the management of this important life-threatening condition. The guidelines

were drawn up by international experts and based on the experience of centers of excellence across the world. The guidelines were simplified into ten steps to facilitate teaching and implementation Figure 14-6.[161]

At that time, there was little evidence available and virtually no randomized clinical trials of treatment options so current knowledge of pathophysiology and best practice was the basis for the recommendations. Although the guidelines were slow to be adopted[162] and are still not used in many areas, considerable improvements in mortality have been demonstrated when they have been implemented[163–167] although the results have been less favorable in some areas notable Southern Africa.[109,110] Over the last few years, there have been some clinical trials of aspects of management but for many other steps there has been no evaluation.[162] The guidelines did not contemplate the contribution of HIV-AIDS to the profile of SAM although this has radically increased the prevalence of severe malnutrition in Southern Africa where mortality rates for SAM remain high.[110] In recent years, there have been major advances in our understanding especially in the pathophysiology of kwashiorkor. In the light of these new findings; a review of the available evidence[162]; the now extensive experience of applying the guidelines in different countries[41,110,20]; and new opportunities offered by simpler diagnostic measures and RUTF the guidelines are currently being reviewed. Nevertheless, the basic principles and the value of standardized care remain relevant today and form the basis of the following discussion.

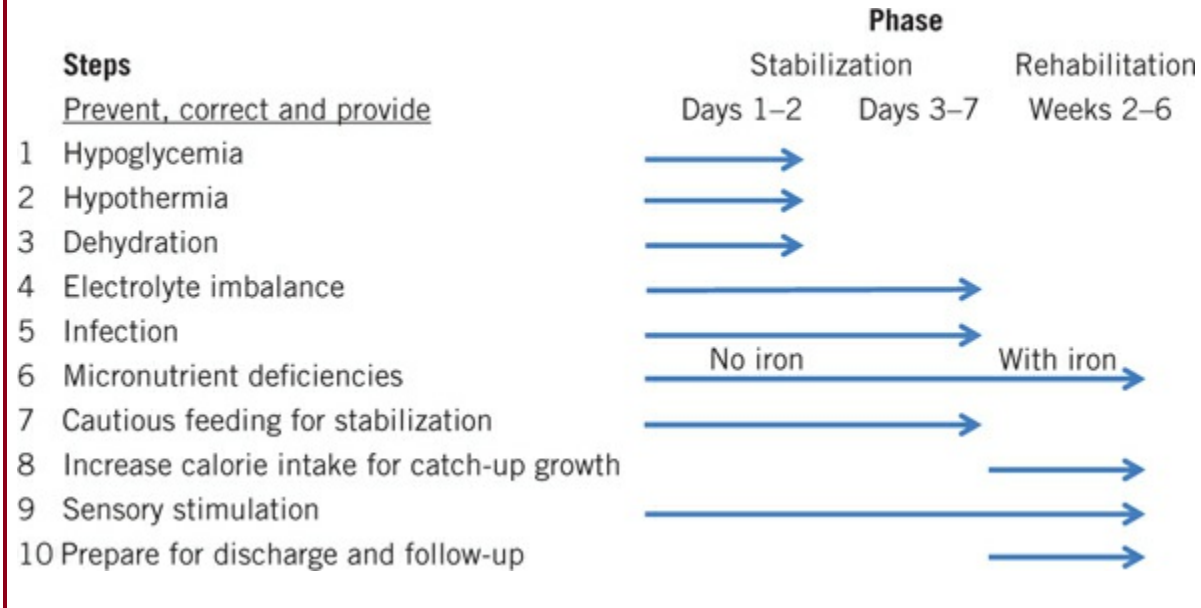

Figure 14-6 Ten steps for the Management of a child with

severe acute malnutrition[161]

CLINICAL ASSESSMENT AND TRIAGE-HOSPITAL VERSUS COMMUNITY REHABILITATION

The diagnosis of SAM has already been discussed and Table 14-1 shows the current recommended criteria.

When malnourished children first present, health personnel are usually faced with a question about whether hospitalization is necessary and advisable. This is often a tricky decision and deserves some discussion. If medical complications associated with increased mortality, for instance, pneumonia, severe diarrhea (more than six stools a day, dehydration), signs of sepsis, hypothermia, severe anemia, fever, electrolyte abnormalities present,[121,168,169] children should be admitted urgently to a hospital or specialized facility. Assessment of appetite is also critical, children with no appetite need admission. Very severe malnutrition and young age are also associated with increased risk of mortality. However, when children are screened either in community household surveys or at presentation in a refugee type setting, as many as 80% of children do not present with life-threatening complications and can be managed at home with domiciliary visits, or in outpatient community-based centers.[6] Table 14-2 lists factors to be taken into consideration when deciding on admission.

Two advances in the management of SAM have made this possible. First, the use of MUAC has simplified the diagnosis. This is easy to use, portable, simple, cheap, and does not require using a chart.[170,6] Recognizing malnutrition in the community, identifying uncomplicated cases, and starting treatment early avoids hospital admission.[6] Second, the availability of RUTF which is nutrient dense, micronutrient fortified, resistant to contamination, and palatable has revolutionized feeding of malnourished children[171–174,012] and has greatly facilitated home or community rehabilitation. Locally made versions of RUTF have also been successful[175] which is good news as the cost of imported RUTF is an issue.

Even when hospitalization is required for the severely ill child with SAM once the acute condition has been treated, and the child is improving, they may be referred to a rehabilitation centers or community care.

Improved appetite is a good sign of recovery. Increasingly, community care following a short stay in hospital is being shown to be feasible especially when ready to use therapeutic food (RUTF) is available. The importance of local support and intensive nutrition education was demonstrated in a study in Bangladesh where community nutrition promoters working within an integrated nutrition project were able to rehabilitate children with moderate malnutrition even without food supplements.[176]

USE OF PROTOCOLS

The child admitted with SAM should be treated according to a locally agreed protocol that takes into account the WHO guidelines. The use of such protocols has been shown to reduce mortality.[6,162,166] The management of malnutrition is a team activity, and all staff who comes into contact with the child or the child‘s caretaker in any way should be trained in the management plan.

An important aspect of these improvements is the organization of services with a view to preventing complications. Early deaths, within the first day, are often attributable to failure to recognize and treat infections adequately, poor management of dehydration and failure to correct electrolyte imbalance especially potassium depletion.[7] Later deaths may be owing to overwhelming infections, but sudden unexpected deaths after a few days may be caused by cardiac failure associated with the refeeding syndrome.[110]

The WHO guidelines were presented as 10 steps Figure 14-6 divided into three phases:

1. The initial or acute phase (2–10 days) when the child is being treated for complications such as dehydration, hypoglycemia, hypothermia, and infections. Dietary therapy starts.
2. The second phase of recovery or rehabilitation (two to six weeks) when the child will increase dietary intake and gain weight.
3. The follow-up phase (6–26 weeks), which may be after discharge.

Phase 1: Examination and Emergency Treatment

A full clinical history should be obtained; symptoms suggestive of infection and diarrhea are particularly relevant. Birth history is important

because low birth weight may explain the infant‘s low weight, and it is essential to review any growth data that may be available. A developmental history and past medical problems may reveal concomitant conditions that cause or contribute to the malnutrition. Most children will have been chronically ill, and information on medication and therapies, including traditional healers, may be relevant. It will be essential to have information on the child‘s diet history, including breast-feeding, family diet, food constraints, and access to food programs, as well as a full social and family history, but this information may be better obtained once the acute phase is completed and is part of building up a relationship with the family. A detailed clinical examination is essential, including length/height and weight and MUAC, but care should be taken not to stress the patient and to protect him/her from cold. Table 14-3 shows some signs and symptoms of particular importance and their management.

Hypoglycemia

As has been mentioned severely malnourished children are susceptible to hypoglycemia. Hypoglycemia is defined as a blood glucose less than 3 mmol/L. If hypoglycemia is diagnosed it may be treated with oral glucose or sucrose, WHO guidelines recommend 50 mL 10% glucose or sucrose orally[5], but this has been criticized because of the possibility of inducing hypoglycemic rebound and intracellular flux that exacerbates hypophosphatemia, hypokalemia, and hypomagnesemia early components of the refeeding syndrome.[110] If children can take orally, they should be started on small frequent feeds from admission rather than oral glucose. On the other hand, children in coma should be assumed to have hypoglycemia and given an infusion of 10% glucose (5 mL/kg) followed by oral glucose or diet. Children with hypoglycemia should be assumed to have infections and be treated with parenteral antibiotics.

TABLE 14-2 Factors to Consider When Admitting Children With SAM

Child Factors	
Severity of the malnutrition	The more severe the malnutrition, the greater the need for specialized refeeding, monitoring, and intervention to treat complications such as infection, electrolyte abnormalities, hypothermia, and hypoglycemia
Edema	Children with edematous malnutrition may not appear to be ill and do not induce the same shock horror response as a child with marasmus. Their edematous weight masks the severity of

	their condition.
Presence of infection	Malnourished children should be regarded as immunodeficient so that infections are more likely to need parenteral antibiotic treatment and close monitoring, which is difficult to do at home. Persistent diarrhea may present special problems and usually quickly improves with a clean diet and appropriate therapy in hospital.
Presence of other conditions	Malnutrition is not always a consequence of primary energy and protein deprivation. The presence of other conditions such as congenital heart disease, cystic fibrosis, and tuberculosis may determine where these children will be best managed. Therapeutic malnutrition units may not be best able to cope with these pediatric emergencies.
Family Circumstances	
Social circumstances	The ability of caregivers to follow treatment schedules at home, who looks after the child, conflicting work and other family constraints on outpatient attendance, nearness to health facilities, availability of backup services and nutritional support in the community are all factors to be taken into consideration.
Previous treatment	Previous attempts at treatment should be taken into account. A child who is worsening despite being in an outpatient or community care program should not have to wait to reach a specific degree of severity to be admitted once the alternatives have failed.
Home social circumstances	These include the nearness to health facilities able to deal with emergencies or monitor the child and the presence of community support with or without food supplements. Children treated in well-organized programs may avoid hospitalization, although there needs to be provision for those who deteriorate, and this may occur suddenly and catastrophically.
Economic considerations	Inevitably, economic considerations will influence decisions and sadly often are the deciding factor, although not in the interest of the child. However, it is very important that health professionals do not add to financial burden with unnecessary tests that do not change management or expensive versions of medicines or medicines of no proven efficacy that compete in the household budget for the food that the child needs or dissuade parents from seeking help for their children.
Hospital Facilities	
Infection risk	Children with severe malnutrition are vulnerable. If admission to hospital means being on a general ward with children with measles and diarrhea, then they may be safer at home, despite the severity of their condition. Obviously, the best option is to provide isolation facilities and hand washing, but

	this may not always be the case in practice.
Feeding arrangements	Children with malnutrition require frequent feeding. Emergency departments may not have provisions for feeding; even on the ward, provision of food may depend on parents, and this may present an additional complication for caretakers if their time is split between home and hospital. Families may have to buy or prepare the food for their child.

The main thing is to prevent hypoglycemia. Travel to the hospital and waits to be seen in the emergency or outpatient department can place the child at risk, and this may be exacerbated by hospital policies such as “nil by mouth” until the child is reviewed and reluctance to start any “treatment” until experts are consulted or test results are available. Mothers should be encouraged to breastfeed their babies while waiting, and a triage system that quickly identifies children with severe malnutrition and directs them into a protocol providing immediate feeding will reduce the risk of hypoglycemia and the attendant mortality. Frequent feeds every two to four hours are needed at first. Night time, when staffing levels are reduced, often provides a challenge, and health facilities should have a plan to cope with this. This might involve having prepared diets or ingredients always available in the emergency department or on the ward and using nasogastric tube feeds if staff or family is not available for the time-consuming process of encouraging the malnourished child to eat frequent feeds. Monitoring is very important. If the mother is accompanying the child, she should have access to refreshments; otherwise, she may be tempted to share the child‘s ration.

TABLE 14-3 Identification and Management of Complications of SAM

Sign or Symptom	Findings	Management
Edema	Usually symmetric and positional; pretibial edema may be evident only on pressing on the shin with a finger and looking for the indentation. The presence of edema also means that gross weight underestimates the child‘s degree of malnutrition.	Edema indicates kwashiorkor and is an indication of severity. Dietary guidelines for kwashiorkor should be applied.
Odd faces, palmar creases, heart murmurs,	Chromosomal and congenital disorders may contribute to malnutrition.	These children should receive the same treatment for their malnutrition, but concomitant conditions will affect outcome

cyanosis, signs of congenital abnormalities		and long-term management.
Developmental assessment	An adequate developmental assessment is not possible in a sick or malnourished child, but signs such as increased tone and contractures may point to cerebral palsy and degenerative neurologic disorders may be discernable.	
Infection	Malnourished children may not mount a full-blown inflammatory response to infection, so signs may be attenuated and diagnostic tests misleading. The febrile response is reduced.	WHO recommends starting all children with severe malnutrition on a broad-spectrum antibiotic such as cotrimoxazole (sulfamethoxazole 25 mg plus trimethoprim 5 mg) even in the absence of signs of infection.
Sepsis	Difficult to distinguish from dehydration. Recent apathy, reduced level of consciousness, jaundice, abdominal distention (babies), fever or hypothermia, hypoglycemia, petechiae, and poor peripheral perfusion are all indicators of possible sepsis.	If there is any doubt, the child should be treated as septic and intravenous antibiotics used. These should be broad-spectrum and cover gram-negative bacteria. Combinations of aminoglycosides such as gentamicin (7.5 mg/kg IM daily) with ampicillin (50 mg/kg 6 hourly) or amoxicillin or third-generation cephalosporins such as ceftriaxone are recommended but should be tailored to local resistance patterns.
Focal infections	Pneumonia is common, but cough may be absent. Tachypnea and subcostal recession are preserved. In otitis media, the tympanum may not appear red, and infections may present with perforation and otic discharge. Urine should be examined for urinary tract infections, but false positives owing to dehydration mean that it is better to obtain nonurgent samples after rehydration. The skin should be carefully examined all over.	Infections should be treated as in well-nourished children, using appropriate antibiotics preferably based on local sensitivity patterns. Because of the depressed immunity, disturbed gut function, which might reduce absorption of oral preparations,[162,163] and limited muscle bulk for frequent intramuscular injection, intravenous antibiotics should be used for all serious infections.

HIV/AIDS	In many parts of the world, a large proportion of children presenting with severe malnutrition will have HIV/AIDS	The same management principles apply and the malnutrition should be treated actively. Improving the malnutrition will improve the child‘s quality of life.
Tuberculosis	Clinical manifestations may be absent. Radiographic changes may be seen only when the child starts to recover from malnutrition. Tuberculin skin tests are usually negative. A positive family history should be sought.	Tuberculosis therapy should be started once tracheal aspirate or gastric cultures have been collected. A trial of therapy is sometimes needed in children in whom there is a suspicion of tuberculosis.
Diarrhea and dehydration	Diarrhea is common, and signs of dehydration should be sought (see Table 14-4)	Diarrhea is not a contraindication to starting diet. Dehydration should be managed as indicated below.
Electrolyte disorders	All malnourished children should be considered to have sodium retention and potassium depletion. Measurement of serum electrolytes is useful to guide management, but low serum sodium is not necessarily an indication for administering sodium. Children with kwashiorkor may urinate infrequently and in small volume; neither this nor normal serum potassium should deter the administration of potassium supplements. Hypotonia may be a manifestation of hypokalemia.	Severely malnourished children are best managed with relatively low sodium ORSs. The old standard WHO ORS (90 mmol sodium) is not recommended. A solution with 60 mmol sodium was found to be superior and to speed recovery. [164] WHO recommends ReSoMal (see Table 14-5), but if not available, the new standard 75 mmol ORS could be used. Potassium at 40 mmol/L is recommended. Treatment schedules are given below.
Hypoglycemia	Blood sugar < 54 mg/dL or 3 mmol/L. Floppiness, unresponsiveness, hypothermia, convulsions, and coma are signs of hypoglycemia. If the child is convulsing, hypoglycemia should be assumed and treatment started empirically even before procedures such as lumbar puncture to exclude meningitis.	If the child is conscious, oral glucose (50 mL of 10% solution) may be given, by nasogastric tube if necessary. Follow with milk or diet as soon as possible. If in coma, an intravenous infusion of 10% glucose (5 mL/kg) should be given and followed by oral glucose or diet. Children with hypoglycemia should be considered septic and treated with antibiotics.
Hypothermia	Rectal temperature is more accurate, and, ideally, a low reading thermometer should be	The child should be warmed gradually either by wrapping in blankets, warming the room, or

	available. Rectal temperature < 35.5°C is diagnostic. Axillary temperature < 35°C is suggestive.	using the skin to skin kangaroo technique. If the child is hypothermic, assume sepsis.
Anemia	Malnourished children are often anemic, but in nonmalarial areas, severe anemia, <8 g/dL, should not be assumed to be due to nutritional deficiency, and other reasons should be sought.	Intestinal parasites, especially hookworm, may be present and should be treated. Anemia is usually chronic and only needs immediate treatment if there are signs of cardiac failure or hemoglobin <5 g/dL. In this case, transfusion should be given with great care as discussed with intravenous therapy.

Hypothermia

Children with SAM, especially those with marasmus, have less insulating fat and a relatively large surface area, so that body temperature tends to reflect ambient temperature, and they are very vulnerable to hypothermia.[168,177] Hypothermia (core temperature <35.5°C) can only be detected with a low reading rectal thermometer, something that is often not available. Hypothermia should be treated with gentle warming for instance by wrapping in a warm environment. Skin–to-skin contact with the mother may be recommended if it is possible. Children with hypothermia should be assumed to have sepsis and treated accordingly.

Prevention is most important and requires planning to avoid having the child unclothed for long periods, for instance, while having radiographs or during medical examination, and providing an ambient temperature that is warm, 25°C-30°C, without draughts. Washing or bathing should be kept to a minimum, and the child should be dried and wrapped immediately. At night, temperatures often fall, so additional precautions may be necessary.

Management of Diarrhea, Dehydration, and Electrolyte Imbalance

The principles of management, rehydration, and continued feeding are not different in the malnourished child (see Chapter 59, “Diarrheal Diseases” for details). Signs of dehydration and their management are shown in Table 14-4. Particular attention has to be paid to the volume of fluid given and electrolyte management. Children with SAM are usually low in potassium and when given high carbohydrate foods hypokalemia can be exacerbated. Additional potassium (final concentration 40 mmol/L) should be added to rehydration fluids and to the diet.

Most children with dehydration can be managed with oral rehydration therapy. In moderate dehydration, 70–100 mL/kg of ORS should be given over 8–12 hours, starting frequently (5 mL/kg every 30 minutes). Picot et al. reviewed the available randomized trials of different ORSs. In one trial comparing standard WHO rehydration solution (3.5% NaCl, sodium 111 mmol/L, glucose 90mmol/L, osmolarity 311 mosmol/L), versus lower osmolarity ORS (H-ORS: 2.6% NaCl, sodium 75 mmol/L, glucose 75 mmol/L, osmolarity 245 mosmol/L), children receiving H-ORS had fewer diarrheal stool and more rapid recovery.[162,178] ReSoMal, a solution containing additional minerals, low sodium, and higher concentration of potassium was recommended in the original WHO guidelines. Only one trial has evaluated ReSoMal compared with standard WHO formula ORS and although ReSoMal resulted in less hypokalemia, it was associated with severe hyponatremia in some children with high purging rates.[162] There is no advantage of ReSoMal over standard low-osmolar ORS with added potassium. Rice-ORS was more effective than Glucose-ORS in cholera with less diarrhea, shorter duration and better weight gain.[162,179]

TABLE 14-4 Signs of Dehydration and Interpretation in SAM

Sign	Mild or Absent		Moderate	Severe (with shock)
	Plan A	Plan B	Plan C	Comment
Conscious level	Normal/alert	Agitated/irritable	Lethargic/comatose	Agitation is typical. Infection and hypoglycemia also give lethargy.
Eyes	Normal	Sunken	Very sunken	Ask mother about eyes
Tears	Present	Absent	Absent	Tears often absent
Buccal mucosa	Moist	Dry	Very dry	Mouth breathing may cause dryness
Skin pinch	Returns quickly	Returns slowly <2 s	Returns very slowly >2 s	More difficult in SAM
Thirst	Drinks normally	Drinks avidly	Unable to drink	If avid, useful

While children continue to have diarrhea, their clinical state should be monitored at least hourly. If vomiting occurs, then rehydration can be

temporarily held for 15–30 minutes and then resumed administering small amounts frequently. If the child refuses to drink or becomes very tired by the effort of drinking, a nasogastrictube should be used. If the child drinks avidly, then only small amounts should be offered by spoon, never by bottle, as taking a large amount at a time may provoke vomiting. One option if vomiting continues is to use continuous rehydration with a nasogastric tube but care should be taken to avoid unintentionally large volumes being administered. If the child does not show signs of recovery (improved general condition, passing urine), consider sepsis. If diarrhea is ongoing, estimate diarrhea losses and increase the rehydration fluid volume accordingly. A diarrheal stool in a child less than 2 years can be estimated as 50–100 mL and 100–200 mL in an older child or in very severe diarrhea. As soon as the child shows signs of clinically recovery and dehydration has improved, the child can be started on frequent small amounts of diet, even though the programmed amount of ORS has not yet been completed or diarrhea continues. Both ORS and diet should be provided in alternate fashion.

Intravenous Therapy

WHO guidelines advise intravenous infusion for children with severe acute dehydration with shock. In these cases, intravenous fluids are essential and lifesaving. Brewster[110] recommends delayed capillary refill time as a useful indicator for dehydration and the need for IV fluids.

In these circumstances, Ringer‘s lactate (RL) has been shown to be as effective as low osmolar fluids.[162] Potassium chloride should be added to provide 20 mmol/L. Concerned about fluid overload, the WHO guidelines recommended slow infusion rates at a maximum of 30 mL/kg/h; however, this may not be adequate to correct shock.[110] A study from Kenya[180] compared half-strength Darrows solution (HSD) at a maximum of 30 mL/kg/h with RL at 40 mL/kg both over two hours. Oliguria was more effectively treated by the RL but neither regime adequately treated shock, which was still present eight hours after starting the infusions in 68% of the HSD and 52% of the RL. Case fatality was unacceptably high at 58% (HSD) and 42% for RL and the trial had to be stopped. Thus, severely dehydrated children in shock, independent of their degree of malnutrition, need more aggressive initial rehydration (60–100 mL/kg rapidly), but in light of the danger of fluid overload frequent and careful hourly monitoring of hydration status, pulse, and respiratory rate for signs of heart failure is mandatory and infusions should be reduced as soon as there are signs of improved hydration[162]. Diuretics such as furosemide 1 mg/kg may

be given if there are signs of heart failure. If the child was dehydrated, improvement should be obvious; if not, septic shock is likely, and parenteral antibiotics should be started, if not already given.

While intravenous infusions should not be withheld when necessary, inappropriate use for instance because it is a “routine in all sick children” or “in case it is needed” intravenous infusions and IV lines should be avoided as they are themselves associated with increased mortality.[109] If antibiotics are to be given intravenously, a heparinized cannula, rather than a continuous infusion, is safer to avoid excess IV fluid. It may be difficult to establish venous access in malnourished children, especially those with edema, but prolonged attempts and “cut-downs” performed without anesthesia and with little attention to sterility place the malnourished child at risk of hypoglycemia, hypothermia, sepsis, and stress, which increase mortality.

Infection

Infections are common in malnourished children but because of a reduced acute-phase response clinical manifestations may be muted. The WHO guidelines advised treating all children with oral antibiotics on admission but at the time no trials had supported this empirical approach. Reluctance to follow this advice and delay in starting antibiotics resulting in deaths due to sepsis was identified as the main avoidable causes of mortality in South African hospitals when WHO guidelines were first being implemented.[164] Recently a randomized controlled trial in children in Malawi with uncomplicated SAM treated at home showed that a one week course of either amoxicillin or a cephalosporin, cefdinir significantly reduced mortality.[181]

Tuberculosis (TB)

Tuberculosis is often common in the same populations that have high rates of SAM. TB can be difficult to diagnose in these children. Clinical signs, Mantoux tests, and X-ray changes may be absent because of attenuated inflammatory responses. In one study in South Africa TB was diagnosed clinically in 24% of children but could only be confirmed in 4%.[162,182] Newer rapid diagnostic techniques are needed.

Human Immunodeficiency Virus

Human immunodeficiency virus (HIV) infection is often associated with severe malnutrition in adults and in some areas, especially in sub-Saharan Africa children with SAM are often HIV positive. For instance, HIV was

detected in 51% of children with SAM in one hospital in Saharan Africa[182] and a review of 4891 children with SAM in sub-Saharan Africa found that 29.2% were infected with HIV and these children had a higher mortality.[183] Malnourished children should be treated with highly active antiretroviral therapy (HAART) but otherwise the management of their malnutrition should be unchanged. Bachou reported that treatment outcomes were no worse in HIV infected children in Uganda[109] although experts agree that more studies are needed on the management of SAM in the context of HIV.[184]

Parasites and Gut Flora

Parasites may also be common and should be treated if identified in the stools. If *Giardia lamblia* is present, metronidazole is recommended. A lower than usual dose, 12.9 mg/kg/d, has been suggested on the basis of pharmacokinetic studies.[185] As mentioned previously, bacterial contamination of the small intestine has been described in children with SAM. Children admitted to the hospital from highly contaminated home environments were found to have bacterial contamination of duodenal fluid regardless of nutritional or diarrheal status.[186] The bacterial flora reduced within days of eating a clean diet and without antibiotic therapy.

Recent studies using modern genomic techniques that can differentiate distinct patterns of the bacterial flora (the gut microbiome) have now demonstrated the importance of this flora in the susceptibility to kwashiorkor.[15]

Dietary Management

Timely initiation of oral feeding is essential and one of the most important messages of the WHO guidelines. This requires planning to have food available, negotiation to avoid the routine “nil by mouth” and consideration of feeding at the same level of importance as treatment of infections, hypothermia, anemia and other more obvious clinical problems. Early initiation of oral feeding was one of the major management changes associated with the introduction of a specific protocol for SAM in Bangladesh that halved mortality. Specifically, deaths from hypoglycemia were reduced.[7]

Dietary therapy is best accomplished when a protocol is in place and specific dietary therapy should be prescribed when the child is first seen. The exact diet to be used will depend on local circumstances. In some cases, it may be the easiest to have infant formula available when the diet

kitchen or daytime nursing is not available, even though it is too expensive to continue. When families are expected to provide food for patients, a special diet will need to be prescribed and made available until family food can take over. This might be the WHO-recommended F75 and F100 (Table 14-5), which have been designed and tested in malnutrition treatment centers.[5,20] The F75 is designed for the initial phase and F100 for the rehabilitation phase, but many centers use F100 from the start, especially in marasmic children. Alternative local diets have been used successfully; an example used at the Instituto de Investigacion Nutricional, Lima, is given in Table 14-6. This diet is palatable and despite containing lactose was well tolerated in most children but requires addition of a vitamins and a mineral mix Table 14-7, but this can be difficult to obtain. Whatever diet is chosen, this should have an energy density of 75–100 kcal/100 mL, the osmolarity should be lower than 350–400 mOsmol/L,[169] and 6%–12% of the calories should come from protein, [187,188] and at least some of this from an animal source (milk, chicken meat, or egg).[41,20] Techniques such as fermentation and the combining complementary vegetable proteins can improve the protein quality and may add valuable vitamins.[189] However, although diets based on vegetable protein have been used successfully, nitrogen retention is usually less than that seen with milk diets.[190,191] When milk is used, it is important to give small frequent feeds and be alert to possible lactose intolerance. At least 50% or more of calories can come from fat; higher fat results in higher overall energy absorption.[126] Diets should be liquid if nasogastric tube feeding is to be used; they should not thicken on standing, a problem of higher proportions of carbohydrate, and they should be palatable. Amylase rich flour has been used successfully to reduce viscosity and increase dietary intakes and acceptance in malnourished children Bangladesh,[192] Malt is an alternative. Sodium should not exceed 2 mmol/kg/d, and potassium should be added to give 5–7 mmol/kg/d. Additional vitamins and minerals should be added as mentioned below.

Ready to feed therapeutic foods (RUTF) high-fat solid rehabilitation diets resistant to bacterial contamination and with excellent preservation of micronutrients[193,194,12] have changed the dietary management of malnourished children once they have overcome acute complications. The composition of RUTF is shown in Table 14-8. Children should receive 80–100 kcal/kg/d; <80 kcal/kg is insufficient to maintain metabolic needs, and >100 kcal/kg may put the child at risk of the refeeding syndrome if high carbohydrate diets are used. Feeds should be given every two to four hours

at first. The amount actually consumed should be monitored by direct observation. Continuing or developing diarrhea does not necessarily mean that the diet should be changed. Only if diarrhea becomes worse, for instance more than six voluminous liquid stools per day, or dehydration occurs, it is necessary to change to a low-lactose or lactose-free diet with the same calorie content. Oral rehydration fluid should be given between meals to compensate for stool losses. An algorithm illustrating the dietary management in the acute phase is shown in Figure 14-7.

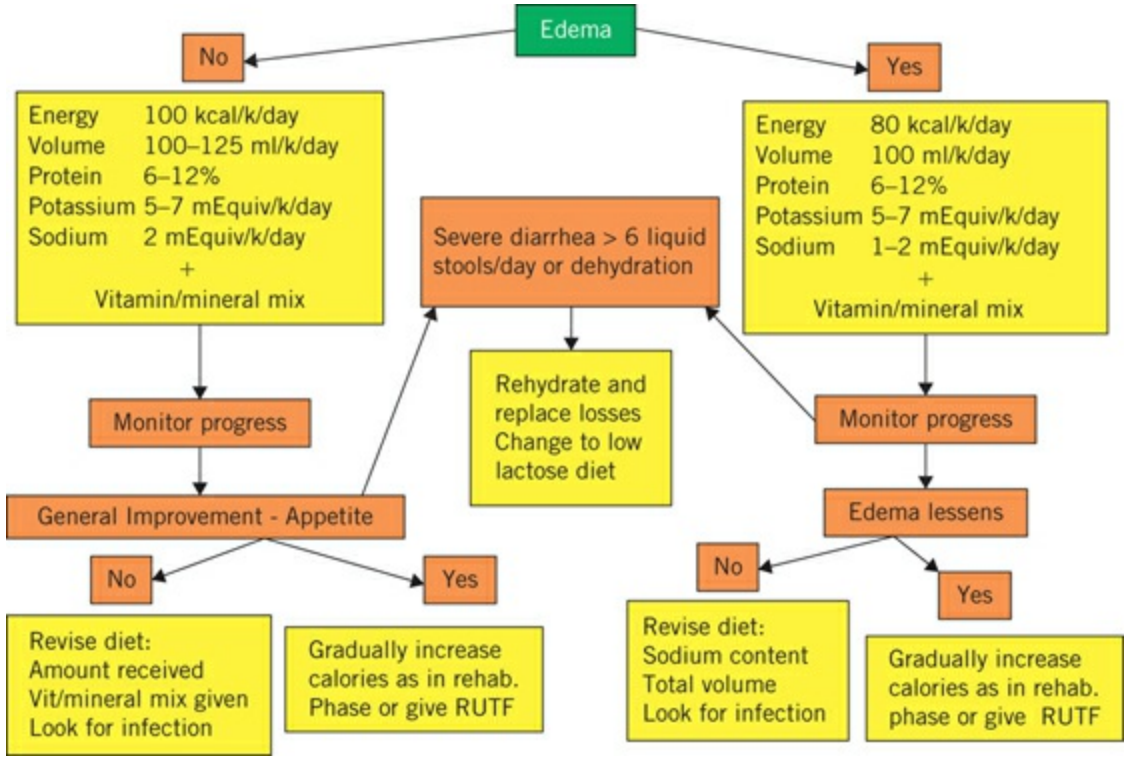

Figure 14-7 Dietary management

Breast-Fed Children

The mothers of breast-fed children should be encouraged to nurse as breastmilk continues to provide important nutritional support even through the second year of life.[57] Breastfeeding should be encouraged in the hospital whenever the child is strong enough to suck; if possible, breastmilk may be extracted to add to the diet, and this may help the mother feel involved and important.

Younger exclusively breast-fed babies may occasionally present with SAM. This may be a result of intrauterine growth retardation but in some cases, especially within the first month, poor weight gain is likely due to poor breastfeeding technique and correcting this may be enough to reverse the situation. These babies must be followed closely and if they do not start putting on weight additional food should be given. For babies under 4 months of age, a modified cow‘s milk formula is the recommended food; for infants older than 4 months, a cereal milk diet can be given. Relactation may be tried to increase breast milk supply once the baby is improving, to try and prevent the mother losing her milk supply and the baby losing the many advantages of breastmilk. The youngest babies present a problem when infant formulas are beyond the resources of parents or the hospital, but priority should be given to obtaining milk

formula for babies under 4 months. Complementing with another woman‘s breast milk is recommendedonly if a safe, sterile supply is available.

Mineral and Vitamin Supplements

Micronutrient deficiencies are common in malnutrition.[20] Prepared diets such as F75, F100, and RUTF are already fortified but for any locally prepared diet additional vitamins and minerals should be added to provide one to two times the daily requirement, sufficient zinc, potassium, magnesium, phosphorus, and thiamine are especially important.[20] Nicotinic acid supplements have been shown to improve weight gain.[195] A local vitamin supplement can be used, but it is often harder to find a mineral source, and WHO provides a recipe for a mineral mix that can be made in a local pharmacy or biochemistry department.[5]

Potassium should be added to the diet to ensure a total of at least 5 mmol/kg/d or more. Higher doses of potassium have been shown to be effective.[47]

Zinc supplementation of malnourished children has been shown to improve weight gain and improve immunologic outcomes, and 1 mL/kg/d of a 1.5% zinc acetate solution daily is recommended although a recent review[162] found the evidence of benefit in SAM inconclusive.[20,196,197] Zinc supplements generally appear to be less effective in children under 1 year[198] and care should be taken not to provide too much zinc as mortality was increased in Bangladeshi children receiving 6 mg/kg/d.[199] Zinc supplements (40 mg/d) given with oral rehydration therapy reduced duration of diarrhea.[200]

Copper deficiency has been reported in malnourished children[201] and copper sulfate should be added to the diet if not included in the mineral mix.

Magnesium is needed for potassium to enter cells, and magnesium supplements should be added to the diet. If not given in the diet or ORS on the first day, an alternative is to give magnesium sulfate 50% solution, 0.3 mL/kg intramuscularly (maximum 2 mL) once, and then include it in the diet. Hypophosphatemia is associated with increased risk of dying and the refeeding syndrome and should be included in the diet. Milk provides an excellent source.

Iron supplements are not recommended during the acute phase because of the risk of producing iron free radicals, as described earlier in the chapter. However, iron supplements are essential once growth and rehabilitation start and muscle and blood are being synthesized. Ferrous

sulfate or fumarate syrup may be given 4 mg elemental iron/kg body weight.[5] As mentioned earlier, electrolyte disturbance is part of the pathophysiology of malnutrition. A triad of interrelated electrolyte deficiencies, potassium, magnesium, and phosphate, occurs. Deficiency of these elements may become especially critical once treatment is instigated and recovery starts.

Regardless of signs of vitamin A deficiency, this should be assumed and retinol palmitate given orally on admission, 50,000 IU for children <6 months age, 100,000 IU for children age 6–12 months, and 200,000 IU for older children. A repeat dose should be given the next day and a third dose after two weeks or on discharge, whichever is sooner.[202] The WHO guidelines recommend a single oral dose of 5 mg folic acid on admission is recommended followed by 1 mg daily.[5] Other vitamins and minerals are best given with the diet or as a daily supplement during recovery.

Children with rickets should be treated with a single intramuscular dose of 600,000 IU of vitamin D as ergocalciferol or cholecalciferol repeated at 12 weeks plus calcium supplements providing 1g calcium as calcium carbonate or lactate daily for 12 weeks. The combination of vitamin D and calcium is more effective than vitamin D alone.[203] Malnourished children, especially those who are predominately breastfed are at risk of vitamin D deficiency. Even children in sunny climates may not get enough exposure to sunlight because of cultural considerations or of the adverse effects of the sun and diets are often low in calcium. Dairy foods to provide calcium should be included in the diet, and vitamin D supplements (400 IU daily) as cholecalciferol or ergocalciferol should be provided, cod liver oil may be a practical alternative.[204]

Anemia

Children with SAM are frequently anemic but this is not usually severe. Blood transfusions should be administered only when the hemoglobin is <5 g/dL as children with less severe anemia have a higher mortality when transfused.[10]

Refeeding Syndrome

The refeeding syndrome is a potentially lethal complication of an increase in calorie intake following starvation. Sudden onset of lethal cardiac failure occurring during refeeding was first reported in the classic studies of experimental starvation in adults in Minnesota and later in starved Japanese prisoners of war, the survivors of concentration camps, and

following the wartime famine in the Netherlands, when, following starvation, there was sudden access to unlimited food.[205–207] This syndrome also occurs in severely malnourished children and may be responsible for considerable mortality, although the precise incidence is difficult to know as, clinically, the syndrome may be difficult to distinguish from pneumonia and sepsis deaths. Sudden death shortly after refeeding has started in a child who seemed to be doing well is suspicious. The syndrome also occurs with parenteral and enteral feeding.

When glucose becomes available during refeeding, especially with carbohydrates, gluconeogenesis is inhibited, and there is a rise in plasma glucose and insulin excretion. Rebound hyperglycemia may occur with polyuria and dehydration. There is a flux of glucose, potassium, magnesium, and phosphate into cells, which may result in rapid lowering of serum levels. The sudden reduction of serum levels of these three electrolytes is thought to explain most of the consequences of the refeeding syndrome.[110,207] Phosphate depletion results in anorexia, adverse neuromuscular effects (e.g., diaphragmatic weakness and respiratory insufficiency), and a reduction in myocardial contractility.[208] The effects of depletion of potassium and magnesium deficiency are similar. Cell membrane electrolyte fluxes are perturbed, and there is an intracellular accumulation of calcium, sodium chloride, and water, which may result in edema and is probably one of the mechanisms that explain recurring edema when children with kwashiorkor are refed too rapidly. Thiamin deficiency may also be important and has been reported in refeeding alcoholics and following starvation treatment of obesity.[207] Its role in the refeeding of malnourished infants is not known. Thiamin is an essential cofactor for various enzymes, and carbohydrate refeeding causes increased thiamin utilization.

The key to prevention of the refeeding syndrome is the avoidance of rapid refeeding, especially with high-carbohydrate diets, whether intravenous or enteral, replenishment with potassium, magnesium, and phosphate, and restricted sodium intake. The safest way to correct phosphate deficiency is with milk diets because oral phosphate salts are laxatives and may well exacerbate diarrhea. Milk is also useful as a good source of magnesium, as well as protein and energy, but lactase intolerance can be a problem. Mixing the milk with a cereal such as rice or sugar reduces the sodium, protein and lactose load, slows gastric emptying and has been used successfully. If intravenous treatment is unavoidable and oral feeding is delayed, phosphate can be given intravenously with care and should be included in parenteral feeding regimens. If children are

dehydrated, magnesium and potassium can be added to oral rehydration therapy as in the ReSoMal recommended by WHO. Vitamins, including thiamin, should be added to the diet from the start. For more details of the management of the refeeding syndrome the reader is referred to several reviews.[207,41]

Skin and Eye Care

The skin lesions of kwashiorkor improve with dietary therapy but, in the initial phase, may become infected and are a potential source of pathogens causing sepsis. Care should be taken to avoid pressure on affected areas and the skin should be kept clean and dry; 1% potassium permanganate solution may be applied to the worst areas. If possible, the perineum and buttocks should be left uncovered and carefully cleaned and dried immediately after defecation. Special care should be taken of the eyes of children with signs of vitamin A deficiency (xerophthalmia). Vitamin A supplements should be started immediately and the eyes should be protected with pads soaked in saline. Atropine and antibiotic eye drops should be applied at least four times daily until there is no sign of inflammation.[209]

Phase 2: Rehabilitation

The initial phase of management lasts while metabolic and electrolyte abnormalities are corrected and infections treated. This phase may last from one to seven days, sometimes longer, if infection is difficult to treat and edema slow to resolve. The recognition of recovery is subjective but usually obvious to staff. There is a general improvement in the child‘s condition. The return of appetite, reduction in apathy, and return of smiling are encouraging signs indicating improvement. Weight gain may not occur at this stage, and in kwashiorkor, there is usually a brisk weight loss as edema disappears. If the child does not seem to be recovering and edema continues without obvious cause, suspect occult infection, for instance, tuberculosis, inadequate potassium repletion, orphosphate deficiency.

Diet

During the rehabilitation phase, the dietary calorie intake should be increased, Figure 14-8. This should be gradual, for instance, an additional 25 kcal/kg/d every other day, to avoid the refeeding syndrome and should be guided by the child‘s appetite and general condition. Diets are calculated based on body weight, so correction will need to be made for

the child‘s changing weight. Most children will reach intakes of between 150 and 250 kcal/kg/d, and rapid weight gain at this stage is desirable as it is associated with the same body composition as lower weight gains.[210] If F75 was used, then F100 should be substituted at this stage if appetite returns, and the child is eating they can be started on RUTF, if available. Whenever possible they can be transferred to rehabilitation care in the community so long as adequate monitoring and support in the community is available. RUTF has facilitated this transition.[110] However, too early discharge in the absence of follow-up rehabilitation leads to very high post discharge mortality.[211]

During this phase, iron supplements should be started at 3–4 mg elemental iron/kg/d and other micronutrient supplements should be continued.

Whatever diet the child eats during this phase as they improve, attention needs to be given to preparing for the home diet. The child may continue to be given RUTF but must ultimately return to eating the family diet. Wherever possible, mothers should be taught about diets based on nutrient-dense local weaning foods and if possible should prepare and feed these preparations in the hospital or community rehabilitation unit. For long-term successful recovery and to prevent relapse, the health personnel needs to work closely with the family during this phase.

An algorithm for the dietary management of the child during this phase is shown in Figure 14-7.

Discharge criteria have been reviewed[6] and increase of 15% weight gain based on % change from admission weight is advised for marasmus and a two weeks after clearance of oedema for children with kwashiorkor.[6] However, recent studies suggest that MUAC is better as this avoids the paradoxical longer stays for children with higher weight on admission which means that when measured as a percentage they have to gain weight in absolute terms.[212]

Physical and Emotional Stimulation

Early physical and emotional stimulation are very important. Even during the initial phase, mothers can be encouraged to talk to and hold their children. They can be taught to massage their children, which has been shown to increase growth recovery. Children should be provided with a visually interesting environment. As soon as possible, play therapy should be instigated. The WHO manual provides examples of easy-to-make toys.[5] Studies in Jamaica and India showed that an early stimulation program

improved growth, complementing micronutrient supplements.[147,149]

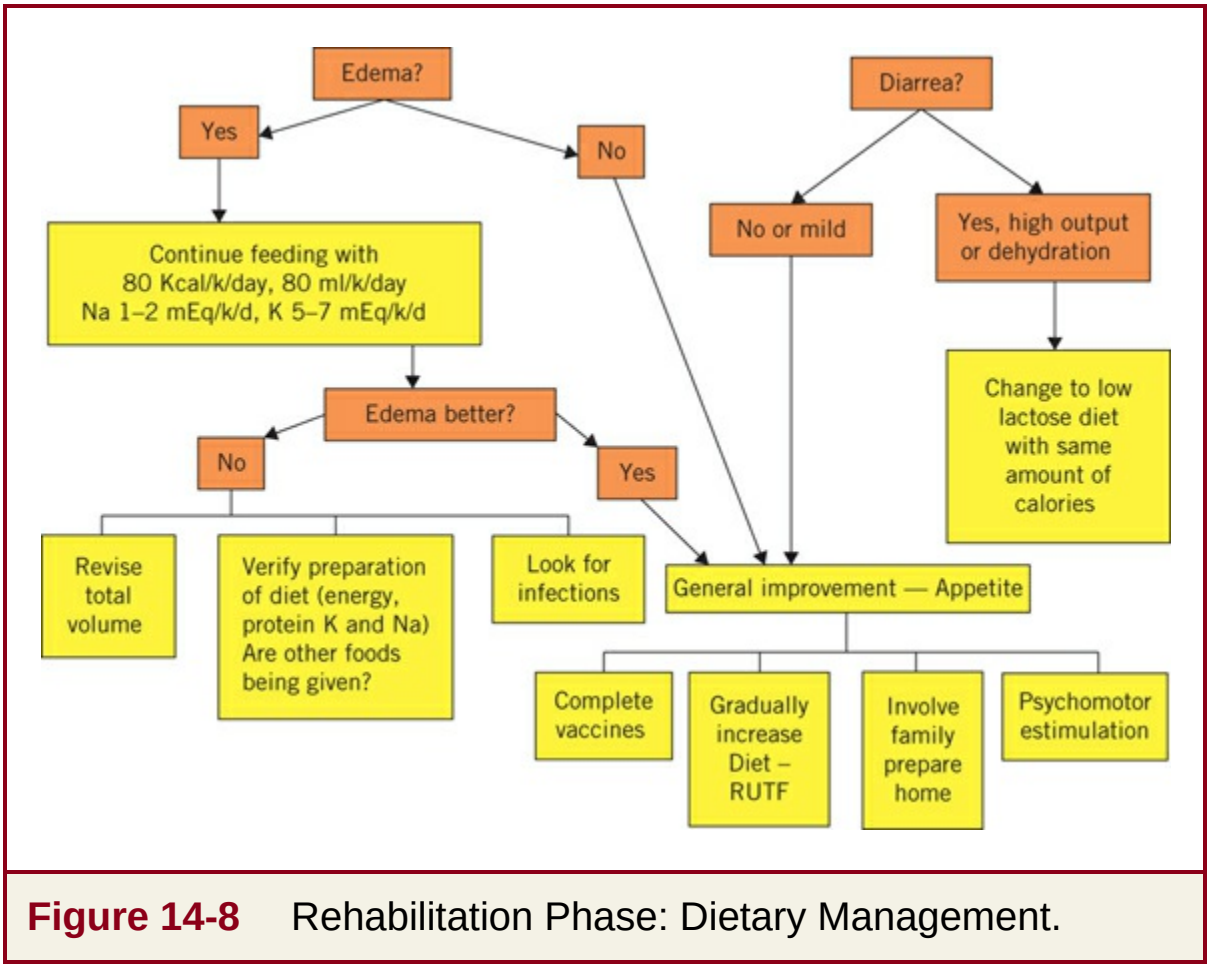

Figure 14-8 Rehabilitation Phase: Dietary Management.

Phase 3

Follow-up of children once they go home is essential as recently recovered malnourished children often relapse, and children may have high mortality rate after discharge.[211] Families should have easy and rapid access to medical care, ideally on the unit where the child is known. The choice of follow-up, like the length of hospital stay, will depend on the availability of services. The availability of a well-designed follow-up program can make all the difference to subsequent risk of dying.[213] Studies following children treated for severe malnutrition have shown variable recovery of nutritional status and intellectual development.[214,215] Sustained recovery of nutritional status is possible, although stunting usually remains.[216] Growth following rehabilitation depends on the favorable home circumstances.[145] When family circumstances remain unchanged, the outlook is poor.[217] A study in Lima comparing children returning home with those who had to be adopted and were integrated into families with

few resource constraints showed both the importance of follow-up care and the potential for recovery of these children.[145] Children should be followed up for at least six months to ensure successful rehabilitation.

CONCLUSIONS

The last few years have brought exciting advances in management of severe malnutrition. Lessons learned in the past are now being applied in hospitals and rehabilitation centers all over the world, although much more need to be done to ensure that this information reaches and changes practice in all of the situations in which severe SAM exists. Greater understanding of the pathophysiology of SAM has contributed to more rational therapy, and some clinical trials of therapies, new diet possibilities, and management strategies are being reported. Nevertheless, there is a great need for more research. The pathophysiology of kwashiorkor is still unclear, but the role of the gut microbiome together with nutrient deficient diets has been a major breakthrough.[15] Even 15 years after the publication of the WHO guidelines there is a lack of evidence in many crucial areas of management.[162]

The long-term goal, of course, is to prevent SAM. Some aspects could be relatively easily achieved. Medical practices, for instance, that deprive children of food while they are ill, especially with diarrhea, have been unequivocally shown to be unnecessary and harmful, but the use of diluted diets or “resting the gut” continues. Attention is now being given to early enteral feeding of critically ill children, which reduces malnutrition and mortality. Great strides have been made in understanding the importance of exclusive breastfeeding and the requirements for adequate complementary feeding practices, but much work is still needed to change complementary feeding practices in many countries and overcome the constraints on food security. Changing child care practices is never easy but a randomized trial showed that nutrition education through the health services was able to prevent stunting in poor periurban population in Peru[218] and an intensive education program in the community was also successful in preventing malnutrition in Bangladesh.[219] Infections, which are very common among the most deprived populations, contribute to malnutrition. Where As children with access to sufficient food of high nutritional value experience only transient effects, those on marginal diets are caught in a cycle of infection, exacerbating malnutrition, and vice versa. Interventions that reduce the burden of disease will reduce malnutrition in these populations. Measles was once a common precursor

to kwashiorkor and severe vitamin A deficiency but, with vaccination, has now disappeared in many countries. Other vaccines against diarrheal diseases could make important contributions. Severe SAM is an entirely preventable disease, but it will continue to killand contribute to the deaths of millions of children while war and natural and man-made disasters continue to affect large parts of the world.

NUTRITION A KEY FACTOR FOR HUMAN AND SOCIAL DEVELOPMENT

The nutritional status of children is directly related to their health condition; both in turn are important determinants of the human and social development of communities around the world. Improvements in nutritional and health status increase the chances of child survival and both are preconditions for economic and social development. UNICEF has proposed a conceptual model to understand the causation of malnutrition beyond the obvious immediate determinants; more recently in 2013, the Lancet has updated the classical model focusing on necessary actions to achieve optimum fetal and child nutrition and development.[1–4] Undoubtedly, the basic determinants relate to the social, economic, cultural, and political structure of society. These define what resources are controlled by individual families including access to information and education, household food security, care of women and children, access to

health, and a healthy environment. It is within this context that children have inadequate access to food in terms of quantity and quality; in addition, infection will further compromise nutrition by augmenting nutrient losses and increasing nutrient needs. (Figure 15-1)

In 2011, 6.9 million children under the age of 5 years died worldwide, one third of them related to increased susceptibility to illnesses due to undernutrition. An estimated 178 million children under 5 years are stunted, 55 million are wasted, and 19 million of these are severely affected and are at a higher risk of premature death, the vast majority being from Sub-Saharan Africa and South-Central Asia.[5] The risk factors for undernutrition include low birth weight, inadequate breastfeeding, improper complementary feeding, and recurrent infections. Infectious diseases often coexist with micronutrient deficiencies and exhibit complex interactions leading to the vicious cycle of malnutrition and infections. Diarrhea, often linked with a short duration of exclusive breastfeeding, and the poor selection and intake of complementary food are major contributors to undernutrition.[1]

Nutrition a basic human right and has been expressly recognized as such by international human rights covenants since 1924,[6] yet this "right" is commonly the subject of political demagogy rather than being actively upheld, respected, protected, and promoted. The relationship between poverty and malnutrition has been defined as a vicious cycle, where "poverty conditions nutritional status" and vice versa "poor nutrition leads to poverty" However, the relationship is by no means linear. There are multiple examples that illustrate how nutrition can improve despite economic limitations. While economic development is by no means sufficient to improve nutrition, especially in countries where wealth is concentrated among the few. The UN Human Development Index illustrates how nutrition and health can be dissociated with economic status.[7] Recent analysis of trends reveals significant reductions in malnutrition assessed by underweight or stunted linear growth except in Sub-Saharan Africa and Central America. These regions have experienced protracted civil strife and Africa as a region has been stricken by HIV/AIDS and its consequences. On the contrary, Latin America and the Caribbean combined have reduced malnutrition to about a third of the 1970 figures despite the minimal changes in the proportion of families living in poverty (Figure 15-2).[8] This concept should be stressed since health professionals frequently work under the assumption that nothing can be done in terms of prevention and control of malnutrition unless social conditions change and poverty reduction is achieved. Undoubtedly,

both should proceed in tandem, since improved nutrition will contribute to socio-economic improvement and vice-versa socio-economic progress leads to lower malnutrition rates.

WHO, UNICEF, and other international organizations concerned with malnutrition have recognized for several decades the role of malnutrition as a key determinant of infant mortality? The immediate cause of death may be diarrhea or pneumonia but the risk of dying from these conditions is increased substantially by severe and moderate malnutrition. The work of Puffer and Serrano in the Americas in the 1970s and more recently Pelletier and Habicht working with data from Africa and Asia have documented with precision contribution of malnutrition to infant mortality.[9,10] The conclusion reached by both is that over half of all infant deaths are determined by malnutrition. The recent Lancet series discusses nutrition and infection interactions and the contribution of malnutrition to infant death as crucial factors. Breastfeeding initiation within 24 hours of birth is associated with a 44%–45% reduction in all-cause and infection-related neonatal mortality, and is thought to mainly operate through the effects of exclusive breastfeeding. Vitamin A supplementation also reduced the incidence of diarrhea and measles in children aged 6–59 months, but there was no effect on mortality and morbidity related to respiratory infections. Preventive zinc supplementation in populations at risk of zinc deficiency reduces the risk of morbidity from childhood diarrhea and acute lower respiratory infections.[2]

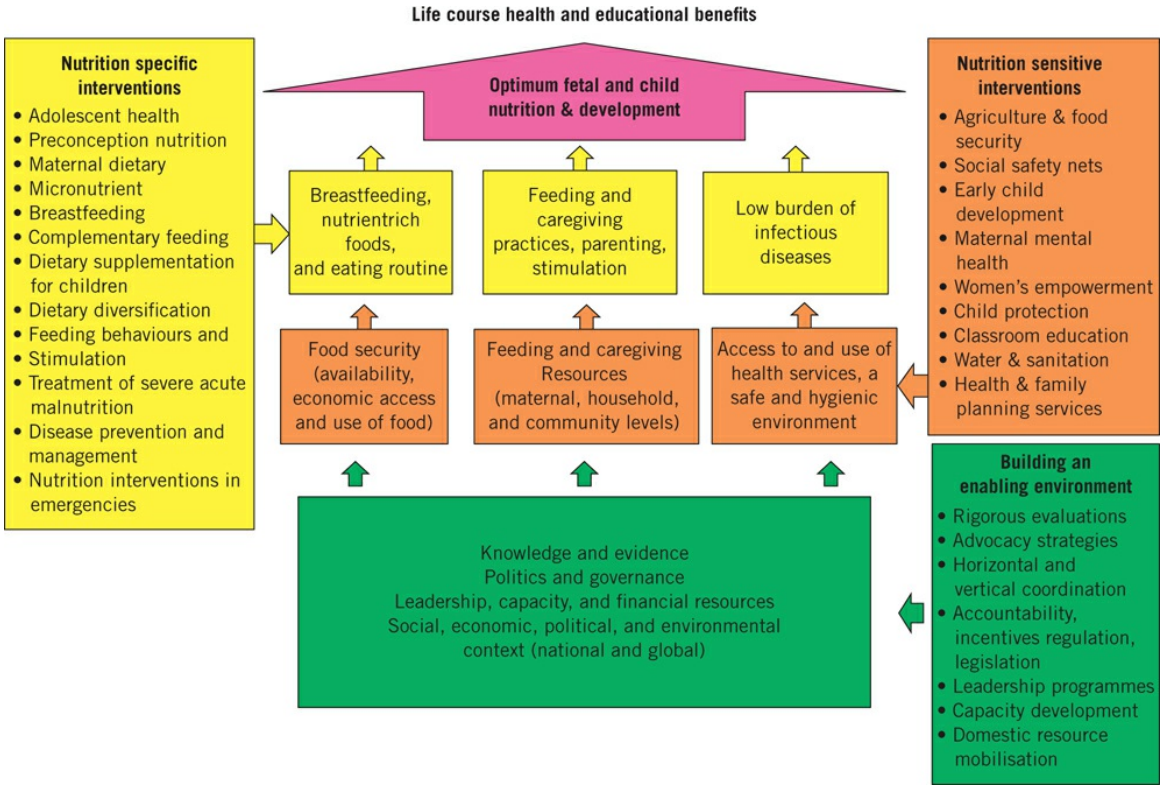

Figure 15-1 Conceptual Model of Child Development useful in the analysis prevention and control of malnutrition. Adapted from Lancet 2013. Modified from Black RE, Victora CG, Walker SP, et al.[1]

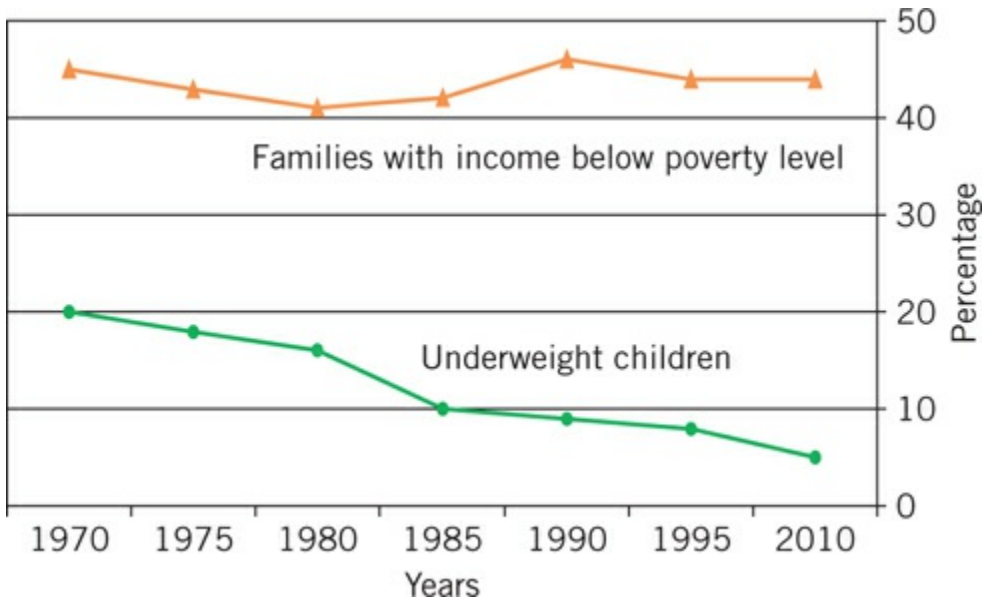

Figure 15-2 Child undernutrition in Latin America and the Caribbean: trends, reasons and lessons. Over the past 30 years, population under poverty line has remained stable, but malnutrition has declined significantly.

MALNUTRITION AS A GLOBAL PUBLIC HEALTH PROBLEM

Weight, height, and mid-upper arm circumference (MUAC) measurements are widely used to assess nutritional adequacy. A low weight-for-age is a useful indicator of malnutrition but has limited clinical significance since it does not distinguish children who are thin (wasted) from those who are short (stunted). Thus, short children may be underweight-for-age but of normal weight-for-height. A low height-for-age represents the cumulative impact of adverse events from conception onward, and the prevalence of stunting in a population is used as a proxy measure for social disadvantage. Additionally, the relationship between child malnutrition (underweight and stunting) and adult adiposity needs to be considered relative to rising prevalence of noncommunicable chronic diseases in developing and transitional countries.[11]

Malnutrition as a public health problem is assessed based on growth indices relative to those derived from a standard population. The child growth standards have been developed by WHO based on the growth of more than 8000 healthy infants and children (from middle income, nonsmoking and well-educated mothers from Brazil, Norway, India, Ghana, USA, and Oman), who were exclusively breast fed for four to six months and then given appropriate complementary foods in addition to breast milk. A finding of the new standard is that child growth during the first years of life is very similar across different ethnic backgrounds. This confirms that existing differences in growth across countries are predominantly environmentally derived and can be narrowed over time. The new standard supports the right of all children to grow equally well and demands that society provides an environment that does not restrict growth. The National Center for Health Statistics (NCHS) growth reference should no longer be used for infants 0 to 36 months, this is derived from children growing in a relatively affluent, predominantly artificially fed, and rural community from Yellow Springs Ohio over 30 years ago.[12]

Most countries have adopted the WHO growth standard which

provides harmonized best practices in child growth assessment and established the breast-fed infant as the norm against which to assess compliance with children's right to achieve their full genetic growth potential.[13]

The sixth report on the world nutrition situation (Administrative Committee on Coordination [ACC]/Sub-Committee on Nutrition [SCN] 2010) provides a broad perspective among regions and a comparison of more than 30 years (ACC/SCN, 1993), this time using the WHO's anthropometric standards.[14] Surveys reporting the prevalence of underweight and stunting in the world measured by serial anthropometry provide a measure of the changes. Based on underweight trends available from 86 countries in Africa, Asia, South-Central America, and Caribbean, the SCN report found that 44% of the countries are improving while 21% deteriorating, although the overall tendency was toward improvement. In Asia, 14/25 were improving and only one deteriorating; in Africa, 18 improved and 14 deteriorated; in South-Central America and Caribbean prevalences are in general lower than other regions and less likely to change accordingly; the report showed no change in 11/19 and 2/19 deteriorating.

There are a number of countries in transition from high to low prevalence (Thailand, Vietnam, Brazil, Bangladesh, India, Sri Lanka, Costa Rica, Mexico, China, and Indonesia) with an average rate of underweight reduction of 0.7–1.0 percentage points per year in the last 30 years or more, this trend is similar for some Asian countries, while the African region has not initiated a consistently downward trend yet. Several factors contribute to this situation among them HIV /AIDS, drought and abrupt climate change, and permanent economic–social distress in selected areas.

Presently, 165 million children < 5 years have a height-for-age *z*-score of –2 or lower (thus are stunted) on the basis of the WHO Child Growth Standards, a 35% decline from an estimated 253 million in 1990. The prevalence decreased from an estimated 40% in 1990, to 26% in 2011—an average annual rate of reduction of 2.1% per year. East and West Africa and South-Central Asia have the highest prevalence [42% for east Africa and 36% for West Africa and South-Central Asia]; the largest number of stunted children, 69 million, live in South-Central Asia. Population-based surveys from 79 countries conducted after 2000 reveal that stunting prevalence in children <5 years was 2.5 times (1.0–7.6) greater in children in the poorest income quintile relative to richest. According to 2011 UN estimates, >100 million children <5 years old, or 16%, were underweight,

and a 36% decrease from an estimated 159 million in 1990. Prevalence of underweight was highest in South-Central Asia 30% and in Western Africa it was 22%. The UN estimate for wasting based on WHO Standards was 8% (52 million) globally in 2011, an 11% decrease from an estimated 58 million in 1990. Seventy percent of the world's wasted children live in Asia, mostly in South-Central Asia, where an estimated 15% (28 million) are affected. Much the same regional pattern occurs for severe wasting in 2011 global prevalence was 3% or 19 million children. Most children with severe wasting can be found in South-Central Asia (5.1%) and Central Africa (5.6%).[1]

In Central America, there is no improvement while in South America progress has been significant. Data on children under 6 years of age show that in Latin America and the Caribbean, the prevalence of low Weight/Age (<−2SD) vary from country to country (from 0.7% to 19.2%). In Haiti and Guatemala, this prevalence is over 15% and in Ecuador, Bolivia, Peru, and El Salvador is close to 6%. As for severe malnutrition (<−3SD Weight/Age) in Haiti, Guatemala, Honduras, Ecuador, and Bolivia, the prevalence vary from 1.2% to 7.3%.[15]

Independent of the improvement of national figures, severe malnutrition including edematous forms can still be detected in hospital settings in some regions of the world.[16,17]

The causes behind the insufficient progress are multiple and complex in their interactions. Political strife, government unresponsive to the needs of the community, stagnant economies, low status of women and unequal rights, poor education and inadequate access to health, poor sanitation and unclean water, high prevalence of infections and low birth weight interact in determining poor postnatal growth and high rates of malnutrition.[18] Since most of these factors are interrelated, it becomes virtually impossible to isolate their effects from retrospective trend data or regression models. Decreases in the prevalence of malnutrition have been described in relation to improvements in household food security, supply of clean water and environmental sanitation, education of women, early treatment of diarrhea with oral rehydration solutions in the community, early treatment of respiratory infections, promotion of breast feeding, appropriate complementary feeding, immunization, growth monitoring, and surveillance for early identification of malnutrition. Smith and Haddad have attempted to explain the key factors responsible for the different rates of progress across regions of the world (see Figure 15-3).[19] They examined the contribution of national food supply, women's status, women's education, and health environment based on proxy indicators

from available country data. Improvements in women's education contributed by far the most, accounting for 43% of the reduction in child malnutrition between 1970 and 1995, while improvements in per capita food availability contributed about 26%. In fact, this information served to define the Millennium Development Goals adopted by heads of state and the UN system to be met by 2015 (http://www.un.org/millenniumgoals/). The overall reduction in the prevalence of child malnutrition in South Asia for the 25-year period was estimated to be 16.5 percentage points.

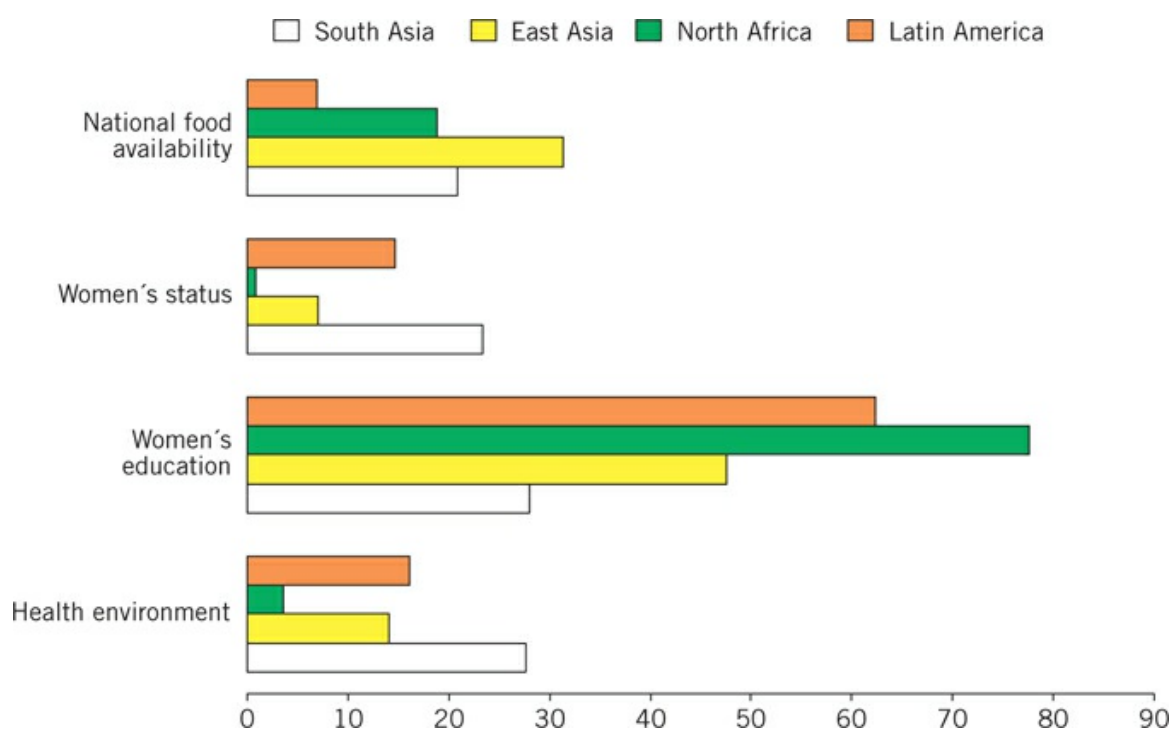

Figure 15-3 Contributions of underlying determinant variables.

The greatest contributions to this reduction came from increased education of women and improvements in health environments; each accounted for about 28%. Gains in the status of women accounted for about 25% of the reduction, and improvements in food availability for about 20%. The total reduction for Sub-Saharan Africa's malnutrition rate over the study period was only 4.2 percentage points. Most of this was explained by increases in women's education, followed by improvements in health environments. Increased education of women made strong contributions in all periods except for the late 1980s, when enrollments actually declined. Improvements in health environments have made their

greatest contribution after 1985. Women's relative status as evidence by gender differences in life expectancy has continually declined in the region since the 1970s, most precipitously after 1985. The consequence has been a recent worsening in prevalence of child malnutrition in the region. Changes in food availabilities have played a large role in both directions. Substantial improvements in the late 1980s and early 1990s were outweighed by deteriorations during the 1970–1985 period.

Latin American and the Caribbean experienced an estimated 11 percentage point reduction in child malnutrition over the study period, most of which took place during 1970–1980. Since then, reductions in child malnutrition have continued at a much slower pace. Like the other regions, the greatest contribution comes from women's education, which explained 62% of the improvement; while the contribution of environmental health to this improvement has steadily declined. Strong improvements in the status of women in the 1970s were followed by very small improvements in the 1980s. Food availability improved in the 1970s, but declined slightly in the early 1980s.

Prevention and control of infections is clearly a critical aspect of malnutrition reduction efforts. Infection has a definite adverse effect on nutritional status, while malnutrition compromises the host defenses and immune responses increasing case fatality and disease susceptibility.[20] Relative risk (RR) of death from infection is directly correlated with severity of malnutrition: RR 8.7 (CI 95%, 5.5–13.7) for severe protein energy malnutrition (PEM), 4.2 (IC 95%, 3.1–5.5) for moderate PEM, and 2.0 (IC 95%, 1.7–2.4) for mild PEM.[21] Yet, since the severely malnourished represent a small proportion of total population most malnutrition related deaths are accounted by moderate malnourished individuals. It has been estimated that close to 80% of all malnutrition infection-related deaths are attributable to moderate and mild malnutrition.

The adequacy of breastfeeding and complementary feeding also plays a key role in malnutrition prevalence. In most countries where malnutrition prevails, the time of onset is >6 months, this is when breast milk may be insufficient to meet the infant energy and micronutrient needs and also a time when mothers have increased competition for their time/dedication to the infant. This is coupled by inadequate, low energy density, and low nutrient density complementary foods. Under these conditions, increased feeding frequency, added oil, and appropriate complementary to increase energy and nutrient density become crucial to prevent malnutrition.[22] A recent study in Bangladesh examined the role of education during the weaning period demonstrating that education on complementary feeding

given to mothers was effective in enhancing weight gain despite the fact that no external sources of foods were provided. The authors suggest the educational efforts on what constitutes adequate complementary feeding and on how to prevent microbial contamination of weaning foods are important as malnutrition prevention strategies.[23]

There are no easy answers or "magic bullets" in combating malnutrition, several options can be suggested based on the success and accomplishments of some countries in malnutrition reduction. In most cases, poverty reduction efforts need to go hand in hand, but should not be considered a pre-condition for success. As presented in Figure 15-1 poverty reduction is a precondition for success, this may be unrealistic since malnutrition is not only a determinant but also a consequence of poverty. However, this does not imply that efforts to improve nutrition should be postponed until major political or economic events improve the economic condition of the poor since reducing malnutrition contributes by itself to poverty reduction. The notion of human capital formation as a major determinant of economic growth has been recognized globally with the award of two Nobel prizes in economics addressing this issue over the past decade.[24]

A strategy for action, based on what has worked in different settings around the world (Costa Rica, Thailand, Cuba, Chile, Kerala-India, among others), is proposed in Figure 15-4. This serves to analyze the necessary interactions among the key social actors required for successful implementation of malnutrition control and prevention programs. The basic and critical component is social mobilization to establish the demands for action from the political actors; this process should lead to community actions as well as responses by government. A responsive government is one that responds to community demands; this requires some degree of participation by society in government, ideally but not necessarily a government by the people, from the people and for the people. Communities that are so empowered and able to participate in the political process will be successful in demanding appropriate actions from governments. Malnutrition needs to become unacceptable to society in order to trigger the level of action required to address the issue frontally. What does it take to trigger this process? In most cases, pro-active academics and/or non-governmental organizations (NGOs) that have a strong voice, independent from government have catalyzed the process and led the way. "Political will" does not come easy nor it is generated from within; professionals, academics, NGOs, community leaders and the press should act in concert to elicit action. The role of the press in generating

public awareness and communicating public concern of malnutrition as a key restriction for national development is crucial. Recruiting and training select journalists will serve to generate widespread recognition of the problem and make people aware that the solutions are credible and feasible by illustrating what has worked elsewhere. Academics and professionals should propose the necessary actions that are required to implement effective programs to control and prevent malnutrition, ideally based on technical consensus rather than political considerations. They should promote a critical review of policy options based on what may work in a given setting; international organizations can assist in reaching a technical consensus by providing evidence and expert advice on successful examples of malnutrition reduction. The private industrial or business sector is usually a latecomer in this scene. Yet, public private partnerships are a must for sustainable programs since industry is a key partner in the implementation of programs; for example in nutrient supplementation, fortification, and other food-based strategies.[25] By the end of the day, unless we activate the political process and include industry, we get no action.

Governments must be committed to generate the necessary actions to solve malnutrition as a public health problem. Governments are usually restricted in meeting social demands by the available monetary resources and are not willing to commit funds unless they see a clear return on investment. Thus, it is crucial to clearly present the cost benefit analysis of various programs for nutrition improvement.

Moreover, if the community is truly aware and the issue has become a political priority, there may be a clear political benefit as well as an economic gain in terms of human capital formation. The involvement of the press in facilitating social communications is important in open societies. For example, the cost of providing half of all critical micronutrient needs per person per day by fortifying a staple food has been estimated to be less than a dollar per year; this is less than a pack of cigarettes in most countries. The World Bank has estimated the cost benefit ratio of micronutrient fortification to be at least 17:1. Not all programs are equal in terms of cost benefit or cost effectiveness, thus the tools of economic assessment should be used in defining policy options. As previously discussed (Figure 15-4), the mix of policies that will work differs in various settings. Working through networks is particularly helpful in countries where human and material resources are limiting, so the potential for complementarity and synergy between groups should be exploited. However, there are multiple preconditions to operate successful

networks. Groups must share clearly stated objectives, common short- and midterm objectives, participants must share decision making, activities must have continuity and be sustained. It is also helpful to geographically map where the problems are and where agencies are located and programs are in place in order to improve resource utilization.

The impact of maternal education has been shown to work across all regions, yet we must bear in mind that access to education by women is in itself an index of multiple social economic and cultural factors. In Peru, Penny et al., working with families living in conditions of peri-urban poverty, where access to food was not a limiting factor demonstrated that nutrition education, delivered through pre-existing health services significantly decreased the prevalence of stunting in young children by 11 points.[26] In our experience in Bolivia, we have come to realize that understanding the cultural representations of the mother, the family and the health team is fundamental to interpret health behaviors that otherwise appear irrational and incomprehensible.[27] Language/cultural barriers can also significantly affect the uptake of services by the community, thus need to be considered and appropriate strategies need to be in place.[28]

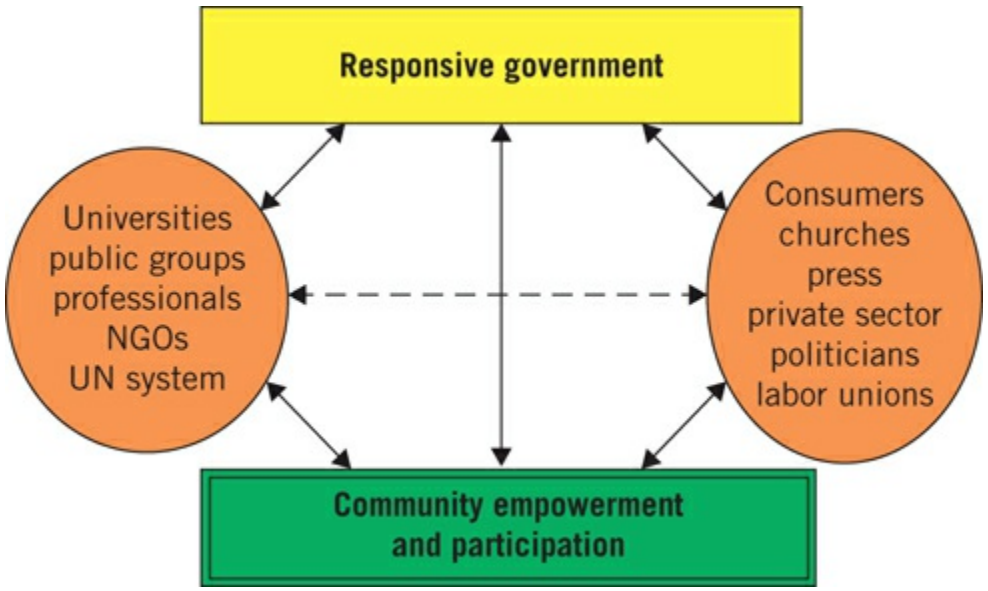

Figure 15-4 Networks and malnutrition. Scheme for strategic analysis of protein energy malnutrition control and prevention. See text for details on dynamic interactions between stakeholders. NGO, Non-governmental organization.

Nutrition and food policies should be integrated in the context of national development strategies. Nutritional problems are determined by economic and labor policies, health and education sector policies as well as welfare policies. The integrated approach may be more difficult to implement in most settings, since government structures are sectorial, yet harmonization of policies is a must to avoid duplication, wasteful use of resources and overburden personnel budgets.[29] Cost effectiveness evaluation of programs should be included at the outset in the present climate of fiscal policies. Today, program sustainability in a world of competing interests will progressively depend on the capacity to demonstrate cost effectiveness over time. Technical considerations should prevail over political interest in defining what should be done, because this is the best way to optimize chances of success. This is true at all levels, national and international programs are not always guided by best technical advice but many times, respond to politically motivated actions.

Nutrition and food policies need to be guided not only by considering the biological and medical aspects but also by the ethical dimension. Human rights concerns including the right to safe and nutritious food can no longer be ignored; in a world of plenty, malnutrition can no longer be justified as a problem of the poor or a problem that affects others but not "us". This includes not only addressing income differences but also ethnic and cultural differences which still represent major barriers for access to health and nutrition in many regions across the world.

Globalization should be not only about business and trade, but mostly about how we as humans face a common future. We cannot afford to have over a third of the people in the planet under conditions of poverty and malnutrition. Pediatricians should be concerned with the status of children worldwide. As we are convinced that our research should not ignore that we are citizens of a common planet, our advocacy and our research should not only serve those around us but also children around the world. Funding for applied research in nutrition and health of children should be as important as the present emphasis given to protection from bio-terrorism and the "war on terror". Providing for a better future for children across the world will do more for peace than the outburst of violence and wars that periodically take place. Controlling and preventing malnutrition should top the list if we are looking for world peace.

Potential Strategies for the Treatment and Control of Severe and Moderate Malnutrition

First, we should clearly establish that prevention and treatment of malnutrition are complementary. Although the adage "prevention is better than cure" is a public health imperative, it cannot be used to withhold treatment from those already affected by malnutrition. Both strategies must work together to avoid malnutrition from occurring and to rehabilitate those who are moderately or severely malnourished and at risk of death and/or severe disability. Although the actions for prevention differ from those necessary for effective treatment, they should be seen as part of a spectrum of efforts needed to combat malnutrition. What can we learn from experience, either success or failure, in the treatment of malnutrition?

Hospital Treatment

Even though severe malnutrition (i.e., severe wasting and/or edema) is commonly seen in pediatric wards in developing countries, few doctors and nurses have been trained in its management. Consequently, case-fatality rates are high. Severely malnourished children die in large numbers if treatment does not take into account the physiological and metabolic changes that arise during reductive adaptation.[30] One way to try to prevent children dying during treatment is to provide case-management guidelines. WHO first produced such guidelines in 1981. These encapsulated the basic principles of care that are still recognized today, namely *stabilization* with small frequent feeds day and night of specially formulated low-protein, low-lactose milk, rehydration with low-sodium fluids, provision of potassium, magnesium and micronutrients, and antibiotics for all children as infections are often silent, followed by *rehabilitation* with a high-energy, high-protein diet to rebuild wasted tissues. With advances in knowledge, notably the importance of withholding iron during the stabilization phase and providing zinc and other trace nutrients and psychosocial stimulation, WHO updated the guidelines in 1999[31,32] and developed a training course.[33] Where the guidelines have been fully implemented, deaths among hospitalized severely malnourished children have fallen dramatically, for example case-fatality rates of 30%-45% have fallen to <10%.[34]

In many hospital facilities around the world, staff have accessed the WHO guidelines and implemented them successfully with minimal or no outside help, and the improvements in the children's rates of recovery and survival have supported the use of the WHO guidelines in becoming hospital policy. In other hospitals, training courses have been the necessary trigger for change. There are also examples, however, where training courses have led only to a transient or partial adoption of improved

practices: the reasons vary; they include high staff turnover and lack of motivation. Factors that favor adoption of improved practices and sustainability are:

- a functioning health system, and basic resources
- leadership, mentoring, and managerial support
- in-service education so that everyone is confident about what to do
- induction of new staff on the treatment of malnutrition
- supervision of junior staff and carers
- regular audit and feedback, and discussion of critical incidents and lessons learned
- good teamwork

A major hindrance to reducing case-fatality rates is that treatment of severe malnutrition is not included in many medical and nursing curricula. The consequence of this omission is illustrated by experiences in a South African hospital where the case fatality rate increased from 18% to 38% with the arrival of newly qualified doctors who had no specific training in the management of severe malnutrition. The sudden rise in case-fatality coincided with lower prescribing of potassium (13% vs 77%), antibiotics with gram-negative cover (13% vs 46%) and vitamin A (76% vs 91%).[35] In many hospitals in developing countries, severely malnourished children comprise the majority of pediatric deaths, so it is imperative to train young doctors and nurses to care for these children correctly. This will require recognition of the importance of malnutrition in clinical practice, establishing a severe malnutrition ward or "corner" where correct treatment is provided day and night, having adequate supplies, and having ward and emergency staff trained in malnutrition case-management.

Community-Based Treatment

Some of the lowest case-fatality rates for severe malnutrition are to be found in humanitarian emergencies where well-trained staffs systematically follow treatment protocols. When thousands of families congregate in crowded camps the risk of disease increases so, as far as possible, case-management should be provided in their communities.[36,37] Likewise, hospital wards expose children to infection so if a child has "uncomplicated" malnutrition and families have access to adequate resources it is best if the child is rehabilitated at home. Community outreach workers screen children for wasting and edema. A MUAC of <115 mm indicates severe wasting in those aged 6 months to 5 years.

Children identified as having mild/moderate edema or are severely wasted but have a good appetite and are alert and appear clinically well, are treated at home with ready-to-use therapeutic food (RUTF). Only those who have poor appetite or are ill, or have severe edema, or edema plus wasting, are referred for inpatient care.[38]

The components of community-based care include:

- community sensitization and active case-finding to identify malnourished children early, before their condition deteriorates
- community mobilization to improve access to care and achieve high coverage
- treatment of moderately malnourished cases
- treatment of severely malnourished children with good appetite and who are clinically well (uncomplicated severe malnutrition).

Carers are instructed how to manage their child's recovery at home. Antibiotics, antihelminthics, and RUTF are provided. Vitamin A is provided for children with eye signs of deficiency, severe diarrhea, or recent measles. The child's progress is monitored every week for programs implemented in an emergency context, or every two weeks in non-emergency settings. In 21 programs in Malawi, Ethiopia, and Sudan, more than 22,000 children have been treated in this way, with a case-fatality rate of 4.8% and coverage rates of more than 70%.[39]

Where an effective system of community-based care is in place, children requiring inpatient management can be discharged after completion of the stabilization phase and their rehabilitation completed at home with supervision by a trained health worker at a health post, or health center, or by home visits where these are feasible.[40] Treatment in the community can:

- benefit children by reducing their exposure to hospital-acquired infections
- benefit families by reducing the time carers spend away from home and the risk of possible neglect of siblings
- benefit families by reducing the opportunity costs associated with hospital treatment
- act as a catalyst for strengthening nutrition activities within clinics for treatment and prevention of malnutrition
- lead to community action to prevent malnutrition

Rehabilitation at home can be achieved by provision of RUTFs or by families using their own resources to make specific mixtures of family

foods. High energy intakes (>150 kcal/kg/d), high protein intakes (4-5 g/kg/d) and provision of micronutrients are essential for rapid weight gain. RUTFs are specially designed for home-feeding in the rehabilitation phase: they contain electrolytes, minerals, and vitamins and have low water content so pathogens cannot grow in them.

Advantages of well-run, effective community-based programs are that:

- timely action should reduce the number of cases requiring inpatient treatment.
- the rehabilitation phase can be completed in the community rather than in hospital, which should reduce length of stay.
- discharged children can be provided with continuity of care.
- treatment is more cost-effective.

Early discharge must always be linked with effective follow-up, but at present there are many countries where this is non-existent. Hospitals with a policy of early discharge and no system of follow-up are usually unaware of high rates of post-discharge mortality. Failure of children to appear at outpatient clinics is easily misinterpreted as parental irresponsibility, rather than to child death.

Nutrition Rehabilitation Centers and Day-Care Centers

There is a long tradition of treatment of moderate and severe cases of malnutrition in residential or daycare nutrition centers, but their low coverage and high opportunity cost make these the least favored option in many settings. Nevertheless, such centers could be a “half-way-house” between hospital and home. For example, attendance for one week could achieve rapid weight gain and provide practical education sessions for mothers and carers and precede rehabilitation at home. Center staff could monitor progress during home rehabilitation through home visits and/or having children return to the center for assessment. Centers could also receive moderately wasted children and treat uncomplicated severe malnutrition. In urban areas with high numbers of severely malnourished children, well-resourced nutrition centers could be alternatives to hospital admission if staffs are sufficiently trained. The centers should be integrated into the child health services and could be attached to a clinic.

Factors for successful rehabilitation. Successful programs share several features:

- all follow the basic principles of treatment of severe malnutrition (i.e., high-energy, high-protein intakes in the rehabilitation phase along with potassium, magnesium, minerals, and vitamins)

- all provide frequent meals (at least 5), comprising specific food mixtures that families can afford, or RUTF
- those not giving RUTF make considerable efforts to teach mothers about child feeding in a memorable way, using a variety of teaching methods and providing opportunities for mothers to practice preparing children's meals
- most address the wider social, economic, and health issues that face poor families: some integrate rehabilitation with poverty alleviation activities
- all have motivated and carefully trained staff.

TABLE 15-1 Characteristics of Different Treatment Modalities for Malnutrition: Advantages and Disadvantages

At Home With RUTF[a]

Advantages

- Independent of home resources
- RUTF contains electrolytes and micronutrients; needs no cooking or refrigeration
- Liked by carers/children: few defaulters
- Can achieve high coverage, rapid scaling-up
- Responsive to fluctuating numbers
- Avoids need for formative research as to which home foods to promote
- Avoids need for intensive teaching of carers on what to give

Disadvantages

- Little opportunity to learn about good child feeding practices and malnutrition prevention
- Need clinic/health post nearby for monitoring progress, and so on
- Need efficient transport and distribution networks
- Need quality control measures if RUTF is locally made.

At Home Using Own Resources

Advantages

- Cost-effective
- Liked by carers: few defaulters
- Teaches mothers about child feeding
- Potential to prevent malnutrition in the long term by learning to make good food mixtures and feed frequently and responsively
- Potential ripple effect

Disadvantages

- Families must have food resources
- Carer must be at home full-time
- Need formative research to develop educational messages
- Need clinic/health post

• Responsive to fluctuating numbers.	nearby to monitor progress and provide timely treatment when ill • Need to provide micronutrient supplements • Need motivated staff; good communicators
Residential or Day-Care Nutrition Centers	
Advantages • Supervised feeding with high chance of success • Opportunity for teaching mothers • Potential for preventing malnutrition in the long-term • Circumvents poor primary health care system	Disadvantages • Need high malnutrition prevalence, or a center attached to a clinic • High institutional cost if "stand-alone" • Burdensome to carers, with risk of defaulting • Low coverage
[a]RUTF ready to use therapeutic feeding..	

The advantages and disadvantages of (1) residential and day-care nutrition centers, (2) home rehabilitation with no free food given, and (3) home rehabilitation with RUTF (are shown in Table 15-1)

Each option has advantages and disadvantages: some options may be better suited to particular contexts, such as urban families, mothers working for a wage, or food insecure communities. Health system infrastructure, accessibility, and staff competencies must also be taken into account. For successful rehabilitation, the system chosen should:

- achieve intakes that will promote catch-up growth and improve immune function
- provide timely treatment of infections and close monitoring of progress.

Ideally, the system should integrate both the treatment and prevention of malnutrition.

Khanum and Ashworth compared the cost-effectiveness of three treatment modalities in 437 severely malnourished Bangladeshi children aged 12 to 60 months. The children were allocated either to (1) inpatient treatment, (2) day-care treatment, or (3) one week of day-care followed by home care. The three groups were comparable at admission: most (98%)

had edema and the mean weight-for-height was <70%. The costs to reach the target of 80% weight-for-height were compared. The days required to reach the target in the three groups were 18, 23, and 35 days, respectively. Although the home-treated group took the longest time, it was the most cost-effective treatment. The respective costs expressed in US$ were $156, $59, and $29 per treated child. Mortality was equally low (<5%) in all three groups (Figure 15-5). Home treatment was the option most preferred by parents: day-care was the least preferred option.[41,42]

The next section includes a case study of how Chile succeeded in reducing malnutrition and shows the need to examine not only the specific actions to treat severely and moderately malnourished children but also the multiple programs that acted in synergy to achieve this goal. A key component was the primary health infrastructure with wide coverage and the human/material resources necessary for effective action. The capacity to identify and refer the severely malnourished to nutrition recovery centers when appropriate was vital for success. A nutrition recovery program focused on treatment of the severely malnourished working in isolation will have little or no impact unless it is coordinated with an effective prevention program working through the primary health system.[43]

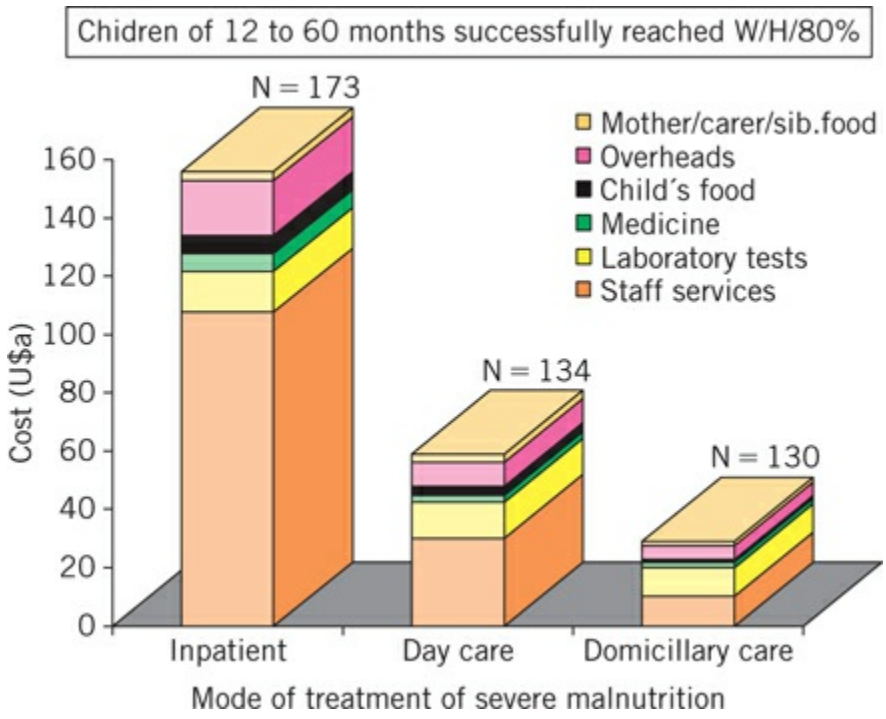

Figure 15-5 Cost effective treatment in severe malnutrition. Cost

effectiveness of various treatment for severe malnutrition. Children were allocated to hospitalization (*n* = 173), day care nutrition recovery center (*n* = 134), and ambulatory treatment (*n* = 130). All achieved a similar degree of recovery (weight for height 80% of Word Health Organization Standard). Cost is expressed in US dollars per treated child for treatment to reach the goal.

IMPLEMENTATION OF PROGRAMS TO PREVENT AND REDUCE MALNUTRITION AT THE NATIONAL LEVEL: THE EXPERIENCE OF CHILE AND BOLIVIA

Chile stands out among countries of Latin America and the Caribbean for the notable improvement of its health and nutrition situation, particularly in pregnant women and young children. This improvement has been achieved progressively and continuously through comprehensive health, nutrition, sanitation, education, and reproductive health strategies initiated in the 1940s. Results came 30-40 years later but much earlier than the considerable economic progress experienced by the country during recent decades. A key element in the success of the Chilean experience has been the uninterrupted application of programs defined based on technically consensus independent of major political, social, and economic changes. The programs remained in place and were even expanded in periods of social instability, radical political changes, and serious economic crisis. Only recently, poverty reduction has contributed to improved food security and to the improvement of the quality of life of low income groups.

The achievements obtained in children's health can be appreciated in the declining rates of infant mortality, mortality due to acute diarrhea and to bronchopneumonia. Infant mortality dropped by approximately 90%, and mortality due to respiratory infections and acute diarrhea by over 95%. Between 1940 and 1960, total infant mortality was reduced in Chile from 193 to 120 per thousand live births. From 1960 to 1990, it fell to 17 per thousand, and over the past decade, it dropped to around 10 per thousand. See Table 15-2 for degree of achievements of 2000 goals for nutrition of children and women, note the virtual eradication of malnutrition and the rise of obesity as the major diet and nutrition related public health problem.[44,45]

A key strategic factor in the development of Nutritional Programs in Chile has been the emphasis placed on the political dimension of

nutritional problems. Nutrition of the population, and especially its more vulnerable sectors, has been at the center of the political debate for the past 40 or 50 years. It has been transformed into a key indicator to assess social justice and equal opportunity for all. The 1970 Presidential election campaign is a good example of this. All three main candidates to the Presidency (one representing the conservative right, a second representing the center left Christian Democratic, and the third representing the Socialist left) proposed the eradication of malnutrition as a key target of their respective future governments. Salvador Allende, the socialist candidate was elected on that occasion with the promise of providing half a liter of milk per day to every child up to 15 years of age in the country.

The community demanded access to health and food, not only to meet this basic need but as a fundamental human right. The process initiated by academic researchers led to policy development and implementation of nutritional programs. The expansion of these programs became part of the social demands made by the population to the governments, and those politicians that satisfied these demands of providing more food to the economically vulnerable groups were elected and maintained in office. Community organizations, political parties, the Catholic Church, concerned academics, labor unions as well as multiple social organizations played key roles in demanding action. Most of the nutrition programs were eventually built into the law specifying universal coverage and the respective yearly budget allocations. Any changes to the supplementary feeding programs have always been undertaken with extreme caution by governments, since they are reluctant to take risks on a matter of such high political sensitivity.[40,41]

TABLE 15-2 Degree of Achievement of Nutritional Goals Chile 2000–2005

Indicator (%)	Base 87–89 (%)	Goal 2000 (%)	2005[a] (%)
Pregnant women with low W/H	25	15	12
Anemia in infants	30	10	3
Anemia in pregnant women	25	10	25
Newborn with low birth weight	6.9	6.0	5.0
Newborn with insufficient weight	21	15	12.5
Breastfeeding exclusively to 4 mo	44	80	60
Breastfeeding to 12 mo	20	35	34
Student gr. 1 elem. with height <	33	20	10.4

−1 SD			
Under 6 yr old with W/A <−2 SD	2.2	2.0	0.8
Food insecure households	35	20	14
Indigent population	18	15	5
Obesity in preschool children	4.6	3	14
Obesity in children entering school	6.5	4.5	19.5
Obesity in pregnant women	12	8	36

The Bolivian Experience

In 2007, the Government of Bolivia launched its first national program which was designed to address wasting, stunting, and childhood anemia. The program's design was based on "evidence-based interventions" as described in The Lancet Series of mother and child malnutrition 2008.[46] The program was able to raise awareness of the effects of early malnutrition in later years and was able to build a wide social and political commitment to fight this condition as a national priority.

The main characteristics of the program were: taking a multi-sectorial approach, emphasizing social mobilization across all ethnic/cultural groups, focusing on geographic/regional vulnerability to food insecurity, and addressing the differential age vulnerability of children, prioritizing children under two years of age. Technical features include the use of the 2006 WHO Multicenter Growth Study, use of height for age and weight for height indicators to diagnose acute and chronic malnutrition in the entire health system and the Integrated Management of Common Illness (IMCI) approach which was modified to reinforce prevention and early interventions for malnutrition.

Nutrition-focused IMCI was delivered through primary healthcare clinics. Health workers were trained to measure height/length, identify severely malnourished and treat those with mild and moderate forms. Nutritional care in the community clinics was upgraded. In summary, the implementation meant developing support mechanisms within established community organization to prevent disease, helping families to care for sick children, and getting children to clinics or hospitals when needed.

After five years, the program was able to reduce mortality of severe malnourished children in the country from 25% to less than 5% based on widespread implementation of the WHO's 10 steps protocol for hospitalized care and the application of community malnutrition

management. Stunting (chronic malnutrition) fell from 27% to 20% in children from 3 to 23 months (DHSS 2003–2008)

SELECTING THE BEST APPROACH TO TREAT SEVERELY MALNOURISHED CHILDREN

The selection of treatment modality for malnourished children starts by defining the severity of the malnutrition. Gomez in the late 1940s proposed the first classification of PEM based on weight expressed as a % of normal value for age, despite the limitations of this expression it is still used by many because of its simplicity. First degree or mild PEM is defined as between 75% and 90% of norm, second degree or moderate 60%–75%, and third degree or severe as <60% of expected for age.[47] Bengoa with his functional classification in the mid-1950s established treatment modalities based on the Gomez criteria, indicating that those with first degree should be treated in the primary health or outpatient health clinic by providing education and dietary advice; those with second degree should be treated in the day care nutrition recovery center using complementary foods in addition to education. Severe PEM should be treated in the hospital. Hospitalization should last for strictly the minimal time required "to treat complications and stabilize the patient", then provide nutrient and energy dense foods as tolerated. Closed nutritional recovery centers should be reserved to situations where PEM is highly prevalent, particularly in young infants and family conditions do not permit recovery at the home. The choice of treatment modality should always consider parental choice, cost effectiveness of treatment under real life situations, access to primary healthcare system, availability of health infrastructure, social support system available in the community, maternal education and overall condition, and psychosocial interactions within the family.

The main barriers or impediments in control and treatment of malnutrition relate to the multiple conditioning factors presented earlier. Translating theoretical concepts into practices that lead to improved nutrition and health of children is also a challenge. Treatment norms and preventive strategies may be well known but they are harder to establish as standards of practice. In addition, physicians commonly depart from rules to demonstrate their autonomy and status, or challenge specific aspects of the norm based on anecdotal personal experience rather than on firm evidence. Health professionals often consider malnutrition as an unavoidable consequence of poverty, thus may accept it as a social problem outside the health realm. The common acceptance of malnutrition

by communities and the political leadership as a chronic unsolvable problem inherent to social structure for ages leads to passive acceptance and inaction. Physicians often define health expenditure priorities, particularly those with greater status such as surgeons and internists; unfortunately, the choice is often based on what is more attractive for medicine per se, rather than basing decisions on objective measures of impact on burden of death and disability. Physicians often have greater incentives and are more interested in providing individual health care rather than addressing public health problems.

The organizational environment is also an important barrier, physician lead administration usually centers on medical interests rather than on patient's needs. Moreover, other health professionals are seen as subservient to the physician rather than team members with equal participation. Physicians in general have limited skills for networking and to develop partnerships, they are poorly trained for team work; they associate success with individual recognition rather than group effort. These traits prevent physicians from leading multi-professional multidisciplinary teams such as those needed to address malnutrition effectively. Promoting new attitudes and skills, training for team work, active listening, and defining funding priorities based on public health needs of the community are mandatory to establish effective malnutrition prevention and treatment programs.

Factors That May Explain the Effect of Nutrition Interventions in Rising Obesity Trends

The transit from undernutrition to good nutrition often leads to increasing rates of overweight and obesity, countries may reach the goals linked to reduced undernutrition but at the same time have rising prevalence of obesity and related chronic disease.[48] In order to prevent this from occurring PEM prevention programs should include from the outset the need to consider obesity prevention strategies. For example, there is a need to monitor not only of weight-for-age, but also of length-for-age as well as weight-for-length. The use of combined indicators should permit identification of the stunted overweight or obese child. Beneficiaries should not be selected based solely on socioeconomic conditions, but on true assessment of nutritional status. Stunted children of low weight-for-age but normal weight-for-length should not be given therapy that provides excess energy, since this will lead to obesity. The quality of the foods provided is crucial in pre-school and school feeding programs; fruits and

vegetables should be included in the diet of children to provide micronutrients and prevent energy excesses. Obesity prevention requires optimizing linear growth and lean tissue mass gain; thus, micronutrients and quality of the protein source are important.

PEM prevention programs need a periodic evaluation, including targeting of beneficiaries, definition of real needs and impact on obesity. Food products may need to be modified in urban settings. For example, in situations where stunting and obesity coexist, providing Fe- and Zn fortified skimmed milk in pre-school feeding programs, rather than full-fat products, is highly recommended.

Programs should be redesigned on the basis of actual need, considering the rapid transition of most urban communities in developing countries. Planners should consider the assessment of physical activity; if low, increased activity should be promoted. Food programs designed to combat PEM may become outdated as rapid improvements in socioeconomic and environmental conditions occur. Slashing social benefits without redirecting them is always unpopular. Policy makers can prevent this reaction by reallocating these funds to alternative social programs that enhance the quality of life of the poor. Thus, the changes will not be seen as taking away benefits from the poor, but rather as responding to a new situation where other needs become more relevant. Ideally, the right to food should be upheld by providing access to safe and nutritious foods, based on what people can buy or grow for themselves.[49]

Cost of Hunger and Malnutrition (The Case of Latin America)

Child malnutrition is a recognized cause of mortality and morbidity. The economic costs of child malnutrition are extremely high. The total cost is a result of higher expenses for health treatment, educational process inefficiencies and lower productivity. The increased chance of having malnourished children proportionally increases costs in the health sector which in the aggregate, equal to the sum of the interactions between the probability of malnutrition in each population group, the likelihood that this group will suffer each of the diseases because of that malnutrition and costs of treating the pathology (diagnosis, treatment, and control). To this is added the costs paid by individuals and their families product of time and quality of life lost.

What less recognized is that it also generates permanent mental and physical consequences that have serious consequences, not only economic

but also human. Malnourished children are more vulnerable to infections, which in turn increase the riskier malnutrition and premature death. Besides the above, malnutrition interferes with proper physical and brain, the latter is expressed not only in lower cognitive learning and lower capacity but in multiple other brain functions necessary for a healthy and productive life.

In Costa Rica, El Salvador, Guatemala, Honduras, Nicaragua, Panama, and Dominican Republic, it was estimated that in 2004, the cost of malnutrition $6.658 million. In Bolivia, Ecuador, Paraguay, and Peru, the cost of undernutrition in these countries totaled US $4.331 million in 2005, equivalent to 3.3% of the combined GDP of these countries. The results show that the economic impact in these countries ranges between 2.0% and 5.9% of GDP. The productivity losses for higher incidence of death and lower levels of education account for 95% of the price paid by society over a life course.[50,51]

Finally, international experience indicates that it is more cost-effective to invest in eradicating child malnutrition than to suffer the social and economic consequences. To achieve this we need not only resources, but well-defined evidence based policies and cost-effective management models that maximize impact and efficiency. Thus, it is necessary to achieve the commitment and active participation of all sectors of society. It is estimated that approximately one million Central Americans and Dominicans (2004) have dropped out of school as a result of malnutrition; this results in a two year lower school attendance in the malnourished which translate in social and economic losses not only to those affected but to society at large.

CONCLUSIONS

Undernutrition affects close to a billion people, stunting and underweight affects close to 180 million children under 5 years of age mostly found in South Asia and Sub-Saharan Africa. The overall trend is toward a small decrease in the proportion of undernourished children with a minute decrease in the absolute number. Unfortunately, the goal established by the UN for year 2015 two decades ago to reduce malnutrition by 50% was not met. The present level of progress is less than half of the decrease required to reach this goal by the next 20 years. Moreover, some regions like Sub-Saharan Africa show a rising prevalence of malnutrition. This situation is worse in countries affected by civil strife and draught, were famine condition the death of children at rates 20-40 times greater than those

found in the general population. We can firmly state that malnutrition and growth failure of children remains “an issue” which affects not only survival but also the quality of life of children in many parts of the world. Prevention is the best form of treatment. There is no doubt that sufficient knowledge exists to treat and prevent primary malnutrition in virtually all children. The condition should be considered a preventable disease, but its eradication requires full commitment by society to assign a high priority to the well-being of children. Changing the social, economic, and political forces that condition abnormal growth and development in PEM goes beyond the realm of specific medical action but concerted participation of physicians as advocates for children in the political process. Placing demands on political leaders is essential to assure that children from the time of conception throughout their various development stages are provided adequate nutrition to allow for the full expression of their genetic potential. Acceptance of this basic premise by the community is essential before appropriate prevention strategies can be successfully undertaken.[8]

Treatment of childhood malnutrition initiated as a response to a basic humanitarian duty to prevent death during the first half of the past century remains a problem in many regions of the developing world. Presently, the mandate is based on the right to adequate food and nutrition for all children as part of the global human and social development agenda. National and International Nutrition and Food Programs developed over the past 50 years have been implemented as integral components of broader strategies of primary healthcare and education, oriented toward preventing deaths, and improving quality of life of low socioeconomic groups. Pediatricians worldwide also should be aware of malnutrition as a conditioning factor delaying recovery from illness and as a major determinant of the quality of life of children with chronic disease.[8]

The key for effective malnutrition prevention is integrating health care, household food security and care as proposed by the updated conceptual model presented at the outset. The following are some of the components of malnutrition primary prevention programs that have been developed and tested over past decades throughout the world in a variety of political and social settings:

1. Promote early contact between mother and infant to improve chance for successful breastfeeding. Establish hospital and other health routines that support breastfeeding while in the maternity ward and later, successful early bonding and documented breast feeding is vital. Support breastfeeding by health team and by

legal framework that promotes, protects, and sustains the right of working women to practice it.

2. Monitor growth and development with adequate standards (present standards are being revised based on present recommended feeding modes). Intervene only when appropriate to prevent malnutrition and specific micronutrient deficits. Mothers should be familiar with growth monitoring cards and be ready to take appropriate actions when growth faltering occurs. The degree of actions taken by the community will depend on the strength of the primary health care.
3. Introduce appropriate micronutrient rich complementary foods and supplements at 6 months of age. If complementary foods are needed earlier consider the risks associated with interference of breastfeeding. Ideally, these should be based on local foods that are accessible to the population. Micronutrient will be required in most cases, new developments include fortification at the household level either with tablets, sauces or sprinkles. Food donations should be incorporated into existing programs and not be dependent on whether surplus exists in industrialized countries. Occasional food donations no matter how well meaning can have adverse consequences in the long term when they disappear.
4. Identify infants at risk for malnutrition and growth failure based on biological and social risk factors. Provide adequate social and medical support for families with children at risk. Early identification should be based on community surveillance not only of growth but also of caring practices and of critical food insecurity. Early interventions at this level are significantly more cost effective. This area is presently receiving insufficient attention despite being at the core of the problem.
5. Educate parents and adolescent girls (who will be mothers) on how to promote growth and development through appropriate home environment, care, and stimulation. Verbal and cognitive stimulation for malnourished children results in higher growth rates than for children without such stimulation. Interactions with parents, caregivers and other children are essential for the young child and these interactions can be improved by education of parents and other caregivers. Care initiatives should go beyond focusing on individual practices and behaviors to bring in dimensions of care for the family and the

community.

6. Provide universal coverage of children to basic healthcare services, full coverage for all children with immunizations to prevent infectious disease and avoid their adverse effects on nutritional status and provide early diagnosis and treatment of diarrheal disease at the community level using oral rehydration. Linking this effort to the community-based surveillance for effective prevention and control of mild and moderate PEM. Depending on what is available in the country the approach may not require expensive infrastructure but rather be community based and sustained.

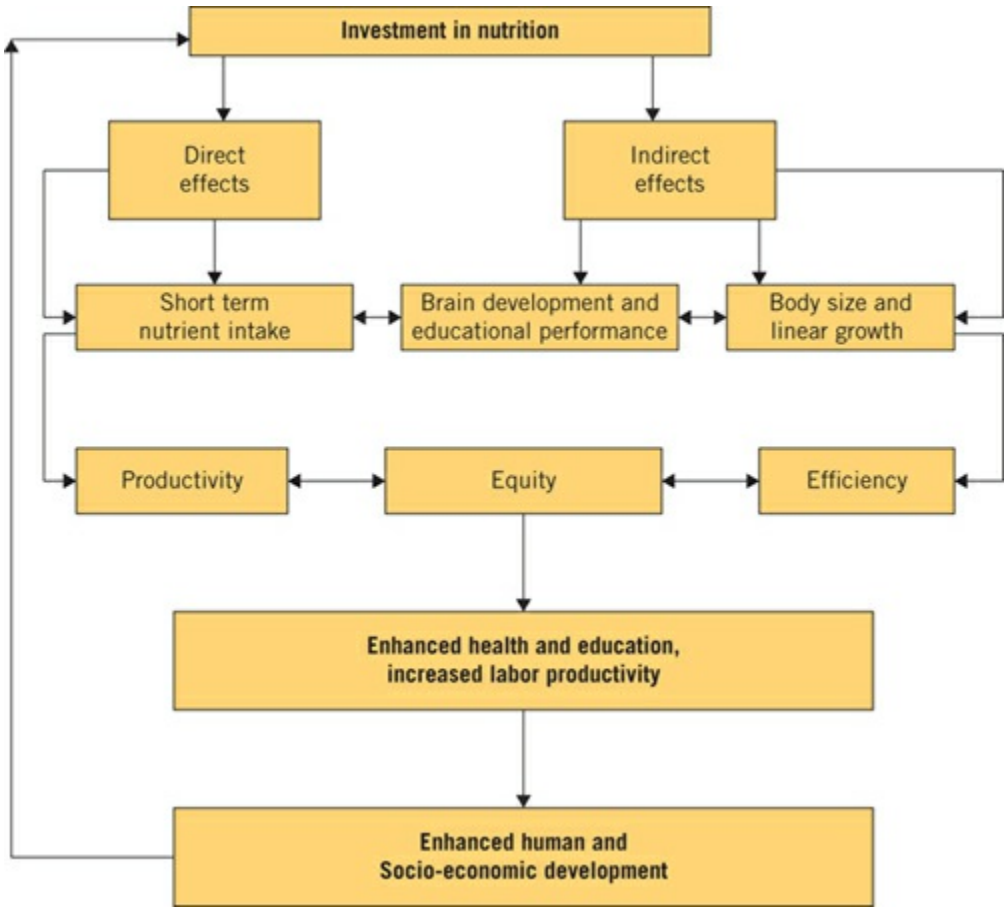

Figure 15-6 Investment in nutrition and socio-economic development.

Treating hundreds or thousands of affected children will not solve the problem of malnutrition as a global public health problem. Unless society at large confronts this issue in its full dimension the problem will continue.

Access to adequate amount and quality of food represents a basic human right and is a necessary precondition for health. In turn, good nutrition and health are prerequisites for human, social, and economic development (Figure 15-6). Physicians and specially pediatricians should not be passive bystanders but rather be activists in this process. Reducing malnutrition of infants and young children means a brighter future for humankind and will contribute in giving world peace a better chance.

16 Community Nutrition and Its Impact on Children: Highly Industrialized Countries

Johanna Dwyer, DSc, RD, Kristy Hendricks, DSc, RD, Janice H.Y. Chow, MS, RD, and Melanie Reyes, MS, RD, LD

If the future of a society is to be shaped by its children, then a strong national commitment is needed to develop their bodies, minds, and spirits. Good nutrition plays a role in the growth, development and later health, prevention, control and treatment of disease, and improvement of quality of life. Community efforts are the key to making this happen. This chapter focuses on issues of public health importance in community nutrition using examples from English-speaking North America.

REASONS FOR CONCERN

Nutrition is an important component of health care for infants, children, and adolescents. Infants grow rapidly and have requirements for protein, energy, and other essential nutrients that are higher per unit of body weight than at any other time in life, making them vulnerable to dietary

deficiencies and growth failure. Dietary habits of toddlers and preschoolers are important in shaping their later health and may play a role in increasing or decreasing obesity, high blood pressure, other cardiovascular diseases such as high serum cholesterol, and dental caries later in life. Adolescence, a time of emotional, physical, social, biologic, and educational transitions, is a period of particular susceptibility to weight concerns, eating disorders, alcohol abuse, and other poor dietary habits. Children with special health care needs at all ages, because of a variety of disabilities, handicaps, and chronic illnesses and conditions that afflict them, often need special complex and involved care and require particular attention to enable them to achieve their maximum potential.

Eating patterns begin to develop early in childhood and can profoundly affect health throughout life. In childhood, the immediate effects of inappropriate diet are most apparent in such conditions as failure to thrive, obesity, dietary deficiency diseases, and fetal alcohol effects. Later, the risk of chronic degenerative disease increases. Today, the leading causes of death and disability for adults include chronic degenerative disease such as cancers, cardiovascular diseases, osteoporosis, and alcoholism. Each involves risks associated with dietary patterns, as well as other preventable factors. Programs for the family and community must be designed to accommodate and deal with all these diet-related problems.

COMMUNITY NUTRITION AND CHILDREN TODAY: THE UNITED STATES

In the year 2011, there were 74 million children younger than 18 years in the United States (about 24% of the population) down from the peak of 36% in 1964 at the end of the baby boom.[1] American children are racially and ethnically diverse. In 2011, 53% of US children were white non-Hispanic, 15% were black non-Hispanic, 5% were Asian or Pacific Islanders, 1% were American Indians and Native Americans, and 2% were children identified with two or more racial groups. In the same year, 65% of children under 18 lived in a family with two married parents, 27% with one parent, 4% without parents, and 4% unknown. Among children living with neither parent, more than 50% of them lived with a grandparent.

For many socioeconomic and health indicators, gains have been impressive over the past decade. For example, with respect to poverty, now the rate of children living with their families is 10%, which is lower than it has been for several decades. In 2010, 22% of children lived in households reporting any level of food insecurity, slightly down from 23%

in 2009. But problems still exist. For example, children in families below the poverty line are much more likely to experience food insecurity and hunger than their peers in families above the poverty line. Younger preschool children have better diets than older children, but all could use improvement. According to a study using the Healthy Eating Index in 2005, children aged 2–5 years had significantly better diets than children aged 6–11 years, in the categories of "total fruits," "whole fruits," "milk," and "extra calories." Children in families living in poverty were less likely than those from higher income families to have a dietary pattern rated as "good." They also tended to be in poorer health than their more affluent counterparts. Therefore, many health and nutritional problems remain. This chapter focuses on the ways of ameliorating them by community-wide interventions.

As a nation, the United States has made great strides in nutrition over the past century. The situation today differs dramatically from that in 1900, when infectious diseases, dietary deficiency diseases, undernutrition, and food insecurity were major societal problems.[2] Although there are still some individuals who suffer from these problems, there are new faces to malnutrition today. Overnutrition and obesity are increasing; for example, in 2003–2004, 18% of children aged 6–17 years were overweight. Sometimes overweight even coexists in the same individuals who suffer from other dietary deficiencies. Although malnutrition, undernutrition, and other dietary deficiency diseases will probably continue to be problems in some small subpopulation groups in the United States in the future, more prevalent nutrition problems involving overconsumption and imbalances in the types and amounts of food consumed and excesses of certain nutrients are more frequent challenges, particularly in an environment of physical inactivity.[2] Of all the many nutrition problems affecting young children, obesity is the most prevalent and a growing problem.[3] Its causes are many. Social and economic changes, such as altered family structures with more single parents, increasing ethnic diversity, a predominantly urban maternal and child population, high rates of poverty among children and their families, and more eating outside of the home, are some key factors in explaining the new forms of malnutrition we see today.[4]

COMMUNITY NUTRITION AND CHILDREN TODAY: CANADA

In 2011, the population of Canada was 34.5 million, and the number of

Canadian children and youth younger than 14 years was 5.6 million (approximately 16% of its total population).[5–7] The increase in the five years between 2006 and 2011 was 11.0% among children aged 4 and younger; this was the highest growth rate in this age group since the baby boom of 1956–1961.[8]

Both the United States and Canada are culturally and ethnically diverse countries. There were more than 1 million Aboriginal people in Canada in 2006, which included the First Nations (original native peoples), Métis (mixed First Nations and European ancestry), and Inuit (aboriginal people in the Arctic region).[9] Around 5 million Canadians (16% of the population) belong to a "visible minority" (e.g., non-Caucasian, non-Aboriginal ancestry). Note that the terms used to identify minority status in Canada are different from those used in the United States. Visible minority is further defined by ethnicity or native region (i.e., instead of Asian, the percentages of Chinese, South Asians, Japanese, and Korean are reported separately).[10] Community programs targeting ethnic diversity have been created, and these will be summarized later in the section Existing Programs: Canada.

THE FUTURE

There will be more children and a greater percentage of children in the population by the year 2050 than there are today in both the United States and Canada.[1] For this reason alone, continued efforts to improve child health at the community level are necessary. Whether North American children will be healthier in the future will depend on sustained efforts on the part of parents and caretakers, as well as the larger community. Systems for tracking health promotion and disease prevention objectives that include nutrition and other aspects of child and family health are now available that permit us to monitor our progress and to make corrections to improve health when they are necessary.

Table 16-1 summarizes future directions that have been suggested for community nutrition programs in the United States and Canada.

TABLE 16-1 Future Directions for Community Nutrition Programs in the United States and Canada

The United States	Canada

Work with the Canada on universal health care and update nutrition guidelines.

- With Affordable Care Act, the United States is working on providing universal health care for citizens. Collaboration with Canada will be helpful.

Revise current policies to improve food security in certain regions and within certain ethnic communities.

- Food insecurity remains high in the United States, particularly in ethnic communities and "food desserts." Revised policies and community programs are needed to improve the current situation.

Develop a national database for community nutrition resources in each province.

- Due to the absence of a national database for community nutrition resources, it is hard to keep track of program changes and sources of funding. Also, it is difficult to obtain information from different departments within each provincial government.

Develop a national School Nutrition Program.

- There is no federal program that supports school meals. To make sure the continuation of funding sources and provision of standard nutrition, there is a need to implement a national school nutrition program.

Work with the United States on affordable health care and update nutrition guidelines.

- Through the Canada Health Act, Canadians are able to gain access to health services through public health care insurance funded by the government.[69] As the United States is starting to look upon the development of affordable health care system, the collaboration between the United States and Canada is crucial.
- There is a continuous need to update nutrition guidelines under the partnership of Institute of Medicine and Health Canada.

DEFINITIONS

Public Health

Public health is "the science and art of preventing disease, prolonging life, and promoting health and efficiency through organized community effort, so organizing these benefits as to enable every citizen to realize his birthright of health and longevity."[11] The goal of public health is to attain the highest level of physical, mental, and social well-being and longevity consistent with available knowledge and resources at a given time and place.[12] It accomplishes these objectives by focusing on the community or

on large population groups rather than on individuals, and on planning and monitoring rather than on delivering services.

Community Nutrition

Communities are groups of individuals or families living in a defined geographic area that live and work together, hold similar values, are influenced by the same environment and share a number of common concerns. An understanding of the influences of society and the community is necessary for planning effective nutrition interventions. Community nutrition applies scientific knowledge in food, nutrition, and health to a specific group of people to improve their health and welfare. To be successful, it must take into consideration the wide range of societal influences and constraints.

The community nutritionist must have a public health perspective and take into account an individual's cultural eating habits, ethnic background, income, health history, clinical assessment, dietary intake, and use of community nutrition programs to screen, assess needs, and intervene effectively.

The objectives of community nutrition are to promote health; prevent nutrient deficiencies, excesses, and imbalances; prevent diet-related diseases or conditions; and rehabilitate those suffering from nutrition-related problems. This is done by promoting healthful eating habits, ensuring access to food, and integrating nutrition into primary, secondary, and tertiary health care services.[2] Thus, it represents the traditional public health concerns (such as mass prevention and intervention measures) as well as a personal health services focus to ensure that high-risk, high-priority children especially receive health and other services they need. In this respect, community nutrition represents a fusion of both the personal health service's focus on individuals and the public health focus on the entire population.

GOALS OF COMMUNITY NUTRITION

Every decade, the US Department of Health and Human Service (DHHS) produces a document entitled "Healthy People" that summarizes goals and objectives for health promotion and disease prevention for the country. These objectives include nutrition. "Healthy People 2020", the latest edition of the plan, singles out nutrition as essential to promote optimal health and prevent chronic degenerative disease and provides nutrition

goals for children and adolescents, which are listed in Table 16-2.[13] This chapter focuses on needs and meeting these Healthy People nutrition goals at the community level.

TABLE 16-2 Healthy People 2020 Nutrition-Related Goals for Children and Adolescents

- Increase rate of having medical insurance for children younger than 18 years from 94% to 100%.
- Increase the proportion of schools with a school breakfast program to 75% of schools overall.
- Reduce the proportion of people with physical disabilities reporting barriers to local health and wellness programs.
- Target 10% improvement in children and youth younger than 21 years with disabilities living in congregate care housing.
- Increase the proportion of children with disabilities (0–2 years) receiving early intervention services at home or community-based setting from 91% to 95%.
- Target 10% improvement in the proportion of elementary, middle, and senior high schools that require school health education to prevent unhealthy dietary patterns and inadequate physical activity.
- Increase the proportion of preschool Early Head Start and Head Start programs on topics like dietary patterns, physical activity, and dental health.
- Target 10% improvement in the proportion of having official school policies and practices that promote a healthy and safe physical school environment in elementary, middle, and high schools.
- Target 10% reduction in pregnancies among adolescent females from 15 to 19 years old.
- Reduce infections caused by pathogens transmitted through food and number of outbreak-associated infections.
- Target 10% improvement in reducing the proportion of children and adolescents with hypertension.
- Reduce the rate of all infant deaths within 1 year to 6 infant deaths per 1000 live births.
- Reduce low birth weight and very low birth weight and preterm births.
- Increase abstinence from alcohol, cigarettes, and drugs among pregnant women close to 100%.
- Increase proportion of women with childbearing potential with at least 400 µg folic acid daily intake.
- Increase the proportion of infants who are breastfed.
- Target 10% improvement in the proportion of children with special care

having access to medical homes or family-centered and comprehensive programs.

- Target 10% improvement in reducing the proportion of children and adolescents of 2–19 years old who are considered obese.
- Reduce food insecurity among children from 1.3% to 0.2%.
- Increase the consumption of fruits and vegetables in children of 2–19 years old to 2 cups per 1000 calories daily.
- Reduce consumption of sodium, saturated fat, solid fats, and added sugars in children of 2–19 years old.
- Target 10% improvement in reducing iron deficiency among young children and female adolescents.
- Target 10% improvement in the proportion of required daily physical education for students in public or private schools.
- Increase the proportion of children and adolescents who do not exceed recommended limits for screen time.

Source: Adapted from US Department of Health and Human Services.

The goals of child nutrition programs are to optimize growth and to decrease the risk of all diet-related diseases. Strategies to accomplish the goals in the community must include consideration of the child's family; the efforts of the child, the family, and many members of the health care team; and contributions by institutions as well as economic resources in the health, food, education, and welfare sectors of the community. A supportive physical environment is also important.

In the community setting, strategies should focus on health promotion, early intervention (EI), and prevention of diet-related diseases in groups of children and their families. In addition, community-level efforts should focus on ensuring that preventive and curative health services are in place.

Federal and state governments have been committed to promoting child health since early in this century.[14] However, some programs that have been instituted are ineffective unless communities make them available and families take advantage of them. Both states and communities exhibit considerable variation in the extent to which they provide supportive services and extra funds for reaching nutrition objectives. Detailed advice is available for discovering and mobilizing community nutrition resources.[15]

In the clinical setting, community nutrition–related strategies should focus on providing anticipatory guidance, preventive activities, and control of clinical problems and diseases involving both primary and secondary malnutrition in all children but particularly in high-risk children, such as

those who are developmentally disabled.

All health care team members need to understand the importance of community nutrition, know what programs are (or should be) available, know how to obtain them for patients and clients, and know how to advocate their extension. Otherwise, those who provide direct care to children may fail to meet all of their children's nutrition needs.

HISTORY OF COMMUNITY NUTRITION AND HEALTH: THE UNITED STATES

Only in the twentieth century did the federal government begin to play a role in ensuring and safeguarding the health of American children. The Children's Bureau was established in the Department of Labor in 1912 to "investigate and report…upon all matters pertaining to the welfare of children and child life among all classes of our people."[14] It was the forerunner of efforts now centered in the Maternal and Child Health Bureau of the DHHS. The first federal grants-in-aid to the states for planning to improve infant and maternal health were authorized by the Sheppard-Towner Act of 1921. This legislation was first administered by the Children's Bureau in the Labor Department, but since the 1960s, the US Public Health Service in the DHHS has administered such programs.

Title V of the Social Security Act of 1935 initiated the federal and state partnership for maternal and child health that served as the major impetus for the development of public health nutrition services for mothers and children. The states used these federal funds for planning and developing a wide range of programs to improve the health of mothers and children. In 1981, Title V changed with the creation of the Maternal and Child Health Service Block Grant, which provided monies with fewer specific requirements and more state discretion within the general realm of maternal and child health needs. Fifty-nine states and jurisdictions now receive funding. The federal government also provides small amounts of federal set-aside funds to support special projects of regional or national significance. Other categorical programs for specific purposes are funded from the DHHS, the US Department of Agriculture (USDA), and other branches of government. With these funds and their own matching resources, the states provide a variety of services. However, access to health care remains an unresolved issue today for many Americans and their children.[16,17] Lack of access to medical nutrition therapy and other health services is a major problem for children who have health problems

that cannot be solved by community nutrition or public health efforts. Community efforts supplement, but are not substitutes for, individual health services.[18]

Today more than 2000 public health nutritionists are employed in federal, state, and local public health agencies. They also serve as members of health care teams, where they have the responsibility of assessing community nutrition needs as well as planning and directing programs of nutrition services for individuals. Many other health professionals, including around 70,000 registered dietitians, devote some of their time and effort beyond the scope of individual counseling to community programs and also play a role in ensuring that community nutrition needs are met.

HISTORY OF COMMUNITY NUTRITION AND HEALTH: CANADA

Canada is renowned in North America for its health care system, which includes universal health insurance. “Medicare Canada”, which is Canada’s national health insurance program, was established by legislation under Canada Health Act (CHA) in 1957.[19] It was developed to ensure universal coverage and provide reasonable access to medical services for *all* citizens and permanent residents. Medicare Canada is a national program consisting of 13 provincial and territorial health insurance plans; each shares basic coverage and common features. Under the CHA, provincial and territorial governments are responsible for management and delivery of services for their residents, and for setting criteria for insurance plans to obtain federal funding.[20]

NUTRITION SCREENING, ASSESSMENT, AND INTERVENTION

Nutrition screening, assessment, and intervention are important at both the level of the individual and that of population groups. A systematic approach and an integrated structure for screening, assessing, and intervening are needed to deal with nutrition problems in both health and social service settings.[21] The approach is summarized in Table 16-3. Details on how nutrition screening and assessment apply to individuals are provided elsewhere in this book.

The first step in developing an appropriate care plan for a community

is nutrition screening of the entire maternal and child population to identify major problems. This may involve examination of relevant statistics and resources of actual surveys. Next, the specific subpopulation of interest must be considered. Screening aims both to increase nutrition awareness among communities, families, and health professionals and to identify factors increasing nutritional risks in target groups. In the community nutrition context, the screening process might involve review of health indicators, such as the prevalence of low birth weight, with further delineation of high-risk groups using income, ethnicity, age, and other characteristics of parents or infants. Those groups who are found to be at risk are then further assessed.

The second step in care planning is a comprehensive nutritional assessment of the community in which the children live. Nutrition screening and assessment should be used in an effort to find groups at especially high nutritional risk. Some nutritional issues can be easily assessed and remedied by the health and social service systems. Others require further medical or social assessment before the causes of the malnutrition can be assessed. The process of setting priorities for intervention among the groups found to be in need of services and allocating resources appropriately to these efforts depends on the individual initiative and political will of the group's providers.

The final step in care planning is intervention, which may be at either the individual or the community level. This may involve nutritional measures such as food or counseling or other interventions that improve nutritional status more indirectly, such as oral health, pharmacy, and social and mental health services. The ultimate goal is to prevent, control, or ameliorate nutrition-related problems. The end result should always be to improve or ameliorate children's health.

TABLE 16-3 Pediatric Nutrition Screening, Assessment, and Intervention in the Community

Screening	To look for possible risk factors and identify the needs for further assessment for potential health problems and nutritional implications. • Anthropometrics • Medical history • Diet and feeding ability • Laboratory values if available (e.g., serum proteins, iron)

	• Socioeconomic status and related information • Oral and mental health
Assessment	To determine any diet-related problems, inadequacy of nutrition for growth with dietary deficiency or excess in nutrition and imbalance secondary to diseases. • CDC Clinical Growth Charts (2000) - Length of height - Weight - Head circumference • BMI for weight status and risk of overweight and obesity • Clinical signs and symptoms for malnutrition or nutritional deficiencies
Intervention	To use approaches that are specific, family-centered, community-based, comprehensive, and culturally competent. • Social services • Behavioral and mental health • Nutrition counseling, education, and support • Medical care

NUTRITIONAL MONITORING AND SURVEILLANCE AT THE STATE AND NATIONAL LEVELS: THE UNITED STATES

Monitoring and surveillance are analogous to repeated screening and evaluation efforts at the individual level. Monitoring is the periodic measurement of factors that indicate that changes in nutritional status have occurred. It applies to specific individuals, communities, and the general population. Surveillance is the continuous and regular collection of data that are compiled to detect warning signs of problems at the community level early enough to provide feedback for health care team members.

The purpose of monitoring and surveillance is to provide continuous, reliable information on a community's nutritional status and the factors that influence it to find ways to improve it.

National nutrition monitoring involves measurement of health status, food supply, food consumption and composition, and dietary knowledge and attitudes.[21] At the federal level today in the United States, nutrition

monitoring and surveillance are conducted by several different government agencies. Within the DHHS, the National Center for Health Statistics of the Centers for Disease Control and Prevention (CDC) conducts the National Health and Nutrition Examination Survey (NHANES). NHANES is a periodic, population-based survey providing national data on specific health status measures, including dietary intake, eating habits, and biochemical and anthropometric indices related to nutrition. NHANES is now continuously in the field. The NHANES data provide useful benchmarks for the health of these groups. However, the number of children and adolescents surveyed is small, and not all relevant problems can be examined in each survey. Therefore, occasionally, special surveys have been conducted that oversample these groups.

In 1999, the USDA's Continuous Survey of Food Intake of Individuals was merged with the NHANES to produce an ongoing survey with a greater sample size. Both the USDA and the CDC's National Center for Health Statistics now partner on the dietary portion of the survey. The combined survey has been conducted each year since then, and recent results are available at http://www.cdc.gov/nchs/nhanes.htm. Documentation about the dietary screener questionnaire, the interview on individual foods and total nutrient intake, and dietary supplement usage can be found on the website.

The USDA monitors food security in the United States through an annual survey of approximately 40,000 US households conducted as a supplement to the US Census Bureau's nationally representative Current Population Survey. The most recent food security survey revealed that 85% of US households were food secure throughout the entire year. The remaining 15% were food insecure at least some time during the year; that is, these households were uncertain about having or were unable to acquire enough food to meet the basic needs of all household members because they had insufficient money or other resources. About 6% reported that they had very low food security, which signified that there was a reduction in intake or disruption in eating patterns for at least one household member due to lack of resources for food.[22] Minority groups of Black and Hispanic households and single female- or male-headed households had rates of food insecurity and hunger that were substantially higher than the national average.

TABLE 16-4 Health Surveillance Tools Used in Canada

Survey	Comments
Canadian Health Measures Survey	Canadian Health Measures Survey collects important health information through household interview and direct physical measures at a mobile clinic, and it helps to create national baseline data for major health concerns such as obesity, sexual behavior, lifestyle and physical activity, environmental and housing characteristics, as well as demographic and socioeconomic variables. The website is available at: http://www23.statcan.gc.ca/imdb/p2SV.pl?Function=getSurvey&SDDS=5071&lang=en&db=imdb&adm=8&dis=2
Census of Canada	Census of Canada is conducted every five years. It provides demographic information about the Canadian population, including age, gender, ethnicity, education, household salaries, social benefits, etc. It is crucial for determining public health policies and recommendations on a population level. The website is available at: http://www12.statcan.gc.ca/census-recensement/index-eng.cfm.

The USDA also provides funds for grants and contracts to universities and nonprofit organizations to perform analysis and research in support of improving food consumption practices. These include rating food intakes of various portions of the population from national survey data using the Healthy Eating Index, which is currently available at http://www.cnpp.usda.gov/Publications/HEI/healthyeatingindex2005factsh Also program-specific analyses such as studies of the National School Lunch and Breakfast Programs are available.[24] Many other publications on these and other programs are available at http://www.ers.usda.gov.

The CDC of the DHHS conducts ongoing state-based nutritional monitoring activities. The database consists of data collected on children and pregnant women enrolled in health department clinics, the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC), and the Head Start programs at the state and local levels. Programs include the Pediatric Nutrition Surveillance System, the Pregnancy Surveillance System, and the Severe Pediatric Undernutrition Surveillance Systems. These surveys are not necessarily representative of the entire population but provide much useful data on groups at special risk.[25]

NUTRITIONAL MONITORING AND SURVEILLANCE AT THE PROVINCIAL AND NATIONAL LEVELS: CANADA

Table 16-4 provides a summary of two surveys that are used for health

surveillance in Canada.

DIVISION OF LABOR: MANAGEMENT OF COMMUNITY NUTRITION SERVICES

The management process consists of planning, organizing, implementing, directing, controlling, and monitoring. The dynamic aspects of the process of community nutrition service management occur at two levels. First, there is program management at the indirect service level, which includes macro-level planning, administration, supervision, consultation, and training, as well as screening and assessment of problems at the community level. Program management and evaluation efforts generally occur at this level. Second, direct service delivery may be provided to both groups and individuals, and this includes screening, assessment, intervention, and follow-up. Both levels must focus on the child and his/her family if the programs are ultimately to be effective.

Planning

Planning is a process of devising a course of action to reduce uncertainty and to anticipate and initiate change. Community nutrition planning involves analyzing subjective and objective data, writing mission statements, setting goals and objectives, and activating means of achieving objectives. Nutrition planning is influenced by the internal culture and capabilities of each organization involved, as well as by the public agenda, state of scientific knowledge, wants and needs of the families, and advocacy of experts, parents, and professional groups.

Community nutritionists should participate in the planning processes of the agency, study the agency or community health plans, know those who participate in the planning group, get involved, and involve others. Planning goes beyond administrators, leaders, and program managers and should include those who will be responsible for implementation and those who will be recipients of services.[26]

Planning for high-priority nutrition problems can be aided by forming alliances with related constituencies in the service network. Some examples are collaborative planning by nutrition service providers, advocates, and patients. This sort of collaboration may build political support and bridge organizational and ideological boundaries, identify mutual goals, and build cohesion and capacity to act together if potential adversaries are approached, co-opted, and included in the process. In some

instances, it may assist in making difficult decisions about using limited resources.

Implementing

Planning identifies what to do. Implementation begins the process of doing. Effective community nutrition program implementation requires administrative support (budget, staff, space, and equipment); commitment of staff to program goals, objectives, and interventions; and support and respect of a target population who is also convinced of the benefits of the program and willing to commit time and effort to participate.

Screening and assessment at the community level are the responsibilities of the community nutritionist, who ensures that systems are in place in community programs and encourages their institution in personal health services. Nutrition screening and assessment also occur at the direct service delivery level, where they are usually administered by health or social welfare care team members such as dietitians, physicians, nurses, social workers, and physical therapists.

The role of the community nutritionist in implementing these programs varies. Depending on the health and nutritional problems found, children and/or families are referred to different community and personal health services for interventions, including nutritional counseling, food, welfare education, and health programs, or to private physicians.

Monitoring and Evaluation

Community nutrition program implementation must be systematically monitored by the collection and analysis of appropriate data to provide the continuous feedback needed to assess performance. Evaluation involves the systematic measurement of results by comparing the data collected with pre-established standards or controls to decide whether to continue, expand, redesign, or terminate the program.

Monitoring must also be accomplished at both direct and indirect service levels. At the direct personal health service delivery level, the health care team evaluates program impact on a population or community by observing improvements in health. At the indirect level, the management of the community nutrition program may also evaluate effectiveness, efficiency, and cost through cost-effectiveness analysis to determine whether the program's benefits are sufficient to offset its cost.

One current effort of this type in the United States is the Preventive Health Services Task Force. Its publications on health services that are

viewed as effective are increasingly being used as a guide for services.[27] Another key document for monitoring progress at the community level is the tracking system for the Healthy People 2020 objectives.[28,29] In Canada, Canadian Health Measures Survey and Census of Canada are health surveillance tools that are in place.

CURRENT NUTRITIONAL STATUS OF INFANTS, CHILDREN, AND ADOLESCENTS: THE UNITED STATES

This section summarizes the major problems of different age groups today in the United States and some diet-related risk factors. It provides recommendations needing incorporation in both community nutrition programs and personal health and social services for children. Some nutrition problems such as obesity, food insecurity, excessive consumption of calories from solid fats, saturated fat, sodium and added sugars, and iron deficiency affect some children at all ages and are matters of concern across the entire developmental period.[29] Others, as described in the following sections, affect specific age or life stage groups.

Pregnant Women and Infants

Community concern about good nutrition should start before birth of the child. Nutritional needs in pregnancy and lactation at both the individual and community levels have been well summarized elsewhere.[30,31] High-risk women who are poor need to be enrolled in the WIC and provided with nutrition counseling, food education, and other specialized health services.

Adequate nutrition is vital for premature, small-for-date, and other low-birth-weight infants who are at risk of developmental disadvantage. (See other chapters in this volume for more details.) EI programs to encourage and promote good nutrition among those infants most in need are of particular concern.[32]

Nutrition is especially critical in the first year of life.[33] Nutrient needs are high because growth and development are more rapid in infancy than at any other time after birth. Weight usually triples and height doubles in the first year. Approximately one-third of calories consumed is used for growth in very early infancy, and it remains high during the first four to six months. This rapid growth in the healthy term infant during the first

four to six months of life requires more energy, protein, and other essential nutrients per unit of body weight than at any other time in infancy or childhood. The feed of choice for young infants is human milk, or if this cannot be provided, iron-fortified infant formula, in which its nutrient content is specified by law. Feeding additional nourishing foods to infants thereafter promotes adequate growth and good health.

The gastrointestinal tract of the newborn infant is well developed but immature. All of the secretions of the digestive tract contain enzymes especially suited to the digestion of human milk. The ability to handle foods other than human milk or formula depends on the physiologic development of the infant. Thus, it is important to encourage breastfeeding and to feed infants age-appropriate foods selected on the basis of their developmental readiness.[34] This will not only help to prevent complications but also help to build positive attitudes about food and eating.

Attention to feeding the appropriate type and amount of food is essential. All parents and caretakers need appropriate advice and guidance. For the poor with high nutritional risk, WIC, which provides food, health services, and education, may be in order. For the ill, Title V and Medicaid-supported health services, as well as special services for those with especially severe handicapping conditions, may be in order.

Some of the common nutritional and health problems and related risk factors in infants that need attention by community nutritionists are summarized in Table 16-5. Table 16-6 provides recommendations for promoting good nutritional status during this period.

Preschool and School-Aged Children

Table 16-7 outlines some of the current nutritional concerns, and Table 16-8 provides recommendations on promoting good nutrition after infancy in the preschool and school years. New findings in the Feeding Infants and Toddlers Survey 2008 can be assessed at http://download.journals.elsevierhealth.com/pdfs/journals/0002-8223/PIIS0002822310014793.pdf. This population-based survey is one of the latest and most recent studies of very young children in the United States. These data and the NHANES survey provide a glimpse at the dietary status of American infants and young children at present. The US DHHS is now considering to develop dietary guidelines for infants and children younger than 2 years.

In late infancy, children begin to learn to feed themselves independently. They progress from eating with their hands to using

utensils. Children need to be independent and able to try new skills to help them develop positive attitudes about food and eating.

Children's growth rates slow considerably after the first year of age, resulting in decreased appetite and food intake. This normal phenomenon is often mistaken for poor appetite, although it is not. In spite of the slower growth rates, appropriate nutrition is vital to provide needed nutrients and energy to maintain resistance to infections, materials needed to build new tissues as growth proceeds, and adequate nutrient stores.

Good nutrition is important to sustain growth and permit development. It is especially important in the weaning period to prevent the risks of iron deficiency anemia, dental caries, and obesity and diet-related risks that may contribute to later hyperlipidemia and hypertension.

Obesity is increasing in Americans, with estimates of obesity about 20%–30% in children aged 6–19 years.[35,36] Therefore, attention to nutrition must not be neglected in the preschool, primary, and middle school years since problems can develop at any time. In 2008, more than one-third of children and adolescents were overweight, and these figures have tripled since 1980. Also, associated conditions such as cardiovascular diseases and type 2 diabetes are increasing among children, and diet-related chronic disease risks linked to obesity are also on the rise. Minorities and low-income families are often particularly afflicted. In 2010, the White House Task Force on Childhood Obesity published a report "Solving the Problem of Childhood Obesity Within a Generation" to President Obama. Along with the First Lady Michelle Obama's Let's Move Campaign, this report emphasized that childhood obesity was becoming a "national health crisis."[36] Therefore, there is a need for immediate action. The National Institutes of Health have produced many useful materials that are online to help that can be accessed at http://www.nhlbi.nih.gov/health/public/heart/obesity/wecan/, and additional publications are available at the CDC's Division of Nutrition and Physical Activity (access at http://www.cdc.gov/nccdphp/dnpao/publications/index.html).

TABLE 16-5 Current Nutritional Issues and Recommendations for Infants in the United States

Problem	Comments
Growth retardation and underweight	Dietary inadequacies Low birth weight

	Inappropriate introduction of foods
Dental caries	Excessive or frequent consumption of sweets that are retained in the mouth Baby bottle tooth decay Lack of fluoride
Iron deficiency anemia	Early introduction of cow's milk Malnutrition Inadequate dietary intake of iron
Lack of breastfeeding	Inadequate nutrients Increased risk of maldigestion Increased risk of infections, obesity, and type 2 diabetes
Other nutrient deficiencies	Inadequate intake of certain nutrients Poor dietary quality Lack of appropriate supplements
Infections	Malnutrition Lack of breastfeeding

Recommendations:

- Improve nutrition training of health professionals
- Increase nutrition counseling and education of parents and caretakers
- Strengthen breastfeeding support
- Develop nutrition and feeding guidelines for agencies responsible for the administration of health social welfare and related program services
- Enhance research base for current issues in infant nutrition
- Prevent or treat inappropriate weight gain

TABLE 16-6 Recommendations for Enhancing Nutritional Status of Infants in the United States

Early infancy (0–6 months)

- Exclusive breastfeeding until 6 months of age
- If breast milk is contraindicated, feed with a nutritionally adequate and heat-treated infant formula until 6 months of age
- Supplement with vitamin D (400 IU per day) if infant is solely breastfed for the first 6 months of life or if these are not provided in formula
- Avoid providing regular cow's milk and skim milk to infants younger than 1 year and encourage breastfeeding and adequate supplementation
- Ensure that the infant receives enough food by monitoring growth
- Use proper feeding techniques to avoid gas, aspiration, and other problems

- Delay introduction of complementary foods until 4–6 months when the infant is developmentally ready to deal with them
- Avoid foods commonly causing allergies, intolerances, or hypersensitivities
- Ensure that water intakes are adequate
- If family resources are inadequate, obtain assistance from federally sponsored food programs for infants and children
- Obtain relevant anticipatory guidance on feeding and health

Later infancy (6–12 months) Introduce complementary food rich in iron and zinc

- Supplement with fluoride after 6 months of age (limited in communities where fluoride concentration in water is <0.3 ppm)
- Introduce complementary solid foods after 6 months of age, along with continued breastfeeding for 1 year or more. Introduce regular cow's milk or skim milk after 1 year of age.
- Ensure a gradual transition to family diets rather than weaning off suddenly and encourage self-feeding
- Take common problems in stride—temporary refusals of solid foods at weaning and failures to switch over from pureed or baby foods to foods that must be chewed are normal setbacks
- Consult health providers if feeding problems persist
- Realize that some decrease in appetite in late infancy is to be expected as growth slows and that is no cause for alarm
- Avoid struggles and battles of will with the child about food
- Keep environments safe (especially with respect to lead and common household chemicals) and begin to teach child to shun mouthing and eating nonfood objects
- Begin oral hygiene measures

Source: Adapted from (1) American Academy of Pediatrics, Policy Statement on Breastfeeding and Use of Human Milk, 2012; (2) American Academy of Pediatrics, *Pediatric Nutrition Handbook*, 5th Ed.

Strategies that communities can use in helping to address overweight and obesity especially in children and adolescents involve "CARE" (**C**ommunication of the problem and steps to correct it, **A**ctions, **R**esearch, and **E**valuation). These action options include the following:

1. *Physical activity.* Require daily, quality physical education at all school grades. In 2011, about 30% high school students participated in at least 60 minutes of physical activity per day. It is also important to provide safe and accessible facilities for the recreation of people of all ages. Community facilities should be available for physical activity for all people, including on the weekends, and there should be more opportunities for physical

activity at work sites. At the same time, it is important to reduce the time people spend in watching television and other sedentary behaviors. According to a recent survey by the Kaiser Family Foundation, children and adolescents aged 8–18 spend around 7.5 hours per day in front of screen for entertainment; half of time is spent in watching television.[37] The screen time spent can cause further physical inactivity.

2. *Food options*. Ensure the availability of more food options that are low in saturated fat and calories, as well as fruits, vegetables, whole grains, and low-fat or nonfat dairy products, on school campuses and at school events. It is important to enforce existing USDA regulations that prohibit serving foods of minimal nutritional value during mealtimes in school food-service areas, including vending machines. The ChooseMyPlate.gov website provides health and nutrition information for pregnant women, preschoolers and children older than 5 years.
3. *Communications*. Change the perception of obesity so that health, and not simply personal appearance, becomes the chief concern. This means providing appropriate education in schools and communities and training of health professionals about healthful eating habits and regular physical activity, based on the Dietary Guidelines for Americans, for people of all ages.
4. *Growth monitoring*. New growth charts are now available for children and adolescents to evaluate their size and growth.[38] They need to be used on a continuing basis and can be accessed at http://www.cdc.gov/nchs/about/major/nhanes/rowthcharts/htm.

TABLE 16-7 Current Nutritional Issues and Recommendations for Children in the United States

Problem	Comments
Obesity	Excessive energy intake Lack of physical activity
Failure to thrive	Dietary adequacies
Iron deficiency anemia	Malnutrition Inadequate dietary iron intake
Dental caries	Excessive or frequent consumption of sugary foods

	Poor oral hygiene
High blood pressure	Overweight High sodium intake
High blood cholesterol	Excessive intakes of saturated fat, trans fat, and cholesterol
Food insecurity	Lack of access to social service programs Inadequate nutrients

Recommendations:

- Achieve adequate nutrition services in daycare programs and early childhood education
- Increase participation and coverage of child nutrition programs
- Increase parent and community nutrition education
- Improve nutrition training of health professionals
- Enhance the research base to answer existing questions in child nutrition
- Change policy to integrate nutrition services into all aspects of child health care
- Improve policies on increasing access of food and venues for physical activity for children

TABLE 16-8 Recommendations for Enhancing Nutritional Status of Children in the United States

Preschool years

- Ensure that levels of physical activity and rest suffice to maintain normal growth, development, and appetite
- Provide nutritious food at home and school where child eats and encourage healthy food choices
- Teach child to choose and eat nutritious foods for meals and snacks
- Avoid sugary and starchy snacks that can retain in the mouth and encourage oral hygiene and good dental practices
- Foster appropriate eating behaviors by providing suitable role models, by permitting the child to choose food portions, by giving some latitude in food preferences, by exposing him/her to new foods, by fostering table manners appropriate to his/her developmental level, and by keeping meal as times for social exchange
- Recognize and deal with feeding problems early before they become well established
- Handle struggles over food reasonably to avoid the development of feeding problems

- Feed and hydrate children appropriately during illness
- Ensure that iron needs are met by food choices
- Ensure that the child learns to distinguish food and nonfood objects
- Limit screen time to two hours maximum for children older than 2 years.

School years

- Monitor growth in height and weight to monitor nutritional status
- Provide good examples and guidance to instill healthful habits and attitudes about food and eating
- Establish consistent guidelines and follow them to ensure adequate nutrition for the child's diet
- Promote healthy eating and physical activity if child's body weight is concerning
- Ensure that diet-related risks for dental caries are minimized
- Help the child to distinguish reliable sources of information on food choices and promotional messages
- Encourage moderation consumption of sodium, solid fats, saturated fat, and added sugar; encourage diet adequate in fiber
- Limit screen time to two hours maximum for children older than 2 years.

Adolescents

Puberty is a unique and complex developmental period marking the transition from childhood to adulthood. It is accompanied by a series of physical, physiologic, biochemical, hormonal, social, and psychological changes. Adolescence is a nutritionally vulnerable period for several reasons. A dramatic increase in physical growth occurs during puberty. The growth spurt is highly sensitive to nutrient deprivation. Inadequate nutrition during this time may delay or stunt linear growth. Alterations in body composition in puberty and during the consolidation that occurs in later adolescence, as maturity is reached, increase nutrient and energy needs. During the second decade of life, children gain about 20% of their adult height and 50% of their adult weight.[39] After puberty, although linear growth ceases, changes continue until maturity is reached. The larger body requires increased amounts of nutrients. Calcium is a nutrient of particular concern because bone growth and bone mass accumulate rapidly during this time of life. Osteoporosis is a disease that afflicts mostly the elderly, but just as is the case with atherosclerosis; its seeds are sown in childhood. One of the most effective ways to prevent osteoporosis is to build a strong, dense skeleton during the growing years to act as a reserve later in life.[40]

Moreover, the changes in individual behaviors and lifestyle preferences in younger children may last through adolescence and into adulthood, again contributing a lifetime of optimal bone health. An increasing attention is being paid to school programs that will increase bone accretion and muscular strength in children starting in early elementary school, aged 5–7 years, and continuing into adolescence. The interventions now being tested include weight-loading physical activity and calcium-rich snacks for children as well as age-appropriate, behaviorally focused active learning to promote skill building and self-competence while building bone quality and bone strength.

Growing independence, the need for peer acceptability, concern with appearance, and active lifestyles of adolescents often affect eating habits, food choices, nutrient intake, and thus nutrition status. Adolescents are seeking to establish their identity and are susceptible to peer pressure and mass media. They are also preoccupied with physical appearance and body shape and size. Desires to be lean and to have an attractive body, societal pressures, and an abundance of food in the environment can lead to inappropriate weight reduction, dietary aberrations, and nutrient deficiencies.[41] Chronic dieters are at high risk for inadequate diets. In adolescent females, such behavior may lead to eating disorders, such as anorexia nervosa and bulimia nervosa.[42,43]

Common nutritional problems in adolescents are provided in Table 16-9. They include obesity, hyperlipidemia, eating-related disorders, and hypertension.[41–43] These problems of dietary imbalance and excesses may coexist with undernutrition with respect to iron, energy, and other nutrients in some individuals. Dietary factors increasing the later risk for chronic diseases such as osteoporosis (inadequate intakes of calcium and vitamin D), heart disease (excessive intake of saturated fat and cholesterol and low intake of fiber), and some types of cancer may be present.[39,41,44] Table 16-10 provides recommendations to enhance nutritional status during adolescence.

TABLE 16-9 Current Nutritional Issues and Recommendations for Adolescents in the United States

Problem	Comments
Hypertension	Overweight Excessive sodium consumption Low potassium intake

Underweight	Undernutrition Anorexia nervosa Bulimia nervosa
Obesity	Excessive energy intake Sedentary lifestyle
Iron deficiency anemia	Malnutrition Inadequate dietary iron intake Pregnancy without iron supplementation
Nutrient deficiencies	Inadequate nutrient intakes Extended periods of dieting
Eating disorders	Societal pressure to be thin Peer pressure Diet fads
Alcohol and substance abuse	Peer pressure

Recommendations:

- Include nutrition guidelines for school-based nutrition education programs
- Increase nutrition education to parents and communities
- Improve training and continuing education for all health care providers in the area of nutrition
- Integrate nutrition screening, education, and intervention services into health services aimed at teenagers
- Expand school-based health clinics especially for teenagers who have no primary care
- Expand research on nutritional needs of adolescents
- Provide and promote social services for adolescents for behavioral and mental health

Pregnancy and lactation in adolescence also increase nutrition risk because the young female needs a supply of nutrients to support her own growth as well as the growth of the fetus and nutrition of the suckling infant.[45,46] Nutritional needs of pregnancy and lactation are discussed elsewhere in this book.

CURRENT NUTRITIONAL STATUS OF INFANTS, CHILDREN, AND ADOLESCENTS: CANADA

Table 16-11 summarizes nutritional issues of concern for children and youth in Canada. Factors that affect the nutritional status of children in Canada are similar to those in the United States. They include obesity, excess sodium intake, limited physical activity, and lack of fruit and

vegetable intake. Undernutrition, malnutrition, and food insecurity still occur in some Canadian children and youth, particularly among the poor. However, mean overall intakes of Canadian children between 1 and 8 years of age in recent surveys provided adequate amounts of most vitamins and minerals and appropriate proportions of energy from protein and carbohydrate.[47]

TABLE 16-10 Recommendations for Enhancing Nutritional Status of Adolescents in the United States

- Maintain normal healthy weights recommended. Avoid obesity and eating disorders by developing healthful attitudes toward food, appropriate energy intakes, and a physically active lifestyle, including both aerobic and strength-building exercise
- Abstain from self-induced vomiting, bulimia, and laxative abuse
- Eat a variety of foods to ensure dietary sufficiency of protective nutrients, including protein, vitamin, minerals, and fiber
- Identify dietary imbalances and avoid them by educating adolescents on moderate intake of fat, saturated fat, sugars, and salt
- Avoid alcohol and substance use
- Provide assistance on teenage pregnancy, diets for competitive athletes, diets for those with allergies and disease
- Ensure adequate intakes of calcium and vitamin D to maximize bone density

TABLE 16-11 Current Nutritional Issues of Children and Youth Canada

Problem	Comments
Obesity	BMI: 32% of Canadian children and youth aged 5–17 years were overweight or obese in 2009–2011 data.[70,71] Excess energy intake: One in five Canadian children have energy intakes exceeding their needs.[47]
Lack of fruit and vegetable intake	Only 49% of children and youth eat fruit and vegetables more than five times daily.[72] In 2011, 40% of Canadians aged 12 and older reported that they consumed fruit and vegetables five or more times per day.[73]
Excess sodium intake	More than 75% of 1–8 year olds had usual intake of sodium exceeding the upper limit set for their age group (1500–1900 mg/d).[47]

Limited physical activity	Increased screen time: Canadian children see more than 50 fast food commercials on television each month.[72] Sedentary time: Nearly 9 hours or 62% of waking hours is the average of the total daily sedentary time for Canadian children and youth. Sedentary time rises with increasing age.[74] Amount of physical activity: 7% of Canadian children and youth accumulate at least 60 minutes of moderate-to-vigorous activity at least 6 days a week.[74]
Undernutrition and food insecurity	10% of households with children are food insecure as a result of financial challenges faced in having access to adequate food.[70] Fewer servings of fruits, vegetables, and milk products were consumed by children and youth younger than 18 years, demonstrating constraints in food intake.[75]

NUTRITION FOR CHILDREN WITH SPECIAL NEEDS: THE UNITED STATES

Some of the most common nutritional issues of children with special needs are outlined in Table 16-12. Children with special health care needs make up approximately 10%–20% of the pediatric population, depending on the definition used.[48] The term special needs describes a group of infants, children, and youth with or at risk for physical or developmental disability or with a chronic medical condition caused by or associated with genetic/metabolic disorders, birth defects, prematurity, trauma, or infection (including HIV infection). They present a particular challenge to community nutritionists today because many children with special needs who were formerly institutionalized now dwell with their families in the community.

Table 16-13 provides some recommendations for enhancing the nutritional status of children with special needs. Some of the nutrition needs of children with special health care needs are unique (e.g., the child with a metabolic disorder controllable only by diet), but in most aspects, their nutritional needs are similar to those of other children. The child with "special needs" in the family is first of all a child who has the same nutrient needs for optimal health, growth, and development as any other child. Superimposed on these needs, however, may be multiple risks, ranging from social/environmental factors, such as decreased access to food because of limited finances, to factors involving disorders, such as feeding problems or the need for chronic medication.[49] These factors may place a child at risk for inadequate nutrient intake, impaired nutrient absorption or use, or increased nutrient excretion. Such insults, if they are

severe and/or prolonged, and especially if they occur early in life, can have lasting effects on the child's growth and cognitive development. Various handicapping conditions have different nutrition-related problems and needs.[50] These will be discussed in detail in Chapter 47.

TABLE 16-12 Current Nutritional Issues and Recommendations for Children With Special Needs in the United States

Problem	Comments
Growth retardation or underweight	Increased needs Inadequate intake caused by mechanical difficulties with chewing, swallowing, or feeding oneself and malabsorption
Obesity	Reduced resting metabolism Decreased energy expenditure Excessive energy intake
Gastrointestinal complications	Diet inadequate of fiber and water
Nutrient deficiencies	Inadequate intake of certain nutrients Lack of supplementation Increased nutrient needs Drug–nutrient interaction
Infections	Malnutrition
Lack of physical activity	Muscle wasting Overweight Suboptimal bone health and strength

Recommendations:

- Ensure that community programs for children with special needs are in place to screen and assess nutritional problems
- Implement use of standardized screening and referral tools for service providers
- Improve nutrition training of health professionals
- Increase nutrition counseling and education for families
- Develop nutrition and feeding guidelines for agencies responsible for the administration of health, social welfare, and related program services
- Enhance the research base for current issues in nutrition for children with special needs

An amendment (PL 99-457) to the Federal Education for the Handicapped Act gives nutrition professionals the opportunity to have a voice in establishing nutrition policy and standards of care for young

handicapped and high-risk children. Preventive services now extend to children as young as 3 years of age, and Part H of the law provides financial incentives for states to provide services to children with special health care needs from birth to 2 years of age. Nutrition should be included in these services.

TABLE 16-13 Recommendations for Enhancing Nutritional Status of Children With Special Needs in the United States

- Recognize that expectations for growth may be different; develop disease or condition-specific growth charts and guidelines
- Provide adequate nutrition to achieve optimal growth potential
- Consider the extra or lessened energy needs owing to the child's condition and adjust intake accordingly
- Use vitamin and mineral supplements if directed by physician
- Ensure adequate intake of fiber and water
- Consult an interdisciplinary team and develop specific care plan that includes feeding skill progression, appropriate physical activity, recognition of developmental readiness, and enrollment in early intervention programs
- Adjust feeding positioning to allow for adequate food intake, use appropriate nipples and feeding devices for children unable to use standard equipment, and adjust pace of feeding
- Determine family's need for food assistance, financial support, diet information, and emotional support

NUTRITION FOR CHILDREN WITH SPECIAL NEEDS: CANADA

The Canadian Paediatric Society's 2009 position paper on the nutritional status in children with neurological impairment, a group with high risks of problems in nutritional status, is summarized in Table 16-14. Approximately 3.7% of children and youth of ages of 0–14 years have disability in 2006 with a greater proportion of boys (4.6%) than girls (2.7%).[51] The nutritional status of children with special needs is difficult to assess because it varies from condition to condition, and few studies have been done.

EXISTING COMMUNITY NUTRITION PROGRAMS: THE UNITED STATES

Federal Programs

Either the USDA or the DHHS administers most federally funded food and/or nutrition programs for mothers and children. The programs are administered on the state level by the Department of Welfare, Department of Education, or Department of Health depending on their particular focus. One type of federal support is through benefits or cash assistance that goes directly to eligible recipients (such as the Supplemental Nutrition Assistance Program [SNAP], formerly called the Food Stamp program), which provides food vouchers or the School Lunch program that provides inexpensive or free meals). Another type is in-kind services (such as the USDA's Expanded Food and Nutrition Education Program [EFNEP], which provides nutrition education to low-income families).

TABLE 16-14 Key Points From the Canadian Pediatric Society's Paper: "Nutrition in Children With Neurological Impairment"

- A significant number of children with neurodevelopmental disabilities are undernourished. In particular, most children with cerebral palsy are undernourished. However, this is not the only problem; about 8%–14% of them are overweight.
- The causes of malnutrition include inadequate intake, increased losses, altered metabolism, oromotor dysfunction, specific syndromes, endocrine dysfunction, ethnicity, genetic potential, and associated factors such as pubertal status in these children.
- Frequent medical problems of these children include gastroesophageal reflux, pulmonary aspiration, and osteoporosis.
- Improvement of oral intake is crucial if it can be done safely. Oromotor therapy, adjustment of food consistency, and increase in food caloric density can be helpful.
- Multidisciplinary management is important in the nutritional care in children with neurological impairment.
- Careful monitoring of nutrition interventions is needed to avoid excess weight gain or any nutrient deficiencies, and of the need for enteral or parenteral nutrition.

Source: Marchand; Canadian Paediatric Society, Nutrition and Gastroenterology Committee.[76]

Means-tested programs require assessment of economic means or

income before one qualifies for them. They are special cash or in-kind services targeted to provide a safety net to protect children in low-income families. Eligibility for such programs, such as SNAP, Medicaid, general relief payments, Title V funded child health services, or free school lunch and breakfast under the National School Lunch and Breakfast Program legislation, is assessed by review of family incomes. These programs are valuable contributions for maintaining or improving the nutritional status of low-income families. Such families may have limited access or resources available to buy food, and those who are particularly vulnerable from the physiologic standpoint include infants, young children, and pregnant and lactating women.

Community nutrition services for families and children are also available as part of other health and social services, such as intensive infant care programs, services for handicapped children, dental health programs, family planning service, school health, and teenage pregnancy/parenting programs.

The federal government also provides grants for planning and service provisions to states for program development to provide food assistance, nutrition education, and counseling to eligible families at the local level through health centers, school systems, and community action agencies.

Health care providers need to know about the many food and nutrition programs available in their local areas and how and when to refer their patients to them.

USDA Programs

The USDA provides various public health programs at the community level. These include SNAP, School Lunch and Breakfast, Special Milk Program for Children, Child Care Food Program, Summer Food Service Program for Children, WIC, EFNEP, and Commodity Supplemental Food Program (CSFP). About one in every four Americans participates in at least one of these programs in 2011. These programs account for over two-third of USDA's budget in the fiscal year of 2011, totaling $103.3 billion.[52] Food pantries and soup kitchens are also available for some families that lack food. Surplus foods, both dry and perishable, are distributed to food pantries and soup kitchens. Table 16-15 presents a summary of current expenditures on these programs.

Supplemental Nutrition Assistance Program

What It Is

This is the largest and most far-reaching food assistance program for low-income families in the United States to help them buy the food they need for a nutritionally adequate diet. The amount provided is based on the USDA's Thrifty Food Plan, a market basket of suggested amounts of food that make up a nutritious diet and that can be purchased at a relatively low cost. The federal government pays for all benefits issued through the program and shares administrative costs with the states. Puerto Rico, American Samoa, and the Northern Mariana Islands receive cash grants instead under the Nutrition Assistance Program that permits them to provide food assistance programs for their low-income residents. SNAP is a means-tested entitlement program; any house-hold that meets program eligibility requirements may receive them. Households participating in the program actually receive their benefits by an electronic benefits transfer (EBT) card system rather than by stamps or coupons, as in days gone by. Benefits can be used to buy food but not alcohol, tobacco, medicines, or nonfood items such as soap or paper supplies. Nationally, the majority of all SNAP recipients are children, and the preponderance of SNAP benefits is paid to families with children.

Who Qualifies

For families with children, the principal eligibility requirement is that gross household income is below 130% of the federal poverty level and that net income, after various deductions, is at or below 100% of the poverty level. The value of a household's assets (e.g., cash on hand, checking or savings accounts, stocks and bonds, recreational boats and vehicles, some cars, and land that is owned but not inhabited by the household) is also accounted for in determining eligibility.

TABLE 16-15 Food and Nutrition Assistance Program Costs, USDA (Fiscal 2010)

Assistance Program	Program Cost, 2010 ($ Millions)
Food-assistance related programs	
Supplemental Nutrition Assistance Program	68,180
Nutrition Assistance Program for Puerto Rico, American Samoa and the Northern Marianas	2049
Child nutrition programs	
National School Lunch Program	10,458

School Breakfast Program	2843
Child and Adult Care Food Program	2634
Summer Food Service Program	357
Special Milk Program	12
Supplemental food programs	
WIC	6757
Commodity Supplement Food Program	203
Food donation programs	
Food Distribution on Indian Reservations Disaster Feeding Program	93
The Emergency Food Assistance Program	468

Abbreviation: WIC, Special Supplemental Nutrition Program for Women, Infants, and Children.

How to Enroll

Contact the state or local welfare office and obtain an application.

Child and Adult Care Food Program

What It Is

This program provides cash reimbursement and/or commodities for the provision of meals and snacks to institutions such as child care centers and family and group daycare homes providing nonresidential child care to children from low-income families. This program funds the meals provided in Head Start. This is not an entitlement program. Subsidies are approved to provide two meals and one snack per day for children younger than 12 years in independent centers and sponsoring organizations. Children and youth (18 years or younger) are eligible for free meals and snacks if they are in the "at-risk" afterschool care programs. Meals must meet USDA-specified requirements. Family or group daycare homes are paid a fixed reimbursement, depending on the type of meals served. Daycare centers are reimbursed for meals at rates depending on the type of meal and eligibility of children for free, reduced-price, or paid meals.

Who Qualifies

Institutions eligible to participate include child care centers, settlement houses, neighborhood and Head Start centers, and institutions providing day care for the handicapped and their families or group daycare homes. Private daycare centers can participate only when at least 25% of their

enrolled children are from low-income families receiving benefits through Title XX of the Social Services Act.

How to Enroll

Contact your local state agency, the local school authority, or child care center.

School Lunch and School Breakfast Programs

What They Are

Over 90% of all schools in the United States participate in the National School Lunch Program. They receive cash assistance to help purchase food and pay labor costs as well as direct donations of agricultural food commodities. Participating schools must agree to serve meals at a reduced price or free to children who are unable to pay the locally established full price. The federal reimbursement level is such that all meals fed to children receive some subsidies, but they are largest for the poorest children, who receive meals free. To receive a free or reduced-price meal, means tests are required. Each year, the Secretary of Agriculture issues uniform national standards for free and reduced-price meal eligibility based on national poverty guidelines.

To ensure that the nutrition goals of the National School Lunch and Breakfast programs are met, minimum meal pattern requirements are specified, and the USDA periodically updates these. USDA updated the program's meal pattern and nutritional standards based on the latest *Dietary Guidelines for Americans*, which was passed by Congress in the Healthy, Hunger-Free Kids Act of 2010. Table 16-16 outlines the updated breakfast and lunch meal patterns. The new meal pattern goes into effect starting in school years of 2012–2014. There is an increased amount of vegetables, fruits, and whole grains in the menu. Age-appropriate calorie limits are set for grades K-5, 6-8, and 9-12. In addition, sodium content in meals will be gradually decreased, with target goals to be reached by 2023.

Who Qualifies

Any public or nonprofit private school of high school grade or under is eligible. Public and licensed nonprofit private residential child care institutions such as orphanages, homes for retarded children, juvenile detention centers, and temporary shelters for run-away children are also eligible.

TABLE 16-16 USDA Updated Meal Patterns and Dietary Specifications for School Meals in the United States

Meal Pattern	Breakfast Meal Pattern			Lunch Meal Pattern		
	Grades K–5	Grades 6–8	Grades 9–12	Grades K–5	Grades 6–8	Grades 9–12

How to Enroll

Contact the local school authority.

Special Milk Program for Children

What It Is

This program reduces the cost of each half-pint of milk served to children by providing for cash reimbursement at an annually adjusted rate to public and nonprofit schools, child care centers, summer camps, and similar institutions that do not participate in any other federally assisted nutrition program. Participants can choose to provide milk free or at low cost to all children or may elect to serve free milk to children whose families are below 130% of poverty. Schools and institutions can offer only pasteurized fat-free or low-fat (1%) fluid milk; all milk should contain standard levels of fortification of vitamin A and D (vitamin A: 6000 IU per quart; vitamin D: 800 IU per quart) established by the Food and Drug

Administration.

Who Qualifies

This program is available only to institutions that do not participate in the National School Lunch, School Breakfast, or Commodity Programs.

How to Enroll

Contact the local school authority.

Summer Food Service Program for Children

What It Is

This program provides nutritious meals for preschool and school-aged children younger than 18 years in recreation centers or summer camps, during vacations in areas operating under a continuous school calendar, or in areas with poor economic conditions. Meals are served free and must meet the minimum standards established by the USDA.

Who Qualifies

Sponsors of the program must be public or private–nonprofit school food authorities; state, local municipal, or county governments; or public, private–nonprofit residential summer camps. The programs must be in areas where at least half of the children are from households with incomes at or below 185% of federal poverty guidelines; there is no income test for eligibility in these low-income areas, and any child in the program may participate. Other programs that contain at least half of children from families at or below 185% of the federal poverty guidelines may also provide food to all children in the program. Individual children in these programs may participate without regard to their family's income, and they may receive as many as two meals and two snacks per day. The USDA reimburses sponsors of the program.

How to Enroll

Contact the local school authority.

Women, Infants, and Children

What It Is

Since its inception in 1972, the WIC program grew from $20 million to more than $7 billion yearly in authorized funds. The USDA provides annual cash grants to state health departments or comparable agencies on

the basis of a formula that considers food costs and administrative costs. The program is very large, but it is not an entitlement program; rather, it is a grant program with funding limits that are set annually. Participation is an option for states and localities, but today it is available in virtually all parts of the country.

The WIC program differs from all other federal food assistance programs in its close association with health care services and inclusion of food, health, and nutrition education services together.[53,54] These services are defined as ongoing, routine pediatric and obstetric care. Health care itself, other than screening and limited assessment and care provided by WIC, must be supported by state, local public, and private–nonprofit health or human service agencies as well as the private sector. The amount and kind of health services provided to WIC recipients vary from state to state and locally.

The benefits of the program include checks or vouchers or EBT (all WIC state agencies are required to implement the EBT by October 2020) for the purchase of specific foods tailored to the dietary needs of infants, children, and pregnant or postpartum women. Physicians or health professionals may also prescribe special infant formulas and certain medical foods for WIC participants with special medical conditions. In addition to food, WIC also provides referrals to health and social services, including prenatal care, and nutrition counseling and education sessions. In addition, many pregnant women gain initial access to prenatal care via their WIC screening. Efforts are made to adapt the education activities to the individual participant's nutritional needs, cultural preferences, and education levels. Approximately 76% of the current participants are children ranging in age from newborn to 5 years.

Who Qualifies

Low-income pregnant and postpartum women, lactating mothers, infants, and children up to 5 years who are determined to be at nutritional risk by a health professional are eligible if they fall below 185% of federal poverty guidelines. Automatic eligibility is offered for anyone who participates or has family members participating in other benefit programs, such as SNAP and Medicaid. The criteria for nutritional risk include the following: dietary risk, anthropometric risk (e.g., overweight, underweight), biochemical risk (e.g., low hematocrit), and medical risk (e.g., diabetes mellitus) and other factors such as homelessness. A priority system is in place that categorizes participants on the basis of severity of potential effects and outcomes so that those at highest risk are served first.

Participants must be recertified every 6 months to continue receiving benefits.

How to Enroll

To obtain WIC benefits, an individual must apply at a WIC clinic.

WIC's Farmers' Market Nutrition Program

What It Is

This program is associated with WIC. It aims to provide fresh, nutritious and locally grown fruits and vegetables through farmers' markets and roadside stands to WIC participants. In addition to their regular WIC benefits, eligible WIC participants are given Farmers' Market Nutrition Program (FMNP) checks or coupons. These checks or coupons are used to buy eligible foods from farmers at farmers' markets and/or roadside stands that are approved by state agency to accept FMNP coupons. Nutrition education about how to select, store, and prepare fresh fruits and vegetables is provided to FMNP recipients by state agency through local WIC agency.

Who Qualifies

Women, infants over 4 months old, and children who are certified to receive WIC program benefits or who are on a waiting list for WIC certification are eligible.

How to Enroll

Contact your local WIC agency or your FMNP contact person for each state agency. A list of state contacts can be found at http://www.fns.usda.gov/wic/Contacts/farm.HTM.

Commodity Supplemental Food Program

What It Is

This in-kind program provides food and is available at local option in several states. Providing commodity supplemental foods and nutrition education to participants, the CSFP is designed to supplement their diets with nutritious foods. The foods supplied by CSFP are different from WIC foods in their variety (i.e., they consist of canned meat or poultry and canned vegetables). CSFP distributes food rather than vouchers for redemption at the grocery store. Also, the provision of health care to recipients is encouraged but not mandated, unless it was already in

existence prior to 1978. Simultaneous participation in WIC and CSFP is prohibited. The supplemental foods (usually surplus agricultural commodities) are distributed to state agencies, Indian tribes, or groups responsible for administering the program. Each state selects local, private, nonprofit agencies to administer the program at the local level. Local agencies determine the eligibility of applicants, distribute the supplemental foods, and provide nutrition education. Federal funds provide for some of the administrative costs such as outreach, warehousing of food, and transportation to obtain food if necessary.

Who Qualifies

Low-income pregnant, lactating, and postpartum women, infants, and children up to 6 years old are eligible. Women, infants, and children who are below 185% of federal poverty levels and *not* participating WIC are qualified.

How to Enroll

Contact your CSFP State Distributing Agency. A list of state contacts can be found at www.fns.usda.gov/fdd/contacts/sdacontacts.htm.

Expanded Food and Nutrition Education Program

What It Is

This program provides instruction in basic food and nutrition-related topics to low-income families and individuals and is operated through the state cooperative extension service. It is not an entitlement program. Its aim is to develop understanding and awareness through a variety of methods, including direct teaching by nutrition assistants in existing groups (such as employment and training programs and shelters for homeless families), cluster groups consisting of two to five participants, one-on-one home visits, mailings, telephone, and mass media efforts.

EFNEP teaches participants how to plan for daily food needs; prepare nutritious, low-cost meals that meet the daily recommended dietary allowances (RDAs) of nutrients; select and buy food economically; and effectively use other supplemental programs available, such as SNAP, WIC, School Meal Programs, and CSFP.

Who Qualifies

Families with children younger than 19 years, pregnant women, and individuals who are responsible for purchasing and preparing foods (such

as special needs adults, teens living independently) are eligible. To qualify, applicants must have income at or below 185% of federal poverty guidelines.

How to Enroll

Look for state or regional EFNEP contacts on http://www.extension.purdue.edu/cfs/topics/EFNEP/national_efnep/directo

Food Distribution Program on Indian Reservations

What It Is

This program provides commodities to low-income households on participating reservations and to Native American families living in designated areas near reservations. This is an alternative to the SNAP program for American Indians who do not have easy access to food stores. Participants receive a monthly food package containing a variety of foods to meet their health needs and preferences.

Who Qualifies

Program eligibility is based on a person's household income, assets, and residence on or near a reservation, or in Oklahoma (since most native Americans live in that state) that contain at least one person who is a member of a federally recognized tribe. Households may not participate in Food Distribution Program on Indian Reservations (FDPIR) and SNAP in the same month.

How to Enroll

Contact your local Indian Tribal Organization or the Food and Nutrition Service (FNS) Regional Office in your area for further assistance. The FDPIR contacts that administer this program can be found at http://www.fns.usda.gov/fdd/contacts/fdpir-contacts.htm.

The Emergency Food Assistance Program

What It Is

First started as a way to reduce inventories and storage costs of surplus commodities by distributing them to needy households, it now also includes funds appropriated by Congress to purchase additional commodities. The USDA buys the food, processes and packages it, and ships it to the states based on a formula that takes into account the number of people below the poverty level and the number unemployed.

Who Qualifies

States set their own eligibility criteria and select emergency feeding organizations such as soup kitchens, food recovery organizations, and food banks to distribute the food.

Fresh Fruit and Vegetable Program

What It Is

Fresh Fruit and Vegetable Program (FFVP) provides all students in selected elementary schools with healthy fresh fruits and vegetables of reduced price or free. The aim of this program is to introduce school children to a variety of produce and educate them with healthy eating habits. Established in 2002 as a pilot program, FFVP is now available in selected schools nationwide.

Who Qualifies

To be selected for the FFVP, a school must be an elementary school, represent the highest percentages of students certified for free and reduced price benefits, participate in the National School Lunch Program, and complete an annual application.

How to Enroll

Contact your state agency to obtain an application package.

DHHS Programs

The US DHHS provides a wide variety of public health programs at the community level, as well as payments for health services. The public health programs include the Head Start and EI programs. In addition, limited monies are provided for nutrition services such as assessment and counseling. Title V of the Social Security Act of 1935 authorized grants to states to plan for provision of comprehensive health services to mothers and children. In subsequent years, funding of categorical programs provided monies for planning and provision of special services, such as lead poisoning prevention, services for handicapped children, and family planning. Monies for planning such programs are provided from federal funds by the DHHS. Demonstration grant funds have also been available on an increasingly limited basis over the past few decades for high-risk communities and groups. The comprehensive services include medical and dental care, nursing, nutrition, and social work. The American Recovery and Reinvestment Act of 2009 (Recovery Act) provides Recovery Act

funds that aim to improve health and human services.[55]

Head Start

What It Is

This program is particularly well known for its multifaceted approach to child health and development, including social and educational development. Administered by DHHS and funded directly to local agencies, Head Start provides low-income preschoolers and their families with day care, access to medical care and social services, and nutrition services, including meals, nutrition education, and staff training.

Head Start programs are now funded through grants from the Recovery Act and Consolidated Appropriations Act of 2012. These grants are awarded to a variety of local public agencies, private–nonprofit organizations, and public school systems. The program is very large but not an entitlement. It is at the discretion of states and localities and serves primarily children from poor families.

Head Start programs serve a multiracial, multiethnic group of low-income children and families. Each program must offer four major components: education, social services, parent involvement, and health services. With the goal of meeting each child's individual needs, the program offers a wide variety of learning experiences aimed at fostering intellectual, social, and emotional growth. Head Start also aims to meet the ethnic and cultural characteristics of the communities served.

Head Start's nutrition program is part of the health component offered and provides nutritious meals from the Child Care Food Program, as well as nutrition education for children, staff, and parents.

Who Qualifies

To be eligible for Head Start, a child must be between 3 and 5 years of age and come from a low-income family whose total annual income does not exceed 100% of the federal poverty guideline or who is receiving public assistance from programs such as Temporary Assistance for Needy Families (TANF) or Social Security's Supplemental Security Income Program.

How to Enroll

Contact the office of Head Start is located in the Administration for Children and Families, DHHS.

Head Start for Children With Special Needs

What It Is

Head Start is the largest provider in this country of services for preschool children with handicapping conditions.

Who Qualifies

It is mandated to serve preschool children who have a broad range of handicaps. Children with severe or multiple handicapping conditions present additional challenges to Head Start staff in the planning and provision of individual services. Program requirements call for individualized plans for special education, treatment, and related services for all children with handicapping conditions served by Head Start. These plans must be based on the child's specific handicapping conditions, as well as the unique needs arising from those conditions.

How to Enroll

Contact the Office of Head Start, which is located in the Administration for Children, Youth, and Families, DHHS.

Early Intervention Programs and Services

What It Is and Who Qualifies

EI programs and services for infants, toddlers, and their families have existed in many areas of the United States for more than 25 years. These services are organized to address the developmental needs of young children between birth and 3 years of age who may be at risk for poor developmental outcome because of an identified disability or because of biologic or environmental risk factors.[56,57] Although all these programs share the common goal of optimal infant development, they approach it in different ways. That is why collaboration is essential in the development of an Individual Family Service Plan, which addresses all of the child's needs that must be met for the child's potential to be reached. Some EI programs are home-based models, others are center-based models, and others are a combination of those two approaches. Intervention programs also differ with respect to their program philosophy and goals, the population that is served, team composition, program content, and program evaluation. Services are generally multidisciplinary, in recognition of the interrelationship of development in various domains, and may include input by developmental educators, occupational and physical therapists, speech pathologists, psychologists, nurses, dietitians, and social workers.

Federal law significantly influences the development of EI programs. The most applicable law, enacted in 1986, is Title I, Part H, Handicapped Infants and Toddlers, of PL 99-457, Education of the Handicapped Amendments of 1986. That law extends public education to children aged 3 years and older and provides incentives to states to serve children with special needs from birth onward. It includes nutrition as one of eight disciplines to be included on the team providing services to these handicapped infants and their families.

Part H of PL 99-457 requires that services designed for children from birth through 36 months meet their developmental needs. It mandates psychological services, parent and family training and counseling, transition services, diagnostic medical services, case management, and health services that will enable the child to benefit from other EIs. The eight disciplines specified by PL 99-457 include special education, nursing, nutrition, psychology, physical therapy, occupational therapy, speech-language pathology, and social work. This law provides great opportunities for nutrition intervention in preschool children with handicapping conditions and their families. To date, however, most states have done little to develop community-wide networks to provide EI services that include nutrition.

How to Enroll

Visit the National Early Childhood Technical Assistance Center for more information about EI in your state: http://www.nectac.org/contact/ptccoord.asp.

"Let's Move" Child Care

What It Is

"Let's Move!" is an initiative launched by the First Lady, Michelle Obama in 2010. Its aim is to tackle the problems associated with childhood obesity through comprehensive approach. Let's Move Child Care is one of the programs under this initiative. There are five main goals in this program: (1) at least one hour of physical activity throughout the day; (2) no screen time for children younger than 2 years; (3) serve fruits and vegetables at every meal and provide no fried foods; (4) provide access to water during meals and no sugar-sweetened beverages; and (5) promote breastfeeding. Participants will receive certificates, updated resources on promoting children's health and be able to create an Action Plan to reach specific goals.

Who Qualifies

Anyone who is a parent or early care and education provider is eligible.

How to Enroll

To sign up, go to http://www.healthykidshealthyfuture.org/content/hkhf/home/startearly/sign

Maternity Group Homes for Pregnant and Parenting Youth Program

What It is

This program provides support for homeless pregnant and/or parenting young people, as well as their dependent children. Services provided include accommodations, life-building skills education, job assistance, education opportunities, health care and any related resources. The Family and Youth Services Bureau funds Maternity Group Homes for Pregnant and Parenting Youth Program as part of the Transitional Living Program, under the provisions of the Reconnecting Homeless Youth Act of 2008 (Public Law 110-378).

Who Qualifies

Homeless pregnant and/or young people aged between 16 and 22 years and their dependent children are eligible. Services are provided for dependent children up to 21 months or until a young person turns 18 years.

How to Enroll

Contact your regional grantee programs under Family and Youth Services Bureau at http://www.acf.hhs.gov/programs/fysb/resource/fysb-grantee-map.

STATE AND LOCAL PROGRAMS: THE UNITED STATES

There is a great deal of variability between states and localities in the extent to which they supplement federal nutrition funds or provide additional in-kind resources, such as health services. These variations make it essential for community nutritionists to know the specifics of state and local programs in their areas.

EXISTING PROGRAMS: CANADA

Federal Programs

Health Canada

Health Canada is the federal department responsible for the health of the Canadians. It offers evidence-based guidelines, research funding, and health promotion and education for citizens and residents in Canada. Table 16-17 summarizes the existing community nutrition programs for Canadian children under the regulation and monitoring of Health Canada.

Division of Childhood and Adolescence Under Public Health Agency of Canada

The Public Health Agency of Canada is another important institution in Canadian nutrition. It is the major federal public health agency which promotes and protects the health of Canadians through various public health measures. It provides relevant statistics on the incidence of child abuse and general trends related to child and youth health. Table 16-18 summarizes the community nutrition programs for Canadian children under the Public Health Agency of Canada.

Provincial and Community Programs

There are 10 provinces in Canada: Ontario, British Columbia, Manitoba, Saskatchewan, Alberta, Quebec, New Brunswick, Nova Scotia, Prince Edward Island, and Newfoundland and Labrador. Each province has jurisdiction power over many public goods, such as health care, education, welfare, and intraprovincial transportation. Canada also has three territories in addition to provinces: Northwest Territories, Yukon, and Nunavut. The territories have delegated powers directly under the Parliament of Canada (federal government). With different characteristics among the provinces and local communities, each has developed a different version of a similar program. In addition, each province may develop its own policies and guidelines. One example is the school nutrition program. Currently, there is no national school nutrition program in Canada.[58] Provincial government and organizations provide meals or funding to support giving nutritious food to Canadian children. Table 16-19 summarizes the provincial and community efforts on school foods.

WEB-BASED RESOURCES FOR COMMUNITY

NUTRITION: THE UNITED STATES

The US DHHS has developed a number of web-based resources that may be helpful in planning community nutrition efforts. Many nutrition resources not specified in this chapter are listed at http://www.nutrition.gov. The gateway to reliable consumer health information on the Internet is provided at http://www.healthfinder.gov. Healthy People 2020–related materials include a general description of the initiative, which is available at http://www.healthypeople.gov/2020/default.aspx. Information on TANF is available at http://www.neighborhoodlaw.org/aprimer.htm. The Healthy People 2020 Consortium Toolkit, which helps Consortium members in understanding, implementing, and marketing Healthy People, is available at http://healthypeople.gov/2020/consortium/hpConsortium.aspx.

TABLE 16-17 Community Nutrition Programs for Canadian Children Sponsored by Health Canada

Canada Prenatal Nutrition Program (in collaboration with Public Health Agency of Canada)	It is a community-based program that offers support to improve health and well-being of pregnant women, new mothers, and their babies. This program is run on provincial and territorial levels, which allows more flexibility and specificity for regional needs. Main objectives of the program include increasing the rate of breastfeeding initiation and decreasing the rate of unhealthy birth weights. Program details can be accessed at http://www.phac-aspc.gc.ca/hp-ps/dca-dea/prog-ini/cpnp-pcnp/index-eng.php.
Nutrition North Canada	This is a food subsidy program that aims to improve access of perishable healthy food to people living in isolated northern communities in the provinces. Country foods (traditional foods for the First Nations, Métis and Inuits) are also included in the subsidies. This program also funds retail and community-based nutrition education initiatives to increase knowledge and skills on selecting and preparing foods to promote healthy eating. For more information, go to their website at http://www.nutritionnorthcanada.ca/mr/fs_trns-eng.asp.
Canadian Hypertension Education Program	This program is run by Hypertension Canada. It is not a direct community nutrition program, but it targets educating health professionals in both clinical and community settings for treating hypertension, which in turn can educate the public. Education materials and evidenced-based guidelines are developed and can be accessed at http://www.hypertension.ca/education.

TABLE 16-18 Community Nutrition Programs for Canadian Children Directed by the Public Health Agency of Canada

Institution	Comments
Aboriginal Head Start in Urban and Northern Communities	This program focuses on the early development of children in the First Nations, Inuit and Métis. In terms of nutrition, the program ensures that children are provided with essential nutrients, fed at appropriate times, met the nutritional needs by the Aboriginal Food Guide, and educated about the nutritious and healthy eating habits. For more information, visit their website at http://www.phac-aspc.gc.ca/hp-ps/dca-dea/publications/ahsuni-papairun/index-eng.php#a17.
Community Action Program for Children	This program provides long-term funding to coalitions and groups that create programs that promote the healthy development of young children (<6 years old). It is managed at provincial and territorial levels to allow more flexibility. Local CAPC sites will provide locations for families to connect with their local communities and obtain information about access to public health and social services. These include family resources, parenting education, parent/child support groups, home visiting, nutrition education, and so forth. The website is at http://www.phac-aspc.gc.ca/hp-ps/dca-dea/prog-ini/capc-pace/index-eng.php.
Centre of Excellence for Children's Well Being	It provides resources, information, and tools to improve the health of children and youth in Canada. In addition, it collects and analyzes health information and data. It also conducts focus-oriented researches and generates education resources to the public. Moreover, it helps to build local, national, and international networks that involved in children's well-being. More resources can be found at http://www.phac-aspc.gc.ca/hp-ps/dca-dea/publications/centres-program/index-eng.php.
Fetal Alcohol Spectrum Disorder Initiative	This initiative aims to prevent fetal alcohol spectrum disorder and improve the outcomes for individuals with the condition and their families. It also contributes to the development of the Low-Risk Alcohol Drinking Guidelines, which can be found at http://www.ccsa.ca/eng/priorities/alcohol/canada-low-risk-alcohol-drinking-guidelines/Pages/default.aspx. More resources can be found at http://www.phac-aspc.gc.ca/hp-ps/dca-dea/prog-ini/fasd-etcaf/index-eng.php.
Pan-Canadian Joint Consortium School Health	It facilitates the development of knowledge, leadership, and capacity building that supports comprehensive school health. The website is at http://www.jcsh-cces.ca/.

TABLE 16-19 Provincial and Community Efforts on Canadian School Nutrition Program

Province or Community	Comments
Ontario	Ontario Student Nutrition Program has 14 regional and multiple local offices located throughout the province. The funding comes from the Ontario Ministry of Children and Youth Services and aims to provide students with breakfast, lunch, and snacks. Also, its guidelines are in alignment with the Canada's Food Guide.
British Columbia	School Meal and School Nutrition Programs include breakfast, lunch, and snack programs, which are funded under the British Columbia Ministry of Education.
Manitoba	Child Nutrition Council of Manitoba provides funding to schools for nourishment programs and education resources.
Saskatchewan	Multiple efforts are providing funding to schools in Saskatchewan. • Government of Saskatchewan offers school nutrition programs for children enrolled in Community schools. • Child Hunger and Education Program supports the provision of meals for children in community centers and schools.
Alberta	E4C provides School Lunch Program and School Snack Program to schools with demanding needs in the Edmonton area.
Quebec	Club des petit dejeuners du Quebec under Government of Quebec provides school breakfast to those who are enrolled in the Club.
New Brunswick	The Department of Education has the Healthy Minds School Nutrition Program which sets standards for school nutrition policies and guidelines for school lunch programs.
Nova Scotia	Nova Scotia Departments of Education, Health Promotion and Protection develops provincial breakfast program standards with Breakfast for Learning Canada and funds the school breakfast programs.
Prince Edward Island	Department of Health provided Prince Edward Island Eating Alliance with funding for school breakfast and snack programs for three years. PEI Eating Alliance has also developed school nutrition policies that are adopted province-wide.
Newfoundland and Labrador	Kids Eat Smart Foundation supports children with nutrition through Kids Eat Smart Clubs, which are nutrition programs run by volunteers at schools and community centers. Around 20,000 children participate in this program.
Breakfast for	It is a largest national charity which operates in all 10 provinces

Learning Canada	to support school breakfast, lunch, and snacks program. In 2011, it provided meals and snacks to over 400,000 children in Canada.
Breakfast Clubs of Canada	It is a nonprofit organization that offers services and funding to school breakfast programs in Canada. They also provide breakfast programs in the Aboriginal communities.

Several websites focus on physical activity and health. The President's Council on Fitness, Sports, and Nutrition is available at http://www.fitness.gov. Tips for promoting better health for young people through physical activity and sports are provided at http://www.cdc.gov/healthyyouth/npao/publications.htm. For obesity prevention, see http://www.cdc.gov/youthcampaign/. For Let's Move campaign, see http://www.letsmove.gov/.

The USDA provides several websites to improve access to food stamp and food program–related nutrition resources for assisting community nutrition effort.

All USDA websites are available at the National Agricultural Library's homepage: http:/www.nal.usda.gov. Some specific websites include the following:

- *The Food and Nutrition Information Center* is a large, web-based information center backed up with trained nutritionists who can help in locating information and borrowing additional resources from the collection of the National Agricultural Library. Access it at http://fnic.nal.usda.gov/.
- *The SNAP-Ed Connection* is an online resource center for state and local SNAP-Ed providers. It provides professional resources for training and continuing education for educators and offers educational materials developed for SNAP participants. These materials are available at http://snap.nal.usda.gov/.
- The *WIC* program has a website that provides publications on recent studies and educational materials. It is located at http://www.fns.usda.gov/wic/publications.htm.
- *The Healthy School Meals Resource System* is an online resource center for Team Nutrition, which is an initiative of the USDA Food and Nutrition Service to support child nutrition programs through training and technical assistance for personnel working in food service, nutrition education, and school and community health areas. It offers training and educational materials for these personnel. Access it at http://healthymeals.nal.usda.gov/.

- *The Dietary Guidelines for Americans* are available at http://health.gov/dietaryguidelines/. Possible implications for US agriculture from adopting the Dietary Guidelines can be assessed at http://www.ers.usda.gov/media/870329/err31_reportsummary.pdf.
- *CDC's Communities Putting Prevention to Work* has an online resource center for different areas of preventative health work, including tobacco, obesity, nutrition, physical activity, schools, and foundational skills: http://www.cdc.gov/CommunitiesPuttingPreventiontoWork/resources/ir
- *Public Health Workforce* has an online database for nutrition-related resources. It can be assessed at http://phpartners.org/nutrition.html.

RESOURCES FOR COMMUNITY NUTRITION: CANADA

Table 16-20 summarizes the current food and nutrition guidelines in Canada. They include food guides based on nutrient standards and are available on the Internet. Table 16-21 provides some community nutrition resources for Canadian children, including the websites for the major agencies and journals.

LESSONS LEARNED FROM COMMUNITY NUTRITION EFFORTS

Community Investments in Child Health and Nutrition Make Sense

As early as the fourth century BC, the philosopher Plato stressed the importance of investing in children from an early age. Several millennia later, numerous studies confirm Plato's suppositions about the importance of investing in our children.[59] For example, supplementing the diets of pregnant women and infants and immunizing children against early childhood diseases save lives and improve health. It is to be hoped that, in the future, programs such as Head Start, EI, and WIC, with demonstrated success in strengthening the bodies and minds of children, will reach more of their target populations. Also, special attention must be paid to nutrition for children with special needs and other chronic health problems. Current programs do not cover them adequately.

TABLE 16-20 Current Food and Nutrition Guidelines in Canada	
Publication	**Comments**
Canada's Food Guide (Health Canada)	Canada's Food Guide is the most recent guidelines for food and nutrition intake, which can be accessible at http://www.hc-sc.gc.ca/fn-an/food-guide-aliment/context/evid-fond-eng.php. The food guide's goal is to assist the people of Canada in making food choices that promote health and reduce the risk of nutrition-related chronic disease. Development of the food intake pattern was built on findings from reviewing previous Food Guides. The nutrient standards and assessment methods are based on Health Canada/US IOM DRI reports.
Eating Well with Canada's Food Guide—First Nations, Inuit and Métis (Health Canada)	Based on Canada's Food Guide, this tailored food guide is for the First Nations, Inuit and Métis and includes both traditional and store-bought foods. It shows pictures of store-bought foods that are generally available in rural and remote locations and provides unique images and content developed for Aboriginal populations. The Eating Well with Canada's Food Guide—First Nations, Inuit and Métis can be accessed at http://www.hc-sc.gc.ca/fn-an/alt_formats/fnihb-dgspni/pdf/pubs/fnim-pnim/2007_fnim-pnim_food-guide-aliment-eng.pdf.
DRI (Health Canada in collaboration with IOM)	The DRI contains reference nutrient values that are the basis of food and nutrition guidelines in both the United States and Canada. These reference values are specific for age, gender and life stages. The DRI include adequate intake amounts (RDA) and UL for different nutrients and can be accessed at http://www.iom.edu/Activities/Nutrition/SummaryDRIs/DRI-Tables.aspx.
Nutrition for Healthy Term Infants: Recommendations from Birth to 6 Months	The guidelines offer evidence-based recommendations for health care professionals on infant nutrition from birth to 6 months. Breastfeeding and having adequate amounts of specific nutrients are emphasized. The recommendations can be accessed at http://www.hc-sc.gc.ca/fn-an/nutrition/infant-nourisson/recom/index-eng.php.

Abbreviation: DRI, Dietary Reference Intakes; UL, upper levels

Table 16-15 shows current federal spending for a number of key health and food programs involving children.

Community Health and Children's Health Care Must Be Equal Partners

Community health and nutrition efforts expand the traditional focus of direct health services. Both are necessary to ensure child and family health. Also, broader economic factors that affect food insecurity must be

dealt with.[60] The distinctions between traditional public health and personal health services are slowly blurring in this country. In the future, community nutrition concerns will need to be incorporated into both systems. There is the danger that nutrition will "fall through the cracks" because there are other pressing needs. Thus, it behooves all of those who are interested in the health of children to pay attention to ensure that federal, state, and local governments employ nutritionists to look after community needs in nutrition. These professionals must work with others in health, welfare, education, and food agencies in the public and private sectors to ensure that all children are well nourished. At the same time, dietary concerns must be increasingly incorporated into personal health services. Only when these steps are taken will community nutrition realize its potential to have a positive impact on children.

TABLE 16-21 Community Nutrition Resources for Canadian Children

Public Health Agency of Canada	It promotes and protects the health of Canadians through various publi and provides relevant statistics on the incidence of child abuse and ger to child and youth health. More specific information can be found, unde Health" at http://www.phac-aspc.gc.ca/hp-ps/index-eng.php#ch.
Health Canada	Health Canada's website provides specific links to Canada's Food Guic information about Canadians' food consumption and nutrient intake, gu nutrition labeling, and promotional information on infant feeding. Some follows: • Canada's Food Guide: http://www.hc-sc.gc.ca/fn-an/food-gu eng.php • Food and Nutrition Surveillance: http://www.hc-sc.gc.ca/fr eng.php • Nutrition Labeling: http://www.hc-sc.gc.ca/fn-an/label-etiqu eng.php • Infant feeding: http://www.hc-sc.gc.ca/fn-an/nutrition/infan eng.php
Canadian Journal of Public Health	Published by the Canadian Public Health Association, this is a professi reviewed journal carrying articles related to various components of pub epidemiology, nutrition, family health, public policy, etc. This can be ac http://journal.cpha.ca/index.php/cjph.
Dietitians of Canada (DC)	The national professional association for dietitians in Canada. Nutrition educational materials for the public are available on its website. There i on the website for Registered Dietitians in Canada which provides reso continued education, literature reviews, practice guidelines, and career This is accessible at http://www.dietitians.ca/.

Provincial Ministries of Health	Each province in Canada has its own Ministry of Health (the title of the differ) with the aim of establishing a sustainable provincial health syste legislation and policies and monitoring the health of provincial residents summarizing the programs and resources in the province. Websites for Health for each province are as follows: • Ontario: http://www.health.gov.on.ca/en/ • British Columbia: http://www.gov.bc.ca/health/ • Manitoba: http://www.gov.mb.ca/health/ • Saskatchewan: http://www.health.gov.sk.ca/ • Alberta: http://www.health.alberta.ca/ • Quebec: http://www.msss.gouv.qc.ca/en/ • New Brunswick: http://www.gnb.ca/0051/index-e.asp • Nova Scotia: http://novascotia.ca/dhw/ • Prince Edward Island: http://www.gov.pe.ca/health/ • Newfoundland and Labrador: http://www.health.gov.nl.ca/health
Canadian Paediatric Society	A national association of pediatricians in Canada with the mission of pr promoting the health and well-being of children and youth. It issues pra and clinical tools and runs several programs—some along with the fede which include Neonatal Resuscitation Program, Canadian Paediatric Su Program, and IMPACT (a vaccine surveillance program). For more info website http://www.cps.ca/en/.
Canadian Diabetes Association	This association helps patients with diabetes living healthy lives and res related issues. It provides basic information about diabetes, manageme nutrition information for diabetes patients. It also updates clinical guidel years to provide current evidence-based practice data for health care p recently the 2008 Clinical Practice Guidelines, http://www.diabetes.ca/f professionals/resources/2008-cpg/). More information is on the followin http://www.diabetes.ca/.
Heart and Stroke Foundation of Canada	The Foundation is a federation of 10 provincial Foundations, which aim reduce impacts from heart disease and stroke through research, promo living and advocacy. Its “Healthy Kids” program within the organization healthy eating and activity for families with children and youth. More inf found at http://www.heartandstroke.com/site/c.ikIQLcMWJtE/b.3479025/k.802B/ It provides general information for heart disease and stroke, and curren related issues. The website is at http://www.heartandstroke.com/site/c.ikIQLcMWJtE/b.2796497/k.BF8B

Child Nutrition and Physical Activity Are Inextricably Linked, Like Siamese Twins

According to the World Health Organization, both physical activity and sound nutrition in the community help to keep children healthy and ready to learn and also prevent later chronic disease risk.[61] Long-term

community efforts at the school, family, and individual levels are necessary to yield the benefits of lower health risks over the long term. Community leaders, experts in health and education, and parents themselves must be involved in school-based and other prevention-oriented programs.

School-Based Programs Offer Much Potential for Health Promotion and Primary Prevention of Diet- and Physical Activity–Related Risk Factors if Supplemented by Parent, Family, and Community-Wide Efforts

School-based programs are excellent sites for these efforts. However, changes in the curriculum alone are not sufficient to bring about alterations in risk factors for cardiovascular disease or obesity; changes in school meals and alterations in physical education programs are also needed. More attention to physical training components that increase strength may be important in preventing later osteoporosis risk. Thus, multiple risk factors need to be targeted. Also, community efforts to reinforce these efforts are needed.[62]

In addition to school-based efforts, family and community efforts are also required. Children do not spend all of their waking hours in school. The microenvironment of the family is an important milieu for enhancing and carrying forward school-based health promotion and physical education efforts. The macroenvironment of schools and the community must also be conducive to healthy lifestyles.[63,64]

Healthful Eating Patterns for the Whole Family Are Critical

Foods must be eaten to be nutritious, and overall diets are the most important. Children and their families eat foods, not individual nutrients. There is often a gap in teaching about the merits and demerits of individual foods, and broader guidance on healthful diets or eating patterns is needed. Existing scientific evidence shows that overall eating patterns and diets and not consumption of individual foods or nutrients are most closely linked to positive effects on health. Therefore, families need information about healthful, enjoyable eating patterns that provide a broad, food-based context for healthful eating and about healthful physical activity and exercise patterns. When needs cannot be met by food-based solutions alone, supplementation with vitamins and minerals may be considered.

Information on Healthful Eating and Physical Activity Must Be Communicated More Effectively at the Community Level

Consumers and policy makers must view the Dietary Guidelines for Americans and other nutrition education guidance and programs as acceptable and actionable as well as authoritative if they are to be used. The Dietary Guidelines, the USDA's MyPlate (which is based on the Dietary Reference Intakes and the Dietary Guidelines), food labels, and health claims provide such guidance to the community.[65–67] Information about them needs to be communicated, coordinated, and harmonized to facilitate food purchases and consumption decisions, and diet-related efforts must be accompanied and reinforced by physical activity programs. This challenge is one that food producers, marketers, public policy makers, and educators face together. Intervention strategies from the social and behavioral sciences may be helpful in tailoring messages to our diverse population.[68]

CONCLUSION

Community efforts in the United States and Canada are continuing to increase healthy life expectancy, ensure universal access to quality health care, achieve greater equality in health status, and prevent acute and chronic diseases through public health measures. With the joint efforts of federal and state or provincial governments and with the involvement of nongovernmental organizations, private sectors, and global organizations, these goals can be achieved gradually.

Nutritional Epidemiology

17

Carine M. Lenders, MD, MS, ScD, Emily Keefe, RN, MSN, FNP, and Walter C. Willett, MD, DrPH

Nutritional epidemiology is the study of relationships between diet and disease. Although the effects of nutritional deficiencies have been recognized for centuries, the chemical structures of compounds responsible for these deficiencies have been determined only the past 100 years or so. Globally, the four most commonly recognized deficiencies in children include protein–energy malnutrition and iron, iodine, and vitamin A deficiencies. The importance of folate deficiency has also become apparent in the past two decades. Interventions have evolved beyond the treatment of deficiencies to the reduction of disease risk (e.g., food fortification with iodine, iron, and folate; zinc and vitamin A supplementation programs; and breastfeeding campaigns). More recently, the relationship between nutrition and disease has been expanded from that of deficiency to that of excess; the concept of *nutrition transition* has been developed. Countries undergoing modernization and westernization are faced with diseases associated with both undernutrition and overnutrition. Globally, overnutrition and related complications have become the most important nutritional problem.

In contrast to those of most adults, children's nutritional needs vary with time as they grow and mature; therefore, assessment of pediatric diet, nutrition, and associated diseases is more challenging than that of adults. The dietary choices of children depend on their food preferences and parental choice and control, food availability and cost, peer pressure, and advertising. Young children's ability to report their dietary intake is limited; thus, dietary assessment often requires a surrogate reporter. Despite these differences in approaches to assessment, current national

surveys conducted in the United States have shown overall similar dietary trends in adults and children aged 2–18 years.

The development of techniques to assess diet and breastfeeding, the refinement of anthropometric methods, and the identification of biochemical indicators of diet (biomarkers) specific to population groups have greatly facilitated the field of nutritional epidemiology. Information from basic research has been used at the population level, and new questions in epidemiologic studies have been brought to the laboratory bench and the clinical setting. The methods used to investigate the relationships among diet, nutrition, and diseases include descriptive, analytic, and experimental studies. The development of hypotheses often comes from ecologic observations, and prevalence rates and diet–biochemical relationships are typically based on cross-sectional studies. The assessment of etiologic relationships is usually performed using case-control studies and prospective studies, which are typically expensive and of long duration. Each type of study has its own benefits and pitfalls. Although the best evidence for causation comes from experimental studies such as randomized, double-blind trials, in many situations, it is not feasible to randomly assign subjects to diet for long periods of time.

Modern epidemiology suggests a potential interactive association between lifestyle, genetics, and the risk of many chronic diseases. In this updated overview of nutritional epidemiology, we briefly describe issues and approaches for assessing dietary intake, nutritional status, and physical activity, the application of different study designs, and considerations in the analysis and interpretation of data. Because of its vital importance to child health, we use the relationship between folate intake and incidence of neural tube defects (NTDs) to illustrate various approaches in nutritional epidemiology.

ASSESSMENT OF DIETARY INTAKE

Diet exposure can be measured either in terms of foods or as nutrient and nonnutrient components. The power to detect an association between diet and disease is usually greater when using nutrients (from all foods) rather than one food or food group to represent diet, and interpretation of associations is easier to explain biologically. However, food analyses are used frequently because people eat foods, not nutrients, and food can reflect the combined effects of multiple nutrients and differences in bioavailability of nutrients. Each dietary representation has its benefits and weaknesses, and the use of both methods provides the greatest insight.

An association between a food and disease can lead to the identification of a substance that is responsible for disease or its prevention. A classic example is that of scurvy. As recorded by Hippocrates, symptoms of scurvy were already recognized in ancient Egypt, Greece, and Rome. Later, a tree extract provided by North American natives cured scurvy among members of an expedition led by Cartier in the sixteenth century. Lind, in his *Treatise of the Scurvy* (1753),[1] documented that lemons and oranges also cured subjects with scurvy. However, the relationship between scurvy and vitamin C deficiency was made much later. Celiac disease provides another example.[2] Although descriptions of symptoms compatible with celiac disease were recorded in antiquity, the classic symptoms of celiac disease were defined last century to include chronic diarrhea, abdominal distention, and poor weight gain several months after the introduction of solid foods. The relationship between certain types of cereals and celiac disease was determined when the typical symptoms of pediatric celiac disease disappeared during the food shortages of World War II and relapsed after cereal supplies were restored.[3] Gluten, the major component of cereal proteins, was implicated.[4]

Intake of nutrients or foods is typically interrelated, which can result in difficulties in interpreting findings. For example, an inverse relationship exists between dietary fat and fiber intake among children.[5] Therefore, associations between food and disease could be attributable to foods either high in fiber or low in fat, or both. Sometimes multivariate analysis can be used to disentangle these associations. To minimize interrelations, investigators sometimes use food groups or account for the contributions of nutrient intake from various food groups. Also, "pattern analysis,"[6] based on factor or cluster analysis, groups together subjects with similar intakes of food. These patterns can then be evaluated in relation to disease risk.

DIETARY ASSESSMENT METHODS

Methods to measure dietary intake include 24-hour recall, food records, food frequency questionnaires (FFQs), diet histories, and observation (Table 17-1). New tools, including short questionnaires, interactive software, picture cards, and media (e.g., phone, mobile, camera), are being developed to target (e.g., linking kitchen scale, food bar codes, computer, and phone) specific nutrients (e.g., calcium, vitamin D, fluoride,

antioxidants) and foods (e.g., fruits and vegetables) and specific populations.[7–11] Other methods are being developed to assess healthful and unhealthful food and eating behaviors in 9- to 14-year-old children.[12,13] The validity and the reliability of dietary intake methods among 2- to 18-year-old children and adolescents from industrialized countries have been reviewed elsewhere.[11,14,15] Most validation studies have used observation, diet records, or repeated 24-hour recalls as reference standards. Assuming energy balance, the doubly labeled water method is considered the best method for validation of energy intake using traditional dietary assessment methods.

The doubly labeled water method is the first truly noninvasive means to measure total daily energy expenditure accurately in free-living humans and is based on measurement of CO_2 using a nonradioactive isotope. The technique was introduced in the 1950s, but applications started being made among adults in the 1980s. The total energy expenditure obtained from the doubly labeled water method can be accurate,[16] but large interlaboratory variability has been found in a blinded evaluation of multiple laboratories.[17] Also, the reproducibility of this method at an interval of several months or more has not been evaluated in free-living populations of children. Overall, food records and recalls are more accurate than other dietary assessment methods in school-age children.[11] A review by Burrows et al.[15] compared dietary assessment techniques with the doubly labeled water technique in children in different age groups. The findings suggest that the 3-day, 24-hour recall with parents as proxy reporters provided the best estimate for energy intake for children aged 4–11 years, while weighed food records for children aged 0.5–4 years and diet history for adolescents aged 16 years and older were optimal in these age groups.

TABLE 17-1 Advantages and Disadvantages of Dietary Assessment Methods

Method	Recording Time	Period	Inter-viewer Training	Subject Literacy	Affects DietIn-take	Memory	Subject Burden	Food Description	Automated Procedure	Budget
Recall	Short	Defined	High	No	No	Yes	No	Yes	Yes	Expensive
Food record	Defined	Defined	High	Yes	Yes	No	Yes	Yes	Yes	Expensive
Food frequency	Short	Long	None	Yes	No	Yes	Yes	No(ranks)	Yes	Relatively inexpensiveve
Histories	Long	Imprecise	High	No	No	Yes	Yes	Yes	No	Expensive
Observation	Long	Defined	High	No	No	No	No	Yes	No	Expensive

Studies also show that most dietary assessment methods provide better

estimates for the composition of the diet—after adjusting for energy intake—rather than absolute intake of nutrients or energy and for a group rather than individuals.[18] As a measure of validity, correlation coefficients of at least 0.5 between a new method and a standard method, such as many days of food records, are recommended for nutrients of interest in epidemiological studies.

24-Hour Recall

The 24-hour recall method is based on an interview, typically conducted by a trained dietary interviewer. It provides appropriate mean estimations for groups but not for individuals because of large day-to-day variation in individual intakes. Surrogate reporters are required for children who are young (preteen),[19] have mental delays, or are too sick to respond by themselves. Reporting problems can arise if parents spend less time with their children, for example, when they work outside of the household or have a large family.[18]

Twenty-four-hour recalls by children aged 2–18 years, or by surrogate reporters, have been compared to reference standards (observations, food records, and food chemical analysis) and summarized elsewhere.[14] In their review, McPherson et al. found correlation coefficients(r values) of 0.2–0.9 for energy intake and 0.4–0.6 for most nutrients compared with the standard methods.[14] The correlation coefficients for nutrients improved after adjusting for energy intake. Compared with the standard method, recalls tended to either overestimate or underestimate energy intake.[14] The extent of underreporting was greater in adolescents than in all other age groups[20,21] and among girls participating in a dietary intervention compared to control.[22] Food eaten varied from 68% to 84% when diet recall was compared with the validation standard.[14] The validity of the dietary recall improved when individual meals were compared rather than using 24-hour periods[14] and when school-aged children (8–10 years) were trained to record their food intake using diet records and then asked to recall their 24-hour food intakes using the diet records as memory prompts during interviews.[23] Baxter et al. found that the accuracy of dietary recall did not vary with gender or ethnicity.[24]

The number of days for which dietary recording is necessary to accurately identify specific nutrient intakes in children has been calculated by determining the day-to-day intraindividual variation in dietary intake data for infants aged 4–6 months[25] and preschool children.[26] Quandt obtained dietary information using 24-hour recall among 28 mothers for

their infants' diets on 4 random days over approximately 1 month.[25] In contrast to what is the case with adults, investigators found no effect of day of the week on nutrient variation in this age group. Interindividual variation exceeded intraindividual variation for all nutrients except vitamin C.

Stein et al. measured intraindividual day-to-day variation and tracking of nutrient intakes in a longitudinal study of 181 preschool children (93% Hispanic) aged 45–60 months recruited through a hospital-based pediatrics practice in New York.[26] In that study, 24-hour dietary recalls were administered four times in the first year and three times in the third year to children's mothers. Although the reliability of estimates (intraclass correlation coefficients) of energy and 9 nutrients obtained from a single administration of the dietary recall ranged from 0.15 to 0.38, the authors were able to show substantial tracking of underlying diets among preschool children over a 19-month period, despite day-to-day variation. Dietary methods for low-income populations have recently been reviewed elsewhere.[27]

Fisher et al. showed that body weight also influenced the accuracy of dietary reports made by children and their parents in a sample of 146 children aged 4–11 years using the doubly labeled water method to validate the energy intake measured using 24-hour recalls.[28]

Food Record

The food record method consists of a detailed diary of foods consumed over one or more days.[29] It provides appropriate mean values for groups but not for individuals, unless the number of days is substantial. The information is collected at the time of consumption so that memory is not a limitation. However, assessment is imprecise when dining out and can interfere with dietary intake. McPherson et al. pointed out that there were no specific validation studies of portion size collection, and none of the studies reviewed presented results on validity in reporting food items.[14] Underreporting in children's adult-assisted food records increased with age (9–12 years) when energy expenditure was measured with doubly labeled water. In that study, the investigators found differences in reporting by race but not by gender. African American children were significantly more likely to underreport energy intake than were white children.

Black et al. studied the day-to-day variation in energy intake of 48 breast-fed infants using four-day diet records at monthly intervals from age 1.5 to 7.5 months and of 37 fully weaned infants studied at 10, 12, 15, and

18 months of age.[30] Dietary variation was lowest in fully breast-fed infants, increased as solids were introduced, and approached values found for adults in the 18-month-old infants. Nelson et al. showed that with the exception of ascorbic acid, intakes were the lowest in the youngest age groups (<36 months of age) and rose through childhood to peak in adolescence and young adulthood.[31] In contrast to the homogeneity of the intragroup coefficient of variation (CVw) of specific nutrients among children and adults, the intergroup coefficient of variation (CV_b) varied largely by age group and gender, resulting in variance ratios that were relatively low for toddlers, high for children aged 5–17 years, and intermediate for adults. The lower toddler's variance ratios is best explained by their ability to adjust their energy intake at successive meals resulting in relatively constant within-subject daily energy intake.[32] Nelson et al. found that up to 4 years of age, seven days were adequate to estimate all macronutrients except type of fat.[31] For animal protein, the number of days required to achieve a level of accuracy of ranking at and above 0.9 was 18 days (Table 17-2).[31]

As determined by the doubly labeled water method, underreporting of energy intakes on children's assisted food records increased with age.[14,33] Using that same reference method, other investigators have also shown that estimations by food record can be made at the group, but not at individual, level. O'Connor et al. compared measurements of energy intake from diet records and total energy expenditure using the doubly labeled water method in 47 children aged 6–9 years.[34] Although the mean energy intake and the total energy expenditure were not significantly different, the authors showed no significant correlation between energy intake and total energy expenditure. The findings of this study confirm the notion that energy intake assessed by diet records is not representative of total energy expenditure at the individual level but that three-day food records could be used to estimate energy intake at the population level. Even longer periods of dietary records (e.g., 7 days) compared to the doubly labeled water method can underestimate energy intake, especially in overweight adolescents.[35]

Food Frequency Questionnaire

In contrast to food records and 24-hour recalls, FFQs are relatively inexpensive and aim to represent long-term intake. The food frequency method relies on a food list, and participants are asked to report the frequency of consumption of each food item; the design of these

questionnaires is described in detail elsewhere.[18] FFQs can be used to rank respondents by levels of intake. The period of time covered by the FFQ can be weeks, months, or years, and the questionnaires can be classified as quantitative (i.e., food models shown for usual portion size), semiquantitative (i.e., standard serving size used), or nonquantitative (only frequency assessed). Overestimation of intakes of energy and other nutrients was observed in studies using a validation standard (diet record or repeated 24-hour recall) when adults' portion size, rather than children's portion size, was used in children's studies.

TABLE 17-2 Number of Days Dietary Records Are Required for a Correlation Coefficient of 0.9 Between Observed and True Intakes

	Days for Aged Children 1–4 yr	Days for Boys Aged 5–15 yr	Days for Girls Aged 5–15 yr
Protein	5	6	15
Animal protein	6	7	18
Fat	7	8	12
Saturated	8	6	12
Polyunsaturated	15	18	28
Monounsaturated	11	9	14
Cholesterol	27	18	21
Carbohydrate	6	10	9
Folate	6	9	22

Source: Adapted from Nelson et al.[31]

When multiple 24-hour recalls, rather than just one, were used as the validation standard, investigators observed similar estimates for energy intake obtained with the 24-hour recalls and the FFQ, referred to as the Youth–Adolescent FFQ.[18] In that study, further adjustment for intraindividual variation in recalls improved the nutrient correlation coefficients. Inner-city sixth and seventh grade students demonstrated the ability to provide valid estimates of intake of calories and a variety of nutrients over one year. However, children in the fourth and fifth grades in inner-city schools experienced difficulties in completing the same FFQ.[36] This finding shows that surrogates are needed in older children from disadvantaged populations. A FFQ for low-income, 1- to 3-year-old Hispanic, African American, and white children who attended the WIC

program was recently found to have excellent reliability and acceptable validity.[37] Blum et al. also validated the use of a shortened version of the Youth–Adolescent FFQ in Caucasian and Native American children aged 1–5 years, with a parent or guardian filling out the questionnaire.[38] The average correlation was similar to that found in validation studies among adolescents and adults. Finally, the use of a 124-item FFQ has been found to be a reasonably valid method to capture adolescent diet recalled by young adults.[39]

In contrast to the accuracy of repeated 24-hour recalls[40] and weighed diet records,[21] when the doubly labeled water method was used as a standard, energy intake was overestimated by 50% in infants when FFQs were used.[41] Using the same doubly labeled water method as a standard in a group of older children (9–16 years), energy intake obtained from the Youth–Adolescent FFQ was underestimated. However, the authors showed that despite a wide range of variability in reporting accuracy across adiposity status and gender, this method estimated the mean energy intake of a group with appropriate accuracy.[42]

Diet History

Diet history provides information on typical meals, food intakes, and preparation of food using a questionnaire, an interview, or both. This method is more qualitative than FFQs; the interview can take between 1 and 2 hours. The studies in children have shown overestimation of nutrients and energy intakes in the first interview compared with overestimations in subsequent interviews.[29] In addition, Livingstone et al. validated the energy intake assessed by *seven-day* weighted food records and diet histories with that obtained using the doubly labeled water method in 78 subjects aged 3–18 years.[21] Food records underestimated energy intake, whereas diet histories tended to overestimate energy intake in most age groups if it is assumed that the results from the doubly labeled water method were without error.[17]

Observation

Trained personnel can observe patients in a variety of settings, especially schools. Food intake can be measured once or multiple times. The method is intrusive and is impractical in large studies. However, this method is often used as a validation standard for school-aged children and is reliable.[43]

SPECIAL CASE FOR DIETARY ASSESSMENT: BREASTFEEDING

Studies relating breastfeeding to illness are difficult to evaluate because of the use of a variety of definitions for breastfeeding,[44] selection bias,[45] confounding,[46] and reverse causality.[18] As reviewed below, few studies have addressed the reproducibility and validity of breastfeeding assessment methods. Several techniques have been used to evaluate the intake of breast milk among breastfeeding children. The doubly labeled water method is considered the gold standard for evaluating energy intake in breast-fed children.[47] Other techniques include pre- and postnursing infant weights, and the evaluation of the duration and frequency of breastfeeding using observation, recall, and record studies. The Centers for Disease Control and Prevention (CDC) has developed a comprehensive breastfeeding website with current updates and intervention tools (http://www.cdc.gov/breastfeeding/).

The use of doubly labeled water has been validated against periodic open-circuit respiratory gas exchange in infants.[48] Using double-labeled water, Butte et al. showed that energy requirements of infants and toddlers were 80% of recommendations and were lower in breast-fed than in formula-fed infants.[47] As a result, recommendations for energy intake have been decreased in infancy and early childhood and recommendations for physical activity provided.[49]

Test-Weighing Techniques

Conventional test-weighing techniques include weighing either infants or mothers before and after a known or unknown amount of breast milk intake. Brown et al. conducted validation studies of different test-weighing techniques among 64 infants before and after the consumption of a known amount of milk.[50] The measured bottle weight corresponded to 94.9% ± 13.2% of the estimated change in weight of the infant. These techniques allowed good estimates of breast milk consumption to be made, noting that the average amount of breast milk received declined with time from 632 g/d for the 5- to 12-month olds to 368 g/d for the 24- to 30-montholds.[50] Because of the intrusive nature of test weighing, it generally will not be directly useful in epidemiologic studies, but it could serve as a standard in validation studies of other methods.

Observation, Recalls, and Questionnaires

Piwoz et al. conducted a validation study of breastfeeding recall using observation as the reference standard.[51] They obtained 1574 single-day dietary intakes (12-hour observations plus 12-hour recall) and mothers' monthly reports of usual feeding practices. They demonstrated that single-day studies produced a different view of feeding practices compared to the mothers' reports. Exclusive breastfeeding was observed 25% more frequently among infants younger than 4 months than was self-reported. In contrast, self-reported formula consumption was 30% more frequent compared to observation data. Differences between reported and observed practices were related to mothers' age and education, number of children younger than 5 years in the home, and infant age and disease on the observation day. The investigators concluded that consumption of breast milk or formula during the past 24 hours should not be used alone as the basis for classifying infant feeding practices in surveys. Infant Breastfeeding Assessment Tool, the Mother Baby Assessment Tool, and the LATCH assessment tool (L for latch, A for audible swallowing, T for type of nipple, C for comfort [breast/nipple], and H for Hold [positioning]) were evaluated for reliability (6 months) and validity using videotapes of breastfeeding sessions.[52] Using food records and FFQs, the relative agreement for the frequency of breastmilk and study formula consumption was found to be very good.[53]

Most epidemiologic studies have used recalled or observed data to provide information on breastfeeding. Investigators have used information on the duration, frequency, and minutes of breastfeeding rather than test-weighting or isotopic methods to evaluate the relationship between breastfeeding and outcome (i.e., growth and disease), and some, but not all, studies have gathered information on additional sources of foods beside breastfeeding. For example, Zeitlin and Ahmed examined the relationship among breastfeeding, total energy intake, and growth of infants in Bangladesh using observation (minutes of breastfeeding) and 24-hour recall to estimate breast milk and other food intake in infants and children aged 5–23 months.[54] Beaudry et al. used a self-administered standardized questionnaire mailed to every mother 1 week before infants reached 6 months of age to evaluate past breastfeeding and weaning behaviors.[55] Vähätalo et al. found that a dietary interview method including a short FFQ was useful for ranking infant subjects according to the consumption frequency of breastmilk and infant/study formula, as well the amount of formula used.[56] However, the amounts of study formula were overestimated by the dietary interview as compared with two 48-hour

recalls.[56] Types of questions asked during the interview are reported by the authors in the methods section and the FFQ used in that study can be found in the appendix of that article. Finally, some authors have previously suggested that clarification of the intensity and duration of breastfeeding might help detect dose–response effects of breastfeeding. More recent information on infant feeding practice survey is available on the CDC website http://www.cdc.gov/ifps/questionnaires.htm.

ASSESSMENT OF GROWTH AND BODY COMPOSITION

The focus of many studies in nutritional epidemiology is body weight, but recent techniques have evolved to better characterize changes in body weight in terms of body composition. Chapter 4, "Body Composition and Growth," describes the theory and practice of many of these techniques, as well as what is known about developmental changes in body composition.

Because nutritional epidemiologic studies in pediatrics often employ a variety of body composition techniques, the relationships among them are of interest. Densitometry is typically considered the gold standard for a two-compartment model of fat and nonfat tissue in adults and depends on measurements of total body density. Despite the lack of data on fat and fat-free mass densities in children,[57] densitometry has been compared with anthropometric measurements involving weight, height, and skinfold thickness measurements (Table 17-3).[58–63] Likewise, anthropometric data based on weight and height indices have been compared with skinfold thickness measurements (Table 17-4).[64–66]

TABLE 17-3 Correlations Between Anthropometric Measurements and Total Body Densitometry

Of note, the correlation coefficients between predictors of adiposity and total body densitometry tend to be positive when authors have transformed body density measurements using an equation

to estimate fat (as in Maynard or Roche) but tend to be negative when using direct measurements of hydrodensitometry (as in Horsha). In the Bogalusa Study, the authors used W/H^p rather than W/H^3. They calculated the optimal "*p*" for each category of gender, race, and age because they wanted to obtain an index that was independent of *H* during growth and early life development [$\log(W) = a + p \log(H) + e$].

[a]The relationship between body density and triceps skinfold for the nonobese adolescents was [body density = 1.128 − 0.78 log triceps skinfold].

[b]Arm circumference had the highest correlation with both weight ($r = 0.90$) and body density ($r = -0.63$). The authors showed body densities for their subjects similar to those shown by previous authors estimated from skinfold thickness measures [body density = 1.1516 − 0.09256 log triceps skinfold] and comparable to real body density measurements.

[c]Total skinfolds provided (at least 12 sites from the chin to the knee). Overall, correlation for triceps was −0.79 and −0.72 for subscapular.

Data on weight and height were also compared more recently not only for measurement of skinfold thickness but also for dual-energy x-ray absorptiometry (DXA) among children aged 2–19 years.[66] Compared with weight for height and the Rohrer's index (Wt/Ht^3), the Quetelet or body mass index (BMI; Wt/Ht^2) was identified as the better predictor of overweight (but not underweight) when average skinfold thickness measurements were used as standard. BMI was also shown to perform better than the Rohrer index when the standard for percent body fat or total fat mass was estimated using DXA in children aged 3–19 years. No differences were found between BMI and weight for height in detecting overweight or underweight.

As described in Table 17-5, anthropometric measurements are most useful in large-scale studies. A study of bioelectrical impedance analysis (BIA) and BMI in adults[67] suggested that BIA was not superior to BMI as a predictor of overall adiposity. Likewise, Eisenman et al. found that BIA had limited utility in estimating body composition in their validation study among 3- to 8-year-old children (age of adiposity rebound) using anthropometry (BMI, waist circumference, and skinfolds), BIA, and DXA

scan.[68] Recommendations from these studies are to use BMI, skinfolds, and waist circumference measurements in epidemiological studies.

Although BMI does not directly measure body fat, it is typically used to evaluate adiposity in adults and has been recognized as a useful predictor of adiposity in children and adolescents, which, in turn, also predicts risks for present or future medical complications ofobesity.[69] The weight indices are considered adequate when the correlation with percent body fat is high and the correlation with height is low. Although there is no perfect weight index of overweight and underweight—irrespective of height and width—BMI is a reasonable index from childhood to adulthood.[66] Transformation of weight and height is also discussed in the review by Gasser et al.[70] Frontini et al. further demonstrated that the association of weight to height index was not superior to BMI as an indicator of adiposity compared to skinfold thickness measurements as reference standards and related cardiovascular risk factors during childhood in the Bogalusa Study.[65]

Self-reported weight and height among adults is frequently used in nutritional epidemiology. In contrast to the findings in adult studies, results from adolescents aged 12–17 years in the Third National Health and Nutrition Examination Survey (NHANES III) showed that self-reported weights were missing in 40% of 12 year olds and 25% of 13 year olds. On the basis of their findings, the investigators did not recommend the use of self-reported weight and height as proxy measures of weight and height among adolescents younger than 14years.[71] In contrast to these findings, in a study of 72 overweight and obese children and adolescents aged from 8 to 18 years old, self-assessment of height, weight, and sexual maturation were not found to be valid proxy measures for a physician's assessment, although the reproducibility of self-report of height and weight was good or excellent.[72] The renewed interest in body composition, combined with the awareness of the growing obesity epidemic, has resulted in the need for improved reference data for body composition.

BIOCHEMICAL MARKERS OF DIETARY INTAKE

A biologic marker of dietary intake (or nutritional biologic marker) is defined as "any biological specimen that is an indicator of nutritional status with respect to intake or metabolism of dietary constituents."[73] A nutritional biological marker may thus be a biochemical, functional, genetic, or clinical index of status of a nutrient or other dietary component.

This section focuses on biochemical markers of dietary intake (biomarkers).

Biochemical indicators (biomarkers) of dietary intake—blood, urine, stool, and tissue nutrients—can reflect nutrient intake.[74] Biomarkers are important in nutritional epidemiology because they can be used as surrogates for dietary intake when the nutrient content in a food varies greatly, used to validate questionnaire-based assessment of dietary intake, and used as markers of compliance in intervention studies. They can also be useful as markers of disease, even if they reflect intake poorly; serum cholesterol provides a good example. Biomarkers can also be used to validate nutrient intake assessed by dietary assessment methods. When a biomarker needs to represent the intake of a specific nutrient in an epidemiologic study, the most important requirements are its sensitivity to changes in dietary intake and its ability to reflect the cumulative average intake over an extended period of time.[18] As opposed to nutrient intakes, relatively few foods have corresponding specific biomarkers of intake.

Sensitivity of a Biomarker

The sensitivity of a biomarker depends on how well the biomarker reflects true nutrient intake, which can vary with the chemical form of the nutrient. For example, the bioavailability is lower for dietary folate than for supplemental folate, so serum levels will differ with the form of folate. Serum sodium is an example of a biochemical measure biomarker that is not sensitive to intake because it is tightly regulated to remain within a specific range. The 24-hour urinary measurement of 3-methylhistidine is an example of a good biomarker for animal protein intake ($r = 0.77$).[75]

Specificity of a Biomarker

The lack of specificity of a biomarker of dietary intake may result in an association between the biomarker of dietary intake and health outcomes that is confounded by other dietary factors. An example is urinary alkylresorcinol metabolites and whole grain (wheat and rye) affected by vitamin C.[76] Another example is that of folate, which is present not only in fruit and vegetables but also in cereals. As a result, variation in plasma folate is not only associated with cereal but also associated with fruit and vegetable intake, and the extent to which plasma folate is a good biomarker of fruit and vegetable intake will differ by study population. Similarly, serum folate will not be a good indicator of fruit and vegetable intake if folate comes mostly from fortified foods. Variation in biomarkers

can also reflect genetic variation in metabolizing pathways or supplements.

Period Covered by a Biomarker

On the basis of the time period covered by a biomarker, there are two major types of biomarkers: recovery and concentration markers. For concentration markers, ranking of the individual's intake can be estimated based on biomarkers' values because they are correlated. Most markers are in this category; an example is transfat in adipose tissue. A recovery biomarker is a marker that is correlated to dietary intake for a specific period of time: an example is urinary nitrogen over a 24-hour period for protein intake.[77] A special case is that of predictive biomarkers, which are highly correlated with dietary intake like the recovery biomarkers, but, as opposed to concentration markers, only a fraction is recovered (e.g., sucrose plus fructose in 24-hour urine). As a result, predictive biomarker values can be used to estimate absolute intake.

Studies of chronic diseases require biomarkers that are less susceptible to short-term fluctuations. For example, serum folate is sensitive to changes in intake and modestly sensitive to temporary changes in folate metabolism. Data from the Framingham Study demonstrated a strong inverse correlation between plasma homocysteine and folate intake over long periods, assessed using FFQs.[78] Another example is that of plasma amino acids. There is evidence that plasma amino acids are indicators of dietary intake of amino acids if they are measured within two hours of a protein meal.[79] Plasma amino acid measurements in the postabsorptive state (at least eight hours without food consumption) are an indicator of dietary intake of amino acids when similar protein meals have been consumed for at least two weeks.[80] Although red blood cells membrane fatty acids were not found to be reliable as an independent measure of compliance for dietary saturated fatty acids intake in short-term studies,[81] red blood cell levels of the monounsaturated fatty acid, oleic acid, and the polyunsaturated fatty acids such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) were more useful biomarkers during short-term intervention trials. Cholesterol ester appears to be the most suitable serum fraction to assess short-term dietary compliance.[82] Examples that reflect long-term nutrition status include toenail selenium and tissue fatty acid composition.

Source of Biomarker Measurements

Sources of biomarkers in humans include direct measurements of

nutrients, enzyme activity, products of the metabolic pathway, and challenge (tolerance) tests. The biomarker can be measured directly in body fluids or tissues such as plasma, serum, erythrocytes, adipose tissue, muscle, urine, stool, hair, and nails. For example, mean population intakes of iodine and sodium can be estimated by casual urine samples.[83] Another example is that of dietary fatty acids. Using dietary intake from 200 FFQs as well as tissue, whole blood, and plasma levels of fatty acids, the correlation coefficients for α-linolenic acid and linoleic acid was 0.38 and 0.43, respectively, between diet and whole blood, 0.51 and 0.52 between diet and adipose tissue, and 0.39 and 0.41 between diet and plasma. In this study, for α-linolenic and linoleic acid, high correlations were observed between whole blood and adipose tissue (r = 0.59 and 0.67, respectively) and between whole blood and plasma (r = 0.96 and 0.88, respectively).[84] Enzyme activity can be used to evaluate specific dietary nutrients (e.g., alkaline phosphatase for zinc, glutathione peroxidase for selenium, and erythrocyte transketolase for thiamin).

Plasma homocysteine is a sensitive, but not a specific, marker of folate, and 25-hydroxyvitamin D is a good marker for vitamin D deficiency. Although serum ferritin is a sensitive test of iron status and continues to be the leading single determination for individual iron status, it is not recommended in inflammatory states because it is an acute-phase reactant. Serum transferrin receptor is a promising alternative because it is more specific than ferritin. Another example of a nutrient that can be confounded by inflammation is serum betacarotene.[85] Finally, by-products of nutrients can be related to disease, such as protein carbonyl content, which is the most widely used marker of oxidative modification of proteins.[86] See Chapter 3: Laboratory Assessment of Nutritional Status for a detailed description for common nutritional biomarkers.

Factors Influencing Biomarker Measurements

The magnitude of the correlation between a biomarker and dietary intake depends mainly on bioavailability, homeostasis, range of intake, and determinants of the concentration other than intake (e.g., lifestyles, gender, BMI, genetics). Bioavailability of a nutrient can differ with processing of products. An example is that of adding fat to the preparation of vegetables because it increases the bioavailability of fat-soluble carotenoids. The mechanisms responsible for homeostasis may include nutrient absorption (e.g., iron), excretion of excess (e.g., vitamin C), and hormonal pathways (e.g., calcium). As a result, the relationships between concentrations and

intakes are rarely linear and may result in attenuation or plateau of the relationships with higher intakes. The biomarker may be a poor indicator of intake if the plateau phase is wide (e.g., retinol) or the range of intake is narrow and falls in the plateau phase. For vitamin A status, retinol concentration will not be useful unless the liver stores are either very depleted or highly saturated.[87] Biomarkers of long-term intake with large within-person variation are likely to result from a response to short-term fluctuations in intake or to changes in other determinants of its concentration (e.g., gender, body fat). Therefore, several measurements may be needed to improve prediction at an individual level and to account for population trends in intakes.

The relationship between dietary nutrients and biomarkers can be influenced by sample collection, storage techniques, seasonal timing, time of day, study design, contamination (e.g., zinc collected in ethylenediaminetetraacetic acid tubes), stability, storage temperature, and freeze-thaw cycles, as well as level of quality control.[18]

If these factors influencing biomarkers are not taken into account, misclassification of individuals with dietary intake may occur. When the factor is not associated with disease outcome, it contributes to random misclassification and thus attenuation of the true relationship between the biomarker and the disease outcome. When the factor is associated with disease, confounding may occur. An example of confounding is that of serum vitamin E (biomarker for vitamin E intake) and liver disease in preterm infants.

Another complication might be due to reverse causation, which is observed when a disease outcome affects the concentration of a biomarker of dietary intake. An example is cancer and nutrient concentration.

Biomarkers to Validate Dietary Assessment Methods

Biomarkers can be useful for validating other methods of dietary assessment such as FFQs, diet records, or recalls.[18,88] A major advantage is that the source of error in the biochemical measure and intake assessment should be independent. For example, good correlations between folate intake and serum or red blood cell folic acid provided important documentation about the assessment of dietary folate, despite concerns about bioavailability and stability in food processing. Sometimes biomarkers can detect biases in reporting.

Biomarker Limitations

Biomarkers of dietary intake are measures of nutrients and other food components if they are digested, absorbed, and transported in the extravascular system. However, these processes, metabolism in the intestinal bacteria, metabolism in the gut mucosa, metabolism or storage in the liver, and excretion, may affect the relationship between biomarker and intake. An example of anthropometric and dietary factors that may affect the relationship between a biomarker of dietary intake and disease outcome is that of alkylresorcinol metabolites.[76] Sex, BMI, and vitamin C intake were identified as determinants of the proportion of free and glucuronidated 3-(3,5-dihydroxyphenyl)-propanoic acid, and therefore investigators recommended that urine samples be deconjugated prior to quantification.

Analysis of diet and disease typically require the use of energy-adjusted intakes rather than absolute intakes and long-term intakes (see the section on Adjustment for Energy Intake). Because recovery biomarkers reflect absolute intake, a marker of energy such as the doubly labeled water method would be needed, but this measure is expensive and often not available. Therefore, when recovery biomarkers are used, multiple repeated assessments or adjustment for within-person variation in the biomarker is used to estimate long-term intakes. Limitations for use include the cost and participant burden for doubly labeled water assessments. Finally, recovery biomarkers are available for limited number of dietary factors. Although both recovery and concentration biomarkers can be used to validate or calibrate dietary instruments, correlation with a dietary measure are generally greater for recovery biomarkers and thus additional methods (e.g., methods of triads, which is a triangulation technique to calculate the validity coefficient of a food-frequency questionnaire) necessary with concentration biomarkers.

TRACKING DIETARY INTAKE

For adults, year-to-year dietary intakes, assessed by FFQs, show correlations of 0.6–0.7, with decreasing correlations over longer intervals,[18] but diet tracking varies according to age category among children. Although parents have a dramatic influence on their children's dietary intakes, young children's preferences are not necessarily similar to those of their parents; however, as children grow older, their preferences become more similar.[89] Energy-density manipulation studies show that children are able to adjust their daily energy intake when they focus on their own hunger and satiety cues rather than on their parents asking them

to “clean their plates.”[89]

There was substantial tracking of underlying diets in a study of preschool children (45–60 months old) over a 19-month period.[26] After correction for intraindividual variation, the correlations ranged between 0.2 and 0.6. The correlation between nutrient intake at age 2 and 4 was examined in the Bogalusa Study cohort of children aged 6 months to 4 years.[90] Total protein, animal protein, total sugar, sucrose, starch, total fat, saturated fatty acids, polyunsaturated fatty acids, and cholesterol showed correlations of 0.5–0.6 in children aged 2 years compared with children aged 4 years. At 2 years of age, 47%–65% of children in the top tertile for total fat, saturated fat, and cholesterol intake remained in the top tertile by age 4.

Tracking of diets has also been studied in older children and adolescents. Tracking of fruit and vegetable intakes (food records) among children in third grade showed correlations of 0.4–0.5 over 2 years.[91] Calcium and dairy intake (diet histories) from adolescence into adulthood (13–27 years old) showed a correlation of 0.4.[92] Using three 24-hour recalls per survey, a longitudinal study of 984 children aged 6–13 years tracked nutrient intakes over a 6-year period in China.[93] The authors concluded that even under conditions of rapid socioeconomic change, children were likely to maintain their dietary intake patterns from childhood into adolescence. The correlations between dietary intakes measured at a six-year interval ranged between 0.28 and 0.51 for macronutrients and major food groups (vegetable and fruit, meat, and edible oils).

Results from a longitudinal English study of 198 participants with two 3-day food diaries collected in 1980 and 2000 (at ages 12 and 33 years) showed that adolescent food intake was correlated with that in adulthood, but it was not a strong predictor. Dietary changes were influenced by variables including gender, location, and socioeconomic status.[94] However, these results could also reflect longitudinal societal changes over time. As an example, trends in food consumption patterns of 1584 ten-year old children at 7 separate cross-sectional surveys (65% Euro American and 35% African American) changed over time (1973–1994).[95] More recently, a study of 425 children aged 9–14 years in Sweden showed fair tracking of food groups and select nutrients in a 6-year period.[96] Those results were in line with previous studies reviewed in the literature.

TRACKING OF NUTRIENTS AND BIOMARKERS

Using 3-day dietary records, participants in the Penn State Young Women's Health Study showed weaker tracking of nutrients over a 6-year period among subjects who were 12 years of age at initiation of the study until they reached 18 years.[94] Although the year-to-year correlation coefficient for body weight over the six-year period of that study was 0.9, rank and correlation analyses showed low tracking among nutrients examined (fat, sugar, iron, and vitamin C). Another longitudinal study of tracking between 13 and 33 years of age in Amsterdam showed that tracking of nutrient intakes showed relatively low but significant stability coefficients for all macronutrients and micronutrients (0.28–0.52).[97] Overall, most nutrient tracking studies have shown that patterns of dietary intake are already present by 2 years of age. Although tracking varies with age, most studies show a low to modest correlation over time. Possible reasons for conflicting results of tracking could include study design, age groups under study, dietary instrument used to assess diet, socioeconomic background, and prevalence of overweight, among others.

Studies of tracking of diet and disease using biomarkers in pediatrics are few, except for those of cardiovascular disease. One example is that of diet and cardiovascular disease risk factors in the Bogalusa Study, carried out in Louisiana.[98] Dietary cholesterol changes correlated significantly with serum total cholesterol changes ($r = 0.42$) and low-density lipoprotein cholesterol($r = 0.50$) from 6 months to 4 years of age. The correlation between dietary intake and subscapular skinfold thickness measurements was 0.3–0.4 for total protein, total fat, starch, and energy.[98] In another longitudinal study from birth to 5 years of age, tracking of serum cholesterol was similar to that in older children and adolescents once the weaning process was completed.[99] The composition of fatty acids in blood has been shown to reflect the quality of dietary fat. Therefore, the long-term stability (tracking) of the serum (and hence dietary) fatty acid and composition of serum cholesteryl ester fatty acids were analyzed in a randomly selected population sample of 1029 Finnish boys and girls aged 3, 6, 9, 12, 15, and 18 years and again 3 years later. The correlations were high for all fatty acids; both linoleate and arachidonate had correlations of 0.6.[100]

Tracking of biomarkers from childhood to adulthood may need to be adjusted for change in BMI, however. In fact, recent meta-analysis shows little evidence that childhood obesity is an independent risk factor for adult cardiometabolic markers of chronic disease, morbidity, and mortality.[101]

These authors suggested that the lack of adjustment for adult BMI may explain these findings. Studies that adjust for adult BMI even show a weak negative association between childhood BMI and metabolic variables in adulthood, especially for those with low BMI status in childhood and obesity in adulthood.[102]

ASSESSMENT OF PHYSICAL ACTIVITY

Physical activity is related to both diet and chronic disease risk and may be both an important confounder and effect modifier. Physical activity is the most important factor in the variation in total energy expenditure among individuals and is thus highly relevant in dietary analysis. Physical activity is considered a behavior that can be defined as "any bodily movement produced by skeletal muscles that results in energy expenditure beyond resting expenditure" and is not synonymous of physical fitness, which includes "cardiorespiratory fitness, muscle strength, body composition, and flexibility."[103] Although physical fitness is influenced by physical activity behaviors, the determinants of physical fitness and physical activity may differ.[18,104] Measures of physical activity are either direct or indirect, with the majority of children and adolescent studies reporting low to moderate correlation coefficients between indirect and direct measures.[105] Besides direct observation, two methods are currently considered the gold standard for physical activity as they measure energy expenditure: the Doubly Labeled Water and Indirect Calorimetry.

Measures of energy expenditure such as heart rate monitors, pedometers, and accelerometers have become increasingly popular because they can be used with large groups of individuals. Accelerometers have many advantages, including the ability to measure frequency, duration, and intensity of physical activity, but they are fairly expensive. Pedometers are much simpler and less expensive but cannot distinguish between different intensities and forms of activity. Pedometers and accelerometers showed good correlations with oxygen consumption (r = 0.62–0.93) and direct observation (r = 0.80–0.97).[106] Although many studies focus on pedometers and accelerometers, self-reporting has been used in many studies. One method for short-term activity assessment is a diary and/or record of all physical activity performed or a physical activity log. A similar method is short-term recalls, which asks participants about their physical activity in the recent past, usually one day. The most commonly used self-reporting methods used in large epidemiologic studies include routine physical activity questionnaires. In these questionnaires,

participants are asked to provide information on the type, frequency, duration, and intensity of physical activity. Physical activity questionnaires are simple, inexpensive, and put little burden on the participant. However, they have been considered by some to be inappropriate for children younger than 12 years,[107] but can be complete with parental assistance.

A review of physical activity questionnaires was performed recently by Biddle et al.[108] Of the 20 instruments, 3 were recommended for use: the Youth Risk Behavior Surveillance Survey (YRBSS), the PAQ-C or PAQ-A, and the teen health questionnaire. The questionnaires are age dependent and are completed by the parent/guardian or the child. The YRBSS provides information on school and leisure time moderate to vigorous activity (past week or year), frequency of activity, and sedentary behaviors.[108] The PAQ-C targets children aged 8–14 years, while the PAQ-A targets children aged 14–20 years, and both have shown moderate validity.[109–142] These findings support the validity of the PAQ-C as a method of assessing older children's general physical activity levels. More recently, the pre-PAQ[110] and a playground activity assessment[111] were validated with accelerometer and showed promise in preschool-aged children.

The relationship between physical activity and fitness (or performance) is not clear in children and that between physical activity and sedentary behavior is weakly correlated. Measures of fitness[112] and measures of sedentary behaviors have been reviewed elsewhere. Although a relationship between physical activity and health-related physical fitness has been reported, a large part of the variability (80%–90%) is not explained.[113] Due to the fact that children's physical activity is characterized by rapid changes from rest to activity including vigorous intensities, there is recent evidence of a poor relationship between physical activity and fitness.[114] The leading criterion for measuring cardiorespiratory fitness is VO_2max (maximum volume of oxygen a muscle can use while engaged in dynamic exercise). VO_2max can be tested when a subject performs an activity such as running until exhaustion. Other methods of measuring cardiorespiratory fitness used in larger studies include heart rate monitoring, which is an excellent method to estimate energy expenditure but is less reliable in low-intensity activities and easily influenced by other factors. Several methods can be used at the same time in a study. Similar principles to those of dietary instruments can be applied in the study of physical activity in chronic disease, especially to correct for measurement errors.

EVALUATION OF DIET–DISEASE RELATIONSHIPS

The ability to detect an association between a dietary variable and disease requires adequate interindividual variation in that dietary factor.[18] This implies that the likelihood of detecting a risk associated with a specific food or nutrient among homogeneous populations who are characterized by little variation in the food or nutrient studied will be low. Dietary intake can vary with cultural background (e.g., among religious groups), type of foods consumed (e.g., vegetarianism), type of soil (e.g., soil with little selenium or iodine), food preparation (e.g., manioc with cyanide), physical activity, genetic factors, and disease state (e.g., lactose intolerance, heart disease). The detection of an association between food and disease or nutrient and disease can also be limited by errors in measuring dietary intake. An example is underreporting or overreporting of specific foods or energy intake. Variation in diet over time can be considered to be an error if long-term average intake for an individual is etiologically important. Specific data collection and statistical procedures can be applied to minimize the effects of error.

Dealing With Missing Dietary Data and Outliers

A FFQ typically covers a list of 100–150 foods. Individuals will often leave one or more questions blank, which has to be taken into consideration during data analysis. Food items left blank in a questionnaire were typically not or rarely consumed in a repeated survey.[115] Assuming that the blanks indicated lack of consumption of a food item, the correlation coefficients of nutrients between two surveys were 0.97–0.98.[115] When the number of foods left blank is large and the value for consumption of these item by responders who did not leave these items blank is high, imputation of missing data based on the consumption of that food item in the study population may be useful. A criterion of 70 blanks (out of about 130 items) has been proposed to exclude participants from analysis and was validated in the Health Professionals Follow-Up Study.[116] However, this criterion cannot be generalized to all situations.

Another common issue in dietary analysis is the identification of outliers. The use of total energy intake as a primary criterion of allowable range may be useful as it is physiologically fixed within a fairly narrow range. Underreporting is currently defined based on reported energy intake and predicted energy intake[117] and is common in dietary analysis.[118] Investigators from the Nurse Health Study have used an arbitrary

allowable range of 500–3500 kcal per day for women and 800–4000 kcal per day for men as exclusion criteria. Although values at both ends of this range are rarely correct, adjustment of nutrient intakes for total energy intake will largely compensate for overall underreporting or overreporting.

Dietary data are also highly sensitive to coding and data entry errors because nutrients are calculated from large numbers of foods. Even low error rates can result in serious misclassification of an individual for many nutrients. In other cases, food composition database errors may be observed. However, some values may just reflect unusual food intake patterns without obvious error. Whatever decisions are made to handle missing data or possible errors, it is important to confirm that any conclusions are not sensitive to the inclusion of a small number of extreme nutrient values.

Adjustment for Energy Intake

The major components of energy intake have been reviewed elsewhere[18] and include body size, growth, physical activity and fidgeting, and metabolic efficiency. Most of the variation in energy intake among subjects is attributable to differences in body size and physical activity. Although metabolic efficiency and fidgeting also vary among subjects, they are not measured in nutritional epidemiology because of the lack of practical measures. In addition, a large proportion of the variation in nutrient intake is attributable to total energy intake. Adjusting for total energy intake can be viewed as a measure of nutrient composition rather than as a measure of absolute intake. Even though the association between nutrients and predictors of total energy intake is complex, failure to adjust for energy intake can result in misleading conclusions. Thus, and for the same reasons that animal studies of nutrient effects are conducted under isocaloric conditions, taking total energy intake into consideration when evaluating the relationships between diet and disease is usually important. An exception could be when the outcome being evaluated is growth or weight gain. Because adjusting for total energy is important in nutritional epidemiology, especially when energy intake is related to disease, models have been proposed and are reviewed elsewhere (Table 17-6).[18]

Residual Model

Nutrient residuals are computed using a regression model with the absolute nutrient as the dependent variable and calories as the independent variable and then entered into a regression model with disease as the dependent

variable. This model is comparable to isocaloric metabolic studies, in which total energy intake is constant, except for the modification in one nutrient. In the case of macronutrient calories, this model can also be viewed as the caloric substitution of one macronutrient for a similar number of calories from other sources.

To make the interpretation of actual nutrient intake easier, a constant (typically the mean nutrient intake of the study population) is added to the residual values, which have a mean of zero and include negative values. When total energy intake is an important predictor of disease, total energy intake is added to the model, which already includes the nutrient-adjusted variable, as summarized in the second equation in the first model in Table 17-6. However, the magnitude of the relationship between total energy intake and disease can vary among studies because the contribution of foods to total energy intake can be different.

Standard Multivariate Model

In the standard multivariate model, both absolute nutrient intake and calories are considered independent variables in a regression model. Although the nutrient is adjusted for total energy intake in this model, the meaning has changed to calories independent of the nutrient. If we consider that total energy intake includes only protein, fat, and carbohydrate calories and the nutrient studied is protein, then energy intake corresponds to carbohydrate and fat calories.

Energy Partition Model

The energy partition model is very different from the two preceding models. This is not an isocaloric model. Using the same example of total energy intake being equivalent to calories from protein, carbohydrate, and fat, this model implies that we examine the relationship between disease and increasing amount of protein in the diet, while keeping term for other calories (including fat and carbohydrate) constant. Therefore, the relationship between nutrient and disease can still be confounded by total energy intake and could erroneously indicate an effect of protein on disease.

Multivariate Nutrient Density Model

In the multivariate nutrient density model, the nutrient density is calculated as the nutrient divided by the total energy intake in a regression model, in which a term for calories is added as a second independent variable. This

is an isocaloric model. This model can be interpreted as the relationship between the nutrient composition of the diet with disease when total energy intake is constant. Because nutrient densities are not highly correlated with total energy intake, the calories will retain their meaning of total energy intake.

Unlike in the residual model with calories and the standard multivariate model, in which the effect of the nutrient is considered similar in subjects consuming high- or low-energy diets, the nutrient density model can be useful when body size (and therefore total energy intake) varies widely among subjects. However, nutrient densities can result in an erroneous relationship if total energy intake is not included in the model. For example, when a nutrient has a weak correlation with total energy intake or a low variability and is subsequently divided by total energy intake, the nutrient can become highly correlated to total energy intake. Therefore, dividing by another variable does not necessarily mean that its effect is removed. As for absolute nutrient, nutrient densities can result in erroneous conclusions when total energy intake is associated with disease. Given the inclusion of the inverse of total energy intake in nutrient densities, nutrient densities tend to be associated with disease in the direction opposite that of total energy intake.

TABLE 17-6 Possible Models That Account for Total Energy Intake in Epidemiologic Studies

1. *Residual model*
   Disease = nutrient residual
   Disease = nutrient residual + calories
2. *Standard multivariate model*
   Disease = calories + nutrient
3. *Energy partition model*
   Disease = calories (nutrient)[a] + calories (other)[b]
4. *Multivariate nutrient density model*
   Disease = (nutrient/calories) + calories

[a]Calories (nutrient) corresponds to caloric intake from a specific nutrient.

[b]Calories (other) corresponds to calories from other nutrients than those under study.

Source: Adapted from Willet.[18]

It is clear from this discussion that the interpretation of energy intake depends on the other variables added in the models. Therefore, the addition of predictors of energy intake to a model will also modify its

interpretation. For example, if we assume energy balance, the interpretation of total energy intake in a model in which physical activity and body size were included would be that of metabolic efficiency. In another example, when residuals of weight on height (remove the effect of height on weight) and residuals of height on weight (remove the effect of weight on height) are included in a model with energy intake, height represents lean body mass, weight represents fat, and energy intake represents both physical activity and metabolic efficiency.[18]

The relationships between dietary intake and disease are complex. Although the interpretation of energy intake varies with the analytic method, the association between absolute nutrient intakes and disease should take into account total energy intake because the observed association can simply reflect that of total energy intake and disease. The presentation of various analytic approaches could further strengthen the findings of an association between diet and disease.

GENETICS IN DIETARY ANALYSIS

The response to diet varies between individuals because of interindividual variations in genetic, epigenetic, and metabolic phenotype markers. Genetic variation may influence dietary intake and nutrient metabolism and thus the utility of a dietary biomarker as an adequate marker of dietary exposures. Technological advancement in analysis at the level of the genome (large-scale DNA sequencing), gene expression (transcriptomics), protein translation (proteomics), and metabolite network and fluxes (metabolomics) has been key to understanding the relationships between genome and phenotype in nutrient metabolism. In nutrition epidemiology, methods that currently incorporate genetic factors to improve our understanding of the effects of diet on risk of disease include (1) gene–diet interactions; (2) Mendelian randomization, and (3) genetic characteristics of endpoints (outcomes).

Variants in DNA sequences are called “mutations” when their prevalence is <1% and “polymorphisms” when they are common. Numerous polymorphisms in the human genome account for differences in the functions of proteins, which contribute to a variety of dietary responses and increase in familial disease risk. The ability to identify DNA polymorphisms from a small amount of DNA has increased rapidly allowing for the evaluation of several million single-nucleotide polymorphisms (SNPs) on a single DNA chip. Variations that are in close proximity on a DNA strand are typically strongly correlated, and thus one

chip can account for a large number of common variants. As a result, genome-wide association studies (GWAS) have been conducted for most common diseases, only a few gene–diet interactions have been identified. A recent example of gene–diet interactions (n = 649) in pediatrics is the interaction of breastfeeding and SNPs in the *IL12RB1*, *TLR9*, and *TSLP* genes both individually and jointly on food sensitivity.[119] Davis et al.[120] reported an interaction between PNPLA3 genotype and carbohydrate intake on fatty liver disease. Similarly, Christensen's findings suggested an interaction of methylenetetrahydrofolate reductase (MTHFR) polymorphism and low folate status, which was associated with a greater risk for NTDs rather than either variable alone.[121] As more studies are being published, clinically relevant findings may have implications for physicians' office counseling and personalized dietary guidelines.

In principle, the analyses of gene–diet interactions are not different from typical analyses of subgroups and interactions. When an interaction is significantly associated with the health outcome, the sample study is stratified according to the genotype for further analysis. However, the sample size required to identify significant interactions is typically four times larger than that needed to test for main effects.[122] Some of the challenges of GWAS are due to the fact that the number of variables examined is greater than the number of study subjects and that investigators are testing interactions between SNPs and one or more environmental exposures, in addition to determining the main effect of each SNP.[123] The latter authors recommend jointly testing for main and interaction effects, testing for population stratification, and using longitudinal data with multiple measurements of the environmental exposure to reduce measurement error issues. Adequate data are a usual limitation.

A second method to measure genetic factors responsible for variation in dietary responses is Mendelian randomization. This method uses genetic variants as proxy measures of nutritional exposure. There are three levels of evidence using Mendelian randomization. The first level is identified as the simple association between an SNP and risk of disease, assuming the genetic effect on disease is conferred only through the nutrient or food being investigated. The second level is when the genotype and intake of the corresponding dietary factor are associated with the disease. Finally, the third level is when both the genotype and the corresponding dietary factor are associated with disease and the association with diet is modified by the genotype; this combination of evidence provides the strongest support for causality.

Qi et al. defines Mendelian randomization as a method that "combines genetic and classical epidemiological analysis to infer causality for environmental exposures, based on the principle of Mendel's law of independent assortment."[124] Mendelian randomization is a method that is less likely to be affected by confounding and reverse causation. As opposed to environmental exposures (e.g., nutrients), genetic variants are not generally associated with the wide range of behavioral, social, and physiological factors that can confound associations.[125] As an example, in Mendelian randomization, postmeiotic germline genetic variants related to alcohol intake or intermediate phenotypes will not be influenced by the onset of disease. Typically, genetic variants are proxy for long-term differences in exposure levels (over a lifetime) rather than short-term differences in exposure levels (over the study period). Limitations include the need for large sample sizes and the inability to completely remove confounding (e.g., the same gene may metabolize related molecules).[125] Another problem with using Mendelian randomization is that developmental compensation that may occur through a polymorphic genotype being expressed during fetal or early postnatal development. These may influence development in such a way as to buffer against the effect of the polymorphism. A more significant limitation of this approach occurs when a genotype has a weak effect on nutritional status. In this case, it is very difficult to establish an association between genotype and disease risk. Despite these limitations, results from the Mendelian randomization can provide evidence of causality comparable with those of randomized clinical trials (RCTs).[125] Finally, Mendelian randomization can be used to select potential candidates for dietary intervention to be tested in a RCT before implementation.

The third method for measuring genetic factors responsible for variation in dietary responses is the use of genetic analyses to characterize outcomes. This method uses genetic variants to identify specific subset of cancers that may have different etiologies, or as proxy measures of disease progression. This method is most useful in the study of cancer, where DNA is extracted from premalignant or malignant tissue using similar techniques as those for germline DNA (entire sequence or one basepair of a tumor). Clinicians are typically most interested in how changes from normal to malignant tissue relate to prognosis and treatment. Diet and other environmental factors may be associated with certain changes in DNA. The identification of a specific genetic change being associated with an exposure increases the likelihood of an association being causal.

Systems genetics is an emerging discipline that is complementary to

traditional methods that emphasize the function of single genes or proteins. This approach has been defined as "a novel population-based approach for identifying the genetic architecture of complex (Quantitative) traits and gene-environment interactions with emphasis on gene networks."[126] Systems genetics allow the identification of new relationships between DNA sequence variation and intermediate phenotypes (e.g., transcript abundance, metabolomics, and proteomics), environment (e.g., nutrient), and disease outcomes.[127]

Presentation of Data

Data for individual foods are usually collected as ordinal categorical or semicontinuous variables, but are typically presented as continuous variables. However, the traditional presentation of nutritional epidemiologic data is based on rate ratios and rate differences for levels of exposure resulting in the categorization of data.

Approaches used to classify dietary data includes quantiles, standard round-numbered cutoff points or cutoff points using, for example, the recommended dietary allowances.[18] Regardless of the method used, categories have great advantages in dietary analysis. First, the investigator can visualize directly how the actual numbers of cases and noncases vary by level of intake. Second, the use of multiple categories makes no assumptions about the dose–response relationship, thus helping visualize whether the relationship is linear. Third, the use of categories may decrease the influence of outliers. However, it is important point that cutoff points are determined a priori rather than to maximize statistical significance in primary analysis. Alternative cutoff points that best describe the biological relationship can sometimes be justified in secondary analysis.

Arguments can also be made for using continuous variables. First, the greatest statistical power is provided by a continuous variable if the function reasonably fits the data. Second, a crudely categorized variable used as a covariate may not fully account for the effect of that variable, resulting in possible residual confounding. This is especially concerning when the primary variable is highly correlated with the confounder (e.g., fat and total energy intake). Third, the use of continuous variables may facilitate comparisons among studies because a single relative risk is reported (e.g., relative risk for 100 mg of cholesterol per day) that does not depend on the distribution of the dietary factor in the particular population or on the studies' cutoff points. However, caution is warranted in making

quantitative comparisons among studies.

The presentation of a single relative risk and its confidence interval provides a more compact presentation of data than relative risks for several categories. An example is the presentation of the relative risks for one serving per day for each food when many foods need to be summarized. Tests for nonlinearity, such as the addition of a quadratic term, can be used to evaluate the presence of nonlinearity but require large sample sizes and may not always describe correctly the data. For example, the analysis by quintiles could show that a substantial difference in risk exists between the first and second quintile but not between the second through the fifth quintile. The test for a simple linear relationship using continuous data might not be significant (leading to a report of no association) or it might be significant but an added exponential term might be not significant (leading to the report of a linear relationship). The use of locally smoothed regression curves represents an approach that combines some of the advantages of both categorical and continuous analysis.

A few aspects of graphical presentations are particularly relevant to nutritional epidemiology, which include single variable effects, actual versus predicted relationships, joint effects, and locally smoothed regression curves and regression splines.[18]

Other Considerations in Dietary Analysis

Additional methods can be used to improve our understanding of the relationship between diet and disease outcome, which have been reviewed elsewhere.[18] In addition to intake of nutrients, analysis of food intake can be conducted to support the association between diet and disease outcome. The use of multivariate analysis is especially important to help identify whether the relationship between exposure and disease is due to another correlated factor. Repeated measure measurements of dietary intake provide opportunities for reducing the effect of measurement error and evaluate various possible temporal relationships between a dietary factor and a disease outcome. Examination of alternative temporal relationships can be useful to reduce the likelihood of missed associations and to provide insight in the pathogenesis of disease. Dietary pattern analysis may be complementary to traditional analysis of nutrients and food and occasionally reveal missed associations. To correct for error of measurements, data from validation and reproducibility studies can be used. Finally, pooled analysis of select diet and disease relationships can enhance our understanding of the effect of diet on disease.

TYPES OF STUDIES

The case of the relationship between folate deficiency and NTDs will be used to illustrate the contribution of a variety of study designs to the determination of a causal relationship between nutrient intake and an important health outcome. In addition, this example shows how the knowledge of a relationship between a nutrient and an outcome might not be sufficient to develop prevention interventions. Finally, it also demonstrates the value of nutritional epidemiology in establishing and evaluating public health policies.

Descriptive Epidemiology

The description of variation in rates of disease among different populations and locations, and over time, is generally called descriptive epidemiology. An environmental role in the development of NTDs was suspected from ecologic (differences in rates among geographic areas) and migration studies. The frequency of NTDs was higher in the northern United Kingdom and decreased when populations moved from high-prevalence areas in the United Kingdom to the United States. High prevalence of NTDs seemed to plague disadvantaged populations. For example, an epidemic of NTDs was observed during the Great Depression in Boston.[128] Another example comes from the decreasing rates of NTDs in Ireland over the course of one decade concurrent with the use of fortified breakfast cereals.[129]

Clinical Observations and Intervention Studies

Clinical observations often provide important leads for further study. The finding of a relationship between socioeconomic background and NTDs resulted in a study of mothers' and children's folate status in the United Kingdom. Smithells et al. performed blood tests to study micronutrients and found that folate, among others, was low among mothers whose infants had NTDs.[130] It was also observed that drugs interfering with folate metabolism were associated with the risk of NTDs.[131]

Risk of recurrence was examined in a nonrandomized prevention trial of multivitamin and mineral supplementation in England and suggested a beneficial effect of supplementation.[132] Supplementation started at entry to prenatal care for all women. Women who received supplements before six weeks of gestation (which corresponds to the cutoff point for neural tube closure) were further compared with women who received supplements later. Other smaller intervention studies showed nonsignificant lower risk

of NTDs among supplemented women. Overall, intervention studies showed a fourfold decrease in risk of NTDs among women taking a multivitamin, but the studies have been criticized because many of the data were from nonrandomized trials.

Case-Control and Cohort Studies of Vitamin Supplements

In case-control studies, previous diet or use of supplements by cases (or, in this example, mother of the case) is compared with that of controls. In cohort studies, nutrient data are collected before the occurrence or recurrence of disease; thus, these studies tend to take longer and are more expensive. However, cohort studies are less subject to methodologic bias.

Only four studies examined folate intake from the diet; others used information on supplements containing folic acid. Mulinare et al. used a birth defects registry to identify children born with NTDs and retrospectively asked about periconceptional multivitamin use (a period of up to 14 years before the interview).[133] The risk of NTDs was approximately 60% lower for women who reported taking supplements. In contrast, Mills et al. did not find a significant relationship between folate and NTDs.[134] Shaw et al. found a similar reduction in NTD risk when folate supplementation was started after three months of gestation, raising concerns about the causality between folate and NTDs.[135] Milunsky et al. conducted a prospective cohort study of multivitamin use and NTDs by telephoning mothers at the end of the first trimester of pregnancy to inquire about the type of supplement taken.[136] The findings showed a strong inverse relationship between multivitamin intake during the first 6 weeks of pregnancy and protection against NTDs.

In summary, all case-control and cohort studies except one supported a protective effect of periconceptional multivitamin use. It was unlikely that results observed in most studies were attributable solely to chance because of the variety of design and the choice of controls. However, confounding factors could have led to these findings. For example, NTDs occurred more often in populations of lower socioeconomic background, so that, in principle, socioeconomic background could have been a confounding factor. Also, the association between folate and NTDs might have been attributable to other vitamins in the multivitamin preparation.

Case-Control and Cohort Studies of Serum Folate

Daly et al. collected blood samples prospectively from more than 50,000

women attending their first antenatal clinic in Dublin maternity hospitals from 1986 to 1990.[137] They used a nested case-control design (sample from all cases and a matched sample of mothers who did not develop an NTD pregnancy) comparing early pregnancy blood folate concentrations in 81 women with pregnancies subsequently affected by NTDs and in a systematic sample of 247 control pregnancies. Folate levels were found to be lower for mothers who later had children who developed NTDs. The same authors found that a woman's risk of having a child with an NTD was associated with early pregnancy red blood cell folate concentrations in a continuous dose–response relationship.[137] However, in the absence of double-blind randomization, the social and reproductive differences between mothers who took the supplement and those who were considered part of the control group (mothers received supplements after the periconceptional period or refused to take the supplement) led to uncertainty as to the significance of the results.

Randomized Trials

The evidence for the relationship between folate intake and NTDs from randomized trials comes from two studies. One was on the *recurrence* of NTDs (history of previous pregnancy resulting in an NTD) conducted by the Medical Research Council (MRC) Vitamin Study Research Group. This was a randomized trial conducted in five European countries, Israel, and Canada.[138] The other trial was on the *occurrence* of NTDs (first pregnancy resulting in an NTD), conducted in Hungary.[139] In the MRC study of recurrence, women were randomized in a 2 × 2 factorial design to 4 mg of folate versus placebo or to other vitamins typically contained in multivitamins versus placebo. The trial was stopped early because of the findings of a 72% protection rate for folate. The Hungarian study used a multivitamin with trace elements and folate versus trace elements and vitamin C. This trial was also stopped because of a high occurrence of NTDs in the placebo group.

Implications

The findings from these studies led to policy responses that were controversial and unclear. A variety of strategies could have been used to improve the folate status of the population: (1) increase intakes of foods rich in folate, (2) recommend routine use of supplements, or (3) suggest the fortification of foods.

Although increasing intakes of fruits and vegetables rich in folate

would be beneficial in many respects, its effect on occurrence of disease would be minimal. Not only would large amounts of folate be necessary to increase plasma levels but also national programs to increase fruit and vegetable intake have not been particularly successful in the past. In addition, the bioavailability of folate in foods is not as good as that of supplemental folate.[140] Cuskelly et al. conducted a randomized trial of strategies to provide a daily intake of 0.4 mg of folate through either supplementation, food fortification, free provision of folate-rich foods or dietary advice regarding folate-rich foods compared with a control group over a three-month period.[141] Concentration of folate in red cells increased significantly only in the groups receiving folate supplements or folate-fortified foods. This study reinforces the concern of the effectiveness of dietary interventions in view of social and economic barriers.

The strategy that consisted of recommending folate supplementation to women during their reproductive years was supported by most epidemiologic studies and was endorsed by the CDC in 1992. To come up with recommendations, the percentage of NTDs in the population that is potentially preventable by supplementation with folic acid should be calculated. The preventable fraction (PF) is the proportion of cases that would not have occurred in the absence of exposure among the exposed population or the total population. The proportion of cases in a population that is not exposed to supplement is labeled P_1. Therefore, the percentage of NTDs in a population that are potentially preventable by supplementation with folic acid can be estimated as the preventable fraction (PF) multiplied by the proportion of cases in a population that were not already exposed to supplements (P_1): ($PF \times P_1$). The preventable fraction is (1−RR), where the relative risk is obtained from an observational study or a randomized trial. For example, in the prospective study by Milunsky et al., the relative risk was 0.27 and the proportion of cases that were unexposed—that is, the mother did not take folic acid supplements during the critical period—was 0.82. The population preventable fraction in this example would be equivalent to 0.60, which is calculated based on $(1-RR) \times P_1 = (1-0.27) \times 0.82$.[136] In 1992, the Centers for Disease Control estimated that 50% of cases of NTDs in the United States could be prevented by universal supplementation with folic acid among women in the reproductive ages. In absolute numbers that meant that about 1500 of the approximately 3000 cases of spina bifida or anencephaly that occurred annually in the United States would be prevented.

The CDC recommended the use of 0.4 mg of folate daily in women who planned a pregnancy and 4 mg for those who had a history of NTD pregnancies. In addition, folic acid supplement of 0.4–0.8 mg was recommended by the Preventive Medicine Task Force for women who might become pregnant[142]; failure of a physician to advise women appropriately might well be considered negligence if a child was affected with a NTD. Although multivitamin consumption was affordable for most, the timing of supplementation and compliance were of concern. Many institutions supported the notion of informing women about folate supplementation; failure to provide this information was considered negligent. Targeting supplementation to a population at risk was difficult because there were no clear affordable screening tools available to identify subjects at risk and the population as a whole seemed to be at risk, based on the study by Daly et al.[142]

Finally, the strategy of fortifying the food supply had been used long before with success in many countries (e.g., with iron and iodine). Fortification of the food supply would have an impact on the entire population and would not require ongoing educational campaigns. Nevertheless, the level of fortification and the type of foods to be fortified were the center of intense debate. The main concern was the masking of vitaminB_{12} deficiency. However, given that about 25% of the population of the United States consumes multivitamins with 0.4 mg of folate, the rare report of neurologic complications associated with vitamin $B_{12}$was reassuring. Nevertheless, the US Food and Drug Administration (FDA) considered that levels of folate consumption from food and supplements above 1 mg of folate daily were a matter of concern.

Although flour was a good candidate for fortification because it is consumed by most subjects in the population, the amount of consumption varies in the population. Therefore, simulations of food fortification of specific foods were performed by artificially increasing the folate content of products made of flour in existing food intake databases. Results from these simulations showed that folate intakes higher than 0.4 mg would have to be tolerated to increase folate intake of the entire population. Using this method, Oakley et al. showed that fortification with 0.35 mg of folate in 100 g of flour would increase the average intake by 0.25 mg, but 30% of women would still have a total folate intake below the recommended 0.4 mg and 15% of the women would have an intake above 1 mg per day (for most multivitamin users). Fortification with 0.14 mg of folate in 100 g of flour would result in an average increase of only 0.1 mg

per day.[143] The FDA recommended the use of 0.14 mg of folate in 100 g of flour; this was implemented in 1998. Since then, fortification of flour became mandatory in the United States, Canada, and Chile which substantially improved folate and homocysteine status while NTDs rates fell by between 31% and 78%.[144] As of November, 2011, 63 countries now have guidelines to fortify and 57 actually do fortify cereal grains of one kind or another.[145] The CDC has estimated that the spina bifida rate declined 25% from 1995 (prefortification) to 2000, and there was a further decline of 13% from 2000 to 2005.[146] In a review that included intervention studies with folic acid supplements, folate fortification programs, and prospective studies, Heseker et al. concluded that the minimal rate achievable by folate intake is approximately 5–8 per 10,000 pregnancies, which is only modestly below the United States rate after fortification.[147] Johnston has estimated that the reduction of NTDs in the United States after fortification (approximately 27%) could be increased substantially by increasing the amount of folic acid that is currently added to cereal grain.[148] However, the fortification of flour is considered suboptimal to prevent spina bifida and the debate continues.[149] Tragically, recommendations alone in other countries such as in France did not influence trends in NTD.[150]

The demonstration that folic acid plays a major role in the prevention of *recurrence and occurrence* of NTDs stimulated further research on the possible mechanisms underlying the relationship and a possible nutrient–gene relationship. The association of a polymorphism in a folic acid–metabolizing gene with the risk of NTD strongly supports the role of folate in the etiology of NTDs and could indicate a group with a higher folate requirement. A polymorphism in the 5,10-methylenetetrahydrofolate reductase gene is associated with a reduction of activity of that specific enzyme. An increase in the prevalence of this polymorphism was observed in infants born with NTDs and in their parents compared with controls.[151] The possible role of vitamin B_{12} in NTDs is still unclear, as reviewed elsewhere.[152]

The findings on folate and the risk of NTDs have given credibility to the search for other examples in which suboptimal intakes of nutrients could lead to high risk of chronic disease. The case of folate and NTDs was resolved in a relatively short time, in part because of the short interval (first 6 weeks of pregnancy) of exposure during which a nutritional imbalance could result in detrimental effects. In addition, the period between exposure and outcome was relatively short, the exposure could be

evaluated by dietary assessment techniques and biomarkers, safe randomized trials could be conducted, and the strength of the relationship was large. Although a causal relationship is typically based on randomized clinical trials, the case of folate and NTDs suggests that a combination of study approaches can provide sufficient evidence when randomized studies cannot be easily performed.

SUMMARY

Nutrition epidemiology has been highly successful in identifying the responsible factors in many diseases, including scurvy, pellagra, blindness, and spina bifida. Nutritional epidemiology can potentially contribute substantially to our understanding of diseases in children and to the relationship between diet during childhood and risk of chronic diseases and cancer. The latency period between dietary exposure and disease can be years rather than weeks. Support for the long-term effects of diet comes from studies of diabetes and cardiovascular disorders that led to the Barker hypothesis of fetal origin of chronic disease, as well as from studies of cancer. A variety of approaches will provide the best evidence on these relationships, particularly when used in conjunction with clinical, biochemical, and molecular data.

Drug Therapy and the Role of Nutrition

18

Kathleen M. Gura, PharmD, BCNSP, FASHP, FPPAG and Lingtak-Neander Chan, PharmD, BCNSP

The nutritional status of patients and the constituents of their diet can significantly impact the pharmacokinetic (i.e., absorption, distribution, metabolism, transport, and elimination) and pharmacodynamic (e.g., affinities to receptors or tissues) properties of drugs.[1] Body weight and/or surface area are also important determinants of optimal dosages, and abnormal body composition may impact proper drug dosing. Various nutritional components can affect gastrointestinal (GI) motility, blood flow rates, gastric secretions, and enzymatic activity, ultimately affecting biotransformation and disposition of drugs. The magnitude of these effects, however, is highly variable and patient specific, confounded by many other factors, and often difficult to predict. Susceptibility to drug-induced nutrient deficiency appears to be greater during periods of increased caloric demand (i.e., during growth, pregnancy, and lactation). When developing a therapeutic plan for the pediatric patient, it is important that practitioners consider the interactions that occur between nutritional status, age, disease state, and drug action. This chapter discusses the developmental changes that occur in the pharmacokinetics and pharmacodynamics of drugs and presents a discussion on the impact of nutrition on these factors. Figure 18-1 illustrates the relationship between nutritional factors and drug therapy. By definition, pharmacokinetics is the exposure of drugs in the body over a period of time, including the processes of absorption, distribution in tissues,

metabolism, and elimination. This contrasts with pharmacodynamics, which is the study of the biochemical and physiologic effects of drugs and the mechanisms of their actions, including the correlation of actions and effects of drugs with their chemical structure, as well as the effects on the actions of another drug or nutrient. Figure 18-2 provides an example of the age-dependent variation in pharmacokinetic and pharmacodynamic properties. It should be remembered, however, that in the pediatric patient, in addition to true pharmacokinetic and pharmacodynamic differences, some alterations in drug response may be due to perception as medications are often not adequately studied in children of different ages and different disease states. Thus, there may be difficulties in assessing small but significant differences in medication response because limitations associated with conventional outcome measures.

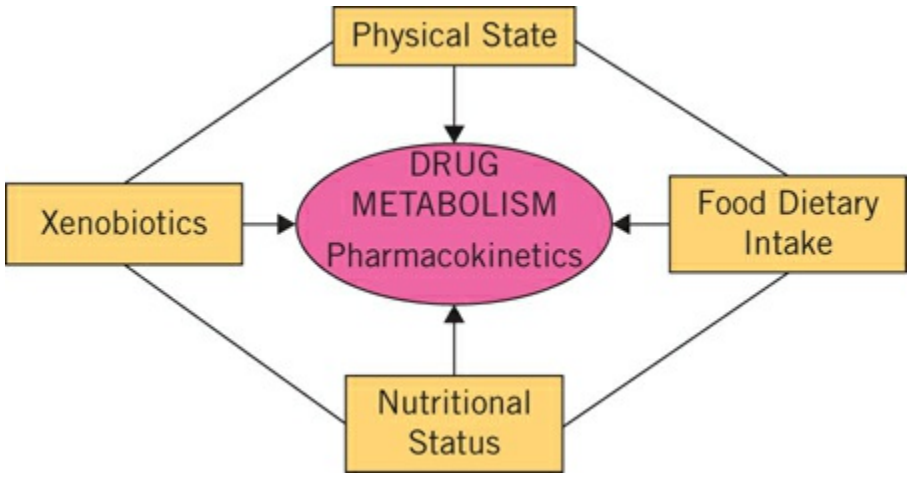

Figure 18-1 Relationship between nutritional factors and drug therapy.

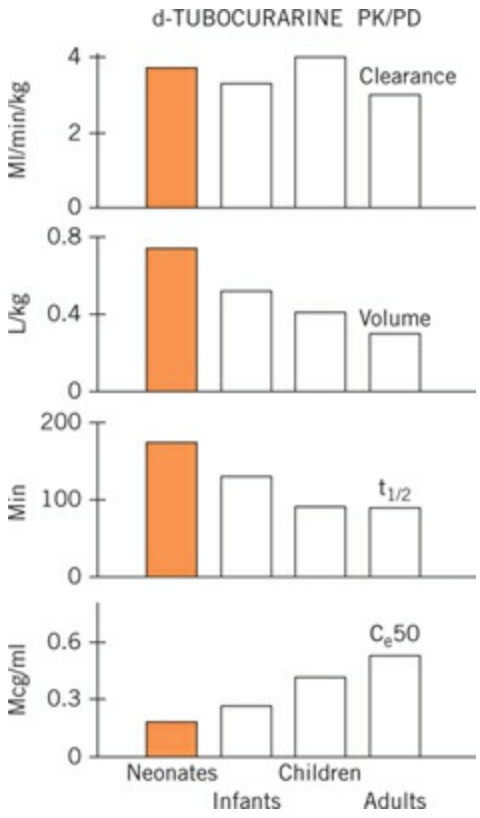

Figure 18-2 Age-dependent variability in the pharmacodynamic and pharmacokinetic properties of *d*-tubocurarine. In this example, neonates require significantly lower plasma concentrations of *d*-tubocurarine to achieve 50% paralysis in comparison to older children and adults, suggesting that neonates have increased receptor sensitivity. The larger volume of distribution in the neonate may also account for the prolonged half-life although plasma clearance is comparable in all four age groups. (Adapted from Fisher et al.[257])

DEVELOPMENTAL CHANGES IN BODY COMPOSITION

Unlike the adult, the body composition of a pediatric patient is undergoing constant changes due to the tremendous growth and development. Children should not be thought of as "little adults," because there are a number of developmental aspects that must be considered when approaching pediatric therapeutics. In fact, during the first decade of life, growth is erratic and does not follow a linear path, thus making simplified dosing approaches inappropriate.[2] Drug–receptor interactions, ontogenetic changes in

receptor number, receptor affinity, receptor–effector coupling, and receptor modulation and regulation change as the child grows.[3] Moreover, during infancy and childhood, the proportions of body weight contributed by fat, protein, intracellular water, and extracellular water change dramatically. In the full-term neonate, total body water comprises approximately 70%–80% of body weight.[4] By age 5 months, this decreases to 60%. From infancy to young adulthood, extracellular water decreases, although the percentage of total body water does not change significantly. In addition, neonates have reduced muscle mass, lower concentrations of albumin, and less intracellular fluid than adults.[5] The change in body water content may significantly affect the volume of distribution of drugs, especially those that are highly hydrophilic. Changes in serum protein (e.g., albumin) may alter the free concentration of certain drugs and thus change the patient's pharmacodynamic response. During the second year of life, fat mass is reduced with a corresponding increase in protein mass. For additional information, refer to Chapter 4, which reviews the differences in body composition in premature infants, neonates, and adults.

Moreover, epigenetic factors influenced by the nutritional state of the mother in the periconceptional period can later influence DNA methylation in the infant. Supplementation with vitamin B_{12}, folic acid, and some amino acids during pregnancy can alter DNA methylation that can offer some protection against infection and immune response.[6]

As the child grows, there is a corresponding change in liver and kidney size, with each organ reaching maximum relative size for weight in the 1- to 2-year-old child, when the capacity for drug metabolism and elimination is high.[3] For example, in the term infant, the glomerular filtration rate (GFR) is approximately 2–4 mL/min/1.73 m^2, while a premature infant may be as low as 0.6–0.8 mL/min/1.73 m^2, and adult values are achieved within the first 8–12 months of life.[2] In the infant and young child, body surface area is greatest relative to body mass in comparison with the older child or young adult. As a percentage of adult norms, intestinal length in infants and children exceeds other anthropometric measurements.[2] Furthermore, the absorptive surface of small intestine is proportionately greater, whereas GI transit time is shorter.

During adolescence, there is an approximately 25% increase in height, whereas weight nearly doubles.[3] In prepubertal males and females, lean body mass, skeletal mass, and body fat per unit body weight are similar, but, by adulthood, women have twice as much fat relative to total body

weight in comparison with adult men.

Recently, research has begun to focus on the relationship between genes (including genetic polymorphisms in drug-metabolizing enzymes and transport proteins) and related systems, developmental, changes, and lactation. Similarly, acute-phase reactions may alter the disposition of certain amino acids and cofactors which in turns can change the functions and/or expression of these enzymes and transporters. For example, the presence of an acute infection or renal failure can substantially alter iron status, which results in changing the metabolic activities of a major drug-metabolizing enzyme, cytochrome P450 (CYP) 3A4.[7]

FACTORS THAT AFFECT DRUG KINETICS

The aforementioned differences in body composition in the pediatric population are an important consideration when determining the pharmacokinetics of a given medication (Table 18-1). Nutrients and drugs delivered via the GI tract need to go through an absorption phase prior to reaching the systemic circulation and the sites of action. Absorption from the GI lumen into the hepatic portal vein and subsequently to the systemic circulation is a series of complex processes including the dissolution of the solid dosage form, passing of the chyme along the GI tract (i.e., gastric emptying and intestinal transit), passive diffusion, active transport, and presystemic metabolism of the compounds. Each of these processes alone may affect the pharmacokinetics of the drug.

GASTRIC EMPTYING AND INTESTINAL TRANSIT

The oral route continues to be the most widely used route of administration in the pediatric patient. As a result, intraluminal pH in different areas of the GI tract can impact medication stability, dissolution rate of solid dosage forms, and possibly the extent of drug absorption in some cases. Neonates typically have a higher gastric pH (>4), and thus, acid-labile drugs such as penicillin G are more bioavailable and lower doses can be used while weakly acidic drugs such as phenobarbital require much larger oral doses to reach therapeutic levels.[2] With the exception of a few acidic drugs (e.g., aspirin), maximal absorption of most drugs and nutrients take place in the small bowel. Therefore, gastric emptying and intestinal transit time have a significant impact on the rate and magnitude of the oral absorption of the drugs and certain nutrients.

Table 18-1 Factors Associated With Differences in Pharmacokinetic/Pharmacodynamic Parameters in Neonates versus Adults
Altered receptor sensitivity
Enhanced intramuscular absorption
Greater blood–brain barrier permeability
Hepatic enzyme immaturity/limited enzyme capacity
Higher gastric pH
Immature renal function
Increased percutaneous absorption
Larger liver:body weight ratio
Limited protein-binding capacity
Reduced fat mass
Slower GI absorption/increased gastric emptying time

Gastric emptying time changes in early postnatal life and is likely one of the many explanations for erratic drug absorption rate and oral bioavailability in infants and young children.[6] During infancy, the rate of drug absorption is slower than in older children. As the intestinal tract matures, antral contractions improve and with it a marked increase in gastric emptying. Similarly, intestinal motor activity increases in amplitude and frequency as well as duration of contractions.[2] In addition, gastric acid secretion is low in infants and does not reach the normal adult gastric pH until 3–7 years of age.[8]

The lack of developed physiologic regulation of GI motility and gastric acidity during infancy and early childhood suggests that the oral route may not be a reliable route for optimal drug delivery. For instance, delayed absorption and/or decreased bioavailability have been observed for acetaminophen, phenytoin, and phenobarbital in young children.[9]

As the child continues to grow, GI motility increases by both neuronal and hormonal input.[10] Vagal stimulation increases upper gastric contraction and decreases pyloric sphincter and duodenal contractions. As a result, gastric emptying is promoted, and the time it takes for the drug or nutrient to reach the small intestine is shortened. For drugs that are absorbed in the small intestine, this action can result in shortening the time of reaching peak plasma concentration and may promote faster onset of drug action. In addition, because of the decrease in intestinal motility, more complete absorption of the drug may be achieved. Anticholinergic

drugs (e.g., sedative antihistamines, phenothiazines, tricyclic antidepressants) can reverse these trends by counteracting the effect of the vagus nerve.

PRESYSTEMIC CLEARANCE

Presystemic clearance, also known as first-pass effect, refers to the removal of orally ingested compounds prior to reaching the systemic circulation. Presystemic effect occurs primarily in the intestine and the liver, whereas the stomach has only a minor role.[11] Type III alcohol dehydrogenase, for example, is present in the gastric mucosa and is responsible for the activation of some biogenic amines and steroids.

Many drug-metabolizing enzymes and active transport proteins are present in the intestinal epithelial tissues. For example, CYP3A4 isoenzyme is present in the small bowel and plays a role in the regulation of oral bioavailability of a large number of medications. Induction or inhibition of the enzyme in the gut by nutrients can affect the oral bioavailability of drugs. Certain nutrients are known to affect the enzymatic activity of intestinal CYP3A4 and change the pharmacokinetics of the object drugs. Grapefruit juice is a classic example of an intestinal CYP3A4 inhibitor.[11] Its action is discussed in further detail below. Water-soluble vitamin E (d-alpha-tocopheryl polyethylene glycol succinate) has also been found to increase oral absorption of cyclosporine.[12] The primary mechanism appears to involve inhibition of an intestinal efflux protein, P-glycoprotein (P-gp) instead of intestinal CYP enzymes.[13]

HEPATIC METABOLISM

The metabolism of a drug involves different steps once it has been absorbed from the GI tract. As drugs are metabolized, they first undergo biotransformation (i.e., phase I metabolism), which results in the formation of a more polar compound by oxidation, reduction, hydroxylation, and so forth. This results in either an activation of the drug or a deactivation. The second phase (i.e., phase II reaction) is a synthetic process, involving conjugation of the polar compound with endogenous molecules such as glucuronic acid, sulfate, glutathione, glycine, and acetate, resulting in a more hydrophilic compound that is more suitable for excretion into bile or urine.[14] It is important to point out that some drugs do not have to go through phase I metabolism prior to undergoing phase II metabolism. Lorazepam, for example, undergoes phase II metabolism (glucuronidation) by UDP-glucuronosyltransfersae (UGT) 2B7 without any phase I reaction

involved. The resultant conjugated metabolite is then excreted renally. An enzyme system responsible for the metabolism of most nutrients and drugs is the CYP enzyme super family, principally located in the endoplasmic reticulum of the hepatocytes and enterocytes, which is somewhat unique in its ability to use a wide range of substrates.

The maturation of phase I and phase II enzymes varies among individuals. Limited studies suggest that fetal and neonatal CYP, the most important phase I enzyme in metabolizing drugs and biogenic amines and steroids, has about 50%–70% of the adults' activity and continues to mature throughout childhood. Although some children may have fully matured CYP enzyme activities as early as 6 months of age, it may take up to 12 months for others.[8] For example, the serum half-life of theophylline, a bronchodilator primarily metabolized by CYP1A2 and CYP3A4, is significantly longer in neonates and younger infants than in adults. Similarly, *N*-demethylation of diazepam, a CYP2C19-mediated pathway, is also significantly slower in infants. There is no well-documented dietary factor known to promote the maturation of these enzymes during the prenatal period and infancy. Table 18-2 describes the impact of various nutrients on Phase I/mixed function oxygenase metabolism.

RECTAL ADMINISTRATION

Rectal route of drug administration is an alternative way of drug delivery when the enteral route is not preferable. Unlike the small bowel venous mesentery, the rectal capillary blood supply collects blood directly into the inferior vena cava instead of the hepatic portal vein. Although certain phase II enzymes are present in the colon (e.g., UGT1A9), there is no strong evidence to suggest the presence of drug-metabolizing enzyme in the rectum.[15] Hence, presystemic metabolism of the administered drug is prevented. Therefore, compared with oral administration, the relative bioavailability of the drug is usually higher with rectal administration.[16] Drugs that are more commonly delivered rectally in children include anticonvulsants (e.g., diazepam), antiemetics (e.g., trimethylbenzamide), and sedative agents (e.g., chloral hydrate).

Table 18-2 Impact of Nutrients on Phase1/Mixed Function Oxygenase Metabolism

Nutrient	Effect on Metabolism	Proposed Mechanism
Ascorbic acid	Deficiency: ↓	Alterations in CYP450 and CYP 450

	Excess: ↑ CYP450 activity	reductase via changes in expression of specific CYP isoenzymes depending on deficiency or excess state
Carbohydrates	Excess: ↓	May be due to ↓protein or inhibition of CYP 450 via ↓ in supporting enzyme components
Fats	High intake saturated fatty acids: ↓ High intake polyunsaturated fatty acids: ↑ Activity and induction of CYP enzymes Deficiency: ↓ Excess: ↑	Decreased CYP activity may be due to requirement of PUFAs in the B-postion of phosphatidylcholine (lecithin), which is an essential component of the CYP system
Iron	Deficiency: ↑↓ Excess: ↑ Microsomal lipid peroxidation	↑ Lipid peroxidation may lead to damage to the integrity of the system
Protein	Deficiency: ↓ Rate of metabolism Excess: ↑ Rate of metabolism	↓ Protein synthesis ↓ Synthesis of other elements (i.e., hormones) involved in enzyme induction
Pyridoxine	Deficiency: ↓	Impaired protein synthesis ↓ Synthesis of heme
Riboflavin	Deficiency ↑↓ depending on severity	↓ Reductase activity but ↑ CYP450 activity such that drug metabolism may be altered (↑↓)
Thiamine	Deficiency: ↑ CYP450 activity Excess: ↓ (both reductase and CYP 450)	↑ Activity of specific CYP450 isoenzymes and perhaps other enzymes in deficiency due to an unknown mechanism Excess may be due to decreased substrate binding
Vitamin E	Deficiency: ↓	May be due to a reduction in antioxidative mechanisms (e.g., protection of the lecithin component thus the activities of CYP450 and reductase are unaffected)

DRUG–NUTRIENT INTERACTIONS

By definition, a food–drug interaction is one that is the result of a chemical, physical, physiological, or pathological relationship between a medication and a nutrient.[17] They are clinically relevant if the interaction alters the therapeutic response of the medication: either decreasing the

bioavailability of the drug (and increasing the risk of treatment failure) or by increasing is bioavailability (and increasing the risk of toxicity).

There are four basic classifications of drug–food interactions that are based on their nature and mechanism.[18]

1. *Type I ex vivo bioinactivations*. These are interactions that occur between the nutrient and the drug, usually in the delivery device, via biochemical or physical reactions. Examples include: complexation, hydrolysis, neutralization, oxidation, and precipitation.
2. *Type II*. These interactions impact absorption by modifying the bioavailability of the medication. The causative agent may alter the function of the enzymes or transport systems that are responsible for drug biotransformation.
3. *Type III*. These interactions are involved in the systemic disposition of the drug and occur after the medication or nutrient has been absorbed from the GI tract and has entered the systemic circulation. This can result in changes in tissue distribution, transport, or penetration to a specific organ or tissue.
4. *Type IV*. In this type of interaction, the elimination or clearance of the drug or nutrient is impacted. It may modify either the renal or the enterohepatic elimination process.

DRUG AND NUTRIENT TRANSPORT SYSTEM

Oral drug absorption across the GI tract is highly dependent on its lipophilic properties and its affinity for membrane transporters. Since the most drugs are most efficiently absorbed in the small intestine, transport protein present in the enterocytes play a pivotal role in facilitating the absorption of many drugs.[19] Although most transport proteins facilitate absorption by increasing the intraluminal uptake of compounds, some transporters efflux molecules already absorbed in the cytoplasm of the enterocyte back into the intestinal lumen, thus decreasing the bioavailability of certain compounds. This is believed to be an intrinsic protective mechanism by the host to minimize xenobiotic exposure. P-gp is a representative of this type of efflux system.[20] P-gp belongs to the family of adenosine triphosphate–binding cassette (ABC) transporters and is an efflux protein widely distributed in normal tissues, including the intestinal epithelium, renal tubule, liver, and blood–brain barrier. Hepatic

transporters are membrane proteins that facilitate nutrient and drug transport into the cell via uptake transporters or pump out toxic entities via canalicular transporters.[21] Although it is known that foods, in particular fruits and vegetables that contain photochemicals have the potential to alter drug absorption, research continues to be limited. Recent studies, however, suggest that phytochemicals can serve as substrates and modulators of specific members of the superfamily of ABC transporting proteins (i.e., P-gp, MRP1, MRP2, and BCRP). For example, isothiocyanates, a class of chemotherapeutic agents derived from cruciferous vegetables (i.e., broccoli, cabbage, watercress) may influence the pharmacokinetics of substrates of these transporters and interact with ABC efflux transporters.[22] CYP3A4 and P-gp are the two most important limiting factors in regulating the oral bioavailability of drugs.[23] It is estimated that CYP3A4 is responsible for the metabolism of more than 50% of all medications.[24] For instance, cyclosporine is a known substrate for both CYP3A4 and P-gp. After oral administration, absorption of cyclosporine across the epithelium in the small intestine is limited by P-gp efflux and prehepatic CYP3A4 metabolism. The P-gp-mediated efflux of cyclosporine from the intestinal cell back into the lumen enables the CYP3A4 enzymes another opportunity to metabolize the drug when it again enters the enterocyte. These mechanisms explain why the oral bioavailability remains poor despite improvement of its formulation to microemulsion.[25] When cyclosporine is coadministered with a CYP3A4 and P-gp inhibitor, such as ketoconazole, erythromycin, or diltiazem, significantly higher maximum blood cyclosporine concentration is observed, indicating an increase in absolute oral bioavailability. Oral bioavailability can be increased by over 40% with concomitant administration of water-soluble vitamin E.[12] The mechanism is mediated through intestinal P-gp inhibition by the formulation. It appears that polyethylene glycol, the surfactant incorporated in the liquid formation, instead of vitamin E is the inhibitor of P-gp.[13,26]

BINDING INTERACTIONS BETWEEN FEEDINGS AND DRUGS REVISITED

Feeding and food intake are common causes of drug–nutrient interactions. Enteral feeding is the preferred method of providing nutrition support and also allows easy access for administering drugs to patients who are unable to swallow. However, enteral feeding formulas have been implicated in a

number of drug–nutrient interactions.[27] Moreover, in children with chronic medical conditions receiving tube feedings, nutrient deficiencies are also a concern because multiple medications and complicated feeding regimens can result in a decrease intake due to feedings being held or due to drug interactions.[28] For example, the oral absorption of warfarin, tetracycline, fluoroquinolone antibiotics, thyroid supplements, and phenytoin is decreased with concomitant enteral feeding.[29,30] Possible explanations include a decrease in the anticoagulant effect of warfarin caused by increased vitamin K absorption from the enteral formulas or binding of warfarin by a protein component of the enteral formula.[29] It has also been reported that the acidic nature of most enteral formulas alters the solubility of phenytoin. Phenytoin, a weak acid, is not readily absorbed in acidic conditions and absorption is optimal when it is given in the ionized state. Furthermore, when phenytoin is given with nasogastric feeds, it may become bound to the tubing when it is nonionized in a low pH environment.[31] Drug–nutrient interactions through chelation of divalent and trivalent cations has also been proposed (e.g., enteral feeding formulas or dairy products interact with fluoroquinolones).[25] A case of scurvy was reported in a child who received long-term enteral tube feedings using a commercial product. Scurvy occurred due to the degradation of the ascorbic acid in the formula due to prolonged storage after mixing and from the addition of an iron supplement that further catalyzed the reaction.[32]

Unlike medications given via the oral route, whenever a medication is delivered via feeding tube, tube placement and device characteristics must also be considered. Medications may adhere to the sides of the feeding tube, and thus not be delivered to the patient, or may obstruct the tube in the case of an oral solid not properly pulverized and diluted prior to administration. In some instances, medications are best absorbed in the "fasted" state, requiring that feedings be held so as to optimize absorption. Intragastric administration of a medication may delay gastric emptying rates. Administering solid dosage forms of medications (e.g., crushed tablets) to patients with jejunostomy, nasojejunal, or nasoduodenal feeding tubes present an additional challenge as these devices bypass the stomach where medications are dissolved and diluted with gastric contents. Due to the narrow bore of the devices and direct administration of medication into the small intestine, liquid dosage forms of medications (e.g., oral liquid, suspension, syrup) must be used. When administering oral dosage forms, several factors should be considered, however, including the osmolality of

the drug, its viscosity, and particle size. Medications that are hypertonic and not diluted prior to administration into the small bowel can result in dumping. The osmolality of stomach secretions is approximately 300 mOsm/kg and many liquid medications exceed this value significantly, resulting in an osmotic-induced diarrhea if given in its undiluted stated. Whenever a hypertonic medication is given undiluted, gastric emptying rates are altered, and there is a flux of water and electrolytes into the small bowel and the absorptive capacity of the small bowel is overwhelmed. Proper dilution of the medication can prevent this flux and improved medication as well as nutrient absorption. Moreover if the feeding tube does terminate in the jejunum, pH is an important consideration to assure optimal dissolution of certain dosage forms.

EFFECTS OF MALNUTRITION ON DRUG KINETICS

It has become increasingly recognized that nutritional status is capable of modifying the pharmacologic effect of a medication. Both malnutrition and obesity can substantially alter drug pharmacokinetics and pharmacologic responses by causing functional and structural alterations in organs that directly affect drug disposition.[33] These changes can affect the absorption, distribution, metabolism, and elimination of a medication that can ultimately affect the therapeutic or toxic response of the drug. Moreover, interindividual and intraindividual variations in the pharmacokinetic responses to a medication can further complicate interpreting the actual impact of altered nutritional status on drug disposition. The variation can be 3- to over 20-fold, depending on genetic (e.g., genetic polymorphism) and environmental factors, patient variables, and underlying disease.[33] Pediatric patients, of course, have a higher incidence of undernutrition (see Chapters 14 and 15). Moreover, several epidemiological studies have demonstrated that children with malnutrition have a high prevalence of bacteremia, pneumonia, and urinary tract infections.[34] The pathologic changes seen in malnutrition can impact the pharmacokinetics of drugs in all phases of disposition within the body, suggesting that the degree of malnutrition can determine the body's response to a particular drug. The integrity of the intestinal mucosa is dependent on a continuous intake of adequate nutrition as the turnover of enterocytes in the small intestine takes two to three days and in the colonocyte of the large intestine three to five days.[35] Even short-term

malnutrition can potentially have a negative impact on drug absorption and metabolism, a risk that increases significantly in patients who go without food for more than 5 days due to a decline in mucosal integrity. Physiologic changes of protein–energy malnutrition (PEM) may result in alterations in the absorptive capacity of the GI tract, body fluid status, cardiac output, GFR, and plasma protein concentrations, as well as hormonal and metabolic changes. Therapeutic drug levels may be altered as a result of malnutrition-associated tissue receptor alterations.[36] It is conceivable that the risk of toxicities owing to a drug or its metabolites is greater in malnourished patients, with a subsequent risk of morbidity or mortality. This suggests that close drug therapy monitoring and modification of dosage in malnourished patients are imperative. Drugs with narrow therapeutic indices or narrow dose-response curves (i.e., phenytoin, theophylline) are particularly susceptible as even small changes in absorption can become significant.

Relatively little is known about the handling of drugs in malnourished children despite the fact that the combination of malnutrition and accompanying disease (typically infection) in need of treatment is a common pediatric problem in many parts of the word. It is possible that the high morbidity and mortality so characteristic of malnutrition may be enhanced by adverse drug reactions.[37]

ABSORPTION

Little research has been done on the effect of malnutrition on drug absorption. O'Doherty et al. observed that phenytoin absorption was slow and erratic in PEM, although the peak concentration and time to reach peak concentration did not differ significantly from controls.[38] Mehta et al. reported similar findings with acetaminophen disposition in children suffering from PEM.[39] Like O'Doherty et al., they observed that the absorption rate constant was not altered in malnutrition. This contrasts with work by Raghuram and Krishnaswamy, indicating that tetracycline absorption was significantly reduced in subjects with malnutritionand pellagra but not in patients with vitamin B complex deficiency or in patients with severe anemia.[40]

DISTRIBUTION

The important serum proteins that bind to drug molecules and biogenic

amines and lipids include albumin, alpha 1-acid glycoprotein, sex hormone–binding proteins, and lipoproteins. Only free, unbound drug molecules are pharmacologically active. Because the amount of serum protein changes over the first few years of life, the pharmacokinetics and pharmacodynamics of a drug may change. The changes in circulating plasma proteins can impact the distribution of highly bound drugs. In neonates and young infants, a relative reduction in total plasma proteins can result in increasing the availability of active drug due to an increase in the free fraction of drug.[2] The serum concentration of alpha 1-acid glycoprotein is lower in children. On the other hand, the concentrations of certain fetal serum proteins are higher in infants and may lead to relatively unique pharmacokinetic changes in this population. For example, in neonates, the presence of fetal albumin is associated with reduced binding capacity to weak acids and, this, along with a corresponding increase in bilirubin and free fatty acids, resulting in a high free fraction of highly protein bound drugs such as phenytoin.[2]

Drugs can distribute into various body compartments such as the intracellular fluids, extravascular space, lean body tissue, and adipose tissue. Alterations in body composition, particularly the presence of edema, can influence the plasma clearance of drug by changing the medication's volume of distribution.[41] Many medications, once in the systemic circulation, become bound to plasma protein, such as albumin, globulins, and lipoproteins. These binding proteins play an important role in the intravascular transport of the drugs to the target organs. In the bloodstream, drugs that are not bound to plasma proteins are free and are able to exert their pharmacologic response. Malnutrition can alter the rate of tissue protein synthesis as well as the concentration of plasma proteins. The extent of drug–protein binding depends on the concentration of plasma bind proteins as well as the physicochemical properties of the medication. In malnutrition, albumin and lipoprotein synthesis is reduced, whereas globulin and a1-acid glycoprotein synthesis is increased.[25] Drugs extensively bound to a1-acid glycoprotein, such as propranolol, have a decreased percentage of drug unbound in malnutrition (i.e., decreased in free fraction), resulting in a lesser amount of active drug available to exert a therapeutic response. Other drugs, such as metronidazole, have no significant change in volume of distribution between malnourished and well-fed children.[42] In the case of parenteral penicillin, no significant difference in C_{max} was noted when penicillin was administered intramuscularly to malnourished versus eutrophic individuals, suggesting

that the rate of penicillin absorption from the muscle mass to the systemic circulating is unchanged. On the other hand, in patients with marasmus and kwashiorkor, there was a trend toward a lower volume of distribution for penicillin, suggesting that overdosing could be a concern in some patients if the typical pediatric dosing strategy is used.[43]

METABOLISM

In chronic starvation, the body is able to adapt and various processes are altered to protect or maintain enzyme activities.[44] In fact, in chronic starvation, enzyme activity may even increase. Endocrine tissue is typically affected in semistarvation as many hormones serve as substrates for drug-metabolizing enzymes.[45] For example, elevations in free cortisol are often seen in malnutrition that may enhance the metabolism of contraceptive steroids in malnourished women, thus increasing the risk of contraceptive failure in that population.[46]

CLEARANCE

Hepatic clearance of drugs may be affected by several major physiologic changes that occur during malnutrition. Protein deprivation or malnutrition may result in a reduction in cardiac function with a subsequent decreased perfusion of the liver and kidneys.[47] Typically, hepatic drug clearance is determined by three independent factors: hepatic blood flow, the amount of free fraction of the drug in blood, and hepatic clearance of the unbound drug. Diminished hepatic blood flow can reduce the clearance of drugs with high extraction ratios (i.e., those in which hepatic clearance of the unbound drug depends on hepatic blood flow but not on changes in protein binding). Presystemic metabolism can become altered. Increases in the unbound fraction of a drug owing to hypoalbuminemia provide more available drug for metabolism, resulting in higher clearance (i.e., rate of drug removal from the body) and lower serum concentrations.[47]

The kidney is extensively involved in drug elimination. Renal elimination includes the processes of glomerular filtration, active tubular secretion, and passive tubular excretion. Drugs or their metabolites that are primarily filtered and excreted renally may be affected by nutritional status. Dietary protein increases renal blood flow, GFR, and renal tubular function.[48] Severe PEM is associated with decreased GFR and renal blood flow.[49] When renal perfusion is reduced, less drug is available to be

filtered by the tubules. However, because plasma protein binding is also reduced, more free drug becomes available for renal excretion, thus further reducing plasma drug concentrations. Medications that have decreased renal elimination in severely malnourished patients include penicillins, tetracyclines, cefoxitin, aminoglycosides, and methotrexate.[33]

Refeeding an undernourished patient can often increase the systemic clearance of a medication, necessitating a dosage adjustment to maintain efficacy. For example, with theophylline, the volume of distribution decreases and the rate of elimination gradually increases in malnourished patients given a dextrose-based parenteral nutrition (PN) solution for at least two days.[50] The protein component of enteral or PN, however, appears to be the major macronutrient enhancing systemic clearance of affected drugs in patients transitioned from the “unfed” to the “fed” state. Lares-Asseff et al. confirmed these findings in their study investigating the pharmacokinetics of metronidazole in severely malnourished children.[42] On the basis of clearance data, they recommended that the daily maintenance doses for pediatric patients with severe malnutrition should be 60% less of the usual pediatric dose to achieve and maintain a therapeutic plasma concentration of metronidazole.

DRUGS IN KWASHIORKOR

Kwashiorkor is associated with edema resulting from increases in total body water, extracellular fluid volume, and plasma volume along with a decrease in intracellular water.[51] Lares-Asseff et al. studied the effects of nutritional status of children with autoimmune disease on the disposition of aspirin and its metabolites.[52] The results suggested that a decrease in the hydrolysis and oxidative reaction of the metabolic pathway of aspirin (ASA) and its metabolites occurs in children with PEM with juvenile rheumatoid arthritis. This suggests that the hepatic elimination of salicylates may be altered by disorders of nutritional state.[53]

Based on these and other studies, it is thought that low protein intake results in a negative nitrogen balance that decreases drug metabolism, whereas drug metabolism in patients receiving adequate total calories but with less than optimal protein intake is not significantly impacted.[54]

DRUGS IN MARASMUS

Unlike kwashiorkor, marasmus can be considered as an adaptation to an

insufficient energy intake. There is decreased total body water, reduced intracellular water, increased extracellular fluid, and increased plasma volume.[33] Gentamicin, which distributes predominantly to extracellular fluids, has an increased volume of distribution in malnourished patients compared with well-nourished patients.[55] Antipyrine, a drug model commonly used as an index of hepatic drug-metabolizing capacity, distributes primarily in total body water and has been shown to have no variation in the apparent volume of distribution in malnourished children.[56] Likewise, in patients treated with metronidazole, a medication that also has a large volume of distribution, no difference in volume of distribution was observed between malnourished and nutritionally rehabilitated children.[42] A pharmacokinetic study by Treluyer et al. focused on the impact of human global PEM on quinine metabolism.[57] In that study, they reported that the metabolism of quinine is increased in children with global malnutrition, suggesting that the dosing interval in these children be reduced to obtain the same therapeutic quinine levels as seen in well-nourished children.

Interestingly, the initiation of antiretroviral therapy (ART) in HIV-infected children with marasmus can precipitate the onset of kwashiorkor.[58] Several mechanisms have been proposed. It is thought that some immune competence is necessary to develop the edema associated with kwashiorkor. Second, immune reconstitution inflammatory syndrome may occur soon after ART is started. Finally, the edema that results may be due to refeeding syndrome that may be the result of ART-associated appetite stimulation. It may also be simply a manifestation of ART toxicity in severely malnourished children. Current guidelines recommend initial therapeutic feedings for HIV-infected children with severe malnutrition followed by 50%–100% increased energy intake for the first 6–10 weeks of ART.[59]

In summary, normal or increased drug metabolism occurs in mild to moderate cases of malnutrition, whereas decreased metabolism is seen in severe cases of malnutrition. Given the unique needs of the malnourished ill child, special guidelines have been created for the use of antimicrobial agents.[60] A recent systematic review of antibiotic use in children with severe acute malnutrition (SAM) has attempted to validate these guidelines.[34] On the basis of the evidence to date, the authors support the use of broad-spectrum antibiotics in this population but that well-designed randomized controlled trials are required to further address concerns surrounding the routine use of antibiotics in uncomplicated SAM, with

consideration for HIV status.

OBESITY

Obesity (i.e., body mass index [BMI] ≥ 95th percentile for age and sex) results in altered body composition in which there is both an increased proportion and an absolute amount of adipose tissue as well as an increase in lean body mass, blood volume, cardiac output, and organ size.[61] A crude measure of obesity is the BMI, a person's weight (in kilograms) divided by the square of their height (in meters). A BMI equal to 25 or more is considered overweight; an individual with a BMI of 30 or more is generally considered obese. Obesity is linked with physiological changes that can impact pharmacokinetic parameters of many medications, but for most drugs, dosing recommendations do not take into account the need for dosing adjustments due to size measures.

In children, obesity can result in an expansion of blood volume, resulting in increased stroke volume and cardiac output. There seems to be no differences in albumin binding of drugs although increases in CYP2E1 activity and phase II conjugation activity have been observed.[62] Nevertheless, the increased in CYP2E1 activity appears to be down-regulated with weight loss. An increased abdominal fat can also lead to increased intra-abdominal pressure and impact gastric emptying.[63] Drug distribution depends on body composition and may be altered in obese patients. Absorption of drugs evaluated to date appears to be unchanged owing to obesity, although the data are very limited.[64] Severely obese patients who have undergone bariatric surgery for weight loss are more likely to experience altered drug absorption that may affect the clinical responses to therapy. Generally speaking, malabsorption of drugs is more likely to occur with the primary malabsorptive procedures such as jejunoileal bypass and pancreatobiliary diversion. A commonly performed surgical procedure for weight loss is the Roux-en-Y gastric bypass (RYGB), which is a primary restrictive procedure with mild malabsorptive component. Studies aimed to investigate the impact of RYGB on pharmacokinetics are very limited. Existing data suggest that the impact appears to be minimal with the current procedure when the Roux-limb (bypass limb) is not more than 150 cm. In addition, the bioavailability of orally administered liquid medications appear to be unaffected by RYGB. These early data suggest that if oral absorption is a concern in a patient with RYGB or similar upper GI surgical procedures, liquid dosage forms of medications are preferred.

The lipophilicity of a drug determines the extent to which obesity influences the volume of distribution and ultimately whether dosing should be based on actual or adjusted body weight. Highly lipophilic drugs, such as lidocaine, thiopental, phenytoin, verapamil, and most benzodiazepines, have an increased volume of distribution in severely obese patients.[51] Modest increases in volume of distribution have also been reported for aminoglycosides, heparin, ibuprofen, methylxanthines, prednisolone, and vancomycin, suggesting that an adjusted body weight rather than actual body weight be used to avoid toxicity.[64] However, the most accurate approach to adjust for the excess body mass is unknown and appears to be different depending on the characteristics of individual compounds. Therapeutic drug monitoring is recommended when applicable to optimize therapy.

Although the protein binding of acidic drugs is unchanged, the free fraction of basic drugs may be decreased with obesity.[64] Similarly, changes in hepatic drug clearance are variable. Phase 1 reactions and phase I acetylation appear to be unaffected by obesity, but the phase II glucuronidation and sulfation pathways are enhanced. This may result in the shortened duration of action of oral contraceptives and may increase the risk of oral contraceptive failure.[65] Obesity may also affect systemic clearance of highly extracted drugs such as aminoglycosides and unmetabolized procainamide.[64] Both glomerular filtration and tubular secretion also appear to be increased.[40] Renal clearance of drug that mediated by both glomerular filtration and active secretion, such as digoxin and cimetidine, are relatively unchanged in obesity.[64] Table 18-3 provides a examples of dosing strategies for medications used in obese patients.

Aminoglycosides are distributed within the extracellular fluid compartment. Early dosing recommendations suggested that initial dosing be based on ideal body weight (IBW) as it was thought that the drug distributed only into lean body mass. Schwartz et al., however, have since determined that when the volume of distribution is corrected for total body weight, it is significantly smaller when compared with normal-weight subjects.[66] The distribution of aminoglycosides into excess body weight is estimated to be about 40% of that distributed into ideal body tissue. The authors concluded that initial dosing of aminoglycosides in obese patients be determined by adding 40% of the excess weight to the patient’s ideal body weight, with subsequent dosage adjustments based on serum drug levels and clinical status.

Example: For a 7-year-old child, 41 kg, 135 cm, gentamicin 2.5 mg/kg/dose intravenously every 8 hours is ordered:

1. Determine IBW[16]

$$\text{IBW} = \frac{\text{ht}^2 \times 1.65}{1000} = \text{IBW kg, height cm}$$

$$\text{IBW} = \frac{135^2 \times 1.65}{1000} = 30 \text{ kg}$$

2. Determine dosing weight (DW): DW = IBW + (actual body weight [ABW] – IBW) × 0.4 DW (in kg), ABW is actual body weight (in kg)
   DW = 30 kg + (41 – 30) × 0.4 DW = 34.4 kg
3. Calculate gentamicin dose using DW: mg/kg/dose × DW = dose in mg 2.5 mg/kg/dose × 34.4 kg = 86 mg intravenously every 8 hours

Table 18-3 Suggested Dosing Strategies for Medications in Obese Patients

Fixed Doses	Ideal Body Weight	Adjusted Ideal Body Weight	Total Body Weight	Othe
Caspofungin Clarithromycin Co-trimoxazole Linezolid Meropenem Metronidaozole Metoprolol Piperacillin/tazobactam Posaconazole	Acyclovir Filgrastim (G-CSF) Fludarabine Methotrexate Methylprednisolone	Aminoglycosides Amphotericin B, liposomal Busulfan Cyclosporine Phenytoin	Enoxaparin Vancomycin	Ciprof

Source: Adapted from Ref.62.

A similar controversy exists for optimizing theophylline dosing in obese patients and whether actual or ideal body weight should be used to calculate the initial theophylline loading dose. This is attributable to conflicting data suggesting that variations in distribution volume may be the result of differences in the degrees of obesity within study populations.[67] Visram et al. suggested that the differences in theophylline volume of distribution based on ideal body weight and actual body weight increases as the degree of obesity increases.[68] They recommended that theophylline dosing in patients with mild to moderate obesity be based on actual body weight but that ideal body weight be used when initiating

therapy in severely or morbidly obese patients.

Hepatic drug metabolism may also be altered in patients with nonalcoholic steatohepatitis (NASH),[42] including enhanced glucuronidation and sulfonation, causing a faster drug excretion compared with normal-weight subjects.[64] CYP2E1 expression and activities are increased in obese patients with nonalcoholic fatty liver disease, including NASH.[69] Compounds that are metabolized by CYP2E1 include fatty acids, ketones, and ethanol. It appears that the presence of an increase amount of fatty acids, such as in the case of NASH, leads to an induction of this enzyme. The metabolic pathways of fatty acids and other xenobiotics may lead to the release of free radicals, which can cause lipid peroxidation and liver injury, including mitochondrial damage. These changes are partially responsible for the hepatic inflammation and fibrosis sometimes observed in patients with NASH.[70] Patients with fatty liver may also be more susceptible to the toxic effects of drugs owing to impaired metabolism.[71]

EFFECT OF DIETARY MANIPULATION ON DRUG KINETICS

Modifying the intake of specific foods may influence the clinical response of a medication. Populations at particular risk to an adverse event associated with a drug–nutrient interaction include those with chronic disease requiring use of multiple drugs and those requiring specialized nutritional support or some evidence of malnutrition.

Several dietary factors can alter the rate of drug metabolism. Model drugs, such as antipyrine, theophylline, and acetaminophen, have often been used in these studies. Both food and fluids can alter the rate and extent of drug absorption. These alternations in response may occur as a result of influences on gastric pH, gastric emptying time, intestinal motility, and mesenteric and hepatic portal blood flow or biliary flow, or the activities of the enzymes and transport proteins in the gut.[72] Direct physicochemical interactions with dietary components can also alter the absorption of susceptible agents.[73] Interactions such as the binding of the medication with metal ions, solubilization of the drug in dietary fat, or adsorption of the drug to insoluble dietary components may occur.[74]

Dietary changes can alter the expression and activity of hepatic drug-metabolizing enzymes.[75] This can lead to alteration in the systemic elimination kinetics of medications metabolized by these enzymes, although the impact of this change is typically minimal.[75] The rate of drug

metabolism can be accelerated by drugs themselves or by a variety of dietary factors, such as protein supplementation or inclusion of cruciferous vegetables or charcoal-broiled meats in the diet.[76] It has also been reported that charcoal-broiled beef induces the metabolism of antipyrine and theophylline, reducing the half-lives of these drugs by 20%.[77] These effects were related to hepatic enzymatic induction caused by charcoal-broiled beef that contains large quantities of polycyclic aromatic hydrocarbons (PAHs).[78] PAHs are potent inducers of CYP1A2, the primary metabolizing enzyme for theophylline and antipyrine. Conversely, low-protein, high-carbohydrate diets and various vitamin and mineral deficiencies can reduce levels of drug-metabolizing enzymes and consequently the rate of drug metabolism, so that the serum drug concentrations decline much more slowly resulting in increased drug potency.[76]

In general, when orally administered medications are taken with meals, the rate rather than the extent of absorption is more significantly affected. Food affects drug absorption by enhancing gastric blood flow in conjunction with delayed gastric emptying or by altering dissolution. Food can increase, decrease, or have no effect on the absolute systemic availability of a medication.[79] Concomitant food ingestion reduces the absorption of drugs such as ampicillin, penicillin, and isoniazid.[33] Conversely, food may actually enhance the absorption of other medications, including diazepam, lithium, carbamazepine, ziprasidone, and griseofulvin. Table 18-4 lists medications whose absorption is altered by food. In most cases, changing the rate of absorption of a drug alone without affecting the total amount absorbed should not affect its efficacy.

The composition of the meal will alter splanchnic blood flow. Blood flow can be doubled by a high-protein liquid meal and slightly reduced by a liquid glucose meal.[80] The significance of this effect on splanchnic flow is important for those medications with high hepatic extraction.[74] Continued meal intake, especially food with high fat content, will also slow the rate of gastric emptying, which may subsequently cause a delay in drug absorption from the GI tract. Changes in gastric emptying are related not only to the physicochemical properties of the drug but also to the type of meal itself. Hot meals, highly viscous solutions, or those rich in fat have the most significant affect in slowing down gut motility.[74] Melander et al. reviewed the impact of food on the presystemic clearance of drugs.[81] They observed that meals commonly enhanced presystemic clearance of lipophilic basic drugs (e.g., propranolol, amiptriptyline) but

rarely altered the clearance of drugs that were lipophilic acids (e.g., salicylic acid, penicillin). Alternatively, food may reduce presystemic clearance of some lipophilic basic drugs via transient, complex effects on splanchnic-hepatic blood flow. Furthermore, repeated intake of specific nutrients (e.g., protein) and food contaminants (e.g., aromatic hydrocarbons) can enhance presystemic drug clearance by enzyme induction.

Table 18-4 Examples of Medications Whose Absorption Is Affected by Food

Drug Absorption Reduced/Delayed by Food	Drug Absorption Enhanced by Food
Ampicillin	Albendazole
Aspirin	Amiodarone
Atenolol	Atazanavir
Azithromycin	Atorvastatin
Calcium salts	Atovaquone
Captopril	Carbamazepine
Cefaclor	Cerivstatin
Cefixime	Chlorothiazide
Cephalexin	Cefuroxime
Ciprofloxacin	Clarithromycin
Dapsone	Clofazimine
Didanosine	Cyproheptadine
Digoxin	Diazepam
Doxycycline	Efavirenz
Dirithromycin	Etravirine
Erythromycin stearate	Erythromycin estolate
Famciclovir	Erythromycin ethyl succinate
Flecainide	Fluvastatin
Fluoride	Gabapentin
Indinavir	Ganciclovir
Isoniazid	Griseofulvin
Loratidine	Guanfacine
Metronidazole	Hydralazine
Naficillin	Hydrochlorothiazide
Nalidixic acid	Hydroxychloroquine
Penicillin G or V	Isotretinoin
Phenobarbital	Itraconazole
Phenytoin	Ivermectin
Rifampin	Ketoconazole
Sucralfate	Lithium
Tacrolimus	Lovastatin
Tetracycline	Mebendazole
Thioridazine	Methylphenidate
Voriconazole	Metoprolol
Zafirlukast	Nelfinavir

	Nitrofurantoin Pravastatin Propanolol Propoxyphene Rilpivirine Ritonavir Saquinavir Simvastatin Spironolactone Tenofovir Tipranavir Valganciclovir Zalcitabine

In some instances, dietary manipulation can act as a therapeutic strategy. Nutt et al. reported that large neutral amino acids and the medication levodopa compete for transport from the plasma to the brain and may be partly responsible for the "on-off" phenomenon often seen in patients treated with levodopa for Parkinson's disease.[82] By reducing protein intake, patients who failed to respond to a dosage adjustment in their levodopa may see clinical improvement.

IMPACT OF SPECIFIC NUTRIENTS ON DRUG KINETICS

Until recently, most practitioners dismissed the possibility that dietary substances could significantly alter medication response by affecting intestinal transporter and metabolizing enzymes. This is based on the commonly believed misconception that the absorption of most drugs is a passive process and that the role of the intestine in drug elimination is minimal.[75] Since the report of the interaction between grapefruit juice and several medications was described, this premise has changed, and the role of the diet on drug performance is being re-evaluated.[83]

Carbohydrates

The impact of carbohydrates on drug metabolism is conflicting. It is known that high carbohydrate diets may induce the expression of several glycolytic and lipogenic hepatic enzymes,[84] but some suggest that carbohydrates have little impact on drug metabolism.[85] Kappas et al., however, noted that antipyrine and theophylline metabolism decreased in carbohydrate-supplemented diets but increased in the protein-enriched

diet, suggesting that carbohydrates and protein have opposite effects on oxidative drug metabolism.[76] Although many medications are often given to children in a sugar syrup, little research has been done on its effect on disposition and action. Animal studies by Sonawane et al. suggested that dietary carbohydrates and fat may significantly influence the hepatic drug-metabolizing enzymes.[86] It has been hypothesized that these changes may occur owing to alteration in the phospholipid composition of endoplasmic reticulum or by limiting the supply of cofactor(s) necessary for optimal functioning of CYP and UGT.

Protein

Several investigators have reported that medications that undergo extensive first-pass effect, such as propranolol, metoprolol, and lidocaine, can have enhanced bioavailability after a high-protein meal owing to enhanced hepatic blood flow. High-extraction drugs can then rapidly pass through the liver, allowing higher drug concentrations in the systemic circulation.[75,81] A decrease in dietary protein depresses creatinine clearance and renal plasma flow.[87] In situations where there is low protein intake, careful attention is needed to avoid toxicity secondary to delayed drug clearance. Specific dietary proteins can also impact a response to a medication. One of the classic examples is that of the monoamine oxidase inhibitor (MAO-I) drug class and the amino acid tyramine that is contained in aged cheeses, pickled/smoked meats, fermented foods, and red wines. Tyramine is an indirect sympathomimetic amine that releases norepinephrine from the adrenergic neurons, causing a significant pressor response. Typically, tyramine is metabolized by the enzyme monoamine oxidase before any significant increases in blood pressure are seen. If the enzyme is blocked, however, severe and potentially fatal increases in blood pressure can occur when tyramine-rich foods are ingested. Although MAO-Is are not used routinely as antidepressants, other medications, such as the oxazolidinone antibiotic and linezolid, also have MAO-I properties and patients should avoid ingesting large amounts of tyramine while being treated with this antibiotic.[88]

Dietary protein also affects the renal tubular transport of certain compounds, although the mechanism by which this occurs is still not understood. The binding of dietary proteins to a drug may underscore changes in bioavailability after a protein meal. For example increases in both the maximum concentration (C_{max}) and area under the curve (AUC) are seen in patients receiving gabapentin. This enhanced absorption was

attributed to trans-simulation, a carrier-mediated process in which increased intestinal luminal amino acid concentrations result in an upregulation and/or increased activity of the L-amino acid transporter.[89]

Dietary Fat

Lipids are an essential part of cell membrane structure and are involved in many of the normal enzymatic activities located within the cell membrane.[71] Diets that are deficient in fat or essential fatty acids decrease the activity of the enzyme systems responsible for the metabolism of nutrients.[90] Plasma-free fatty acid levels become elevated after consumption of a high-fat meal, increasing the potential to become bound to plasma albumin, and subsequently displace albumin bound drugs, increasing the risk of drug toxicity.[85] Dietary fats along with food-stimulated secretions (e.g., bile salts) may facilitate the solubilization and dispersion of lipophilic compounds. This may contribute to a reduction in the extent of first-pass metabolism due to enhanced splanchnic blood flow.[91] Ingestion of diets high in fat has been associated with the induction of CYP2E1. The extent to which this enzyme is upregulated is dependent upon the type of fat. Polyunsaturated fats such as corn and menhaden oils appear to have the greatest influence in comparison to lard or olive oils. This can result in enhanced peroxidation of the PUFA substrates and contribute to free radical production.[92] The rate of gastric emptying is also influenced by the fat content of a meal. Fat retards gastric emptying to a greater degree than does protein or carbohydrate.[93]

The effect of dietary fat on drug absorption, however, depends on the route of the drug absorption, either portal or lymphatic. For medications absorbed via the lymphatic route, dietary fat enhances the absorption of the dissolved drug while poorly bioavailable lipophilic drugs absorbed by the portal route have their absorption enhanced by improved drug dissolution. Conversely, lipophilic medications that have good bioavailability will less likely to be impacted by a high-fat meal. Hydrophilic medications are probably not impacted significantly when co-administered with fatty meals.[94]

The impact of food on the absorption of cyclosporine is controversial. There are conflicting reports, depending on the formulation studied, stating that food impairs, enhances, or does not affect cyclosporine compared with the fasting state.[95] Similarly, high-fat meals may impact sirolimus bioavailability. When taken with a high-fat meal, the rate of sirolimus absorption is slower and results in a greater AUC in comparison to when

taken in the fasted state. This contrasts with tacrolimus in which a 71% mean decrease in C_{max} and a 39% mean decrease in AUC was seen immediately following its administration after a high-fat meal relative to when the same dose was given in the fasted state.[96]

The antiviral agent zidovudine is also impacted by dietary fat. When administered orally, its absorption is reduced when the drug is taken with a high-fat meal in comparison with when taken in the fasted state.[97] It is recommended that zidovudine be taken on an empty stomach to achieve peak serum concentrations. Similarly, treatment failures can occur if the antitubercular drug cycloserine is taken with a high-fat meal due to decreased absorption.

Minerals

In most instances, mineral deficiencies (i.e., zinc, iodine, magnesium, and potassium) have been associated with a decrease in drug oxidation and drug clearance.[98] Low dietary intake of iron, however, has been associated with an increase in some CYP functions and a decrease in other degradative activities, the reasons for which are not fully apparent. Foods fortified with multivalent minerals, such as calcium, are presenting a new challenge. Any medication carrying a warning to avoid milk, dairy products, or nutritional supplements can be affected by calcium-fortified orange juice.[35] As a class, antibiotics are the most susceptible to chelation and adsorption by fortified cereals, calcium-fortified orange juice or protein supplements. Patients need to be counseled that consuming fortified foods may decrease the clinical efficacy and increase the risk of treatment failure.[99]

Vegetables

Diets rich in vegetables and fruit may also impact the response to medications. Both serve as sources of trace minerals that are contained in metalloenzymes, including several antioxidants. Many plants contain flavonoids, isothiocyanates, and allyl sulfides that are potent modulators of the cytochrome monoxygensease system.[100]

Phyotochemicals are linked with the modulation of a variety of metabolic pathways. The most frequently sources include cruciferous vegetables, citrus juices, and spices. Dietary supplements and herbs are also associated with this category. There are five major families of phytochemicals: carotinoids (e.g., beta carotene, lycopene), alkaloids, phenolics (including flavonoids, coumarins, tannins), nitrogen compounds,

and sulfur compounds (e.g., isothiocyanates, allylic sulfur).[101] Recent research has focused on how vegetables and fruits can influence a variety of enzymatic pathways. Typically induction of these enzyme systems is rapid and plateaus within 5 days of continued daily ingestions of the food with the enzyme-inducing capacity.[101]

Cruciferous vegetables, including brussels sprouts, cabbage, turnips, broccoli, cauliflower, and spinach, contain indols that induce aryl-hydrocarbon hydroxylase enzyme activity as well as the conjugation of phenacetin and acetaminophen.[102,103] In one study, patients fed a diet of Brussels sprouts and cabbage had a 50% lower serum phenacetin level in comparison with the same subjects fed a control diet that contained none of the enzyme-inducing vegetables.[103] A later study investigated the effects of cruciferous vegetables on acetaminophen conjugation.[102] The researchers found that the test diet of cruciferous vegetables enhanced acetaminophen glucuronide conjugation as evidenced by a 16% decrease in the AUC, a 17% increase in metabolic clearance, and an increased plasma acetaminophen glucuronide-to-acetaminophen ratio.

Cruciferous vegetable are not the only plants that can impact drug response. Potatoes, tomatoes, and eggplant contain natural insecticide compounds called solanaceous glycoalkaloids that even in small amounts may greatly slow the metabolism of muscle relaxants and anesthetic agents such as suxamethonium, mivacurium, and cocaine. Cooking does not reduce them, and they may remain in the body for several days after ingestion. Solanaceous glycoalkaloids inhibit butyryl cholinesterase, which breaks down many anesthetic agents, and cetylcholinesterase, which breaks down acetylcholine. When these enzymes are inhibited, patients receiving medications metabolized by them may take longer to recover fromanesthesia.[104]

Grapefruit Juice and Drug Interactions

Bailey et al. discovered that grapefruit juice, which was used as a taste-masking agent for alcohol, caused a two- to threefold increase in oral absorption of the calcium channel blocker felodipine.[105] This finding has subsequently led to the intensive investigation of grapefruit juice and drug interactions. This interaction is the classic example of drug–nutrient interaction exclusively caused by inhibition of intestinal CYP3A4. Oral absorption pharmacokinetic studies of CYP3A4 substrates, such as cyclosporine or felodipine, consistently showed that grapefruit juice increased the oral bioavailability of these agents. Interestingly, the plasma

half-lives of most of the drugs studied were not affected, suggesting that the systemic clearance or hepatic metabolism of these drugs was unchanged by grapefruit juice. It was later determined that this interaction occurs in the enterocytes but not in the hepatocytes. Furthermore, Lown et al. showed that repeated consumption of grapefruit juice inhibits not only the intestinal CYP3A4 activity but also the expression of this gene in the enterocytes.[11] As grapefruit juice inhibits intestinal CYP3A4 expression and thus decreases the presystemic metabolism of certain drugs, the bioavailability of the affected agents will remain increased until the expression of the CYP3A4 gene returns to baseline. This suggests that mere separation of the administration time between grapefruit juice and the potential interacting drugs cannot prevent this interaction.

Grapefruit products also interact with uptake transporters such as organic anion-transporting polypeptides (OATPs).[106] OATPs are uptake transporters distributed in the liver, small intestine, kidney, and brain. In the small intestine, OATPs are expressed on the apical surface of enterocytes, facilitating in the intestinal absorption of orally administered medications. Thus, nutrients can alter OATP activity that can impact the bioavailability of a drug that relies on influx transport systems for its intestinal absorption. Fexofenadine was the first OATP substrate identified to interact with grapefruit juice. Inhibition of OATP1A2 transport by flavonoids in grapefruit (naringin) lowered oral fexofenadine bioavailability significantly.[107] Similar results were observed with orange juice, which contains the flavonoid hesperidin. This decrease in oral bioavailablity among OATP1A2 substrates impacts both hydrophilic and renally excreted drugs such as atenolol and ciprofloxacin, more than lipophilic agents. Medications with greater polarity and which are eliminated mainly by excretion are more dependent on uptake transporters rather than passive diffusion. Thus, OATP1A2 substrates, which are excreted renally unchanged, may undergo significant decrease in oral bioavailability if given concurrently with orange or grapefruit juice.[108] Conversely, the oral bioavailability of a medication such as imatinib, an OATP1A2 substrate that is mainly metabolized by CYP3A4, is increased in the presence of grapefruit juice because CYP3A4 inhibition is more dominant than OATP1A2 inhibition as it relates to imatinib pharmacokinetics.

As the aforementioned examples illustrate, the clinical significance of these interactions depends on the pharmocokinetic and toxicity profiles of the co-administered medication. Rather than empirically reducing the dose of the affected drugs to avoid toxicity, it is more advisable to suggest

patients avoid grapefruit juice if they are taking an interacting drug since the magnitude of interaction is inconsistent among individuals and difficult to predict. In some centers, grapefruit juice has been removed from the institutional formulary to minimize the risk of this interaction.

HIGH-FIBER DIETS

Dietary fiber and other bulk-forming compounds may interfere with the GI absorption of a medication.[109] The bioavailability of digoxin is reduced significantly when given with a fiber-rich meal, with almost half of the dose sequestered in or bound to the fiber.[110] Similar effects have been reported with lithium salts and lovastatin.[111] Stewart reported that several patients with recurrent major depression who had been successfully treated with tricyclic antidepressants became refractory to treatment after beginning a high-fiber diet.[112] Nutrient absorption can also be negatively impacted in the presence of a high-fiber diet. Zinc absorption in the intestine is reduced by the binding of zinc to a number of materials, including phytate, which is found in high-fiber diets.[113]

COOKING METHODS

Drug metabolism can also be enhanced by the ingestion of charcoal-broiled beef. Patients fed such a diet saw a significant drop in serum phenacitin levels in comparison to the same subjects fed a control diet. It has also been reported that charcoal-broiled beef induced the metabolism of antipyrine and theophylline, reducing the half-lives of these drugs by 20%.[114] It has been postulated that these effects were related to the large quantities PAHs present in charcoal-broiled beef.

VEGETARIANISM

Drug metabolism among vegetarians will vary dramatically depending on the protein intake. Most research has focused on Asian vegetarians in which the half-lives of drugs that underwent significant hepatic metabolism (e.g., antipyrine, acetaminophen, phenacetin) were significantly longer than in nonvegetarians.[115] When similar studies were conducted in white vegetarians, they found no significant difference in half-life between the vegetarians and nonvegetarians.[116] Protein quality may contribute to these findings as the authors found that protein intake

between the white vegetarians and the nonvegetarians was similar.

Vegetarian diets are also associated with lower circulating concentrations of sex steroids hormones, increased fecal excretion of estrogens, and different hormonal profiles in comparison to individuals consuming an omnivorous diet.[117] Vegetable intake may influence total body estrogen load via the modulation of CYP enzymes involved in estrogen metabolism. CYP 13C, found in cruciferous vegetables, can increase estrogen hydroxylation.[118]

VERY LOW CALORIE DIETS

In diets involving severe protein–energy restriction, such as extreme slimming diets, the metabolism of drugs may be affected in one of two ways. First, tissue protein is catabolized and used as an energy source, thus reducing the availability of amino acids for protein synthesis, which in turn reduces the amount of enzymes available for drug metabolism. Second, endogenous substrates derived from carbohydrate and protein such as glucuronide, sulfate, and glycine could also compete for the tissue needs for these nutrients and that of the drug metabolism/detoxification.[119] Eating behaviors, especially among dieters that omit or severely restrict whole categories of foods, have a negative impact on micronutrient status. Diets that eliminate all animal foods provide almost no cyanocobalamin and have been associated with other vitamin deficiencies including vitamin C. Moreover, skipping meals and fad diets to lose weight frequently compromise micronutrient intake. It should be routinely assumed that it is extremely difficult to meet all the requirements at intakes of less than 1200 calories per day. An analysis of 11 published weight loss diets showed that none provided 100% of the US Recommended Dietary Allowance (RDA) for representative vitamins.[119]

In a review by Anderson, the author suggests that the metabolic improvements seen after obese patients receive very low calorie diets (VLCDs) are not different from those obtained by equally large weight loses promoted by other methods.[120] Patients with VLCD weight loss have improved hyperinsulinism as a result of a reduction in basal insulin production as well as enhanced hepatic insulin extraction. Moreover, it is thought the weight loss through VLCD lowers the hepatic glucoronidation of drugs leading to higher plasma concentrations of the affected drugs.[121] Despite this, however, the fatty liver may still be more susceptible to drug toxicity.[122] For example, several reports have suggested that caloric

restriction may contribute to acetaminophen hepatotoxicity by altering drug metabolism although under controlled conditions, Schenker et al. saw no impact on food restriction of acetaminophen metabolism.[123]

OTHER DIETARY RESTRICTIONS

In addition to caloric restriction, restriction of other dietary components can also impact drug response. In patients who have sodium restricted diets, there is an increased risk of acute renal failure if these same patients are given concomitant angiotensin-converting enzyme inhibitors or nonsteroidal anti-inflammatory agents. There is enhanced nephrotoxicity in patients who are sodium depleted and are given cyclosporine or tacrolimus. Sodium restriction can also increase the renal tubular absorption of lithium, leading to toxicity. Patients receiving aminoglycosides, amphotericin B, cisplatin, or radiocontrast media in conjunction with a low sodium diet have an increased risk for hemodynamic nephrotoxic and ischemic acute renal failure. For reasons still not known, the efficacy of calcium channel blockers is reduced in patients on a sodium-restricted diet.[124]

IMPACT OF BEVERAGE TYPE ON DRUG BIOAVAILABILITY

To most practitioners, the term beverage refers to any drinkable liquid other than plain water. They are typically classified as caffeinated, alcoholic, milk-based, mineral waters, or fruit/vegetables juices.[125] Depending on the type of fluid taken with a medication, drug absorption may be impacted. Mixing drugs with fruit juices or other beverages to mask their taste may impact absorption due to changes in gastric pH, which in turn can affect dissolution of solid dosage forms and formulations with a pH-sensitive coating. Dairy products decrease the absorption of tetracyclines and reduce their bioavailability due to the formation of insoluble chelates between the drug and the calcium present in the beverage. Similar decreases in bioavailability were noted when fluoride tablets are taken with milk. Tannins present in teas may impair iron absorption. Alcoholic beverages reduce the absorption of folic acid, cyanocobalamin, and magnesium. Soft drinks, such as colas, may decrease the drug absorption for a variety of reasons. The phosphoric acid and sugar present in these drinks can slow gastric emptying, and the tendency to

serve them chilled may also reduce the rate of blood flow within the intestines. Moreover, the carbonation may increase mixing and possibly motility. Interestingly, the acidic pH of cola beverages can be used to optimize clinical responses of both ketoconazole and itraconazole when administered as solid dosage forms in patients with gastric hypochlorhydria, such as those patients with AIDS gastropathy. Acidic beverages improve dissolution of tablets and capsules, thus can improve and stabilize oral bioavailability if these drugs are ones that are poorly soluble in higher pHs.[125] The effects of grapefruit juice on drug disposition are discussed separately.

PARENTERAL NUTRITION

Lack of oral nutrient intake during PN leads to mucosal atrophy of the bowel along with a reduction in gastricbiliary, pancreatic, and intestinal secretions.[126] Bacterial overgrowth can result in a progressive decline in intestinal function owing to impaired motility and depressed enzyme activity. This may alter the rate and extent of absorption of specific nutrients as well as various drugs. Decreases in nutrient absorption include fat, iron, peptides, and vitamins A and B_{12} as well as drugs such as chloramphenicol, chloroquine, tetracycline, and rifampin.[47]

PN has been observed to decrease hepatic drug and xenobiotic metabolism in animals and humans.[127,128] Drug metabolism may be altered due to jejunal and ileal mucosal hypoplasia and hypofunction as parenterally administered nutrients bypass the intestine. Studies using antipyrine as a marker have shown that PN regimens containing amino acids have higher antipyrine clearance than regimens consisting mainly of dextrose.[127] Burgess et al. investigated the response of PN regimens on antipyrine clearance.[128] Patients receiving a postoperative 2000 kcal PN regimen providing all nonprotein calories as dextrose showed a 34% reduction of mean antipyrine clearance after 7 days of PN compared with unfed controls. This effect was seen also in patients receiving a 1600 kcal dextrose-based regimen. More over, in patients receiving a 2000 kcal PN regimen in which 500 kcal was provided as lipid, mean antipyrine clearance was not significantly different from that of the unfed control group. This study suggested that hepatic CYP1A activity may be affected by different PN regimens.

EFFECTS OF DRUGS ON NUTRIENT STATUS

Drugs can alter the use of many nutrients by a variety of mechanisms, both specific and nonspecific. Malabsorption syndromes may occur from direct toxic effects of the medication to the intestinal mucosa, inhibition of enzymes, binding of bile and fatty acids, alteration of dietary ions, or alteration of GI pH. Indirect, nonspecific effects of a drug may manifest themselves as a decrease in appetite, ultimately leading to a decrease in food intake.

Although the concept of drug–nutrient interactions is not a new one, only recently has it reached the forefront in the medical world. Malnutrition, as well as the composition of the diet, can affect the disposition of a medication's half-life.[129] In addition to traditional dietary components, nonnutrient ingredients, such as food additives, preservatives, antioxidants, sweeteners, flavoring, and coloring agents, can interact with a medication. Natural products, such as plant food groups containing alkaloids, flavonoids, and other compounds, can behave in the body in the same manner of that a drug and, consequently, can be involved in a variety of interactions and are potentially toxic if they are consumed or accumulate in the body.[130] Drug–nutrient interactions are typically defined as situations that result from chemical, physical, physiologic, or pathophysiologic relationships between nutrients and drugs.[131] Infants and adolescents, like the elderly, are at particular risk for drug–nutrient interactions. Several factors may influence the possible interactions: first, their nutrient needs are typically higher; second, the systems for detoxification of nutrients may be incomplete; and third, adolescents (especially females) tend to restrict their diets and thus are unable to meet the actual recommended intakes for a variety of micronutrients.[132] Furthermore, the minimum dietary requirement may be insufficient when a patient is under psychological and pathologic stresses, as in the case of pregnancy or athletic training. In pathologic states, the requirement for some micronutrients may be increased.

Drugs may potentially cause vitamin deficiency ranging from subclinical deficiency to potentially fatal sequelae. The clinical intensity of the interaction in many cases may depend on the nutritional status of the patient. Patients with borderline intake of vitamins or those in poor nutritional health appear to be at a greater risk of developing symptomatic vitamin deficiency states. Other factors include the type of drug treatment, dose, and duration of therapy, as well as the age of the patient. For example, individuals on a normal diet rarely become vitamin K deficient,

although malnourished patients, regardless of cause, often have moderate or significant deficiency, often with prolonged bleeding times.[132,133] Cohen et al. reported that hospitalized patients may become vitamin K deficient within 7–10 days after admission, with those at greatest risk being those who were previously malnourished and had received antibiotics for 7 or more days.[134] Adolescents, due to periods of rapid growth, are particularly sensitive to micronutrient status. Even a typical diet may not meet their high nutrient demands necessary for growth. Intake of folate and vitamin A tend to be less than optimal.[126]

ABSORPTION OF NUTRIENTS

There are also many secondary mechanisms that can interfere with nutrient absorption. Medications may alter gastric or intestinal secretion, pancreatic exocrine function, or hepatic bile secretion. For example, H_2 antagonists and proton pump inhibitors inhibit gastric acid production. Chronic use of these medications can significantly decrease the bioavailability of the dietary source of vitamin B_{12}.[135]

The direct systemic effect of a drug on one nutrient may have secondary effects on another nutrient. Isoniazid and cimetidine inhibit the hydroxylation of vitamin D in the liver and kidney, and phenytoin and phenobarbital promote the breakdown of vitamin D metabolites, each resulting in a functional deficiency of vitamin D and secondary impairment of calcium absorption.[136] Neomycin, colchicine, and para-aminosalicylic acid may damage intestinal mucosa and destroy intestinal villi and microvilli, resulting in an inhibition of brush border enzymes and intestinal transport systems.[137] Nonsteroidal anti-inflammatory agents can cause multiple small hemorrhages of the intestinal mucosa leading to iron-deficiency anemia and decreased absorption of vitamin C.[138] Folic acid deficiency and macrocytic anemia can occur in patients on chronic aspirin therapy, especially if their diet is low in dietary sources of folate.[139]

Laxative abuse has also been implicated with malabsorption of vitamin D and calcium. Use of irritant laxatives, such as phenolphthalein and bisacodyl, may damage intestinal epithelial cells and impair colonic reabsorption, resulting in steatorrhea, protein-losing enteropathy, and decreased absorption of glucose, potassium, calcium, and vitamin D.[140] Other stool regimen medications, such as docusate, alter electrolyte transport and can cause hypomagnesemia owing to GI losses and failure of colonic reabsorption.[141] Orally ingested mineral oil can coat ingested food

particles along with the surface of the intestines. This forms a mechanical barrier to the digestion and absorption of nutrients. Mineral oil also increases gastric motility, which reduces the time required to adequately absorb ingested nutrients.[142] Furthermore, studies have shown that mineral oil, especially when taken at mealtime or during the postprandial absorptive period of optimal nutrient absorption, can reduce the absorption of vitamin D.[142]

Alterations in vitamin and mineral absorption can also occur owing to chelation or precipitation with a medication. Cholestyramine, a basic anion-exchange resin, binds bile salts and impairs the absorption of fat-soluble vitamins, vitamin B_{12}, folic acid, and the minerals such as calcium, iron, and zinc.[143] Aluminum- and magnesium hydroxide–containing antacids may form nonabsorbable phosphate in the gut lumen, resulting in hypophosphatemia along with anorexia and secondary syndromes of hypomagnesemia and osteomalacia.[136]

Alteration in GI pH may also cause drug-induced malabsorption. Drugs that increase gastric pH (e.g., H_2 antagonists) can theoretically decrease the breakdown of fat necessary to complex with calcium, thus reducing gut absorption.[144] Antacids can also reduce the bioavailability of riboflavin and folic acid as well as copper and iron, all of which depend on a low pH.[145] In some cases, the effect of drugs on nutrient malabsorption may be indirect. Proton-pump inhibitors (e.g., omeprazole, lansoprazole) suppress gastric acid release and induce a dose-dependent achlorhydric state. The increase in gastric pH reduces the amount of cobalamin liberated from diet. This, in turn, limits the binding of cobalamin to intrinsic factor in the jejunum. Chronic use of this class of drugs may lead to malabsorption of cobalamin in some patients. These drugs do not affect the bioavailability of crystalline vitamin B_{12} which is commonly used in vitamin supplements. Thus, as in the case of RYGB surgery recipients, oral vitamin supplementation may be necessary and is an effective approach to minimize the risk of developing anemia in patients receiving chronic acid reduction therapy.[146]

METABOLISM OF NUTRIENTS

Drugs may affect nutrient metabolism by several methods. They may inhibit the essential intermediary metabolism of a nutrient, usually a vitamin, or promote the catabolism of the nutrient. Medications with these properties may be used therapeutically, as in the case of coumarin

anticoagulants or methotrexate. In other cases, this may be an unwanted side effect, as in the case of pyridoxine antagonism seen in isoniazid and hydralazine use. Isoniazid and hydralazine can result in pyridoxine deficiency by the inhibition of pyridoxal kinase. Both compounds deplete pyridoxine stores and consequently the neurotransmitter gamma-aminobutyric acid, resulting in seizures. Administration of pyridoxine in cases of isoniazid overdose eliminates seizures and metabolic acidosis, which often occur.[147]

Many medications induce drug metabolism enzymes leading to greater activity of these enzymes, increasing the demand for their vitamin cofactor, and, with chronic drug therapy and marginal nutrient intakes, can precipitate signs of deficiency of several vitamins, especially folic acid. Triamterene can inhibit dihydrofolate reductase, resulting in megaloblastosis.[148] The 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitor class of antihyperlipidemic agents (i.e., statins) can lower plasma concentration of endogenous ubiquinone (coenzyme Q), a cellular antioxidant.[149]

Patients receiving chronic anticonvulsant therapy are at particular risk of developing metabolic bone disease as a result of these types of reactions.[150] Several mechanisms have been suggested. One suggests that drugs such as phenytoin, a potent inducer of multiple CYP enzymes, stimulate the catabolism of vitamin D to produce an inactive metabolite since the biotransformation of vitamin D is mediated by numerous CYP-dependent pathways.[151] Although not well proven, another theory suggests that phenytoin, alone or in combination with phenobarbital, interferes with vitamin K metabolism, with a corresponding elevation in serum osteocalcin levels without a-carboxyglutamate (Gla) residues, resulting in metabolic bone disease because osteocalcin-containing Gla residue is necessary for normal bone mineralization.[152]

Patients treated with cephalosporin antibiotics may develop hemorrhagic states owing to drug-induced vitamin K deficiency.[153] It is thought that these antibiotics block the vitamin K reductase, which is necessary for vitamin K activation.[154] They may also block carboxylation of vitamin K–dependent peptides to yield Gla residues that are required for calcium binding in the conversion of vitamin K–dependent proenzymes to their active state, which are needed in the coagulation cascade.[154]

Some drugs have been linked with subnormal serum folate levels, probably owing to weakly bound folate to serum proteins that can be easily displaced by drugs.[155] The mechanism for this interaction has yet to be

described, but it appears that there is a decrease in serum binding of methyltetrahydrofolate caused by the drug itself or one of its metabolites.[156]

Folate deficiency secondary to long-term phenytoin therapy is a common occurrence; approximately 75% of patients taking anticonvulsants have low serum folic acid levels.[157] However, progression to megaloblastic anemia is relatively rare.[158] Supplementation of folic acid with as littleas 1 mg per day may lead to a significant decrease in serum phenytoin concentrations in 15%–50% of the patients.[159] Although the exact mechanism is unknown, pharmacokinetic analysis of phenytoin suggests that folic acid may increase the affinity of the metabolic enzyme(s) involved in the elimination of the phenytoin without causing overall enzymatic induction.[159,160] To avoid potential folate deficiency and subsequent fluctuations in serum phenytoin levels, practitioners should routinely supplement all patients with folate when phenytoin therapy is initiated.[159]

Like phenytoin, sulfasalazine, an anti-inflammatory agen tused to treat Crohn's disease and juvenile rheumatoid arthritis, is one of the leading causes of drug-induced folic acid deficiency in children.[160] Megaloblastic anemia, caused by folate deficiency, has been reported in patients receiving high doses of sulfasalazine for prolonged periods.[161]

Aspirin has also been linked with folate deficiency. Serum folate levels are known to be low in many patients with rheumatoid arthritis.[160] It is thought that aspirin alters the transport of folate by competing for binding sites on serum proteins.

Methotrexate, a chemotherapeutic agent that is also used to treat psoriasis, rheumatoid arthritis, and Crohn's disease, limits the availability of methyl groups derived from one-carbon metabolism by inhibiting competitively a key enzyme in the intracellular folate metabolism.[162] Methotrexate functions as an antimetabolite, reversibly inhibiting dihydrofolate reductase.

Valproic acid (VPA), an antiepileptic agent, has been associated with folate deficiency. Like other agents, the mechanism is not fully understood, although it is thought that VPA causes an alteration in the methionine cycle.[163] This results in an elevation of tetrahydrofolate levels and a reduction of both formulated forms of folate. This could also explain VPA's role as a teratogen.[164] In addition, it has been established that VPA may induce L-carnitine deficiency. Patients who develop VPA-induced carnitine deficiency typically experience hyperammonemia syndrome with

no other abnormality in the liver function tests. If diagnosed early, the clinical presentation, which includes altered mental status or encephalopathy, can be reversed by L-carnitine supplementation.[165]

DRUG EFFECTS ON NUTRIENT TRANSPORT

There are several mechanisms by which a drug can impact nutrient transport and then lead to nutritional deficiency. A nutrient can become displaced from plasma protein binding sites by a medication, leading to an increase in the renal excretion of the nutrient, or a drug may compete with a nutrient such that intracellular use of the nutrient is impaired.[166] This may occur when folate stores become depleted in patients receiving therapeutic doses of aspirin.[166]

Table 18-5 Examples of Drug–Nutrient Interactions

Medication/Drug Class	Nutrient	Interaction
5-ASA derivatives	Folic acid	Decreased serum folate levels
Albuterol	Glucose	Hyperglycemia (in diabetics)
Aminoglycosides	Potassium Magnesium Sodium Calcium	Increased urinary excretion of potassium and magnesium and may also deplete sodium and calcium
Amphotericin	Masium Potassium Sodium	Electrolyte wasting
Aspirin	Folic acid	Decreased serum folate levels
Bisacodyl	Glucose	Decreased absorption
Calcium carbonate	Iron	Decreased iron absorption
Captopril	Potassium	May cause hyperkalemia
Chloramphenicol	Protein Riboflavin Vitamin B_6 Vitamin B_{12}	Decreased protein synthesis
Cholestyramine	Fat MCT Vitamins A,D, E, K Vitamin B_{12}, folate, calcium Glucose, xylose	Decreased absorption

Cimetidine	Vitamin B_{12}	Depletion of vitamin B_{12} stores
Cisplatin	Magnesium	Magnesium depletion
Colchicine	Vitamin B_{12} Vitamin A Folate Potassium Sodium	Causes intestinal mucosal damage, decreases vitamins A and B_{12} absorption
Corticosteroids	Glucose	Hyperglycemia
Digoxin	Bran fiber Calcium Magnesium Potassium	Decrease drug absorption Arrhythmias Hypomagnesemia or hypokalemia may enhance toxic effect of digoxin; arrhythmias
Ethambutol	Copper Zinc	Copper and zinc depletion
Fluconazole	Potassium	Hypokalemia
Fluorouracil	Thiamine	Inhibits conversion of thiamine to thiamine pyrophosphatase; increase thiamine requirements
Foscarnet	Calcium Magnesium Phosphorus Potassium	Electrolyte wasting
Furazolidine	Tyramine-rich foods	Increased risk of hypertensive effects if used chronically or at high doses with tyramine-rich foods
Furosemide	Calcium Magnesium Potassium Sodium	Electrolyte depletion
Gemfibrozil	Vitamin E Ubiquinone	Decreased absorption
Insulin	Dextrose	Increased insulin requirements
H-2 antagonists (cimetidine, ranitidine, famotidine)	Vitamin B_{12} Zinc	Depletion of vitamin B_{12} stores May deplete zinc
Isoniazid	Pyridoxine Tyrosine-rich foods Histamine-rich foods Tyramine-rich foods	Vitamin B_6 antagonism Blocks conversion of tyrosine to niacin May cause headaches, itching, redness, chills, hypotension Isoniazid has some MAO-I activity; tyramine-rich foods may cause hypertensive crisis
Linezolid	Tyramine-rich foods	Linezolid has some MAO-I properties; tyramine-rich foods may cause

		hypertensive crisis
Lithium	Sodium	Increased sodium intake decreases lithium's effectiveness; decreased sodium intake may increase lithium toxicity
Metformin	Coenzyme Q10 Folic acid Cobalamin	Depletes stores
Methotrexate	Folic acid	Methotrexate may cause folate deficiency; folate supplementation may decrease methotrexate effects
Mineral oil	Fat-soluble vitamins	Decreased absorption of fat-soluble vitamins with chronic use
Neomycin	Fat-soluble vitamins MCT Cobalamin Sodium Glucose Lactose Sucrose Xylose	Impaired absorption
Nonsteroidal anti-inflammatory agents	Potassium	Hyperkalemia in patients with renal disease or receiving potassium supplements or potassium-sparing diuretics
Orlistat	Vitamin E Vitamin D Beta carotene	Reduced absorption
Oral contraceptives	Ascorbic acid Folic acid Pyridoxine	Ascorbic acid, folic acid, and vitamin B_6 requirements increased
Paraaminosalicylic acid (PAS)	Vitamin B_{12} Folate Calcium Iron Magnesium	Decreased absorption of cobalamin, folate, calcium, iron, magnesium
Penicillamine	Acidic foods/beverages	Decreased penicillamine absorption/inactivation
Penicillin	Acidic foods/beverages	Penicillin inactivation
Phenobarbital	Ascorbic acid Vitamin D	Decreased ascorbic acid absorption Interferes with vitamin D metabolism
Phenytoin	Folic acid Pyridoxine Vitamin D	High-dose folic acid may antagonize phenytoin effects; phenytoin may cause folate deficiency resulting in megaloblastic anemia

		May antagonize phenytoin Interferes with vitamin D metabolism
Primidone	Folic acid	May cause folic acid deficiency leading to megaloblastic anemia
Proton pump inhibitors	Iron Cobalamin Magnesium	Decreased absorption
Pyrimethamine	Folic acid	Decreased serum folate levels
Sevelamer	Folic acid Vitamin D Vitamin E Vitamin K	Decreased levels
Spironolactone	Sodium Potassium	May cause hyponatremia May cause hyperkalemia
Sulfasalazine	Folic acid	Inhibits the absorption of folic acid
Terbutaline	Glucose	Hyperglycemia (in diabetics)
Theophylline	Caffeine Carbohydrates Charcoal-broiled meat Protein	Increases theophylline side effects Decreased carbohydrate intake may decrease plasma half-life of theophylline May decrease theophylline half-life Increased protein intake may decrease plasma half-life of theophylline
Thiazide diuretics	Magnesium Potassium Sodium	Increased electrolyte wasting
Triameterene	Folic acid	May cause folic acid depletion
Trimethoprim	Folic acid	May cause folic acid depletion
Valproic acid	Carnitine	May cause carnitine deficiency with hyperammonemia
Warfarin	Vitamin K Onions, garlic Vitamin E	May inhibit warfarin response; increase dose needed Excessive amounts may increase the fibrnolytic activity of warfarin May enhance anticoagulant effect of warfarin
Zidovudine	Carnitine Folic acid	May cause carnitine deficiency May cause megaloblastic anemia
Zonisamide	Biotin Vitamin B_1 Vitamin B_2 Niacin Pyridoxine Vitamin B_{12} Vitamin K	May deplete stores

Excretion

Thiamin deficiency can occur in patients treated with chronic loop diuretic therapy. Seligmann et al. reported that patients with congestive heart failure treated with long-term furosemide therapy had increased urinary excretion of thiamin, leading to frank deficiency over time that may have contributed to poor cardiac performance.[167] Similar findings were reported by Brady et al., who observed laboratory evidence of thiamin deficiency in congestive heart failure patients being treated with loop diuretics on a chronic basis.[168]

Drug-Induced Fluid and Electrolyte Imbalance

Several widely used medications can affect electrolyte balance, as summarized in Table 18-5. Sodium balance is altered by thiazide diuretics and the neuroleptic carbamazepine.[169,170] Patients treated long term with carbamazepine have been reported to develop the syndrome of inappropriate antidiuretic hormone (SIADH), resulting in hyponatremia and water retention.[170] In those patients, hyponatremia develops owing to the enhanced renal conservation of water. Similarly, patients receiving excessive diuretic therapy with fluid loss replaced with excessive water are prone to developing SIADH.[169] Conversely, certain medications can cause hypernatremia as a result of water loss and subsequent dehydration. Hypernatremia, secondary to excessive lactulose therapy for hepatic encephalopathy or constipation, is a common drug-induced cause of this disorder.[171]

Renal wasting of potassium, resulting in hypokalemia, has been associated with thiazide and loop diuretics, corticosteroids, amphotericin B, and antipseudomonal penicillins.[172] Insulin and inhaled β2-agonists (e.g., albuterol) can cause a shift of potassium from the extracellular to the intracellular spaces.

Potassium-sparing diuretics (e.g., spironolactone), angiotensin-converting enzyme inhibitors (e.g., enalapril), heparin, and trimethoprim can cause hyperkalemia.[172] A variety of mechanisms are involved. Trimethoprim has weak diuretic properties with potassium-sparing activity.[173] Heparin can suppress aldosterone, leading to sodium wasting and potassium retention. Patients with renal insufficiency or diabetes mellitus appear to be more susceptible to heparin-induced hyperkalemia.[174]

The impact of medications on phosphorus balance is important in patients receiving nutritional support as the synthesis of new cells

increases the need for phosphorus. Patients already at risk for refeeding syndrome are particularly susceptible to the effects of drugs known to decrease available phosphorus stores.[175] Drugs such as antacids and sucralfate can alter the absorption of phosphorus from theGI tract by binding to dietary phosphate, thus preventing its absorption. Conversely, patients with renal dysfunction are at risk for development of hyperphosphatemia owing to the inherent phosphate content present in the phospholipid emulsifiers in intravenous fat emulsion or clindamycin phosphate injection.[175]

As discussed previously, medications such as isoniazid and cimetidine can inhibit the hepatic and/or renal hydroxylation of vitamin D, leading to impaired calcium absorption.[176] Odes et al. concluded that even short-term therapy with cimetidine altered vitamin D metabolism in humans.[176] The researchers came to this conclusion after studying 25-hydroxyvitamin D_3 levels for 30 days in patients treated with cimetidine.

Chronic corticosteroid use can cause a net negative calcium balance and increased bone resorption owing to suppressed intestinal absorption of calcium in conjunction with increased renal calcium and phosphate excretion and a subsequent decrease in renal tubular calcium resorption, resulting in bone osteopenia.[136,177] Even frequent use of inhaled steroids has been associated with this response.[178]

Hypomagnesemia as a result of renal wasting can occur in patients treated with loop diuretics, thiazide diuretics, amphotericin B, aminoglycosides, cisplatin, or cyclosporine. Cisplatin-induced hypomagnesemia is dose and duration dependent.[179] Cisplatin induces hypomagnesemia by reducing magnesium reabsorption in the ascending loop of Henle and the distal tubule.[180] Forastiere et al. reported that the total exposure of free platinum contributes to direct injury and renal toxicity.[181] Carboplatin, an antineoplastic with a chemical structure similar to cisplatin, has been reported to have a lower incidence of hypomagnesemia.[182]

Renal wasting of magnesium is also common in patients on prolonged courses of high doses of aminoglycosides.[136,183] Aminoglycosides can inhibit the proximal tubular transport of magnesium in the kidney, predisposing patients with already low intakes of magnesium to hypomagnesemia.[183]

If left untreated, hypomagnesemia will ultimately lead to hypocalcemia. Magnesium deficiency can induce a transient hypoparathyroidism by reducing the secretion of parathyroid hormone

(PTH) and a blunted PTH response. This results in an inhibition of the hypocalcemic feedback loop.[179] Other agents, such as aluminum salts, also suppress PTH secretion, resulting in hypocalcemia. Treatment for hypocalcemia induced by hypomagnesemia involves correcting the hypomagnesemia first and then managing the magnesium losses. In some cases, calcium supplementation may be unnecessary.[179]

TRACE ELEMENTS

Zinc is essential for the function of hundreds of enzymes such as dehydrogenases, aldolases, and peptidases and is involved in a variety of metabolic processes.[184] The formation and activation of zinc-dependent enzymes are regulated by zinc tissue levels.[185] Zinc metalloenzymes are responsible for structural integrity at the cellular level and for the regulation of various aspects of RNA and DNA metabolism.[185] Zinc deficiency limits the activity of these enzymes, resulting in decreased cell replication and tissue growth and repair.

Zinc interacts with several other nutrients. At supplemental doses, zinc may impair copper absorption.[186] Zinc deficiency can also negatively impact vitamin A metabolism by impairing the mobilization of retinol from the liver and altering retinal visual pigment metabolism, which may contribute to the night blindness seen in zinc deficiency.[187] It is thought that zinc deficiency may result in abnormal dark adaptation and/or age-related macular degeneration.[188]

Patients receiving PN are at risk for developing zinc deficiency. Zinc balance during PN depends on the infusion of zinc in amounts sufficient to offset urinary and GI losses that occur independent of zinc intake.[189] Premature infants receiving PN will experience a progressive decline in plasma zinc levels despite 14 days of continuous treatment, reflecting their high metabolic demands.[189]

GLUCOSE

Patients with diabetes mellitus or others with insulin resistance (e.g., severe infections, catabolic stress) are susceptible to the effects of medications known to impact glucose metabolism. Thiazide diuretics, corticosteroids, and cyclosporine have all been associated with inducing hyperglycemia in susceptible patients.[190] Hyperglycemia occurs in approximately 20% of patients treated with pentamidine.[191] Moreover,

protease inhibitors have been recognized as a cause of hyperglycemia.[192] The long-acting somatostatin analog octreotide has been shown to inhibit insulin secretion and may result in a transient deterioration in glucose tolerance on initiation of therapy.[193] In most cases, alteration of carbohydrate metabolism does not appear to be a problem. Table 18-6 lists some of the more common medications that alter glucose metabolism or response.

Table 18-6 Medications That Alter Glucose Metabolism/Response

Medication/Drug Class	Response
Acarbose	Hypoglycemia
ACE inhibitors	Hypoglycemia
Acetazolamide	Hyperglycemia
Acritretin	Hyperglycemia
Amiodarone	Hyperglycemia
Amprenavir	Hyperglycemia
Arginine	Hyperglycemia
Chloroquine	Hypoglycemia
Clofazimine	Hyperglycemia
Corticosteroids	Hyperglycemia
Clonidine	Hyperglycemia
Cyproheptadine	Hyperglycemia
Diazoxide	Hyperglycemia
Didanosine	Hyperglycemia
Emtricitabine	Hyperglycemia
Epinephrine	Hyperglycemia
Ethionamide	Hypoglycemia
Etravirine	Hyperglycemia
Fosamprenavir	Hyperglycemia
Fosphenytoin	Hypoglycemia
Glucagon	Hyperglycemia
Glycerol	Hyperglycemia
Haloperidol	Hyperglycemia/hypoglycemia
Imatinib	Hyperglycemia
Indinavir	Hyperglycemia
Isotretinoin	Hyperglycemia
Lamivudine	Hyperglycemia

L-Asparaginase	Hyperglycemia
Lithium	Hyperglycemia
Loop diuretics	Hyperglycemia
Megestrol	Hyperglycemia
Metformin	Hypoglycemia
Micofungin	Hyperglycemia/hypoglycemia
Nelfinavir	Hyperglycemia
Nicotinic acid	Hyperglycemia
Oral contraceptives	Hyperglycemia
Octreotide	Hyperglycemia/hypoglycemia
Paricalcitol	Hypoglycemia
Penacillamine	Hypoglycemia
Pentamidine	Hyperglycemia/hypoglycemia
Phenytoin	Hyperglycemia
Posaconazole	Hyperglycemia
Proton pump inhibitors	Hyperglycemia/hypoglycemia
Quinine	Hypoglycemia
Ritonavir	Hyperglycemia
Saquinavir	Hyperglycemia
Sertraline	Hyperglycemia
Sirolimus	Hyperglycemia/hypoglycemia
SSRIs	Hypoglycemia
Tacrolimus	Hyperglycemia
Valganciclovir	Hyperglycemia
Zalcitabine	Hyperglycemia

Hypoglycemia is the most common metabolic abnormality associated with pentamidine therapy.[194] The mechanism responsible for this adverse effect may involve a direct cytolytic effect on pancreatic beta cells, resulting in insulin release and hypoglycemia and a subsequent insulin deficiency owing to loss of beta cell function.[195] Eventually, however, pentamidine-induced pancreatic beta cell damage may lead to insulin deficiency and result in hyperglycemia, although this is considerably less frequent than hypoglycemia.[195]

Drugs or foods that have the ability to induce a rapid release of insulin can increase the risk of hypoglycemia, especially if taken with alcohol. Beta-blockers such as propranolol can inhibit glycogenolysis and, during periods of vigorous exercise, induce hypoglycemia.[196]

FAT

With increased awareness of lipid abnormalities and coronary artery disease, drug-induced lipoprotein abnormalities must be considered; especially in patients in whom no other causes of dyslipidemia exist. Some of the most common causes of secondary dyslipidemia are medications. When a drug is used for a short period only, practitioners need to be aware of the effects on the patient's lipoprotein profile versus the chance that an underlying dyslipidemia has been exacerbated. Drugs used chronically may be more problematic as they may predispose the patient to atherosclerosis.[197] Table 18-7 lists medications associated with dyslipidemia.

Protease inhibitors interfere with some proteins involved in fat metabolism (i.e., cytoplasmic retinoic acid–binding protein type 1).[198] Protease inhibitor binding to low-density lipoprotein (LDL) receptor–related proteins (LRPs) impair hepatic chylomicron uptake and triglyceride clearance by the endothelial LRP–lipoprotein lipase complex. The resulting hyperlipidemia contributes to central fat deposition and insulin resistance.[198] It is also thought that protease inhibitors may also disrupt steroid hormone production, leading to lipodystrophy.[199] See Chapter 49 for a full discussion of HIV lipodystrophy.

L-Asparaginase has been reported to cause abnormalities in lipid metabolism, ranging from hypocholesterolemia and hypotriglyceridemia to hypercholesterolemia and hypertriglyceridemia. Parsons et al. suggested that this alteration in lipid metabolism is caused by structural changes in the high-density lipoprotein (HDL) particles from high density to lower density that is reflected in an altered ratio of lipid to protein.[200] The authors suggested that prior to the initiation of L-asparaginase therapy, HDL-cholesterol particles are protein rich but gradually become lipid rich because of an asparaginase-associated reduction in protein synthesis. They also concluded that modifications in asparaginase therapy are not necessary, although close monitoring is recommended for patients whose triglyceride levels exceed 2000 mg/dL when the risk of pancreatitis is increased.

In addition to asparaginase-associated lipid abnormalities, patients being treated for acute lymphoblastic leukemia often receive corticosteroids that may alter lipid and lipoprotein metabolism by increasing hepatic cholesterol synthesis.[200] Corticosteroids increase the frequency of hypercholesterolemia and hypertriglyceridemia with elevations in LDL and HDL levels, often in a dose-related manner.[197]

Females appear to be more susceptible than males to these changes. Switching to alternate-day therapy may reduce lipoprotein levels in some patients.[197]

Orally administered estrogens decrease serum LDL and increase serum HDL levels in a dose-related manner.[197] Moreover, these agents are known to increase serum triglyceride levels by 30%–87%.[197] It has been suggested that low-dose estrogens be used to minimize elevations in triglyceride levels without compromising their favorable impact on LDL and HDL levels.[197] Interestingly, other routes of estrogen administration (topical, intradermal, intramuscular) tend not to have as pronounced an effect on lipoproteins, perhaps because these routes bypass first-pass metabolism through the liver, thus having a smaller impact on hepatic protein synthesis.[197,201] Progestins, often used in combination with estrogens in various oral contraceptive products, can also affect lipoprotein levels. Generally, progestins elevate LDL levels and decrease triglyceride, HDL, and very LDL levels, correlating with the androgenic activity associated with specific progestins.[197] Second- and third-generation progestins (e.g., levonorgestrel, desogestrel, and norgestimate) when used in combination with low-dose estrogen, do not have any appreciable alterations in lipid profiles or at best mild increases in serum cholesterol, LDL, and triglycerides.[201]

Table 18-7 Medications Associated With Dyslipidemia

Medication	Total Lipids	Total Cholesterol	Triglycer-ides	Low-Density Lipoprotein	High-Density Lipoprotein	Very Low-Density Lipoprotein
Abacavir			↑

Like estrogens, anabolic steroids can also cause profound, dose-related

effects on lipoprotein metabolism. Reductions in HDL levels in conjunction with an elevation in LDL levels are often seen in patients using these agents.[197] The exact mechanism has not yet been defined, but caution is advised in using these agents in patients prone to dyslipidemia or atherosclerosis.

GASTROINTESTINAL ADVERSE EFFECTS

Many medications can adversely affect the function of the GI tract. Most are minor and resolved over time without any specific intervention. Others, however, can be significant and resulting in severe GI illness (e.g., esophagitis, colitis) that can negatively impact the tolerance to an oral or tube fed diet. Drug-induced esophagitis can occur with doxycycline capsules, iron sulfate tablets, extended-release potassium chloride tablets, and tetracycline.[202] Typically, this occurs in adolescents who drink inadequate amounts of fluid with their medications, or patients with left atrial enlargement or cardiomegaly as the heart impinges on the esophagus, thus increasing the transit time of the medication in the esophagus. Switching to a liquid medication or administering the problematic drug with plenty of water often helps alleviate the situation.

DRUGS AND APPETITE

Impairment of nutritional status owing to drug use often results in drug-induced nutritional deficiencies in those cases in which the medication results in appetite suppression and decreased food intake. Often these signs and symptoms of nutrient deficiencies are nonspecific and may mimic those of other diseases and conditions.

Drugs can reduce food intake through a variety of mechanisms. Drugs that affect appetite (Table 18-8) may do so by either a central or a peripheral effect, including loss of appetite, inducing sedation, or evoking adverse response when food is ingested.[203] The primary effect typically centers around appetite suppression, a centrally acting mechanism that includes the catecholaminergic (e.g., dextroamphetamine), dopaminergic (e.g., levodopa), serotoninergic (e.g., fenfluramine), and endorphin (e.g., naloxone) modulators, which may all act to suppress appetite.[204] Peripherally acting mechanisms that can indirectly suppress appetite include those agents that inhibit gastric emptying (e.g., levodopa) or bulking agents (e.g., methylcellulose).

A secondary response may also occur when an adverse response to

food caused by the drug results in a loss of appetite. The emetic center, located within the brainstem, is easily stimulated by the action of many drugs. These include drugs that cause nausea and vomiting (e.g., digoxin toxicity), drugs causing a loss of taste (e.g., penicillamine), drugs causing stomatitis (e.g., fluorouracil), and hepatotoxic agents (e.g., alcohol).[203]

Altered taste perception can also lead to a decrease in nutrient intake. Medications such as angiotensin-converting enzyme inhibitors, allopurinol, amiodarone, baclofen, lithium, metronidaozole, and terbinafine have all been linked with causing taste perversions. Taste is regulated by chemosensory nerves that respond to stimulation chemicals by direct receptor binding, opening ion channels, or secondary messenger channels using nucleotides or phosphorylated inositol.[205] Medications that disrupt these cellular processes can cause a loss or distortion in taste. Similarly, dry mouth due to reduced saliva production can alter ion concentrations between saliva and plasma that results in decreased taste sensation. For example, anticholinergic drugs such as antihistamines and tricyclic antidepressants can cause dry mouth as a side effect that can lead to anorexia.

Another way in which medications can cause anorexia is through depletion of various nutrients. High doses of aluminum- or magnesium-containing antacids can result in phosphate depletion, leading to muscle weakness and anorexia.[206] Similarly, loop diuretics can lead to depletion of sodium, potassium, and magnesium, which can result in anorexia.[207] Drugs known to deplete folate, such as phenytoin, sulfasalazine, and trimethoprim, can result in weight loss and anorexia.[208] Penicillamine, which induces zinc depletion, can lead to diminished taste acuity and possibly decreased food intake.[209] Ironically, even a nutrient can induce anorexia. Belle and Halpern reported that patients taking relatively large doses of niacin for hyperlipidemia experienced GI symptoms that resulted in poor appetite and moderate weight loss.[210]

Zinc supplements have been used to treat drug-induced hypogeusia with mixed results. Although zinc supplementation has been used successfully to manage hypogeusia in patients undergoing dialysis, Others, however, did not see similar findings when patients with acetazolamide-induced taste disturbances were given zinc supplements.[211]

In some cases, weight gain may be an undesirable side effect of a medication. Antiepileptic drugs (AEDs), both old and new, have weight changes associated with their use. AEDs associated with marked weight gain include carbamazepine, gabapentin, VPA, and vigabatrin. Both lamotrigine and lecvetiracetam are considered weight-neutral, while felbamate, topiramate, and zonisamide have been associated with significant weight loss.[212]

APPETITE ENHANCERS

Appetite enhancers are useful in reversing the anorexia of disease, in particular cancer cachexia and HIV wasting. Several medications are frequently used, although none have yet become a standard of therapy.

The appetite-boosting properties of corticosteroids have been well established.[213] Their impact on weight gain seems to be short term, however. Moertel et al. suggested that patients treated with dexamethasone saw appetite improvement after two weeks of treatment, but the effect disappeared by week 4.[214] Some attribute the improved appetite to the mood-enhancing properties of steroids rather than a specific effect on appetite.[215] The antihistamine cyproheptadine has become one of the most commonly used appetite stimulants in pediatric patients, particularly those with anorexia nervosa. It is a potent serotonin antagonist. By decreasing brain serotonin levels, appetite is enhanced and food intake is increased, resulting in weight gain.[216] Megestrol acetate is a drug with antiestrogen properties whose original indication was in the treatment of breast cancer. It was one of the first drugs used to treat HIV wasting. It is a powerful appetite stimulant, and weight gain seen with its use is substantial, although it tends to be mostly fat, with minimal increases in lean body mass.[217] Megestrol also lowers testosterone levels in males, which may explain its minimal increases in lean body mass. Adrenal suppression has also been reported with long-term megestrol use; thus, abrupt discontinuation should be avoided.[218] Megestrol acetate also has been used to stimulate appetite and promote weight gain in a limited number of patients with cachexia associated with neoplastic disease. Although the exact mechanism of action has not been determined, it has been suggested that megestrol and/or its metabolites may, either directly or indirectly stimulate appetite, resulting in weight gain, or may alter metabolic pathways by interfering with the production or response of mediators such as cachectin, a hormone that inhibits adipocyte lipogenic enzymes.[219]

Dronabinol is a derivative of marijuana that is primarilyused in pediatric patients as an antiemetic but has some use in treating anorexia, primarily in HIVwasting.[220] Like megestrol, it can stimulate appetite as well as interest in food. Its effects on mental status, however, limit its usefulness.

Because cytokine effects on appetite can contribute to the anorexia of disease, anticytokine monoclonal antibodies and receptor antagonists may have a role in inhibiting cytokine action.[221] Some agents such as the corticosteroids inhibit the transcription of interleukin (IL)-1, tumor necrosis factor (TNF), and other cytokinases. Other agents appear to act by binding a mitogen-activating protein kinase necessary for the translation of messenger RNAs.[221] Fish oil supplements that are rich in omega-3 fatty acids decrease the anorectic effect of IL-1 and TNF.[222] Unfortunately, the

fishy taste associated with these supplements makes them a less-than-desirable option.

APPETITE SUPPRESSANTS

Although, for long-term success, weight loss takes a great deal of self-control to resist the many internal and external cues to eat, appetite suppressants can augment weight loss by reducing the hunger drive, thereby assisting the patient to adhere to a restricted caloric diet.[223] Currently, the major class of drugs in use for the adjunctive treatment is the centrally acting appetite suppressants. This class is further subdivided into those that act on the noradrenergic nervous system and those that act on the serotoninergic nervous system.

Given their high potential for abuse and numerous side effects, the noradrenergic agents (e.g., dextroamphetamine) are no longer routinely used in weight loss management unless other therapies have been proven ineffective. These agents block the reuptake of dopamine and norepinephrine from the synapse, thus increasing the amount available in the cerebral cortex and reticular activating system.[223]

The neurotransmitter serotonin is responsible for appetite suppression and satiation. Serotonin, as part of a complex negative feedback loop, accumulates in certain areas of the brain in response to feeding.[223] Sertraline, paroxetine, and fluoxetine inhibit serotonin reuptake at presynaptic spaces. They have few central stimulatory effects. Lorcaserin, the newest agent in the class, exerts its appetite suppressing effect by binding to serotonin 5-HT(2C) receptors.[224]

Other agents that have the potential to cause anorexia and may have a potential role in weight loss management are the thermogenic drugs.[225] These include endogenous hormones (i.e., insulin, thyroid hormone) and sympathomimetic agents with alpha- or beta-adrenergic properties.[225] Currently, exogenous thyroid has no role in obesity management owing to its adverse effects on protein breakdown, cardiovascular complications, and bone mineralization.[226]

VITAMIN AND MINERAL SUPPLEMENTATION/HYPERVITAMINOSIS

Megavitamin therapy has been advocated in the treatment of various disease states, including schizophrenia, cancer, and the common cold.[227] A

megadose is generally considered to be 10 or more times the recommended dietary allowance.[227] Although excess water-soluble vitamins are excreted and usually cause few problems, side effects have been reported in cases of excessively high doses.[228] Dietary supplementation can also impact response to medications. If used carelessly, vitamin and mineral supplementation alone or as part of a fad diet can potentiate or exacerbate nutrient–nutrient interactions, as summarized in Table 18-9 and Table 18-10.

Drug-metabolizing enzyme systems have been shown to be highly dependent on vitamin C status. Houston showed that normal individuals receiving supplemental ascorbic acid had a substantial increase in antipyrine clearance,[229] whereas Beattie and Sherlock reported that vitamin C deficiency was partly responsible for impaired drug clearance in patients with liver disease.[230] When ascorbic acid is taken in excessive amounts, enzyme saturation occurs, and the vitamin acts as a chemical and enters into nonenzymatic reactions.[231] Ascorbic acid is a strong reducing agent and is able to impact other dietary components as well as alter drug disposition.[231] Vitamin C has been shown to significantly affect the regulation of several key CYP enzymes, including CYP3A, some of which can be decreased in times of vitamin C deficiency.[232] Ironically, scurvy, the main deficiency state associated with inadequate dietary intake of ascorbic acid, a relatively rare condition today, can occur in infants born to mothers taking large doses of vitamin C.[231] Both the mother and fetus increase their metabolic destruction of ascorbic acid after maternal ingestion of large doses of ascorbic acid. At birth, any dietary ascorbic acid ingested by the infant is degraded rapidly, leading to a deficiency state. Reports of acute scurvy have been reported in infants breast-fed by mothers who had ingested more than 400 mg vitamin C daily during pregnancy.[233] A similar situation can occur in adults dependent on large doses of vitamin C. Therefore, it is recommended that patients receiving megadoses of vitamin C not be abruptly stopped but rather tapered by 10%–20% until discontinued or on maintenance doses. Other complications associated with megadoses of ascorbic acid include vitamin B_{12} deficiency. Herbert and Jacob reported that even ascorbic acid doses as little as 250 mg may destroy up to 81% of cyanocobalamin in a moderate vitamin B_{12}–containing meal and up to 25% in a vitamin B_{12}–rich meal.[234] To blunt the intensity of this interaction, the authors suggested that ascorbic acid be taken two or more hours after meals. Oxalate stones may occur in susceptible patients receiving doses of greater

than 4 g/d of ascorbic acid. Auer et al. reported that a hematuria and calcium oxalate dihydrate crystal formation in a 25-year-old male 8 days after ingesting 4 g of ascorbic acid daily resolved 5 days after discontinuing ascorbic acid supplementation.[235]

Table 18-9 Examples of Nutrient–Nutrient Interactions

Nutrient	Interaction
Calcium	High calcium intake interferes with fluoride, magnesium, phosphorus, and iron absorptionCalcium absorption is potentiated by vitamin D, reduced by dietary oxalates Excessive protein intake may increase calcium losses
Chromium	A high-sugar diet may increase urinary chromium losses
Copper	High intake may impair zinc absorption
Cysteine	May chelate with copper in parenteral nutrition solutions
Iron	Iron salts might decrease gastrointestinal zinc resorption; impairs manganese absorption Soy products, including soy-based infant formula, significantly reduce absorption of iron Vitamin C enhances absorption of iron Calcium salts may reduce iron absorption Vitamin A deficiency increases liver storage of iron
Magnesium	High magnesium intake may impair calcium absorption, decreases phosphorus absorption
Manganese	Calcium and iron salts decrease manganese absorption Zinc enhances manganese absorption
Phosphorus	High intake decreases magnesium absorption
Potassium	Decreases cyanocobalamin absorption
Thiamine	High carbohydrate diet or intravenous dextrose may increase thiamine requirement
Zinc	High zinc intake may impair copper absorption as well as interfere with absorption and metabolism of iron and vitamin A Zinc may increase manganese absorption Iron salts may impair zinc absorption
Vitamin A	Megadoses may interfere with iron, iodine, copper, calcium absorption; can also interfere with absorption of ascorbic acid, vitamin K, vitamin E, and vitamin D
Vitamin C	Increases iron absorption, impairs copper absorption, interferes with cyanocobalamin absorption
Vitamin D	Reduced intake impairs calcium and phosphorus absorption and utilization
Vitamin E	Inhibits the reticulocyte and hemoglobin response to iron

Table 18-10 Examples of Vitamin–Drug Interactions

Nutrient	Medication	Interaction
Ascorbic acid (vitamin C)	Coumarin anticoagulants	Shortens prothrombin time, may antagonize warfarin response
	Gentamicin	Acidifies urine, decreases efficacy of gentamicin
	Iron salts	Increased iron absorption; intermittent use may cause contraceptive failure
	Oral contraceptives	Megadoses (>2 g/d) may reduce therapeutic response of tricyclic antidepressants
	Tricyclic antidepressants	Ascorbic acid can increase the absorption of aluminum hydroxide
	Aluminum hydroxide	
Folic acid	Fosphenytoin, phenobarbital, phenytoin, primidone	Reduces fosphenytoin, phenobarbital, phenytoin, primidone bioavailability, may antagonize anticonvulsant action of these agents
	Pryimethamine	Reduces pyrimethamine efficacy
	Raltitrexed	Folic acid may diminish the therapeutic effect of raltitrexed
Niacin	Adrenergic blockers, aspirin, HMG-CoA reductase inhibitors (“statins”), isoniazid	Enhances vasodilation, may cause orthostatic hypotension, aspirin decreases flushing seen with niacin use; increased risk of statin-associated myopathy/rhabdomyolysis with concurrent use; increased niacin requirement seen with isoniazid use
	Bile acid sequestrants	Bile acid sequestrants may decrease the absorption of niacin
Pyridoxine (vitamin B6)	Barbiturates, levodopa, fosphenytoin, phenytoin	Reduced barbiturate response, reduces levodopa response; megadoses may impair fosphenytoin/phenytoin effect, cause decrease in phenytoin levels
	Fosphenytoin	Pyridoxine may increase the metabolism of fosphenytoin. This is most apparent in high pyridoxine doses (e.g., 80–200 mg daily)
	Altretamine	Pyridoxine may diminish the therapeutic effect of altretamine. Specifically when altretamine is used in combination with cisplatin the response duration may be diminished
Vitamin A	Aluminum hydroxide, coumarin anticoagulants, isotretinoin, oral contraceptives	Reduced vitamin A absorption; megadoses of vitamin A can enhance anticoagulant response, increase risk of bleeding; isotretinoin competes with vitamin A; increases serum vitamin A levels
Vitamin D	Aluminum hydroxide	Vitamin D analogs may increase the absorption of aluminum may be increased, leading to increased serum aluminum concentrations
	Digoxin	
	Sucralfate	Vitamin D may cause hypercalcemia, leading to

		arrhythmias Vitamin D may increase the serum concentration of sucralfate. The absorption of aluminum from sucralfate may be increased, leading to an increase in the serum aluminum concentrations
Vitamin E	Courmarin anticoagulants Vitamin A Iron salts Cyclosporine	Potentiates anticoagulant response Increases serum vitamin A levels Inhibits the reticulocyte and hemoglobin response to iron therapy Vitamin E may decrease serum concentration of cyclosporine
Vitamin K	Coumarin anticoagulants	Antagonizes anticoagulant response

Source: Adapted from Gura.[259]

The daily consumption of vitamin B_6 (pyridoxine) in doses of 50–500 mg is not unusual given the currently available strengths of over-the-counter products. High doses, however, may have a toxic action on the nervous system.[236] Sensory neuropathies have been reported in adults who received daily doses of 2 g of pyridoxine over a four-month period or as soon as two months when daily doses of 5 g were ingested.

Megadoses of folic acid given to patients on long-term phenytoin therapy exhibit seizures and electroencephalogram abnormalities.[237] It appears that folic acid supplementation increases phenytoin liver metabolism; studies suggest increased phenytoin parahydroxylation while another suggests increased O-methylation of the catechol metabolite.[238] Another study concluded that folic acid does not stimulate phenytoin metabolism, but rather it changes the rates of elimination.[239]

Trace elements such as manganese can also impact the absorption of other nutrients such as iron. In patients with iron deficiency, there is a greater absorption of manganese. When iron supplementation occurs, there is a corresponding decrease in the amount of manganese absorbed with a greater amount appearing in the feces. This interaction appears to be due to competition for similar binding and absorption sites of (nonheme) iron and manganese.[240]

Hypervitaminosis A and D has been described in children, but the occurrence is rare.[241,242] Both are life threatening on an acute basis; vitamin A may cause increased intracranial pressure, whereas vitamin D may cause fatal hypercalcemia. Infants and young children are especially susceptible to excessive doses of vitamin A. Acute toxicity has been reported in infants receiving doses of 50,000–100,000 µg (166,666–

333,333 IU) retinol as palmitate. Individual variation is significant, however. Field studies have used periodic massive doses of vitamin A, with thousands of 1- to 6-year-old children receiving 200,000 IU of retinyl palmitate (60,000 µg retinol), with approximately 1% exhibiting signs of intolerance that disappeared within hours of administration.[243] Chronic toxicity seen in infants and young children usually results from daily doses of 10,000–50,000 µg (33,333–166,666 IU) for several months.[244] Symptoms gradually disappear on discontinuation. The American Academy of Pediatrics recommends that daily vitamin A supplementation doses of more than 3000 µg (10,000 IU) for young children be used only under medical supervision.[245]

Kutuzova and DeLuca have described the impact of vitamin D and drug metabolism. They reported that 1,25 dihydroxy vitamin D3 regulates the genes responsible for the production of enzymes (e.g., CYP3A4) that are responsible for detoxification in the intestine although the clinical significance has yet to be realized.[246] In typical doses, however, vitamin D is used to prevent and treat rickets.[247] Serious poisoning can occur with excessive doses. Reports of sustained daily intake of as little as 1800 IU in children has been associated with adverse events.[248] Excessive vitamin D leads to increased absorption of calcium from the GI tract and enhanced bone resorption, with a subsequent loss of renal concentrating ability. Children typically will present with anorexia, vomiting, polyuria, or irritability associated with the increased serum calcium concentrations.[249] It should be noted, however, that very high doses of vitamin D have been effective in some patients with hereditary vitamin D–resistant rickets (HVDRR).[250] HVDRR accompanied by alopecia reflects a more severe form of vitamin D receptor resistance and is rarely responsive to vitamin D. Initial ergocalciferol therapy for children with vitamin D–resistant rickets is 1000–2000 µg/d (40,000–80,000 IU) with phosphate supplement. The daily dose is increased at 3- to 4-month intervals in 250–500 µg (10,000–20,000 IU) increments.[251]

In 1992, an outbreak of hypercalcemia owing to vitamin D intoxication was noted. In the case series, eight patients suffered vitamin D toxicity that was traced to excessive amounts of the vitamin in milk produced by a single dairy.[252] These were the first reported cases of hypervitaminosis D from commercial food products in the United States since fortification became commonplace in the 1930s. A second study summarized the findings of an analysis of 42 containers of milk and 10 cans of infant formulas from supermarkets in five states.[253] Nearly two-thirds of the milk

container samples had less than 80% of the stated amount, whereas 4 of the 42 samples had over 120% of the labeled vitamin D content. The 10 infant formulas tested had vitamin D levels ranging from 111 IU for every 100 kcal to 250 IU per 100 kcal, exceeding the maximum permitted by the US Food and Drug Administration (FDA) regulation of 100 IU per 100 kcal. FDA-compliant studies on both dairy products and infant formulas compiled over a 10-year period also showed some variance in vitamin D levels but not to the extent that would constitute a health risk.[254]

Vitamin K–rich foods (i.e., green leafy vegetables, cabbage, broccoli), when intake is irregular, can alter response to anticoagulants such as warfarin. When ingested in high amounts, these foods can be associated with anticoagulant failure, resulting in the need for higher doses. Similarly, when patients who have been stable on warfarin suddenly decrease their intake of these vitamin K–rich foods, they can put themselves at risk for bleeding because they are suddenly receiving too large a warfarin dose. Warfarin creates a partial deficiency of the active form of vitamin K involved in the posttranslational modification factors (II, VII, IX, X, and proteins C and S).[255] Other sources of vitamin K, such as intravenous fat emulsions that are prepared from soybean or safflower and soybean oils, contain phytosterols that contain vitamin K.[256] Warfarin resistance has been reported in patients taking warfarin who also received intravenous fat emulsions.[256] This interaction presumably occurs because of the vitamin K content of the intravenous fat emulsion. Frequent monitoring of the international normalized ratio and warfarin dosage adjustments are imperative in these patients.

CONCLUSION

The human diet is highly heterogeneous in its composition, method of preparation, quantity, and time of consumption. These variations may alter the body's responses to drugs. Consequently, pharmacokinetic and pharmacodynamic responses as a result of diet vary widely in subjects based on age, gender, culture, genetic makeups, and economic status. Even within the same individual, seasonal variations will occur that impact dietary habits and ultimately drug-related effects. Although each factor may play a small role by itself, a much larger synergistic effect could occur when combined with other dietary factors, as well as genetic and environmental factors.

Nutrition and Gene Expression

19

Mona Bajaj-Elliott, PhD and Ian R. Sanderson, MA, MSc, MD, FRCP, FRCPCH

Altering the expression of genes has become a rapidly developing area of research in medicine. The realization that gene expression is important in a wide range of diseases, and not just in inherited disease, has resulted in recognition of the whole field of gene expression as one that may bring new therapeutic options. Although more recent attention has focused on the benefits of altering gene expression by inserting or silencing genetic material by a variety of vectors, the expression of genes can also be altered by other means, most notably by changing the molecular environment that cells inhabit. Utilizing the natural responses of a cell to changes in its surroundings offers a new and amenable way to alter the expression of its genes. Many ways of altering these surroundings can be proposed, but no single act alters the environment of the cells of the body more than the ingestion of food. Thus, the future of nutrition as a therapeutic tool may lie in its potential for influencing gene regulation.

In recent years, epigenetic modifications have also emerged as a mechanism by which nutrition may modulate downstream metabolic traits.[1] Studies have begun to identify and associate nutritional risk factors with diseases such as metabolic disorders and predisposition to obesity with changes in epigenetic patterns. This chapter will examine this emerging field and will lay down some concepts that may prove useful in establishing the scientific basis from which future treatments may develop.

The survival of a child to reproductive age and beyond requires an ability to respond to external demands. Every organ in the body is attuned to this need. Many organ systems have two levels of response to external

changes. There is a rapid response, often occurring within seconds of a new stimulus; for example, contraction of muscle fibers following a neuronal impulse or the breakdown of glycogen by the liver during hypoglycemia. Such responses do not involve changes in gene expression. The cells maintain themselves in a state of readiness, responding rapidly to external stimuli by altering protein/ion activity. Behind this immediate response, there lie other slower, but more lasting, responses that require genetic control. For example, exercise on a regular basis leads not only to muscle mass increase but change in activity of the attendant enzymes that serve the increased metabolic need also occurs. Similarly, regular exposure of the liver to drugs induces the expression of enzymes that catalyze their breakdown.

There are few external stimuli on a child more important than his or her nutritional environment. The metabolic processes underlying the rapid response of cells to nutritional variations have long been documented in humans and other mammals.[2] However, the mechanisms whereby gene expression changes in response to nutritional stimuli have till recently remained poorly understood in humans or indeed in any multi-organ animal. Progress in the study of nutrient-gene interactions in eukaryotic cells has been slower for two main reasons. First, the molecular mechanisms controlling gene expression are more complex than in prokaryotes,[3] and second, it is more difficult to identify the metabolites of nutrients that may be responsible for inducing such changes. This review will therefore cover some of the recent advances in the study of nutrition and gene expression in the human and, where necessary, in other mammals.

Nutritional changes ultimately impinge on most cells in the body; however, it is the epithelium of the gastrointestinal (GI) tract that first encounters any variation in nutrient intake. Much of this chapter will therefore concentrate on how nutritional factors can alter the expression of genes in intestinal epithelial cells (IECs). The relevance of nutrient-gene interactions to human physiology will also be stressed. Finally, because manipulating nutritional intake may be a way of treating disease in children, the review will discuss nutritional therapy in childhood in the light of its effects on gene expression.

PHYSIOLOGIC IMPORTANCE OF NUTRITIONAL REGULATION IN GENE EXPRESSION

The effect of nutrients on gene expression may have different implications in different individual situations (Table 19-1). First, genes may be up-regulated to better utilize the supply of a particular nutrient when it is scarce. Transporters of nutrients and the enzymes that metabolize them are examples of proteins that may be induced by nutrients. Second, the expression of genes required for the storage of a particular nutrient may be altered according to that nutrient's abundance. Third, nutrients regulate the secretion of hormones that control the homeostasis of metabolic processes. For example, insulin synthesis increases after increased carbohydrate intake to maintain glucose homeostasis. Finally, food is part of our external environment and, as such, represents a challenge to the cells that come into intimate contact with it. This challenge is met in the main by the epithelial cell lining the gastrointestinal tract.[4] The ability of these cells to alter the expression of their genes with changes in food intake is one of the ways by which the intestinal epithelium can dominate the intestinal environment.

TABLE 19-1 Physiological Importance of Nutritional Regulation of Gene Expression

To satisfy the nutritional needs of an organ
Managing storage fuels required by other organs
Production of hormones essential to whole body metabolism
Direct interaction with the body's external environment along the gastrointestinal tract

Certain fundamental characteristics are found in the mechanisms that underlie each of these different aspects of nutrient-gene interactions. They include (Figure 19-1) a specific interaction between the cell and a particular nutrient (sensing) and a pathway by which such an interaction may translate into alterations in gene expression (signal transduction). We have little understanding of these mechanisms at present. However, some aspects of the molecular biology of these two functions will be examined later in this review.

Genes Controlling the Nutritional Requirements of Individual Organ Systems

Survival of cells depends on their ability to extract nutrients and other essential molecules from their surroundings, and they synthesize proteins

specifically for this purpose. Broadly speaking, two categories of genes are involved: those genes that express proteins that transport nutrients across cell membranes and those genes that express enzymes that metabolize nutrients. In both cases, genes are regulated purely to satisfy the requirements of an organ system. The cells are changing their phenotype to their own advantage, rather than to suit the needs of the body as a whole.

A good model of how cells may respond to their nutritional environment for their own needs is the utilization of glutamine.[5] Glutamine is the most abundant amino acid in milk and it also serves as a major fuel for the large intestine. Lactation promotes glutamine utilization (for milk synthesis and fuel provision) interestingly lactation induces a mild catabolic state in which skeletal muscle proteins are degraded to provide the additional glutamine required. One may speculate that glutamine supplementation during this crucial period is likely to be beneficial for both, the mother and the child's well-being.[6]

Glutamine availability modulates muscle turnover, and glutamine is an important source of amino-nitrogen for muscle cells.[7] Glutamine and glutamate are transported into cells by sodium-coupled transporters. For experimental purposes, rat skeletal muscle can be grown as primary cell cultures. These cells exhibit an up-regulation of the inward transport of both glutamine and glutamate when they are deprived of an exogenous glutamine supply, [8–10] in addition the activity of glutamine synthetase (GS) simultaneously increases. This enzyme catalyzes the addition of an amino group to the carboxyl moiety of the glutamate molecule to form glutamine. Two different nutrients, glutamine and glutamate, can therefore ultimately satisfy the glutamine requirements of the muscle cell through separate pathways, each of which is under genetic control. This system exemplifies how different nutrients can cross-stimulate the expression of a related set of proteins: removal of glutamine or glutamate from the cell medium results in an enhancement of the transport of both amino acids. Not only does lack of glutamine and glutamate enhance the expression of their own transport proteins, but deprivation of either substrate will also up-regulate the transporter of the other.[8] A study of the kinetics of transport 10 demonstrated that withdrawal of glutamine (or glutamate) enhanced the maximum rate at which the amino acid is transported into the cell (Vmax) and did not alter the affinity of the transporter for its amino acid. This suggests that deprivation resulted in an increase in the production of the number of transporters available, an effect that occurs at the transcriptional level. Studies in muscle-specific GS knockout mice indicate that GS is dispensable under "fed" conditions, however, becomes

vital to mounting an adaptive response during fasting by contributing to ammonia detoxification and urea synthesis highlighting how local nutritional status may impact on metabolic functions.[11]

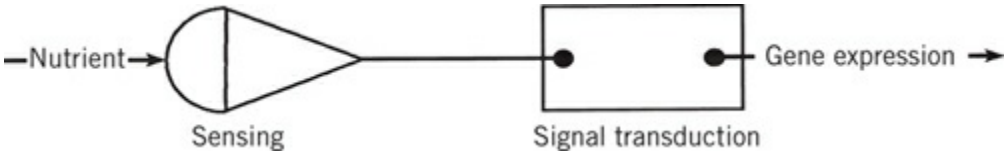

Figure 19-1 The regulation of gene expression by nutrients requires two generic mechanisms. First, molecules (either receptors or enzymes) within the cell must recognize the nutrient. Second, this interaction must initiate a sequence of events which ultimately alters the transcription or translation of genes. These functions of sensing and signal transduction have been depicted in this cartoon using electronic symbols.

In recent years, there has been an explosion in our understanding of the physiology of glutamine transporter systems.[12] At least four distinct families have been identified to date which include the Na+-dependent glutamine transporter, system N (SN1), system A (ATA1, ATA2), system ASC/B and system y (+)L, the latter encoding for Na+-independent glutamine transporter genes.[13,14] Molecular characterization of these systems suggest specific roles in glutamine efflux and uptake,[14] however, the exact mechanism(s) by which transport regulates gene expression remain unclear.

In vivo, glutamine homeostasis is to a large extent determined by the activities of glutamine synthetase (GS) and glutaminase.[15] Both enzymes exhibit regulation of gene expression at both transcriptional and post-transcriptional levels. During stress and sepsis, glutamine production is enhanced primarily due to greater GS activity in the skeletal muscle, beneficial effects of glutamine during sepsis include improvement in intestinal microcirculation with reduced leukocyte activation.[16]

Although glutamine regulates the expression of health- promoting proteins in the gut epithelia,[17] overall the glutamate/glutamine circuit constitutes only a minor part of nutrient homeostasis in vivo. Glucose, on the other hand, is central to human metabolism. Glucose, galactose, and fructose are the major dietary saccharides and the derangement of glucose handling in diabetes mellitus constitutes the most common condition

requiring nutritional advice. Intensive research in the last four decades has revealed the great complexity involved in glucose transport. Glucose is transported into enterocytes primarily by the sodium-glucose co-transporter (SGLT-1). Two Na+ ions must first bind to the transporter, and then one molecule of glucose or galactose may be actively transported into the cell. To date, 12 members of the SGLT-1 family in humans have been identified on the basis of sequence homology within the human genome.[18] Efforts to curb the ever burgeoning epidemics of diabetes and obesity has made dietary manipulation and therefore the SGLT family an attractive therapeutic target.[19] One must also not forget that oral rehydration therapy (ORT) developed to treat diarrheal dehydration is intimately linked with carbohydrate digestion. The therapy relies on the ability of SGLT1 to co-transport water without affecting Na+ or glucose uptake. In addition to SGLT proteins, facilitative-diffusion glucose transporter (GLUT) proteins catalyze glucose transport into cells. To date, 14 mammalian GLUT proteins had been identified, each a separate gene product with unique transport properties[20] GLUTs 1, 3, and 4 can transport glucose and galactose but not fructose, whereas GLUT-2 can transport all three whereas GLUTs 5 and 7 recognize fructose.[20–23] The GLUT family can be divided into three groups: class I (the previously known glucose transporters GLUT1-4), class II (GLUT-5, 7, 9, 11), and class III (GLUT-6, 8, 10, 12, and the myo-inositol transporter HM1T1). The various members exhibit both tissue and sub-cellular specificity, which most likely represents another level of regulation. Analysis of GLUT protein levels in patients with non-insulin- dependent diabetes mellitus revealed a 4-5-fold induction in SGLT-1, GLUT-2 and -5 protein levels, highlighting dysregulation in monosaccharide transport.[18] Identity of mechanism(s) by which these essential dietary carbohydrates directly affect their own uptake (via availability of GLUT and SGLT proteins) is most urgent if we are to understand the marked increase in the incidence of childhood obesity and diabetes facing the developed world.[24,25]

Genes Regulating the Storage of Nutrients

The storage of nutrients is essential to provide energy in times of fasting, and the mechanisms that control this function must be regulated by nutrient intake to be effective. The two most important organs involved in nutrient storage are the liver and adipose tissue. Both cell types transport glucose and other nutrients and convert them into fat; in the case of the liver, glucose is also converted to glycogen. Insulin is the major hormone

that promotes glucose utilization and induces storage. Its sensitive response to dietary intake complicates the study of the direct effects of nutrients on genes that regulate storage. The direct effects of glucose in particular, on the expression of transporters and metabolic enzymes have to be dissected from the effects of insulin on these same genes. Genome-wide association studies (GWAS) in recent years have highlighted a plethora of candidate genes that regulate and exquisitely fine-tune glucose homeostasis.[24] Exploring association between genotype and clinical phenotype will no doubt contribute to improved personalized medicine in the very near future.[24–26]

Research in the last decade has led to dramatic improvement in our understanding of the molecular mechanism(s) by which glucose directly modulates lipogenic enzymes. In 2001, Kawaguchi and colleagues identified a hepatic transcription factor carbohydrate response element-binding protein (ChREBP), which is regulated at two different levels - nuclear entry and DNA-binding via phosphorylation events mediated by glucose and cAMP.[27] Earlier studies focused on the three main control points of glucose metabolism before it enters the mitochondrion as pyruvate. These are the enzymes – glucokinase (GK), 6-phosphofructokinase (PFK), and L-type pyruvate kinase (PK). Fructose is also metabolized to pyruvate, bypassing the first two enzymes. PK is therefore a regulatory enzyme in the metabolism of both monosaccharides. Greater complexity in glucose-pyruvate biochemical axis was recently highlighted by the fact that the M2 isoform of PK tends to be predominant in cancer cells where it diverts glycolytic flux away from the mitochondria to serine and glycine biosynthesis.[28] Manipulating these cellular pathways offers an attractive therapeutic strategy for metabolic disorders and oncology.

Both in vitro and in vivo studies have identified a second critical transcription factor, sterol regulatory element binding protein (SREBP) in insulin-mediated transcriptional control of genes involved in glucose, fatty acid, and triglyceride metabolism.[29] -Three mammalian SREBP isoforms (SREBP-1a, SREBP-1c, and SREBP-2) have distinct and yet overlapping lipogenic transcriptional programs. SREBP-1a activates fatty acid and cholesterol synthesis, SREBP-1c fatty acid synthesis, and SREBP-2 cholesterol synthesis and uptake (for a recent update, see Ref. 30). The involvement of at least two transcription factors (ChREBP and SREBP) for optimum lipogenesis may reflect the degree of molecular complexity required for coordinated integration of hormonal and nutritional signals in

regulating energy requirements of a cell.[31]

Insulin has a major effect on the activity of the three glycolytic enzymes via transcriptional and/or posttranslational modifications.[31] Glucokinase mRNA expression is induced by insulin via an IRS-1-PI-3-kinase-dependent pathway.[32] PI-3-kinase and p44/p42 mitogen-activated protein kinases (MAPK) activities play a role in the transient activation of PK by insulin.[33] However, glucose itself independently alters the expression of pyruvate kinase by increasing the transcription of pyruvate kinase mRNA.[34] Glucose similarly enhances the expression of fatty acid synthase (FAS), a key enzyme in lipogenesis.[31] Glucokinase regulates the flow of substrate to pyruvate kinase. Because glucokinase requires insulin for its activity, it has been difficult to study the independent effects of glucose and its metabolites on pyruvate kinase expression. Nevertheless, two separate approaches directly demonstrate the effects of glucose on pyruvate kinase expression. The first approach was to demonstrate that the effects of insulin on transcription of pyruvate kinase mRNA were glucose-dependent, thus identifying glucose as a separate variable.[34–36] The second approach examined a particular hepatoma cell clone (mhAT3F) whose glucokinase (which is insulin-dependent) had been replaced, through spontaneous mutation, by hexokinase (which is not insulin-dependent). This allowed the effects of pyruvate kinase to be examined in the absence of insulin.[36] Several signaling pathways that may play a key role in glucose-dependent L-PK gene transcription have now known (for a recent review, see Ref. 37). The glucose-response elements in the promoter region of the L-PK gene are known to interact directly or indirectly with various families of transcription factors including the Sp1 family and the upstream stimulatory factors (USFs).[38] The complex interactions between the various factors (UFSs, COUP-TF II, ChREBP) is likely to act as a "glucose-sensing" mechanism allowing the cell to respond appropriately to continuous variation in its nutritional status.[37]

Nutrient Stimulation of Hormone Secretion

Insulin

In children, hormones are secreted into the circulation in response to nutritional stimulation for two main reasons: (*a*) to effectively store nutrients in appropriate storage molecules; and (*b*) to signal to tissues that substrate for growth is available to coordinate the cellular manifestations of growth (cell proliferation, differentiation, and controlled cell death) with the influx of nutrients. These two actions are mutually compatible,

and a number of hormones and growth factors serve both functions to varying degrees. Insulin, for example, is mainly a storage hormone, but it is also able to stimulate growth; the increased weight of babies born to diabetic mothers is due to increased fetal insulin acting as a growth hormone. Similarly, factors primarily responsible for growth, such as insulin-like growth factor-1 (IGF-1), which mediates many of the actions of growth hormone, are able to vary the rate of glucose uptake into cells.

The secretion of insulin by the pancreatic islets is tightly controlled by glucose concentrations in the blood. Alterations in gene expression play no part in these rapid responses to glucose. Regulatory proteins within islet cells are ready to respond to increases in glucose. Release of insulin from storage granules occur following calcium influx, which in turn is probably induced by minor increases in ATP from the metabolism of glucose and other nutrients. Circulating hormones also affect insulin release. The quick-acting mechanisms that do not involve control lie beyond the scope of this review. Again, the reader is referred to several excellent reviews on the subject.[39–41]

In addition to these rapid responses, glucose also exerts a more lasting effect on insulin production through increased translation and transcription of the insulin gene. This allows a child to adapt to longer periods of starvation or carbohydrate repletion. Glucose enhances the rate of translation of pro insulin mRNA to protein by three methods.[42] It increases the transfer of initiated insulin mRNA from free to membrane-bound ribosome. It also decreases the rate of pausing of the pro insulin mRNA as it passes along the ribosome. Lastly, glucose directly stimulates the cellular machinery involved in the elongation of proteins in pancreatic islet cells.[43,44] Long-term changes in insulin production are also mediated by transcription. Rats fasted over 4 days have low insulin mRNA concentrations, which return to normal on re feeding.[45,46] These changes control the ability of the pancreas to secrete insulin during dietary manipulations, and they enable the islet cell to adapt to long-term dietary changes.

Paired box 6 (Pax6) is a transcription factor belonging to the paired-box gene family. Mice heterozygous for Pax6 mutations develop diabetes suggesting Pax6 also regulates glucose metabolism.[47] Pax6 controls the expression of a serine protease convertase responsible for processing of pro insulin to its bioactive form; suggesting that individuals with Pax6 mutations may exhibit perturbed insulin-driven glucose homeostasis. This is indeed the case as a common variant upstream of the PAX6 gene has

been shown to influence islet function in man.[48] At present, the potential role and function of PAX6-mediated pro- insulin processing during fasting remains unclear.

IGF-1 and IGF-Binding Proteins (IGFBPs)

Although we do not fully understand the mechanisms where by children whose nutritional intake is reduced beyond a certain point stop growing, it is certainly true that nutrient intake has a significant effect on final adult height. This is common knowledge in developed countries with large immigrant populations from the developing world. The children in the immigrant communities grow up to be taller on average than their parents, whose childhoods may have been spent in lands where food was less abundant. Poor linear growth also occurs in childhood diseases such as cystic fibrosis. In inflammatory diseases, such as Crohn's disease or juvenile rheumatoid arthritis, the characteristic rate of growth may, in part, be related to poor nutritional intake[49] as well as to the direct effects of intestinal inflammation.[50,51]

IGF-1 and II are a family of polypeptide growth factors whose functions include mediation of growth hormone action, stimulation of insulin activity and autocrine regulators of cellular proliferation.[52,53] IGF-1 has been shown to be a key player in regulating organ and body growth during postnatal development both in rodents and humans.[52–54] There is now compelling evidence that IGF-1 secretion may be the point at which regulation of growth is controlled both in health and disease.[55,56] Although IGF is an important modulator of GH action, GH itself does not correlate with depressed linear growth under nutritional restriction[56] or in children with active inflammation.[57] Alterations in tissue responses to growth hormone may therefore mediate the effects of nutrition on growth. This has resulted in two separate lines of investigation:

1. The effect of nutritional alterations on expression of the GH receptor[58–60] and
2. The study of nutritional factors on IGF-1 and IGF-2 secretion in association with secretion of IGFBPs.

Nutritional status is a major determinant of IGF-1 mRNA expression in liver and non-hepatic tissues. Fasting, caloric restriction animal models studies all show a decrease in circulatory IGF-1 levels,[60,61] although circulating levels of GH remain elevated. Although fasting reduces the binding of GH to its receptor, down-regulation of the GH receptor does not

occur with dietary restriction,[62] and it is believed that neither of the above are principle causes of reduced IGF-1. Further, administration of IGF-1, but not GH stimulates mucosal hyperplasia in surgically stressed rats with intestinal atrophy induced by hypocaloric total parenteral nutrition.[63] Low protein intake studies in a liver-specific IGF-1 deficient mouse model led to a decrease in non-hepatic IGF-1 secretion into the circulation, with an increase in GH levels. Increased IGFBP-3 mRNA was also observed which supports the hypothesis that the binding protein may contribute to greater sequestration of locally synthesized IGF-1.[64] These studies support the view that the splenic GH/IGF-1 axis responds to nutritional stress to maintain tissue homeostasis.

Regulation of IGF mRNA expression is complex. The rat IGF-1 gene contains six exons spanning 100 kb of DNA. Exons 1 and 2 encode alternative amino terminal sequences of the IGF-1 protein. The gene has two distinct promoter regions upstream of exons 1 and 2, which can be separately activated.[65] Post-transcription, alternative splicing results in further heterogeneity of the IGF-1 mRNA. Furthermore, there are two different terminal poly A addition sequences in exon 6, adding to the general complexity. However, these myriad possibilities result in only three different-sized mRNA transcripts: a 3.8-kb, a 4.2-kb, and an 8-kb transcript. The importance of these different mRNAs to IGF-1 production and to growth awaits further investigation, but they are of interest because several studies have demonstrated that different forms of malnutrition affect the transcripts differently.[51,52,66]. Total energy restriction induces a coordinate decrease in all three forms of mRNA. In contrast, protein restriction results in a profound decrease in the 8-kb fragment with less effect on the two smaller fragments.[51,66] These observations open up two questions of further interest: (1) How do different nutrients differentially affect gene expression in a particular family of genes? (2) How do these differences in gene expression translate into differences in a child's final phenotype? We will be returning to similar questions when we consider the small intestinal epithelium, where nutritional variations are greater than those seen in the circulation. Corresponding changes in IGF-1 have been seen in childhood illness. IGF-1 concentration correlates with increased intake and subsequent growth of children with Crohn's disease, whereas growth has no correlation to growth hormone production.[51] Children with CF frequently manifest hormonal abnormalities that may contribute to malnutrition. Interestingly in a study by Bucuvalas and colleagues, no effect of exogenous IGF-1 on linear growth in prepubertal children with

CF was found although an increase in glucose/insulin ratio was observed.[67]

In extracellular fluids IGF-1 circulate bound to IGFBPs, of which six have been cloned and characterized.[52,53] IGFBP-3 is the main carrier of circulating IGF-1 and in the presence of an acid-labile subunit (ALS), a bio-inactive ternary complex is maintained during circulation. The complex allows greater control on IGF-1 bioavailability.[68] IGFBP-3 may also modulate IGF-1-stimulated DNA synthesis.[69] The biological function of each binding protein is under intense investigation.[70] Protection from the hypoglycemic effects of IGF-1 has also been suggested as a function. Nutritional factors alter the circulating levels of IGFBPs. There is an inverse correlation of the expression of binding proteins to that of IGF-1. Protein restriction results in an increase of IGFBP-1, which falls on refeeding. However, IGFBP-1 is sensitive to insulin, and it is not clear how nutrients in the liver alter their expression directly. Interestingly, IGFBPs are predominantly secreted by Kupffer cells, unlike IGF-1, which is synthesized by hepatocytes.[62] The difference between these two cell types in terms of their location and their expression of surface receptors could allow for subtle regulation of IGF action in the face of nutrients and other factors in the circulation, such as cytokines. Significant advances in recent years have provided the basic understanding required for development of IGFBPs as disease therapies. Mecasermin rinfabate (iPLEX™, a complex between IGF-1 and IGFBP-3 intact proteins) is currently in clinical trials for the treatment of conditions associated with poor growth, improved insulin sensitivity has also been reported in response to the drug.[71]

Effect of Intestinal Contents on Genes in the Epithelium

The gastrointestinal (GI) tract is the only mucosal surface that comes into contact with nutrients before they are absorbed. In addition, the large intestine is the natural habitat for trillions of bacteria, collectively referred as the microbiota. The microbiota generally constitutes families of bacteria that exist in a commensal/symbiotic relationship with the host. One can thus appreciate the unique challenges that are faced by the GI mucosal immune system. Simply, it has to exhibit tolerance toward ingested food antigens and its own microbiome, and yet at the same time be able to mount effective immunity toward enteropathogens such as *Enteropathogenic E. coli*, *Salmonella* and *Campylobacter* sps, and *Clostridium difficile*, infectious agents responsible for majority of the cases

of bacterial gastroenteritis worldwide. The luminal contents of the GI tract may therefore constitute a complex milieu containing live/dead bacteria, their byproducts (such as short-chain fatty acids[SCFAs], toxins) and food antigens digested to a varying degree (Figure 19-2). The dissociation between nutrients ingested and the changes observed in the bowel lumen becomes greater the further one proceeds down the GI tract. The contents of the distal colon are completely different from food, although even here they are affected to some extent by dietary intake. This relationship between ingested nutrients and the local environment of the lumen is a separate issue from the impact of that local environment on gene expression of the surface epithelium.

The GI tract consists of a single-cell epithelial lining that protects the underlying mucosa. It has been traditional to assume that gene expression in the small intestinal epithelial cells (IECs) is preprogrammed and that their expression is not influenced by events in the lumen. However, this view is being revised. An alteration in epithelial cell phenotype secondary to nutritional factors offers several advantages (Table 19-2). First, the intestine could adapt to absorb nutrients more effectively if specific digestive enzymes and IEC transporters were up-regulated in response to a particular nutrient. Second, as all mammals begin life on mother's milk, the opportunity exists for breast milk to influence the development of non-immune and immune components of the GI tract through actions of its own constituents. Third, if the genes affected in the IEC were immunologically important, the epithelial lining could mediate changes further afield by signaling information and modulating the mucosal immune system. Each of these areas is likely to represent important physiologic mechanisms that have implications for child health.

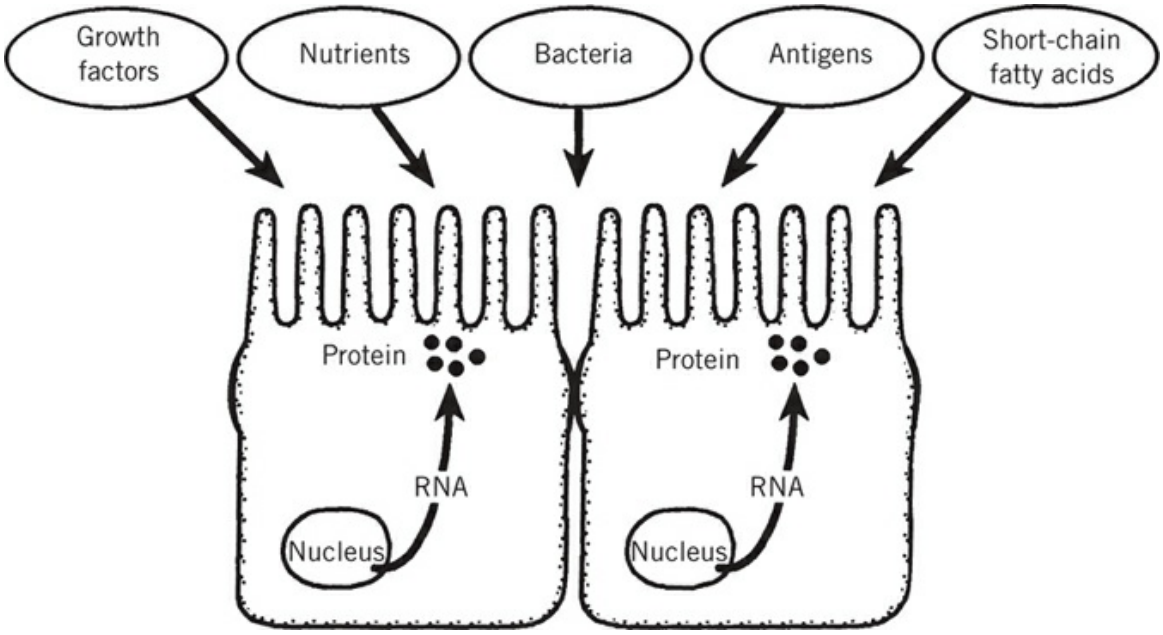

Figure 19-2 The luminal factors that influence gene expression in the enterocyte. Factors can affect individual genes or they may influence enterocyte differentiation and new cell lineages.

Intestinal adaptation
Influence of maternal breast milk
Signaling from lumen to mucosal immune system

Polarity of Epithelia

The cell types that we have discussed earlier in this chapter do not depend on a separation of functions to different cellular poles. For example, the pancreatic islet receives signals from the entry of glucose at any point on the plasma membrane and the insulin response is not affected by the site of glucose entry. Insulin can also be released in any direction, eventually diffusing into the circulation. Cells that form epithelia are different in that they exhibit polarity. This separation between the apical side (bordering the lumen in the case of the intestinal epithelium) and the basolateral side is central to IEC activity. This property is well recognized in the field of intestinal transport. Ions,[72–74] small molecules,[73–75] and macromolecules

[73,74,76] are all transported differently across the apical membrane than across the basolateral membrane (Figure 19-3). It is the polarity of the epithelium that gives direction to the movement of these substances across the epithelium into or out of the body. But this property must also be considered when one is examining all aspects of IEC function. Polarity is also of fundamental relevance in the study of nutrient-gene interactions in the intestinal epithelium. The polarity of the IEC distinguishes the two major mechanisms by which nutrients (and other luminal factors) affect genes: (1) a direct effect on enterocytes and (2) an indirect effect mediated through hormones, growth factor, and cytokines (Figure 19-3). As with the effects of insulin on target tissues, the mechanism(s) of action of direct (bacterial) and indirect (cytokines) mediators on the epithelium are beyond the scope of this chapter. The reader is again referred to excellent reviews on how epithelial cell expression can be regulated by a multitude of agents.[77,78]

The apical membrane mediates the direct effects of luminal factors on the epithelium. The functions of nutrient recognition (sensing) and signal transduction (see Figure 19-1) will therefore lie between the apical membrane and the apparatus of gene expression. The exact molecular mechanisms involved require further investigation. For purposes of investigation they can be considered as a series of black boxes connecting the lumen and gene expression (Figure 19-4). These black boxes contain the mechanisms that regulate gene expression and constitute the way by which molecules in the lumen "cross-talk" with the nucleus of the enterocyte. Figure 19-4 depicts the pathway linking single factors in the lumen to the expression of a single cell in a single gene. This is, of course, a gross oversimplification. As we have mentioned, an alteration in diet may alter different factors at the cell surface, and any one of these factors may have an effect on several different genes through different pathways (Figure 19-5). In addition method(s) by which a particular protein may be expressed is not necessarily always due to the induction of a single gene in cells along the crypt-villus axis. It can also be due to changes in the state of differentiation of the cells in the epithelium, the expression of a particular gene being just one component of that change. Lastly, alterations in luminal contents may not necessarily affect epithelial cells that are already formed along the epithelium, but instead result in the generation of new lineages of cells that express the gene arising from the crypt.[79] In this case, the mechanisms linking the lumen to gene expression would lie in the stem cell at the base of the crypt, rather than in the individual enterocyte itself.

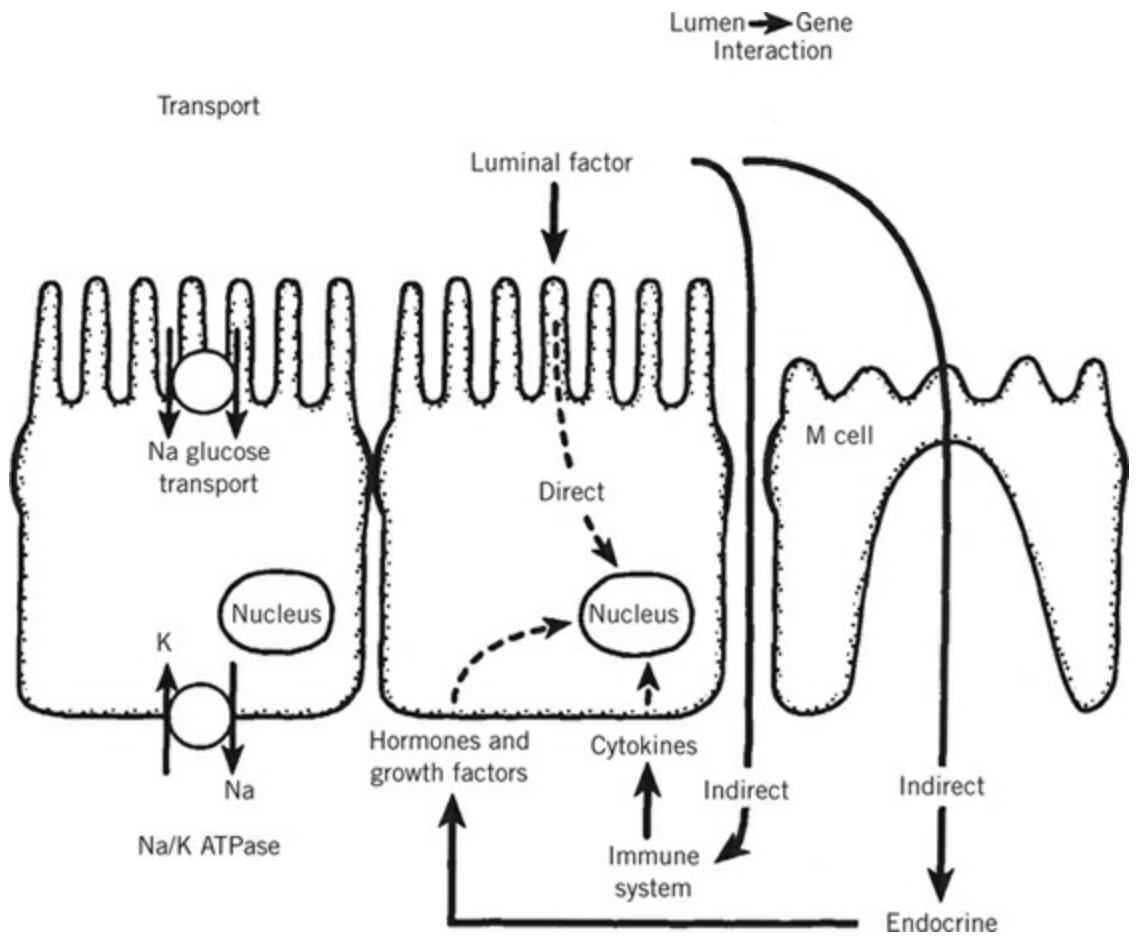

Figure 19-3 Dietary changes may affect gene expression directly (being mediated through the apical membrane) or indirectly (through the basolateral membrane).

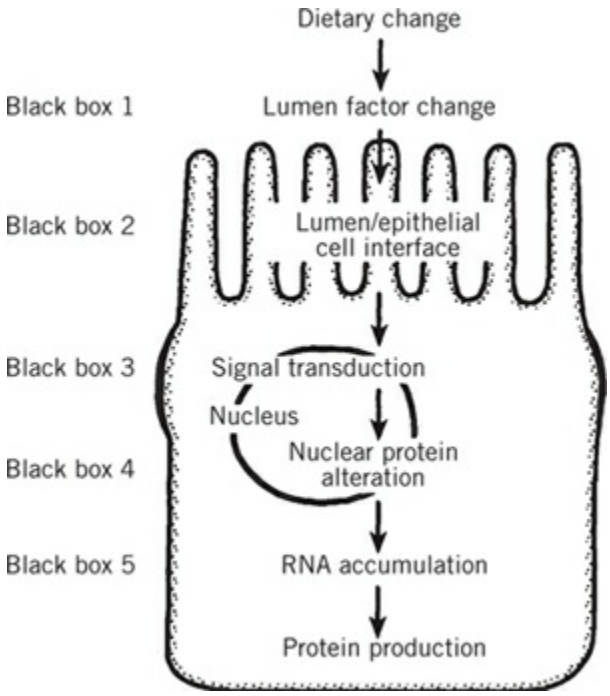

Figure 19-4 The pathway connecting dietary alterations to changes in gene expression is not well understood. It is likely that the pathway is mediated by a series of steps which at present we can only regard as black boxes. Different luminal events will influence gene expression through different series of black boxes.

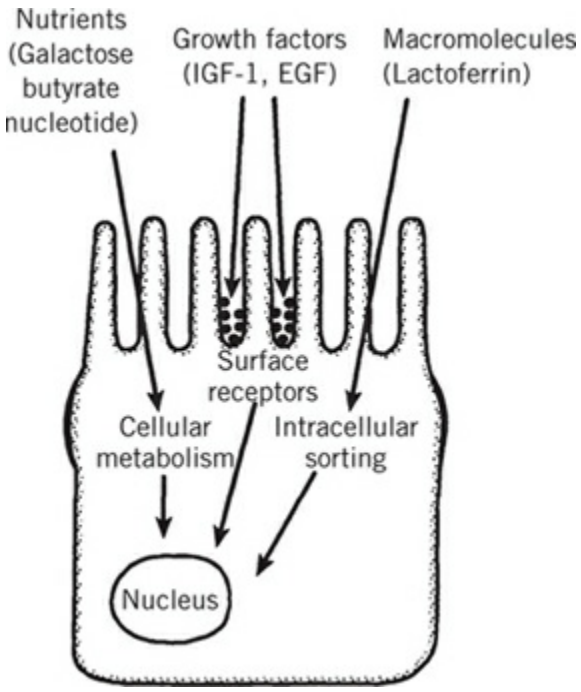

Figure 19-5 Cross talk through the apical membrane will depend on the particular signal involved. IGF, insulin-like growth factor; EGF, epidermal growth factor.

Adaptation of Enterocytes to the Nutritional Environment

The efficient utilization of food requires digestion, followed by absorption of digestion products and their release into the circulation. Adaptation is, by definition, the up-regulation of one or all of these functions in the presence of a relevant nutrient. Adaptive mechanisms are more likely to be associated with foods whose intake varies between different individuals. The similarity here with prokaryotic cells is clear. Bacterial gene regulation was discovered in the study of enzymes that metabolized nutrients whose abundance varied widely in the environment, like lactose or tryptophan. For children, of course, there are many foods whose abundance can vary, but to illustrate this section we have chosen two: dietary fat and sucrose. These two examples demonstrate different aspects of adaptation. Fat digestion is primarily controlled by enzymes secreted from the pancreas and gastric glands, whereas digestion and absorption of sucrose is controlled entirely by the enterocyte itself.

Sucrose Intake

The intake of sucrose can vary greatly between individual human beings. This is especially true when one compares individuals from different times in history. Until the industrial revolution, sucrose was present in the diet only when brought from the East as part of the spice trade, and its availability was limited. The introduction of plantations in the Caribbean in the 18th century, coupled with the industrial process of refining, resulted in an explosion of sucrose intake. In England in 1700, the estimated per capita daily consumption in adults was 4.5 g, rising to 37 g in 1800. By 1968, it had reached 140 g daily, which is around 15% of the total energy derived from food. The reader is recommended to a recent update by Stephens and colleagues where the authors summarize information available on the carbohydrate intake of children below 4 years of age.[80] Sucrose is digested by the epithelial cell brush border, where it is hydrolyzed to fructose and glucose by sucrase-isomaltase (SI). Fructose is absorbed by the carrier GLUT family members 18 and glucose by the specific sodium-dependent glucose transporter. Both sugars exit the cell through the basolateral membrane by facilitated diffusion via GLUT-2.

The up-regulation of any of these proteins by their substrate would constitute a nutrient-gene interaction.[81]

The brush border membrane (BBM) disaccharidases represent the final step in the digestion of carbohydrates.[81] Their activity can affect the glycemic response to oral carbohydrate.[82] Importantly, low levels of hydrolase activity in the face of carbohydrate in the intestine result in osmotic diarrhea.[83] A mechanism whereby expression of these enzymes could be linked to sugar intake would therefore have clear benefits. SI is one of the three β-glucosidases (together with maltase and trehalase). The remaining disaccharidase, lactase, is a β-galactosidase. Although sucrose digestion is the focus of our attention here, one must not forget that the major source of carbohydrate disaccharide in a new born is of course lactose from milk. Lactose is cleaved by lactase-phlorizin hydrolase (LPH) activity into glucose and galactose. LPH activity is crucial, particularly for those who are solely dependent on their mother's milk for nourishment.

In humans, BBM enzyme activity correlates with morphogenesis, as it associates with the formation of enterocytes.[84] Proximal-to-distal enzyme activity gradients are established early in gestation along the length of the small intestine. In addition, crypt-villous gradients are also seen with LPH activity which is highest at the villous tip, while maximal SI activity resides in the mid-villous region.

In humans, a marked increase in SI activity occurs just prior to birth, soon after however there is a sharp decline to levels comparable to those found in early gestation. As sucrase is not generally a major component of a neonate's diet, the role of high SI activity at birth remains ill-defined. SI is composed of two subunits sucrase is anchored to the microvillus membrane by the isomaltase subunit both subunits are synthesized as a single protein that is later cleaved.[85] The regulation of the induction of sucrase is not simple. The timing of its appearance during ontogeny in rodents was elegantly shown to be independent of luminal contents.[86] When the investigators transplanted isografts into animals 5 days younger than the donors, sucrase appeared earlier in the transplanted intestine than in the host. Therefore luminal factors in this case did not induce sucrase nor did circulating factors in the host (whose intestine would have been susceptible to them). This evidence suggests that sucrase is controlled by an internal biologic clock within the intestine itself. However, luminal contents can have a marked effect on the activity of sucrase, which is separate from this internal mechanism: (1) early feeding with sucrose will induce precocious sucrase induction in rodents[83]; (2) reduction of

carbohydrate intake results in a reduction of sucrase activity even when caloric intake is unchanged[87]; (3) feeding with glucose instead of sucrose reduces brush border hydrolase activity[88]; and (4) refeeding sucrose after a period of abstinence leads to rapid recrudescence of the hydrolase activity.[89] Increasing the intake of sucrose of mice from 2 per cent to 55 per cent of total energy intake had differing effects on the enterocyte, depending on the position of the cell in the small intestine.[90] Sucrase activity increased in the duodenum and upper jejunum but not in more distal segments of the intestine. Not surprisingly, the cells showing greatest alterations were those from the mid villus of the proximal intestine, with lesser increases in the villus tip and crypt/villus junction.

The control of sucrase activity is complex and depends on events within the enterocyte in addition to external influences. Sucrase activity depends mainly on events in the sucrase promoter since expression of growth hormone mirrors that of sucrase in transgenic animals containing a sucrase promoter-GH construct.[91] The expression of sucrase may therefore reflect nuclear protein-promoter interactions.[92] Evolutionarily conserved cis-acting elements in the promoter region have been found to interact specifically with transcription factors such as GATA-4 and Cdx proteins.[93–95] Further combinatorial interactions between HNF-1α protein, GATA-4 and Cdx-2 may play a critical role in the temporal and spatial regulation of the SI gene expression during post-natal development.[94,95] Post-transcriptional events may also likely to influence enzymatic activity, for example, reduction in lactase activity following weaning does not necessarily correlate with lactase mRNA but may be regulated during translation.[96]

Glucose Transporter Expression

It is worth noting that most of our understanding of nutrient transport has been gained from rodent studies. Unlike humans, rodent gut is immature at birth, and studies investigating gut maturation in these systems have provided invaluable information pertinent to preterm gut health in humans. Glucose transport is detected early in development and swallowing of amniotic fluid allows direct nutrient acquisition. Glucose enters the IEC primarily by active transport *via* a sodium-coupled glucose transporter, SGLT1 and GLUT2.[20,22,97] It is generally accepted that glucose (and galactose) uptake at the apical surface of the enterocyte is mediated by SGLT1 and exit is mediated *via* GLUT2 on the basolateral surface. Glucose entry via the SGLT1-GLUT2 axis is an exquisite example of how

the polarity of the IEC impacts on tissue homeostasis.

Direct transport studies undertaken before the identification of sodium-dependent transporters showed that glucose uptake increased with glucose feeding.[98] This increase was not due to changes in the affinity of glucose to the enterocyte (K_m), but to an increase in the maximum uptake (V_{max}) indicating an increase in the production of proteins that transport glucose. *In-vitro* and *in-vivo* studies indicate that JAK-2 mediated signalling can enhance SGTL1 expression at the apical surface of IECs with minimal impact on affinity clearly suggesting that this pathway may play a crucial role in maintaining glucose homeostasis in health and disease.[99] Modulation of SGLTI expression by dietary carbohydrates has also been observed in the human intestine.[97] Elegant studies by Wright and colleagues have recently provided a molecular, structural basis for SGTL1 function.[100] Several distinct conformational changes come into play upon ion (Na+) and substrate (glucose) binding. For detailed description, reference[100] is recommended.

Mechanisms involved in the regulation of glucose transport are complex and have been difficult to characterize as two distinct time-scales of dietary carbohydrate exposure are now known to play a role[101] Glucose transporters can respond within an hour to glucose[102] and also exhibit distinct changes in gene expression over a period of 1-3 days to a high carbohydrate diet.[103] Intestinal glucose transport mechanism(s) are also subject to diurnal changes adding further complexity to the system. Interestingly, impact of nutrients on induction of enzymes and transporters in mammalian cells show significant differences when compared to prokaryotes. First, the activity of transporters in bacteria increase by 100- to 1,000-fold in contrast the nutrient transporters in mammals show smaller variation with diet. For example, feeding mice with diets containing high levels of either D-glucose or non-metabolizable analogues of D-glucose results in only a two to three-fold increase in SGLT1 activity.[104] Second, in bacteria, the cell that receives the stimulus is the same cell that exhibits alterations in gene expression. In mammalian intestine, this appears not to be the case with the glucose transporter.[105] Sequential elution of different fractions of epithelial cells was used to distinguish different cells along the crypt-villus axis of mice.[106] Increase in carbohydrate intake resulted in enhanced expression of the glucose transporter (as measured by phlorhizin binding). Importantly, changes were observed in the crypts before they were seen in the villi. Similarly when carbohydrate was stopped, it was in the crypts that the reduction in

transporter was first observed. Thus crypt cells respond to changes in diet before villus cells, indicating that the changes in the expression of the glucose transporter were effected by new cell lineages from stem cells. It is the stem cell producing the new cell lineage that therefore must contain the machinery for detection of carbohydrate. The resulting cell population that ascends along the crypt-villus axis expresses this change. This separates carbohydrate detection temporally and spatially from glucose transporter expression. It is not known whether other genes in the intestine follow a similar pattern. Identification of molecular mechanisms underlying carbohydrate detection and signal transduction are currently under active investigation in several laboratories (see Figure 19-1).[107,108]

Sucrose induces an increase in the enzyme that hydrolyzes it (SI) and in SGLT1 that allows a greater influx into the enterocyte across a concentration gradient. This absorptive system is central to the efficacy of oral rehydration solution in the treatment of gastroenteritis and cholera.[22] The greater the number of transporters, the more sodium and fluid that can be transported into a child during dehydration. Up-regulation of SGLT1 has therefore a potential therapeutic role in alleviating the loss of sodium and fluid with glucose solutions. In this context, a drug that may potentiate JAK2 signalling leading to increase in SGTL1 expression is a viable option.[99] Better understanding of the mechanisms regulating this process would define to what extent and over what time period sodium and fluid transport could be maximized in children with gastroenteritis.

Intake of Dietary Fat

The intake of fat as a component of total energy varies considerably between different children. Fat consumption has been increasing in children from developed countries and has accelerated over the last 100 years. Contemporary comparison of fat intake between nations now shows large variations. For example, Perissé et al. reviewed countries for the Food & Agriculture Organization of the United Nations (FAO), and showed that between wealthy and non-wealthy countries, fat intake varies from about 12% of total energy intake to over 40%.[109] The explosion in the rate of increase in obesity clearly highlights the impact of recent changes in our dietary habits. As obesity begins in childhood, preventative measures early in life need to be in place if we are to reduce the burgeoning health and economic burden.[110,111] It is not only healthy children who have seen a change in fat intake, children with cystic fibrosis have been given much larger amounts of fats. This is because increased calorie intake, particularly that of fat, results in improvements in

respiratory function.[112,113] Much of this fat is digested in children with cystic fibrosis by the use of ingested enzyme preparations given with meals. However, lipases secreted in the gastrointestinal tract proximal to the duodenum (gastric lipase) may also play a prominent role. It is important, therefore, to document whether secretion of this enzyme varies with fat. Knowledge of mechanism(s) underlying this possible adaptive effect may lead to therapeutic optimization of enzyme production and better utilization of fat in children who are continually under threat of malnutrition.

Gastric Lipase

Human milk is rich in lipids and yet, surprisingly, the enzymes required for its digestion are expressed in low levels in the newborn.[114,115] The physiology of lipid digestion varies considerably between neonates and adults; a recent article by Abrahamse and colleagues offers excellent insight into this topic.[116] Gastric lipase accelerates the digestion of triglycerides in human milk,[117] by releasing free fatty acids which enhance pancreatic lipase and colipase activities. The actions of gastric lipase are magnified in children with little pancreatic lipase activity, as in cystic fibrosis. Newborn babies also have relatively low pancreatic lipase activity[114,115] and the relative importance of gastric lipase is exaggerated in the premature neonate.[118,119] There are significant biochemical differences between pancreatic and gastric lipase, most significant of which is the difference in pH required for maximal activity.[120,121] In addition, gastric lipase activity requires no bile salt or colipase. In the human, the gastric mucosa secretes all the preduodenal lipase.[122,123] In the rodent, the tongue is the most significant source, and here the equivalent enzyme is termed lingual lipase. There may also be some lingual production in the preterm human infant because lipase activity has been detected in esophageal pouches of infants with esophageal atresia with no communication to the stomach.[119] The rabbit predominantly secretes its preduodenal lipase from the gastric mucosa, making the rabbit a more appropriate model than the rodent in which to study the effect of dietary influence on this enzyme.[124]

Gastric lipase activity is more susceptible than pancreatic lipase to dietary changes. Increasing the dietary fat intake in rabbits from 2.7%– to 6% of diet for two weeks was sufficient to induce a 100% increase in gastric lipase activity.[124] This increase had no effect on pancreatic lipase production. Indeed, pancreatic lipase activity was only enhanced when the

fat intake was increased to 12% of diet, and then the increase was only modest, a 10% increase in pancreatic lipase activity. Studies in adult human volunteers have shown similar data with a doubling (5.7-9.95 U/mL) of gastric lipase after changing from a low-fat to a high-fat diet.[125] The mechanisms that detect the amount of fat intake (see Figure 19-1) need further examination, but triglyceride composition had no effect on the adaptive response in the rabbit.[124] This implicates a metabolite of fatty acid breakdown, which is not specific for either saturated or unsaturated fatty acids, as the cellular agent that initiates changes in gene expression. The signal may not have to come directly from the lumen of the GI tract because there is preliminary evidence, in neonates at least, indicating that increasing lipid intake parenterally results in enhanced gastric lipase activity. This suggests that signals from the serosal side of the IECs may be possible in this case.

Gastric lipase is therefore under the control of dietary signals. Although we do not at present understand the mechanisms that underlie this phenomenon, their elucidation may eventually allow us to manipulate gastric lipase expression when it is clinically important, as in the nutrition of cystic fibrosis and in the oral intake of the newborn.

Fatty Acid Uptake

Fatty acid (FA) and cholesterol uptake in the GI tract are major pathways involved in maintenance of lipid homeostasis.[126] FA uptake is facilitated by the presence of fatty acid transporter proteins (FATPs). These include (1) FABPpm, a 40 kDa plasma membrane protein homologous to the mitochondrial enzyme aspartate aminotransferase; (2) FAT/CD36, an 88 kDa membrane glycoprotein, also known as the Class B scavenger receptor; and (3) FATP4, which promotes FA uptake and activation by trapping FA inside the cell in their CoA-thioester forms prior to mitochondrial-driven beta oxidation.[127,128] The fatty-acid binding protein (FABP)-2 regulates the concentration of free FA in intestinal cells. It binds saturated and unsaturated FA with similar affinity and aids in transporting FA from the plasma membrane to the endoplasmic reticulum where enzymatic modifications ensue. Epidemiological studies investigating potential association of polymorphisms at codon 54(A/T) in FABP2 gene and insulin sensitivity and type 2 diabetes have been recorded.[129] The review by Rubin and colleagues provides a comprehensive analysis of the data available on FABP2 and its role in FA processing.[130] Ex vivo model studies of fetal jejunum explants implicate FABP2 polymorphism to

specifically influence small intestinal lipid absorption with minimal effect on glucose uptake or metabolism.[129]

A third fatty acid transporter (FAT; CD36) associated with long chain fatty acid as its ligand has recently been implicated to play a role in the pathogenesis of insulin resistance. CD36 -/- mice exhibited enhanced insulin responsiveness on a high-starch, low fat diet.[131] In a separate study, however, CD36 knockout mice were shown to absorb triacylglycerol and FA as well as the wild-type littermates.[132] Although evidence suggests that CD36 plays a role in FA uptake in adipose tissue, its role in the intestine requires clarification.[133]

Breast Milk and Gene Expression

Nutritional and immunological protection of the infant are the primary roles of breastfeeding, properties that are reviewed in greater detail in other accompanying chapters. Nevertheless, the cells of the GI tract are the first cells of the child to encounter breast milk, and it is not fanciful to suppose that breast milk may influence the development of these cells. A number of factors in milk can affect the expression of genes in the intestinal epithelium, particularly those genes that are associated with enterocyte differentiation. Milk-derived growth factors such as epithelial growth factor (EGF), milk fat globule-EGF factor 8 (a major protein associated with milk fat globule membrane; the protein is composed of EGF and factor VIII-like domains), vascular endothelial growth factor (VEGF), and transforming growth factor-β (TGF-β) have all been reported to have potent effects on the immature gut.[134–137] Although the exact effect of EGF in breast milk on the development of the intestinal epithelium depends on the age of the subject, its effect on enterocyte growth and development is not surprising. Less expected, perhaps, is the demonstration that other breast milk components such as nucleotides also affect these same genes.[138,139] Although our current understanding of metagenomic crosstalk between diet, the host microbiome and the GI mucosal immune system is still in its infancy, studies have begun to provide tantalizing clues as to how these various players impact on each other. Shwartz and colleagues compared these interactions in breast-fed versus bottle-fed neonates at 3 months of age and found that breastfeeding promotes functional changes that allow for optimal adaption to extrauterine life.[140] Herein, we describe, lactoferrin, as an example. We will examine what is known about its interactions with the intestinal epithelium, and how this knowledge may be increased in the future.

Lactoferrin

Lactoferrin, an 80kD iron-binding glycoprotein of the transferrin family, is a major component of mammalian colostrum and milk.[141,142] It is also found in mucosal secretions and neutrophil granules.[143] Lactoferrin has bactericidal properties and is a source of iron in breast-fed infants.[144] The protein has been found to have diverse biological functions including facilitating iron absorption, host defense, regulation of cell proliferation and differentiation, modulating the immune system and embryonic development.[145,146]

Specific binding sites for lactoferrin have been observed in a variety of tissues and cell types including immune cells, bone, brain, liver, and the GI tract.[147] The piglet model is considered to be an excellent model for human infants as the GI physiology and function are similar.[148] In neonatal pigs (1 week of age) lactoferrin receptor (LfR) expression is low on brush-border membranes and predominant expression is considered to be intracellular.[149] Increase in duodenum LfR does occur between 1 and 3 weeks of age with minimal changes in the jejunum suggesting site-specific modulation of lactoferrin action. To gain greater insight into the role of lactoferrin-LfR axis in iron metabolism in the prenatal and postnatal periods, a recent review by Lipinski and colleagues is recommended.[150] Lactoferrin is relatively resistant to proteolytic degradation in human infants this stability through transit in the gut suggests it has the potential of interacting directly with the intestinal epithelium.[151] Emerging data indicates that lactoferrin can indeed be taken up by intestinal epithelial cell-lines leading to changes in cell signaling and proliferation status.[152] The lactoferrin protein consists of a bactericidal domain (lactoferricin), which can be generated in vitro by pepsin digestion. This domain comprises of residues 1-45 of human lactoferrin and 17-41 of bovine lactoferrin and exhibits antimicrobial activity against a variety of pathogens.[153,154] An understanding of the actions of lactoferrin/lactoferricin at the molecular level are particularly relevant as some artificial milk formulas now contain added bovine lactoferrin.[154]

There is a school of thought that proposes that the main function of lactoferrin in vivo is not to transport iron into the epithelium, but to scavenge iron (and possible other substances) in the intestinal lumen. This unbound iron might otherwise cause free radical-mediated damage to sensitive tissues.[145,146] Accordingly, lactoferrin would have no direct effect on the intestinal epithelium, and only indirectly interact with it through the sequestration of other substances in the lumen. These luminal

factors, if left free in solution, may have an impact on enterocyte gene expression. An example of this is lactoferrin-mediated effects on microbial lipopolysaccharide (LPS) reactivity, thereby modulating the effect of this moiety on the host.[155] However, a purely luminal role for lactoferrin is difficult to reconcile as emerging studies suggest that once internalized, lactoferrin translocates to the nucleus where it may modulate gene transcription by mechanisms that currently remain unclear.[156]

Because lactoferrin is secreted by neutrophils, its effect on immune and non-immune cell gene expression has been closely studied. These observations have resulted in some intriguing information on lactoferrin function, which may be relevant to the actions of breast milk lactoferrin on epithelia. Lactoferrin interacts avidly with nucleic acids in a test tube.[157–159] He and Furmanski have determined the specific DNA sequence recognized by lactoferrin.[160] Iron-saturated lactoferrin exhibits greater affinity for the DNA sequence than the iron-unsaturated form, suggesting conformation a crucial factor in determining DNA-protein interaction. Lactoferrin has also been shown to modulate promoter activity of genes in granulocytes.[161]

So, taken together, evidence does support the notion that lactoferrin from mother's milk is taken up by receptor-mediated endocytosis allowing the protein to impact on epithelial gene expression in some way. How this is achieved and what benefits this would have for the developing infant are questions that future research may well answer. Previous work from our laboratory indicated that lactoferrin affects the proliferation and differentiation of intestinal epithelial cells, and that this effect depends on the degree of saturation by iron.[159] It is possible that these changes in enterocyte gene expression are mediated by mechanisms similar to those outlined by He and Furmanski in white cells.[160]

Signaling From the Intestinal Lumen to the Mucosal Immune System

The function of the small intestinal epithelium is to absorb nutrients from the environment while providing a barrier to the external world.[162,163] The barrier is not complete, as the intestine allows macromolecules to be sampled and actively absorb nutrients. The success of the intestine in achieving the balance between these competing aims was the critical step in the evolution of multi-organ animals. The ability of the intestine to monitor the environment is a key element in this process in which the mucosal immune system plays an important part. Curiously, until recently,

the possibility that epithelium may respond to luminal factors (and signal their presence to the mucosal immune system) had been substantially ignored. The epithelium has mainly been regarded as a passive barrier with points of selective filtration (Figure 19-6A), surveillance of the luminal contents occurring after this filtration has taken place. Increased appreciation of the impact of the resident microbiome in recent years has highlighted how critical the epithelial immune barrier function is to intestinal health.[164]

The epithelia express Pattern recognition receptors (PRRs), receptors that detect not only microbial signature motifs but also recognize endogenous host danger signals; referred as danger-associated molecular motifs (DAMPs). Toll-like receptors is one PRR family, members of this family reside in appropriate cellular compartments awaiting detection of microbial presence.[165,166] In recent years, a central role for intracellular PRRs the Nucleotide-like proteins (NLRs) in epithelial immune defense has emerged.[4,164,167] Initially, NLRs were considered to regulate inflammation via apoptosis; however, in the last decade, several members of the NLR family have been found to form components of a large protein platform referred as the “inflammasome” complex. Activation of the inflammasome can be triggered by NLR members such as NLRP1, NLRC4, NALP3, and NALP6 as they can sense exogenous and endogenous DAMPs. Once activated, through a series of protein associations, the final step of the complex formation involves the recruitment of procaspase-1, an enzyme that undergoes auto-proteolysis releasing active caspase-1. This enzyme is now known to be responsible for cleaving pro-IL-1β and pro-IL18 to their bioactive form. Both cytokines not only exert cytoprotective effects on the intestinal epithelia but can also modulate adaptive immune responses as the former is involved in differentiation of Th-17 cells while the latter is as known as an interferon-gamma inducing factor.[168,169] In addition to regulating cytokine release, the inflammasome can also activate a novel form of cell death called “pyropotosis”. Due to space constraints, these functions will not be discussed further, instead excellent reviews by Flavell and co-workers and Nunez and colleagues are recommended for deeper understanding of how the inflammasome function (both in non-hematopoietic and hematopoietic compartments) may contribute to GI homeostasis in health and disease.[164,167]

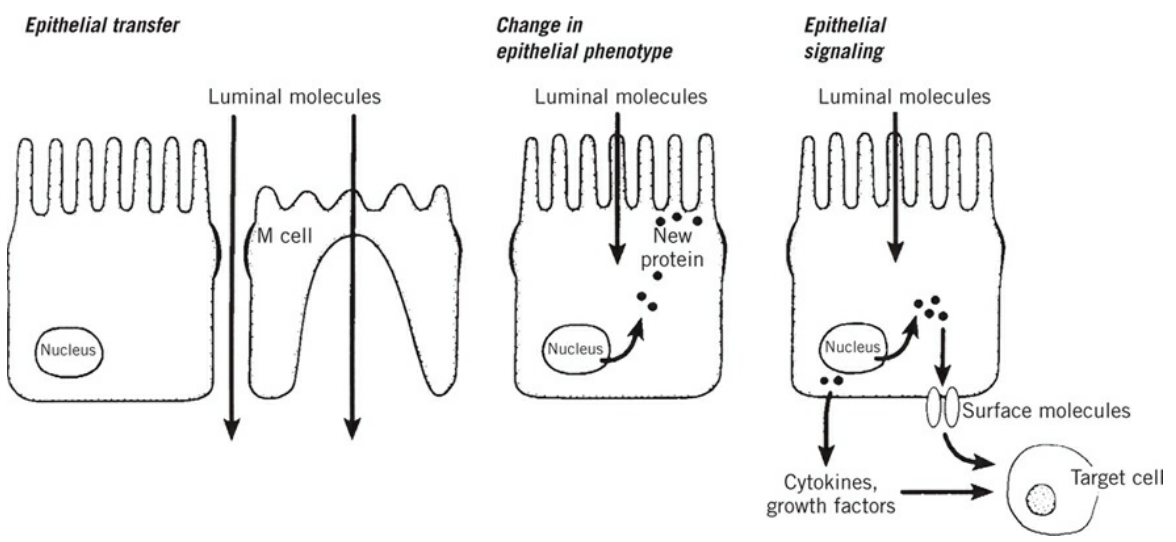

Figure 19-6 Possible interactions of molecules from the intestinal lumen with the epithelium. Traditionally the epithelium has been seen as a selective barrier to molecules, admitting those required for energy intake or immunosurveillance and excluding others (A). However, nutrients can alter the phenotype of the epithelium to adapt to changing nutritional needs (B). When changes in the intestinal lumen induce new proteins that interact with mucosal immune cells, the epithelium can act as a membrane signaling information from the lumen to the immune system (B).

The epithelial cell can also express proteins that may interact with immunocytes within the intestine. These include surface molecules such as class II major histocompatibilty complex and secretory chemokines and cytokines, thus modulating T cell function by direct and indirect mechanisms. This means that the epithelial cell must recognize (or "sense") the nutrient or other luminal factor, and a mechanism must then "transduce" this recognition into molecular changes that can directly alter gene expression (see Figures 19-1 and 19-4). The main difference in molecular terms from the adaptive response described earlier (Figure 19-6B) is that the resultant proteins escape from the compass of the epithelium and interact with receptors on target cells (Figure 19-6C).

Signaling, by transducing molecular interactions with the epithelium into secretion of messenger proteins, allows luminal factors to influence immune responses while maintaining full epithelial barrier integrity (Figure 19-6C). Although the absorption of luminal factors (Figure 19-6A) is an important method by which the mucosal immune system surveys the

intestinal lumen,[4] it requires the entry of molecules through the epithelial barrier. This provides a potential source for invasion by pathogens. The poliovirus, for example, enters by this means, exploiting the normal uptake of macromolecules. The ability of the epithelium to signal information to the mucosal immune system without the need for a physical pathway from the lumen to the serosal surface offers obvious advantages in terms of epithelial protection.

The notion of epithelial signaling (Figure 19-6C) implies that the epithelium can modulate the level of immune activity in the mucosal immune system according to the environment of the intestinal lumen. Mucosal immune responses play a large part in gastrointestinal diseases, particularly Crohn's disease, ulcerative colitis, and celiac disease. The milieu of the intestinal lumen could therefore be manipulated for therapeutic purposes, by alterations in diet.

Genes of Immunologic Importance in the Intestinal Epithelium

An increasing list of immunologically active proteins are now known to be synthesized by the intestinal epithelium (Table 19-3), and these originally were thought to be produced only by other cell types. Human diseases are associated with the increased production of some of these proteins in the circulation and the gastrointestinal tract. We and others have shown that the expression of these proteins in the epithelium is influenced by dietary factors.[170]

Cytokines

An interesting example of a cytokine secreted by the epithelium is IL-8. This protein is small (8,000 D) but has a long half-life in vivo relative to other cytokines, making it a feasible candidate for long-lasting control over mucosal immune responses. IL-8 is a member of a super family of cytokines, "chemokines," which have chemo tactic properties, recruiting as well as activating a number of immunologic cell types. It is a potent chemo tactic factor for neutrophils, and T lymphocytes and may be important in recruiting them into the lamina propria during GI infection and inflammation Invasion by neutrophils, in particular, is a hallmark of Crohn's disease, a condition in which IL-8 production is enhanced.[171] IL-8 also stimulates the release of superoxide radical in neutrophils as well as other potential mediators of damage in intestinal inflammation. Furthermore, it increases the permeability of vascular endothelium to albumin resulting in tissue edema. Its production in intestinal epithelial

cells has been documented in response to bacterial invasion. *Clostridium difficile* infection can result in pseudo membranous colitis in susceptible individuals, a colitis that is exemplified by a marked neutrophil influx causing a cytokine storm that leads to extensive tissue pathology. Animal and human studies suggest excessive IL-8 release most likely contributes to the presence of neutrophils and resultant pathology.[172] We generated MIP-2 (mouse chemokine similar to human IL-8) transgenic mice where the chemokine expression was confined to the small intestinal and colonic epithelium by the use of fatty-acid binding protein promoter.[173] The epithelium from the first generation of the founder showed effects on both neutrophil and lymphocyte recruitment. In the small intestine where the FABPI promoter is active, the neutrophil recruitment expressed as myeloperoxidase activity was significantly greater. In the distal colon where the promoter is inactive, there was no effect. These studies show that the epithelial can, through the release of chemokines, alter the mucosal immune function in vivo. Further analysis revealed increased lymphocyte infiltration ($P < 0.05$), in addition to neutrophils. There was also a doubling of the number of intraepithelial (IEL) lymphocytes. The increase in IELs was due to an increase in both αβ and γδ lymphocyte populations. Interestingly, these cells express CXCR2, the receptor for MIP-2. These studies highlight the potential recruitment capacity of a single chemo tactic activity of the in vivo situation, however, is likely to be more complex with simultaneous alteration of various immune regulators.

TABLE 19-3 Examples or Immunologically Relevant Genes Expressed by Intestinal Epithelial Cells

Cytokines	
IL-1β	Experimental colitis
IL-6	Isolated epithelium Rat IEC-6 cell line with IL-1
IL-8	Colon carcinoma cell lines
MIP-2	Rat IEC-6 cell line with IL-1
Acute-phase respondents	Colon carcinoma cell lines
Surface Molecules	
Class II	Sections of rat small intestine
MHC invariant chain	Freshly isolated mouse epithelial cells, IEC-6 cells
Growth Factors	

IGF-I	Colon carcinoma cell lines
IGFBPs	Colon carcinoma cell lines

Evidence suggests that various epithelial-derived immune regulatory molecules can be altered by dietary factors.[4,174] n-Butyrate is a short-chain fatty acid produced by the metabolism of normal intestinal bacteria whose levels in the intestine vary with diet. Newborn babies have very low butyrate levels in either the small or large intestine. Butyrate levels rise steadily reaching adult levels by 2 years of age. Lionetti and colleagues studied the effect of diet on fecal butyrate levels by comparing the fecal microbiota of children from Europe and a rural African village Burkina Faso (BF).[175] As the dietary habits of the latter population have not changed since the introduction of agriculture, the effect of diet was amenable to investigation. The BF children showed a significant enrichment in Bacteroidetes, with a unique abundance of the genus *Prevotella* and *Xylanibacter*, microbes that can hydrolyse cellulose and xylan. In addition, BF children also showed greater butyrate levels compared to EU children, providing compelling evidence of the impact of diet on butyrate levels.[175,176]

Butyrate levels clearly depend on the type of bacteria in the gut and how much substrate is available for butyrate production. Butyrate levels therefore reflect events in the intestinal lumen, and it is no surprise that butyrate alters intestinal epithelial cell signaling. Butyrate increases IL-8 secretion in enterocytes while simultaneously down-regulating another chemo tactic cytokine, macrophage chemo tactic protein-1 (MCP-1).[177,178] Butyrate-induced histone acetylation is involved in the regulation of chemokine gene expression.[179] Unlike IL-8, which attracts neutrophils, MCP-1 attracts macrophages and monocytes. It is constitutively secreted by the intestinal epithelium, whereas IL-8 is not. These observations are consistent with events in the whole intestine in vivo where, in healthy tissue, neutrophils are absent and macrophages abound. With increasing butyrate levels, IL-8 secretion is induced but MCP-1 production is depressed. Such “chemokine switching” in response to butyrate may well alter the population of immunologic cells in the lamina propria. Thus, butyrate may affect both the number and types of cells in inflamed tissue through changes in chemokine production of epithelium during inflammation.

Antimicrobial Peptides

Several families of epithelial-derived antimicrobial peptides are known to survey the gut lining in health and disease.[180,181] The expression of the β-defensin family and the single human cathelicidin, LL-37 has been observed in enterocytes (the expression of α-defensin family is confined only to Paneth cells). Several studies have shown dynamic changes in the expression of these peptides during infectious and inflammatory episodes implicating them in the front line of host defence in the GI tract.[180,181]

Class II MHC and Invariant Chain Expression

The initiation of an immune response to protein antigen normally requires the help of T lymphocytes. Activation of T cells in turn depends on the processing and presentation of peptides by an antigen-presenting cell (APC).[182] Class II MHC heterodimers (Ia in the rodent) are the molecules that present the processed exogenous antigen to the T cell receptor. In addition to classic APCs (dendritic cells, macrophages, B lymphocytes), a number of cell types express class II MHC (Ia antigen) including intestinal epithelial cells, highlighting the enterocyte as a potential APC. There is evidence that both the small intestinal and colonic epithelium may function as an APC.[183,184] The requirement for cell viability and an intact cytoskeleton suggests pinocytosis as a major mechanism for active antigen uptake by intestinal epithelial cells (IECs), however, passive diffusion and adsorption may also contribute to the process. Processing and presentation of exogenous antigen requires an additional protein, the invariant chain (Ii).[185] Diet has a marked effect on the expression of class II MHC and its associated invariant (Ii) chain in the mouse intestinal epithelium. The expression of class II MHC and Ii mRNA is developmentally regulated[186] in the epithelium (unlike its expression in the lamina propria, where it is expressed from before birth). In addition, the timing of expression can be altered by delaying the age of weaning from mother's milk to normal chow.[187] Expression of class II MHC and Ii chain is apparent three-four days after weaning on chow. However, weaning onto an elemental diet (which contains chemically synthesized amino acids, simple sugars, and fats) did not induce the expression of class II MHC or invariant chain (Figure 19-7). Thus, the expression of these genes in the intestinal epithelium is influenced by dietary manipulation in vivo. The fact that elemental diets used in these experiments were the same as those administered therapeutically in Crohn's disease lends support to the idea that alterations in gene expression may by a significant tool in the treatment of disease (see below).

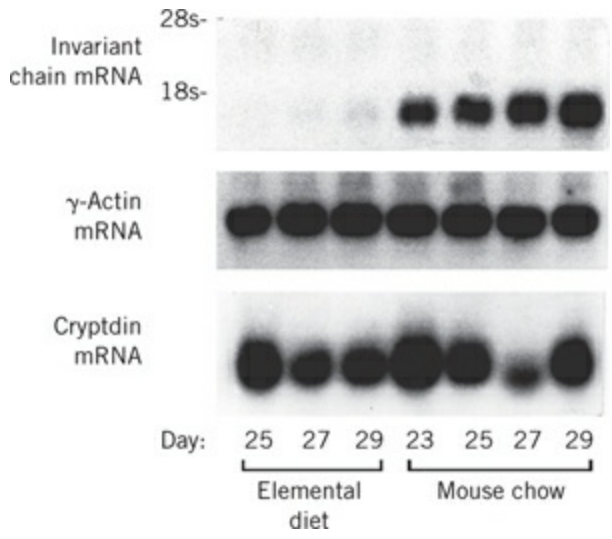

Figure 19-7 Dietary factors alter the expression of Class II MHC and invariant chain expression in intestinal epithelial cells. Northern blot of RNA from epithelial cells taken from individual mice of a single split litter weaned at day 17 onto elemental diet or Purina mouse chow. The blot was probed with invariant chain cDNA and auto radio graphed for 48 hours. Mice were examined at day 23, 25, 27, and 29. Blots were also probed with γ-actin and cryptdin cDNA to verify uniformity of enterocyte extraction. (Reproduced from Sanderson IR et al.[186])

Insulin-Like Growth Factor Binding Proteins (IGFBPs)

Immune responses depend not only on the activation of T cells, but also on the ability of these T cells to proliferate. Earlier sections of this chapter described the importance of IGF-1 in growth. However, IGF-1 is also an agent that affects cells of the immune system.[188] IGF-1 exerts a range of effects on T cell physiology. The growth factor induced a marked increase in the gene and protein expression of both CD25 and IL-2 and modulated T cell proliferation via both autocrine and paracrine mechanisms.[189] Treatment of adult mice with recombinant human IGF-1 induces striking modifications in lymphocyte number and function. Fourteen days of treatment with IGF resulted in increases in both CD4+ T cells and splenic B cells. Mitogenic responses of T and B cells were also enhanced, demonstrating that IGF-1 increases lymphocyte numbers and activity. As discussed earlier, IGFBPs modulate the actions of IGF-1. Because cultured intestinal epithelial cell,[190] secrete IGFBPs, it is possible that the epithelium can influence the proliferation of activated B cells by this

means. Furthermore, studies have shown that nutritional factors affect the production of IGF binding proteins in cell lines in vitro.[191] Therefore, not only may nutritional factors influence IGF/IGFBP secretion by the liver into the circulation, resulting in changes in growth of the whole individual, but nutrients may also affect the IGF/IGFBP system in the intestinal epithelium, leading to alterations in the proliferation of the local immune system.

Nutrient Recognition and Signal Transduction

The mechanisms where by a nutrient (or other factor in the intestinal lumen altered by dietary change) results in changes in RNA transcription are not well understood (see Figure 19-1). It is likely that increases in transcription are the consequence of alterations binding nuclear proteins to the promoter of the particular gene, but the steps by which a cell recognizes a change in that nutrient will differ for every nutrient examined; so too will the mechanisms that trans duce this signal into alterations of nuclear protein binding. In the enterocyte we have seen the variety of mechanisms that might occur simply by appreciating the many factors that may alter when the diet is changed (see Figure 19-2). Different theoretic mechanisms of interaction exist between the lumen and epithelial cells. These mechanisms differ, depending on the exact luminal factor involved (see Figure 19-5). Small nutrients such as butyrate or galactose are likely to enter the cell and affect gene expression through their respective metabolic pathways. Growth factors and lactoferrin involve specific receptors on the surface of the epithelium, and large proteins may enter the cell and alter gene expression as they are sorted. Some complex entities may affect more than one pathway. Bacteria for instance may interact through all three pathways: they could influence enterocyte metabolism; they may produce factors or components of their cell walls (e.g., endotoxin), which may interact with surface receptors; and the macromolecules from which they are composed may enter enterocyte compartments and be sorted inside the cell. Each pathway may influence aspects of nuclear function. In addition, indirect actions of cytokines produced from immune cells may also play a role.

Although sensing and signal transduction mechanisms (see Figure 19-1) in the epithelium require further investigation, there are some data on the mechanisms by which glucose regulates the expression of pyruvate kinase (in the liver) and insulin (in pancreatic islet cells). Three key questions relate to the effect of glucose on the expression of these two proteins: (1) what are the glucose metabolite(s) that set in train the effects

on transcription? (2) how is binding of nuclear proteins to gene promoter elements induced? (3) what is the sequence of DNA in the promoter that confers glucose sensitivity on the gene in question (the so-called nutrient response element)?

In practice, this last question is the easiest to answer because DNA sequences can be easily manipulated in the laboratory. Promoters linked to reporter genes allow researchers to directly measure promoter activity. This was first examined in the pyruvate kinase gene in response to glucose. The actual sequence in the pyruvate kinase promoter was determined by mutational analysis of the promoter and its effects on reporter activity. The glucose response elements in the pyruvate kinase gene and in the insulin I gene were discovered by this means. To determine the glucose response element (GlRE) in the pyruvate kinase gene promoter, promoter DNA sequences were transiently transfected into hepatocytes in culture,[192] and were also examined in transgenic mice.[193] Mutations induced into the DNA demonstrated a glucose response element occurring twice in the pyruvate kinase promoter. This motif is known as an E box because of its resemblance to a similar sequence in a promoter of the adenovirus, which had been given this name. This same DNA sequence also occurs in other genes that regulate glucose metabolism, most notably the FAS gene, whose protein product catalyzes one of the later steps in the conversion of carbohydrate to fat, and one that is up-regulated when glucose is abundant in the diet.

The rat insulin gene also contains an E box, which is termed the Far element. Paradoxically this element does not confer glucose sensitivity to the insulin gene. This attribute is conferred by a sequence 10 bases away termed the FLAT element. We now understand some of the features of the signal transduction from nutrient to nuclear function in the insulin gene. MacFarlane and colleagues[194] have identified a nuclear factor, insulin upstream factor-1 (IUF-1), which binds to the insulin promoter. There was a high degree of IUF-1 binding in cells incubated with 20 mmol/L glucose, but this was abolished in cells incubated in 3 mmol/L glucose. In addition, this protein-DNA binding depended on the phosphorylation of IUF-1. Phosphorylation therefore alters a factor in the initiation of transcription of at least one glucose-sensitive gene. It is particularly interesting that phosphorylation is the signal that transduces glucose intake to induce insulin transcription, because it is also phosphorylation that directly affects the activity of enzymes in the Emden-Meyerhoff pathway. Thus, in this system phosphorylation acts as a common transduction mechanism, responsible for both the quick and slow responses to glucose uptake.

Identification of metabolites derived from nutrients responsible for the change in nutrient gene expression is an active area of research. Glucose-6-phosphate may possibly be the metabolite that activates the glucose response element in the FAS[195] and pyruvate kinase genes. This was demonstrated by comparing the effects of the two glucose analogs, 2-deoxyglucose (2dG) and 3-O methyl glucose (3OMeG). Neither analog can be metabolized. However, 2dG can be phosphorylated, but not 3OMeG; 2dG stimulated transcription, but 3OMeG did not. Therefore, only the phosphorylated sugar was able to stimulate the transduction mechanisms that resulted in transcription, which it did without further metabolism. Whether this phosphate bond provides the energy to phosphorylate a nuclear factor to bind to DNA is not known, but it is an interesting possibility.

NUTRIENT EFFECTS ON BACTERIAL POPULATIONS IN THE INTESTINE

This chapter has already highlighted the possibility that nutrients act on bacterial metabolism, and that the consequent fermentation products modulate gene regulation in the intestine.[196] However, bacteria themselves through the actions of their structural components act on gene expression. This is most evident in the effects on pattern recognition receptors (PRRs) (reviewed in Ref. 197). Many distinct bacteria carry similar pathogen associated molecular patterns (PAMPs). This makes it difficult to understand how changing the microbiota through diet could have a major impact on innate immune signaling. Recently,[198] innate lymphoid cells (ILCs) have been shown to express class II MHC (but not T or B cell receptors). Furthermore, they present antigens to the adaptive immune system, limiting commensal-bacteria T cell responses. Thus, the varying structures that make up bacteria can be sensed in detail. It has now become relevant to ask how dietary changes affect bacterial populations as an intermediary to its effects on intestinal gene expression.

While studies on how diet affects bacterial populations have been conducted for some time, it is only since the development of high throughput bacterial genome sequencing (bases on the DNA that codes for the 16S rRNA in the past 5-10 years.[199] Although this is a relatively new field, interesting concepts have emerged. First, it is likely that every person has a distinct detailed microbiota, that those genes that the microbes express perform similar functions. This is analogous to other ecosystems:

tropical rain forests in different parts of the world support differing plant species, but the functions that the plants undertake, for example, photosynthesis, transpiration, and so forth, are similar to each.[200] Second, different human beings may not lie on a continuum of varying bacterial species, but particular groups of bacteria may preferentially segregate together. These groups of distinct bacteria have been termed enterotypes.[201] This clustering appears to be independent of nationality, sex, age, or body mass index. However, diet may be a determinant. Using dietary interventions and 16S sequencing to characterize fecal samples from[98] individuals, Wu and co-workers[202] examined the effects of long term diets. Enterotypes were strongly associated with long-term diets. In particular, protein and animal fat predominantly supported Bacteroides-dominated enterotypes, while carbohydrates supported enterotypes with a large Prevotella component. Small changes in the microbiome are detectable within 24 hours, but enterotypes are more stable, requiring sustained dietary changes for over 10 days for a change.

-Within pediatrics, the effect of the microbiome on the transcriptome was studied in breast fed babies and compared to bottle fed babies. Using multivariate analysis, differences in the microbiota correlated with difference with the transcriptome.[203] However, these effects can be explained by bacterial metabolic products (as the authors suggest, and as described earlier in this chapter) rather than the actions of bacterial components directly. Data such as these exemplify how relatively undeveloped our current knowledge is of this complex area. Future work will increase our understanding of the effects of the varied structures.

CLINICAL AND THERAPEUTIC IMPLICATIONS OF NUTRIENT-GENE INTERACTIONS

The role of diet in diseases of many organs has become an area attracting attention from medical scientists and the general public. However, the relationship between dietary factors and the health of most organs has been difficult to examine, other than by using epidemiology.[204] Occasionally, data have emerged suggesting that particular diets benefit certain disease states. For example, renal failure was shown to be less progressive in rats whose protein intake had been restricted,[205] but even this has been difficult to substantiate in children.[206] Furthermore, it is not easy to see how the protein load has its effect. We have no knowledge of which cell types in the kidney may be affected, let alone how their phenotype may be altered

by protein intake. On the other hand, in the small intestine, the relation between diet and gastrointestinal function is clearer.

In clinical practice, one of the most substantial changes in the content of the intestine occurs before and after parenteral nutrition. The effects of such changes have profound consequences for the small intestinal epithelium in human subjects (see Figure 19-6B). Intestinal brush border hydrolase activity is diminished during parenteral feeding. Moreover, the ability of the mucosa to form a barrier is compromised. Moore and colleagues studied 74 patients who had suffered abdominal trauma randomized to receive either enteral or parenteral nutrition.[207] Those fed parenterally had more episodes of infective complications (pneumonia and abdominal abscesses) than those fed enterally. Calorie and nitrogen intake was equivalent in the two groups. As it is thought that the main source of sepsis following trauma is the gastrointestinal tract, this study may be evidence that enteral feeding directly affects the ability of the injured patient to contain bacteria within the gastrointestinal lumen.

The effect of parenteral nutrition on the morphology of the intestine in animals has long been known.[208] Considerable attention has been paid to the question of which enteral components are responsible for maintaining normal bowel morphology and function. No clear answer has yet emerged. For example, Spector and colleagues observed that luminal infusion of 30% dextrose or 5% amino acids were both effective in restoring intestinal weight, protein content, and DNA content after a period of intravenous alimentation.[209] Amino acids were more potent on a weight-for-weight basis or on a molar basis than dextrose. More recently, the changes in the intestine seen in animals fed via parenteral nutrition have been compared with the changes seen during weaning.[82] Intestinal length, mucosal mass, DNA, protein, and disaccharidase activities were significantly lower in animals sustained by intravenous nutrition when compared to normally weaned controls. However, restoration of luminal feeding resulted in a return to normal of the intestine in the TPN-fed group.

There are now many reports of the relationship of intestinal function to parenteral nutrition.[210] However, a study of the interaction between luminal content and the molecular control of intestinal cell protein synthesis is only just beginning, and this relationship is likely to provide the key to our understanding of how enter al feeds maintain a healthy epithelium.

It is also likely that epithelial signaling (see Figure 19-6C) may have important therapeutic implications for diseased intestine. First, the contents of the intestinal lumen are directly amenable to therapeutic manipulation,

whereas the environment that surrounds other, more internal, organs is maintained in strict homeostasis by a plethora of mechanisms. Second, although we do not know exactly how the local environment surrounding the epithelial cell is changed by diet (see Figure 19-2), dietary manipulations are an important aspect of management of gastrointestinal disease states.

The activity of Crohn's disease is greatly influenced by altering the contents of the intestinal lumen. Inflammation subsides in patients who are fed parenterally and receive no oral nutrients and in those receiving elemental diets. (See Enter al Products in Appendix.) These chemically defined diets induce remission as effectively as high-dose oral corticosteroids in both adults and children.[211] The return of inflammatory changes to normal in the intestine has been documented indirectly by the use of markers of intestinal permeability[212] and scanning of labeled neutrophils, and directly by examining the mucosa at endoscopy with biopsies.[213]

It has been hypothesized that a reduction in antigen load in the intestine may underlie the efficacy of elemental diets in Crohn's disease[211] in a fashion similar to that in cow's milk-sensitive enteropathy and celiac disease. However, the switch from normal diet to an elemental diet alters many constituents of the intestinal milieu apart from food antigens (see Figure 19-2). In particular, bacterial populations (and therefore bacterial products) are profoundly altered by dietary alteration. Moreover, giving whole protein in the form of liquid diets (polymeric diets) is also an effective treatment for Crohn's disease.[213] Removal of protein antigen is therefore not essential for the efficacy of the formula diet. It is more likely that the diets are altering many factors in the local environment of the intestinal lumen (see Figure 19-2). The concept of genes in the epithelium signaling events to the mucosal immune system is a first step to understanding the basis of how such events may occur because it seeks to identify molecular pathways from the intestinal lumen, through enterocytes to the mucosal immune system and other target cells beyond the epithelium. Certainly, this would be in keeping with data presented earlier (see Figure 19-7) showing that class II MHC and invariant chain expression in the epithelium are related to dietary factors. There was no expression in epithelial cells of the mice weaned onto an elemental diet,[187] and this diet was the same as that used in the treatment of Crohn's disease. Genes other than class II MHC, with common promoter elements, may also be altered by similar maneuvers, and may be important in regulating

intestinal inflammation.

CONCLUSIONS AND SPECULATION

Certain concepts have been laid down in this chapter that can be used as the basis for examining how dietary factors may affect the expression of genes in various cell types including the intestinal epithelium. The essential components for an effective transition between nutrient and gene expression in cells have been documented. These components (see Figure 19-1) comprise a system of recognizing changes in factors as they interact with a cell (sensing) and a mechanism of converting these external molecule-cellular molecule interactions into changes in gene expression (signal transduction). It is not yet fully understood how these mechanisms are effected in the cell. This chapter has presented evidence that nutritional factors do indeed alter gene expression in cells, but it is likely that different molecular species are sensed by completely different mechanisms. In the case of the epithelial cell, (see Figure 19-5) these sensing mechanisms can be at the cell surface or part of the internal mechanisms of the cell. It is also possible that special receptors exist on the surface of the cell and detect more complex external molecules such as large proteins and oligosaccharides. The apical surface of mucosal epithelial cells expresses a number of molecules belonging to the immunoglobulin super family. Their function is at present unknown, but they have been identified because they form the attachments for invading viruses. One member of the Ig super family (ICAM-1) allows rhinovirus attachment in nasal epithelium. As the primary function of these molecules on the mucosal surface cannot be to serve as a conduit for viral infection, it is tempting to suggest that they and other similar molecules might play a role in the immunosurveillance of macromolecules in the gastrointestinal tract. Signaling through these molecules would require alterations in epithelial cell gene expression for this surveillance to be transmitted to the mucosal immune system. If antigens are recognized by epithelial cells of the GI tract, it is possible that this information is correlated with information garnered from the previous penetration of similar antigens across the epithelium.

Finally, this field of nutrient-gene interaction may have important therapeutic implications; the ability of the epithelium to interact with other immune cells makes it an active member of normal human defense. This physiologic role may allow it to influence inflammatory reactions in pathologic situations. The opportunity exists through dietary means to

manipulate the constituents of the lumen of the intestine by opening up a new vista for treatment of human disease.

Nutrition and Epigenetics

20

Sang-Woon Choi, MD, PhD
and Simonetta Friso, MD, PhD

INTRODUCTION

Epigenetics is defined as a phenomenon that affects gene expression without changing the underlying base sequence. Epigenetics means super-, over-, or above-genetics. Thus epigenetic marks control the expression of a gene above the level of the genetic sequence by repressing or enhancing the gene transcription.[1]

Epigenetic traits have the peculiar characteristic of being heritable. Epigenetic phenomena can also be reversed or modified by environmental factors, including nutrition. It is known that both single nutrients and our diet as a whole can affect physiologic and pathologic processes in our body from conception to natural death. Because of this, epigenetics is now regarded as one of the most important mechanisms by which a nutrient or diet alters the expression of critical genes, thereby affecting facets of our phenotype, including health traits and disease susceptibility.[2]

DNA methylation, histone modifications, chromatin remodeling, and feasibly microRNA are now considered epigenetic phenomena. DNA methylation, a chemical modification of the cytosine base with a methyl group, is the most extensively studied epigenetic mark. Histone modifications are also common epigenetic marks that take place through the addition of a chemical group to the tail of the histone. Some of these chemical additions include acetylation, methylation, phosphorylation, ubiquitination, and biotinylation. Gene expression is modified by the addition of these small molecules by changing the chromatin structure at the site of the histone modification. Chromatin remodeling is a more dynamic modification of chromatin architecture using an ATP-dependent protein complex or combined modifications of histone tails by multiple

histone modifying enzymes. In recent years, microRNA has also been considered an epigenetic mark because microRNA affects gene expression without altering base pairs. Interestingly microRNA can directly modulate other epigenetic marks, and conversely the expression of microRNA can be controlled by other epigenetic phenomena.[3] In this chapter, we will discuss how nutrients, bioactive food components, and our diet modify these epigenetic marks during our lifetime and influence our health.

DNA METHYLATION

DNA methylation is a major epigenetic mark in eukaryotic cells, which entails the addition of a methyl group to the carbon 5 position of cytosine at cytosine–guanine dinucleotide (CpG) residues, thereby forming 5-methylcytosine (Figure 20-1). 5-Methylcytosine is present in an estimated 4%–6% of the cytosine bases within a human genome, depending on cell type. The human genome contains about 30 million CpG dinucleotides that exist in a methylated or unmethylated state. This dinucleotide can be found in small genomic regions (200 bp to a few kb) known as CpG islands that are located in the proximal promoter regions of 75% of human genes. CpG islands at the promoters of housekeeping or developmental genes are mostly unmethylated, whereas nonregulatory CpGs distributed elsewhere in the genome such as heterochromatin regions are fundamentally methylated. The methylation status of regions within a gene-body such as in exons or introns is also important in regulation of transcription.[4] The DNA methylation reaction is catalyzed by DNA methyltransferases (Dnmts).[5] There are several types of Dnmts, each having a unique function. Dnmt1 is a maintenance Dnmt that copies the methylation pattern of the original DNA strand onto the daughter strands after DNA replication, whereas Dnmt 3a and Dnmt 3b are de novo Dnmts and are responsible for methylation at new cytosine sites. Knockout mutations in any of the three mouse genes that encode Dnmts are lethal.[6] *S*-adenosylmethionine (SAM) is the unique methyl donor to this DNA methylation reaction and after donating a methyl group SAM turns into *S*-adenosylhomocysteine (SAH), which is an inhibitor of DNA methyltransferases.[3]

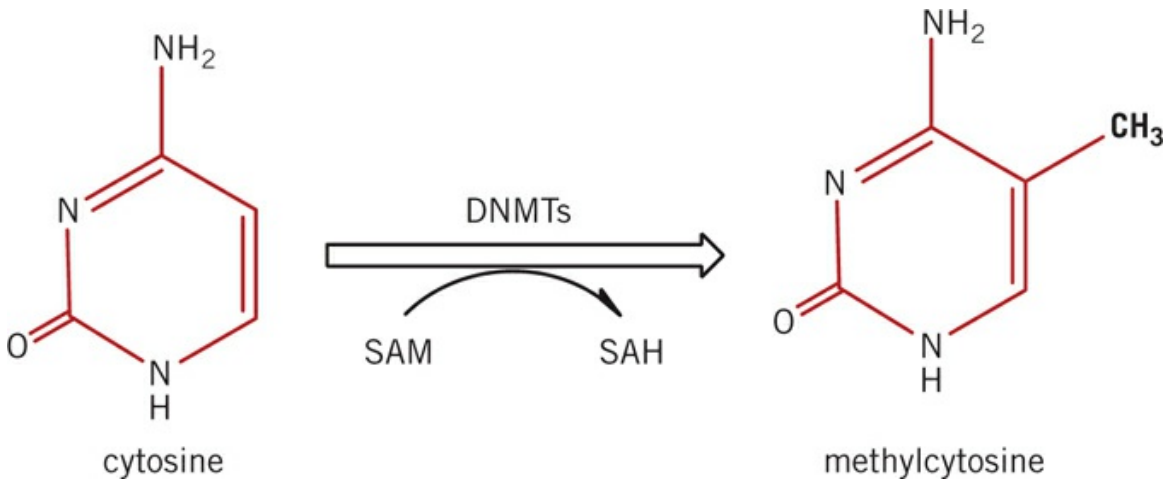

Figure 20-1 DNA methylation: DNA methylation is the addition of a methyl group to the carbon 5 position of cytosine at cytosine–guanine dinucleotide (CpG) residues, thereby forming 5-methylcytosine. The DNA methylation reaction is catalyzed by DNA methyltransferases (DNMTs). *S*-adenosylmethionine (SAM) is the unique methyl donor to this DNA methylation reaction and after donating a methyl group SAM turns to *S*-adenosylhomocysteine (SAH) which is an inhibitor of DNA methyltransferases.

In general, hypermethylation of a specific site of a gene is said to repress the gene by compacting nucleosome structure and recruiting methyl-binding proteins that interfere with the binding of transcription factors and RNA polymerases, whereas hypomethylation activates the gene with the opposite mechanism. However, this is also gene and site specific. Depending on the gene or location of DNA methylation, hypermethylation may increase and hypomethylation may decrease transcription, even though the mechanism is not yet clear.[3]

Compared with DNA methylation reactions, the DNA demethylation process has not been well delineated, even though DNA demethylation is critical during certain cellular processes such as embryonic development and stem cell differentiation. Among several candidate mechanisms, a new epigenetic mark, 5-hydroxymethylcytosine, has been highlighted as a player in the removal of methyl groups from cytosine bases. 5-Hydroxymethylcytosine is as an intermediate in the removal of the methyl group from 5-methylcytosine, returning the cytosine to its unmodified form. The ten-eleven translocation family of proteins are responsible for the hydroxylation of 5-methylcytosine to 5-hydroxymethylcytosine.[7] The

potential regulatory role of 5-hydroxymethylcytosine in gene transcription is somewhat different from that of methylcytosine, in that the affinity of methyl-binding proteins is much lower for 5-hydroxymethylcytosine compared to 5-methylcytosine. Less than 1% of cytosines are hydroxymethylated in mammalian DNA, and the level varies by tissue with the central nervous system having the highest amount. Embryonic stem cells also have high levels of 5-hydroxymethylcytosine, but these levels decrease during differentiation.[8]

DNA METHYLATION DURING OUR LIFETIME

Role of DNA Methylation During Embryonic Development

During embryonic development, each cell secures cell-specific patterns of DNA methylation in a process called DNA methylation reprogramming.[9] On fertilization, methylation patterns from parents are completely erased and newly established through de novo methylation during implantation. These dynamic processes are vital for the fertilization and differentiation of the embryo as well as for establishing the gene expression profiles that characterize each cell. During this reprogramming period, the intrauterine nutritional environment, which is mainly maternally derived, can affect this dramatic epigenetic reprograming, thereby affecting fetal development and even later life health status.[9,10]

Genomic imprinting is a type of DNA methylation by which a gene can be expressed in a parent-of-origin specific manner and plays an essential role in embryonic development and growth. The DNA sequence of the two parental alleles of imprinted genes is identical, whereas the DNA methylation status is different between the two parental alleles. An allele from one parent is repressed by hypermethylation of a specific differentially methylated region (DMR), wheras the other allele from the other parent is active by hypomethylation of the DMR.[11] Currently, approximately 100 imprinted genes have been described in mammals.[12] During the DNA methylation reprogramming period of other regular genes, the parental methylation status in imprinted genes maintain their imprinting status, whereas during germ cell development the parent-specific imprints are erased and new imprints are established. The parental allele-specific DNA methylation pattern is inherited to daughter cells and should be reset in each generation to establish parental specific imprints. The clinical phenotypes of imprinting disorders are diverse but are mainly involved in development and growth, such as Prader–Willi syndrome and

Angelman syndrome.[13] Alteration of imprinting status, as would occur with a loss of imprinting, may cause cancer in the later life.[14] Loss of imprinting of insulin-like growth factor 2 (*IGF2*) is a common molecular event in cancer, especially colorectal cancer, and typically activates the maternally silenced allele.[15]

Impact of Aging on DNA Methylation

During our lifetime, DNA methylation can be changed. Aging is known to affect DNA methylation in a complex fashion. Total 5-methylcytosine in DNA is prone to decrease with aging leading to global hypomethylation in most vertebrate tissues, whereas specific promoter regions tend to undergo a paradoxical hypermethylation in many genes.[10,16,17] We still do not know if these changes are genetically programmed or randomly acquired by environmental factors. Additionally, we do not know whether they are causes or results of the aging process in itself.[2] The most plausible mechanism is that decreased expression of the maintenance *Dnmt1* underlies reduced global hypomethylation, whereas increased expression of de novo *Dnmt3a* and *3b* mediates promoter hypermethylation. Declining levels of sex hormones and diet changes that occur with aging may also contribute to this age-associated DNA methylation changes. In one study, estrogen replacement therapy administered to postmenopausal women increased global DNA methylation in their peripheral mononuclear cells, giving strength to the theory that changes in sex hormones may have an epigenetic effect.[18]

A possible epigenetic connection between aging and cancer has been suggested because global DNA hypomethylation, gene-specific DNA hypermethylation, and altered expression of Dnmts are found in both aging and cancer. This supports the hypothesis that age-associated changes in DNA methylation patterns may provide an epigenetic milieu to develop age- associated diseases such as cancer. Nowadays, the study of DNA methylation has extended to other research fields outside of cancer including neurocognitive diseases,[19] cardiovascular diseases,[20] immune diseases,[21] obesity,[22] and even behavioral diseases[23], due to critical importance of DNA methylationin altering gene expression. It also suggests that we may delay the onset or progress of those diseases by modifying epigenetic mechanisms because epigenetic phenomena can be modulated by environmental factors like nutrition, in contrast to genetic phenomena such as polymorphisms and mutations that are irreversible.

NUTRITIONAL INFLUENCE ON DNA METHYLATION

One-Carbon Metabolism

One-carbon metabolism is a biochemical network that ultimately delivers methyl groups to many biological reactions including DNA methylation (Fig. 20-2). The water-soluble B-vitamins, folate, B_{12}, B_6, and B_2, act as coenzymes in one-carbon metabolism. Folate accepts a methyl group from serine and delivers the methyl group to homocysteine to reform methionine. Methionine, which is derived either from the diet or homocysteine remethylation, turns to SAM, the universal methyl donor to biological methylation reactions including DNA methylation. After donating a methyl group SAM turns to SAH, which is further converted to homocysteine. Importantly, SAH is an inhibitor of methyltransferases including Dnmts. Homocysteine can be remethylated by folate coenzymes as described above or by betaine, which is from the diet or converted from choline. Homocysteine can either be exported directly to blood or further metabolized to cystathionine and cysteine that ultimately form glutathione and taurine.[3] Because so many factors in one-carbon metabolism can be derived from the diet, deficiency or supplementation of those nutrients has a potential to alter DNA methylation by changing the status of SAM and SAH.

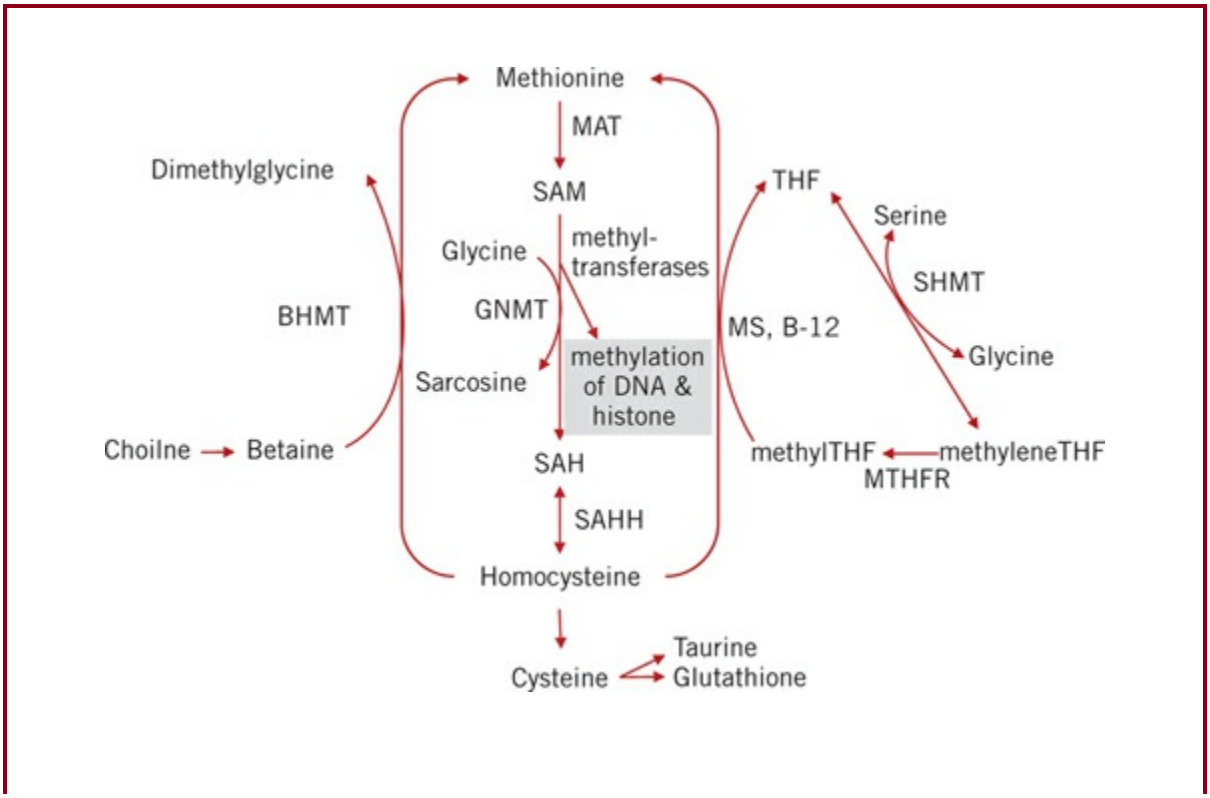

Figure 20-2 One-carbon metabolism: One-carbon metabolism is a biochemical network that ultimately delivers methyl groups to many biological reactions including DNA methylation and histone methylation. B-vitamins act as coenzymes and methionine, choline, betaine, and serine are methyl donors in one-carbon metabolism. BHMT; betaine homocysteine methyltransferase, GNMT; glycine N-methyltransferase, MS; methionine synthase, MTHFR; methylenetetrahydrofolate reductase, SAHH; *S*-adenosylhomocysteine hydrolase, SHMT; serine hydroxymethyltransferase

Folate is the most extensively studied nutrient in regard to DNA methylation. Multiple forms of folate coenzymes are involved in the delivery of methyl groups. Folate depletion decreases and folate supplementation increases global DNA methylation in animal studies, especially when aging is associated with these changes in folate.[24,25] However, the same results have been difficult to reproduce in human studies[26–28] because folate is not the sole determinant of DNA methylation in free living individuals who can get other methyl donor nutrients from the diet. Additionally, humans are exposed to various other environmental factors that may influence DNA methylation compared to animal studies in which animals are under the same environments and same dietary components (except folate) for the study duration.

Maternal folate deficiency has long been known to cause neural tube defects in neonates. Abnormal establishment of DNA methylation patterns from a folate deficiency is one of the most plausible mechanisms for this link between folate and neural tube defects, because low methyl availability induced by a folate deficiency is expected to disturb the DNA methylation reprogramming that is critical for embryonic development.[29] This has been previously shown when assessing the methylation status of particular genes in relation to folic acid intake. In a transgenerational study, periconceptional maternal folic acid supplementation was associated with changes in methylation at a DMR of *IGF2* in children between 12 and 18 months of age.[30] *IGF2* is an imprinting gene in which the methylated allele at the DMR (imprinted allele) is repressed. Children of mothers who took folic acid supplementation had a 4.5% higher methylation at the *IGF2* DMR than control children ($P = 0.014$). This result indicates that periconceptional folic acid supplementation is associated with the imprinting level of *IGF2* in the child, which may affect intrauterine programming of growth and development as well as later life health outcomes.

Deficiency of vitamin B_{12}, a water-soluble B-vitamin, is known to decrease DNA methylation in the rodent colon.[31] Vitamin B_{12} is a coenzyme for methionine synthase that catalyzes the remethylation of homocysteine to form methionine (Figure 20-2). Choline, a water-soluble essential nutrient, is also known to alter DNA methylation after converting to betaine (Figure 20-2). Maternal choline availability is essential for fetal neurogenesis, such as hippocampal development, and memory function throughout the life of the offspring. In a mouse study, dietary choline deficiency altered global and gene-specific DNA methylation in the developing hippocampus of mouse fetal brains, suggesting that maternal choline deficiency during the embryonic period alters fetal brain development through a DNA methylation mechanism.[32] Similarly, prolonged intake of a diet deficient in sources of methyl groups such as methionine, choline, folate, and vitamin B_{12} rapidly induce profound global hepatic DNA hypomethylation in a rodent model, which may contribute to the development of liver cancer.[33,34]

Other nutrients can also modify one-carbon metabolism to alter DNA methylation. Retinoic acid, which controls numerous physiological processes through the retinoid X receptor and retinoic acid receptor (RAR), is also known to alter DNA methylation by increasing abundance and activity of glycine *N*-methyltransferase, which in turn regulates SAM levels by catalyzing the conversion from SAM to SAH[35] (Figure 20-2). Retinoic acid is also known to regulate the expression and enzyme activity of Dnmts.[36] Genome-wide DNA methylation assays demonstrated 166 differentially methylated CpG sites in retinoic acid-treated human embryonic stem cells compared to control cells.[37] Interestingly, another DNA methylation array demonstrated that after retinoic acid treatment 402 gene promoters became demethylated and 88 genes were hypermethylated in neuroblastoma cells.[38] These types of epigenomic studies can demonstrate the effect of nutrients on genome-wide DNA methylation status, but it still needs to be investigated how the nutrient targets-specific genes to be methylated or demethylated and which changes actually have a health effect instead of just occurring as a concomitant phenomenon.

Vitamin D is now considered to play an important role in a wide range of body functions outside of bone health. Vitamin D has taken the forefront in cancer chemoprevention due to the role of the vitamin D receptor, a nuclear receptor that regulates the expression of many genes in cell cycle regulation and differentiation.[39] Recent evidence demonstrates that vitamin D can also modify gene expression through DNA methylation

in cancer cells. Incubation of breast cancer cells with vitamin D_3 reduces the aberrant hypermethylation and restores the expression of *RARβ2*,[40] phosphatase and tensin homologue tumor suppressor gene (*PTEN*),[41] and cadherin-1 gene (*CDH1*) encoding for E-cadherin.[42] These studies suggest that vitamin D may affect gene expression through a DNA methylation mechanism other than the vitamin D receptor that mediates most of biological functions of vitamin D.

DNA methylation may also be affected by periconceptional fasting. Blood DNA methylation status of the *IGF2* gene was assessed in individuals almost 60 years of age who had been exposed to famine periconceptionally during the Nazi embargo of the Western Netherlands near the end of World War II. The methylation status of the same region of the *IGF2* gene was also assessed in participants' same-sex siblings who were not exposed to the famine. Four CpG sites out of five investigated were significantly less methylated among periconceptionally exposed individuals compared with their siblings.[43] This study indicates that maternal undernutrition during the early development period can affect the establishment and maintenance of DNA methylation status in the offspring.

Bioactive Food Components and DNA Methylation

Bioactive food components can be defined as food components that are not essential but helpful for human health by enhancing one or more biological processes that maintain our health. Interestingly, these compounds can alter DNA methylation by directly affecting Dnmts. Evidence indicates that certain bioactive food components, including (–)epigallocatechin-3-gallate (EGCG) in tea, genistein in soybeans, isothiocyanates in cruciferous vegetables, or curcumin in curry spice might inhibit the development of cancer by reducing DNA hypermethylation status in critical genes associated with cancer, such as *p16*, *RARβ*, or *O*-6-methylguanine-DNA methyltransferase (*MGMT*).[44] In a human study, healthy premenopausal women demonstrated that a daily supplementation with isoflavones induced dose- specific changes in methylation of *RARβ2* and cyclin D2 (*CCND2*) measured from the intraductal breast specimens, which were also correlated with serum genistein levels.[45]

Various catechol-containing dietary polyphenols such as bioflavonoids, tea catechins, and coffee polyphenols have also been suggested to indirectly inhibit DNA methylation. The catechol-*O*-methyltransferase-mediated methylation of large amounts of dietary

catechols not only reduces the cellular pools of SAM but also forms an equimolar amount of SAH, an inhibitor of DNA methyltransferase.[46]

HISTONE MODIFICATIONS

DNA is compacted by tightly wrapping approximately 147 base pairs around histone proteins that were previously regarded as an inert packing material for eukaryotic nuclear DNA, forming a nucleosome, the fundamental unit of chromatin. Each nucleosome consists of two pairs of four core histones: H2A, H2B, H3, and H4 (Figure 20-3). Each of the histone proteins consists of a structured core and an unstructured tail domain. Many different types of posttranslational modifications to the N-terminal histone tails can occur, including acetylation, methylation, phosphorylation, ubiquitination, ADP-ribosylation, and biotinylation. These modifications are thought to contribute to the control of gene expression by either altering the ionic charge of the histone tail, modifying chromatin compaction, or by functioning as a binding platform for other proteins. As an essential component of cellular epigenetic machinery, histone modifications are known to influence biological processes including embryonic development and aging.[47] Even though it is not as extensively studied in embryonic development such as DNA methylation, it has been regarded that histone marks are also inherited and the alterations in histone mark control can influence the development process and disease susceptibility in later life. Nutrients and bioactive food components can change histone modifications and thereby alter physiologic and pathologic processes that are mediated by histone marks.

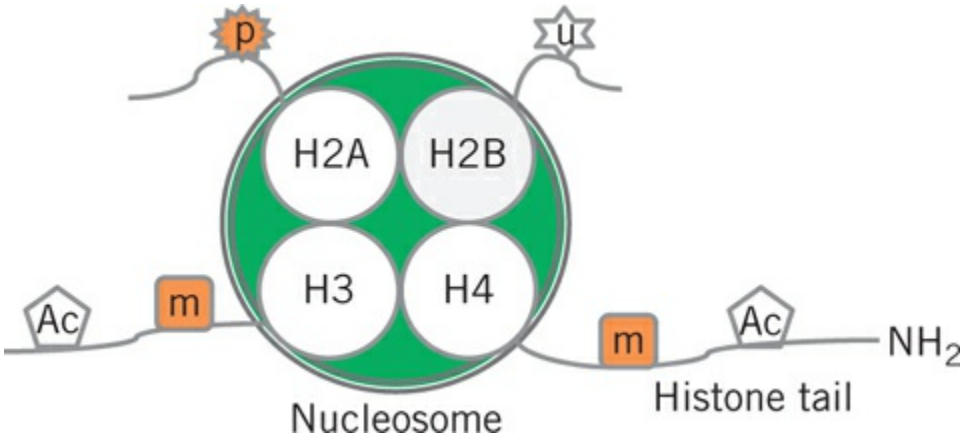

Figure 20-3 Histone modifications: Each nucleosome consists of two

pairs of four core histones (H2A, H2B, H3, and H4) and 147 bp of DNA wrapping around the histone. Each of the histone proteins consists of a core and a tail domain. Many different types of posttranslational modifications to the N-terminal histone tails can occur, such as acetylation (Ac), methylation (m), phosphorylation (p), and ubiquitination (u).

HISTONE ACETYLATION AND BIOACTIVE FOOD COMPONENTS

Histone acetylation is an epigenetic modification caused by the acetylation of lysine residues at the histone tail to alter local DNA compaction, leading to changes in gene expression. The histone acetylation status is maintained by the balance between histone acetyltransferases (HATs) and histone deacetylases (HDACs) (Figure 20-4). HATs are the class of enzymes that transfer acetyl groups onto lysine residues within the histone tail. Through this action the positive charge of the lysine is neutralized. In contrast to HATs, HDACs catalyze the removal of acetyl groups from lysines and restore the positive charge on the histone tail. HATs are generally classified as transcriptional activators, whereas HDACs are repressors.[48] Numerous studies have investigated the effects of bioactive food components on HDAC and HAT. Because the inhibition of HDAC can derepress epigenetically silenced genes in cancer cells, it has been investigated whether certain bioactive food components can be utilized for the prevention and treatment of cancer as HDAC inhibitors.[49]

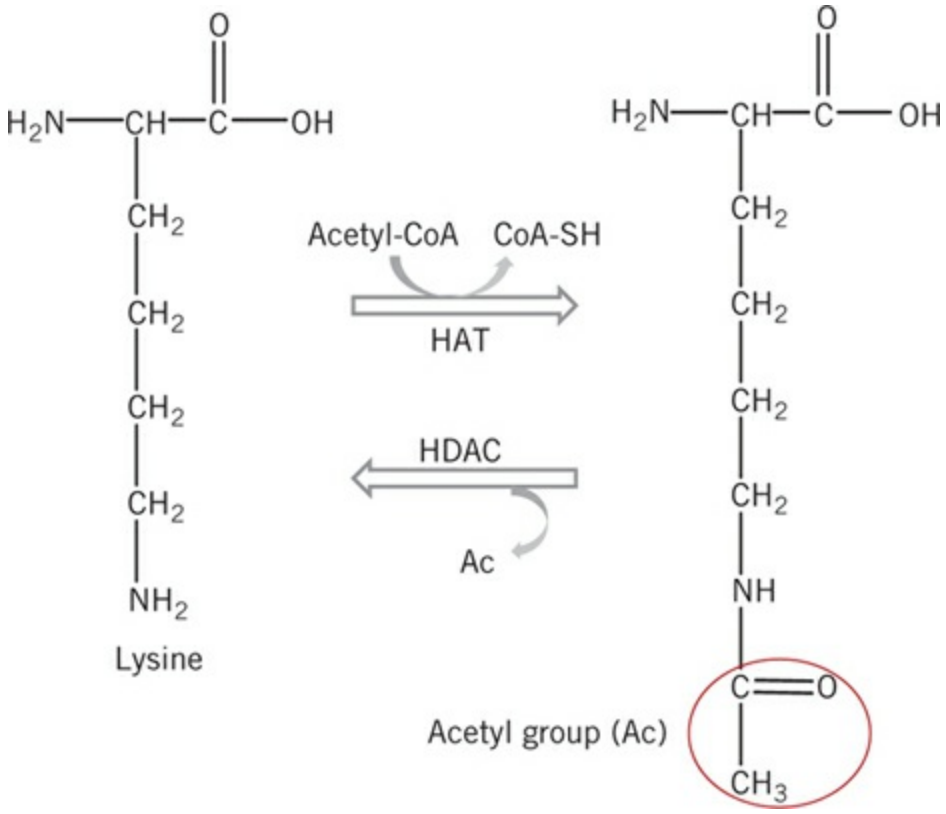

Figure 20-4 Histone acetylation: Histone acetylation is an epigenetic modification that acetylates lysine residues at the histone tail. The histone acetylation status is maintained by the balance between histone acetyltransferases (HAT) and histone deacetylases (HDAC).

Butyrate is a short-chain fatty acid generated during the fermentation of dietary fiber in colon by anaerobic bacteria.[50] Butyrate enters into the active site of HDAC enzymes and inhibits the activity, thereby increasing histone H3 acetylation. Butyrate stimulation may provide an effective method for reprogramming various human adult somatic cells and enhancing derivation of induced pluripotent stem cells.[51] After a report in 1977 that the addition of sodium *n*-butyrate to tissue culture media increases histone acetylation in cultured cancer cells,[52] the health effects of butyrate have been extensively studied as an HDAC inhibitor. This is especially true in cancer research because HDACs have been a promising target in the discovery of new cancer chemotherapeutic agents. Butyrate-induced alterations in histone acetylation have been associated with several processes in both initiation and progression of cancer, including cellular differentiation, cell cycle arrest, apoptosis, and inhibition of

invasion and metastasis in cancer.[53]

Sulforaphane, an isothiocyanate in cruciferous vegetables such as broccoli and broccoli sprouts that has anticancer properties, is also known to have HDAC inhibitory effects. Sulforaphane has been reported to inhibit the growth and proliferation of cancer cells by downregulating HDAC enzymes in different types of human cancer cell lines. In some studies, sulforaphane increased both global and gene-specific histone acetylation around the promoter regions of genes regulating the cell cycle and apoptosis such as *p21* and *Bax*.[54–56] In a human study, a dose of 68 g (1 cup) of broccoli sprouts effectively inhibited the HDAC activity in peripheral blood mononuclear cells 3–6 hours after consumption, with a concomitant induction of histone H3 and H4 acetylation.[57]

Organosulfur compounds in garlic, diallyl sulfide and *S*-allyl mercaptocysteine, also have demonstrated HDAC inhibitory effects. Both compounds are metabolized to allyl mercaptan that is more effective than its precursors at inhibiting HDAC activity.[58] This is due to allyl mercaptan being a good fit for the enzyme's active site. In human colon cancer cells, the HDAC inhibitory effect of allyl mercaptan was accompanied by a rapid, sustained accumulation of acetylated histones. Within 4 hours after the exposure to allyl mercaptan, histone H3 acetylation was increased around the *p21* gene promoter, resulting in elevated p21 protein expression and cell cycle arrest in human colon cancer cells.[58] An animal study demonstrated that diallyl sulfide increases histone H3 and H4 acetylation in colon cells isolated from rats, which was associated with alterations in the expression of a subset of genes.[59]

Resveratrol, a natural polyphenol abundantly found in grape skins and red wine, has diverse biochemical and physiological properties, including antiinflammatory, antioxidation, and antiproliferation effects.[60] Resveratrol is a potent activator of Sirt1, a regulator of cellular lifespan in a yeast model of aging through the reduction of acetylation at histone H4 lysine 16. This change in histone acetylation results in compromised transcriptional silencing at specific loci throughout the genome.[61] In a cultured cell study, the activation of Sirt1 by resveratrol negatively regulated the expression of the antiapoptotic protein, Survivin, by reducing histone H3 lysine 9 acetylation within the promoter of its gene].[62]

Curcumin, a yellow pigment present in the spice turmeric (*Curcuma longa*), has been shown to have anti-inflammatory, antioxidant, and anticancer functions.[63] In cells, curcumin promotes proteasome-dependent degradation of HAT p300 and the closely related cAMP-reponse element

binding protein (CREB). In addition to inducing p300 degradation, curcumin also inhibits the acetyltransferase activity of p300.[64] Curcumin-mediated HAT inhibitory activity was in parallel with decreased histone H3 and H4 acetylation in adult neural-derived stem cells.[65] Because curcumin-mediated epigenetic changes can increase apoptosis in cancer cells and promote neuronal differentiation in stem cells, curcumin might have a therapeutic potential in cancer and neurodegenerative diseases. Additionally, it is also reported that curcumin may prevent diabetes-associated abnormalities in the kidneys by inhibiting p300 and nuclear factor kappa B (NF-κB).[66]

HISTONE METHYLATION AND ONE-CARBON METABOLISM

Histone methylation occurs at the lysine and arginine residues of histone tails. Histone methylation is controlled by histone methyltransferases and histone demethylases. Histone methyltransferases use SAM as the methyl donor and are inhibited by SAH, similar to the Dnmts as discussed above.

Prolonged intake of a diet low in methyl donor nutrients such as methionine, choline, folate, and vitamin B_{12} has been known to induce profound global hepatic DNA hypomethylation and spontaneous liver tumors.[33,34] In this model, liver tumors were significantly decreased in histone H4 lysine 20 trimethylation (44%) and increased in histone H3 lysine 9 trimethylation (40%). Furthermore, the expression of suppressor of variegation 4–20 homolog 2 (Suv4–20h2), a histone methyltransferase that catalyzes histone H4 lysine 20 methylation, was decreased, whereas the expression of suppressor of variegation 3–9 homolog 1 (Suv3–9h1) that catalyzes histone H3 lysine 9 methylation was increased.[67] This study indicates that the development of liver tumors by a methyl-deficient diet may be through the alterations of histone methylation. It also supports a hypothesis that epigenetic reprogramming of the cell caused by the diet is an important prerequisite for the development of cancer.

In a transgenerational animal study using C57BL/6 mice choline deficiency during gestational days 12–17 altered the methylation status of histone H3 in E17 fetal hippocampi.[68] In the ventricular and subventricular zones, monomethylation at histone H3 lysine 9 was significantly decreased by 25%, and in the pyramidal layer dimethylation at histone H3 lysine 9 was also significantly decreased by 37%. This suggests that a maternal deficiency of the methyl donating nutrient choline can influence the

histone methylation status in the offspring's brain.

One of the most interesting observations is that histone methylation is associated with obesity. The histone H3 lysine 9-specific demethylase JmjC domain-containing histone demethylation protein 2A (Jhdm2a, also known as Jmjd1a and Kdm3a) directly regulates genes associated with lipid and energy metabolism such as peroxisome proliferator-activated receptor alpha (*PPARα*) and uncoupling protein 1 (*Ucp1*). The loss of Jhdm2a function in mice results in obesity and hyperlipidemia, along with decreased levels of dimethylation of histone H3 lysine 9 at the PPAR responsive element of the *Ucp1* gene, indicating that histone H3 lysine 9 methylation is important in regulating the expression of metabolic genes.[69] Further studies are needed to understand the role of histone methylation in obesity.

HISTONE BIOTINYLATION

Biotin, an essential water-soluble B vitamin, has been known to modify tails of histone H2A, H3, and H4 through a covalent attachment of biotin to lysine residues catalyzed by biotinidase and holocarboxylase synthase.[70] Even though debiotinylases have not been characterized, histone biotinylation is a reversible process. Although it is rare, biotinylation is a natural modification of human histones. Biotinylated histones are enriched in repeat regions and repressed loci.[71] Biotinylations at histone H4 lysine 8 and lysine 12 have been associated with heterochromatin structures, gene silencing, mitotic condensation of chromatin, and DNA repair.[72] A deficiency in biotin may have profound effects on chromatin structure,[73] but there are many unanswered questions in histone biotinylation, a modification of the histone directly by a nutrient.

CHROMATIN REMODELING

At the chromatin level, which is above the level of DNA and histones, regulation of gene transcription can also occur. By tightly packing the nucleosome to form compact chromatin structure, transcription factors and RNA polymerases can no longer transcribe DNA in those regions and the gene becomes silenced. This compacted chromatin will form not only to prevent transcription of a specific target gene but also to increase integrity of the genome. The mechanism by which chromatin are remodeled to either silence or activate a gene is either through an ATP-dependent

protein complex, or through combined covalent modifications of histone tails by several histone modifying proteins, such as the polycomb repressive complex (PRC).

ATP-DEPENDENT CHROMATIN REMODELING

The SWItch/Sucrose NonFermentable (SWI/SNF) complex is a common ATP-dependent chromatin remodeling protein complex in eukaryotic cells. The ATP-dependent chromatin remodeling mechanism actively alters chromatin structures during gene regulation.[74] This remodeling complex binds to the nucleosome and results in repositioning of that nucleosome.[75] Transcription of targeted genes can be increased or decreased depending on the open or compact chromatin structure induced by the nucleosome repositioning. The SWI/SNF complex plays an essential role in cellular processes, including proliferation, differentiation, and DNA repair and replication[76] as well as in immune responses[77] and carcinogenesis.[78] An animal study demonstrated that the disruption of a novel bromodomain-containing protein 2(Brd2), a transcriptional coactivator/corepressor with SWI/SNF-like functions that regulates chromatin, causes severe obesity, which is accompanied with pancreatic islet expansion, hyperinsulinemia, hepatosteatosis, and increased levels of proinflammatory cytokines.[79] This study suggests that the SWI/SNF chromatin remodeling mechanism may play a critical role in the inhibition of obesity.

POLYCOMB REPRESSIVE COMPLEX

PRC proteins are involved in gene silencing through chromatin remodeling. The formation of the multiple protein complex PRC represses transcription by maintaining the compact chromatin state through particular repressive histone marks and DNA hypermethylation. The composition of the PRC varies between organisms, cell types, developmental stages, and even in some disease states.[80] These complexes are recruited to regions of the DNA, so-called Polycomb response elements, where they regulate gene transcription through histone modifications. In humans, the embryonic ectoderm development enhancer of zeste homolog 2 (EED-EZH2) complex, a component of PRC2, trimethylates histone H3 at lysine 27 and then facilitates binding of PRC1. Recruitment of PRC1 can then lead to transcriptional repression through ubiquitination of histone H2A lysine 119. The addition of the ubiquitin

mark ultimately stops gene transcription by inhibiting mRNA elongation. PRC1 can also be recruited in a PRC2 independent manner.[81] Through this multistep protein recruitment pathway, the gene can be effectively repressed.

PRC is important during embryonic stem cell differentiation. During differentiation, the binding of PRC2, which mediates trimethylation at histone H3 lysine 27, is lost in transcriptionally active developmental genes. Retinoic acid is also involved in differentiation of embryonic stem cells and various types of cultured cancer cells seemingly through histone modifications. Interestingly, a global decrease in histone H3 lysine 27 trimethylation was observed three days after differentiation of mouse embryonic stem cells induced by retinoic acid treatment. The global levels of EZH2, histone H3 lysine 27 methyltransferase, and PRC2 protein also decreased with retinoic acid treatment.[82]

Other research has also focused on the link between dietary components, cancer development, and chromatin remodeling. B lymphoma Mo-MLV insertion region 1 homolog (Bmi-1), a PRC1 protein, is overexpressed in some human cancers including cancers of breast, prostate, lung, and ovary.[83] In a cultured cell study, treatment of SCC-13 cells, a human epidermal squamous carcinoma cell line, with the tea polyphenol EGCG reduced Bmi-1 and EZH2 levels. This was accompanied with diminished cell survival and a global reduction in trimethylation at histone H3 lysine 27.[84] Changes in PRC protein expression were in parallel with reduced expression of proteins that enhance progression through the cell cycle. These findings suggest that EGCG reduces skin cancer cell survival through PRC-mediated epigenetic mechanisms.

MICRORNAS

MicroRNAs are small noncoding RNAs of 20–24 nucleotides in length that play important roles in virtually all cellular processes including development, metabolism, and homeostasis. The primary mechanism by which microRNAs silence target genes is by inhibiting translation of mRNA either by directly binding the target sequence or through the formation of the RNA-induced silencing complex, which is responsible for site-specific cleavage of mRNA and facilitated mRNA degradation.[85] Certain microRNAs are encoded within introns of protein coding genes and are transcribed along with the primary transcript, whereas other microRNAs are transcribed from their own gene, the primary transcript

being called a pri-microRNA, which is then processed into mature microRNA.[86] A single microRNA may have multiple target mRNA and each mRNA may also be regulated by several microRNAs. There is some evidence of feedback between microRNA expression and other epigenetic phenomena.[87] For example, DNA methylation and histone modifications can regulate the transcription of microRNAs, and some microRNAs can alter the expression of Dnmt3A and Dnmt3B, and Polycomb group genes.[88] MicroRNA expression has also been linked to cancer, and aberrant microRNA expression caused by changes in DNA methylation has been discovered in cancer cells.[89] A growing body of evidence indicates that our diet, nutrients, and bioactive components can affect microRNA production. A methyl-deficient diet, which induces aberrant hepatic DNA methylation and histone methylation,[33,67] also changed the expression of microRNA genes, including *miR-34a*, *miR-127*, *miR-200b*, and *miR-16a*, which are involved in the regulation of cell proliferation, apoptosis, cell-to-cell connection, and the epithelial-mesenchymal transition in rat liver.[90] Similar to methyl deficiency, folate deficiency markedly increased *miR-222* expression in human lymphoblastoid cells.[91] In an animal study, Göttingen minipigs fed a high-cholesterol diet showed significantly lower *miR-122* levels as well as an increase in body weight and cholesterol levels compared with those fed the control diet, indicating the association of this microRNA with obesity.[92]

One interesting hypothesis in cancer therapy is that bioactive food components may reduce carcinogenesis through microRNAs.[93] In a cultured cell study using prostate cancer cell line genistein could alter the expression of oncogenic *miR-151* as well as its target genes involved in the progression and metastasis of prostate cancer. Inhibition of *miR-151* in prostate cancer cells by genistein also significantly inhibited cell migration and invasion.[94] In leukemic cells, curcumin upregulates the expression of *miR-15a* and *miR-16-1* and downregulates the expression of Wilms tumor 1 gene (*WT1*), indicating that the antiproliferative effect of curcumin might be through the upregulation of these microRNAs.[95] Additionally, in the human breast adenocarcinoma MCF-7 cell line curcumin reduced the expression of antiapoptotic B cell lymphoma 2 gene (*Bcl-2*) by decreasing the expression of *miR-15a* and *miR-16*.[96]

There is some evidence that exogenous microRNA from food may also have an effect on our cells. *MiR-168a* is abundant in rice, and is one of the most highly enriched exogenous microRNAs in the sera of Chinese subjects. Functional studies have demonstrated that *miR-168a* can bind to

the low-density lipoprotein receptor adapter protein 1 (*LDLRAP1*) mRNA, thereby inhibiting *LDLRAP1* expression in liver.[97] This study provides a new hypothesis that microRNA consumption through diet is a mechanism by which food can affect our phenotype.

CONCLUSION

Chromatin is a quite dynamic structure and has functions outside of being a packaging system for a long string of genomic DNA into the nucleus of each cell. It plays a critical role in controlling the accessibility of transcription factors to DNA. Modifications to the chromatin structure by DNA methylation, histone modifications, and chromatin remodeling can give rise a variety of epigenetic effects on gene expression. Because of its reversible characteristics, epigenetics is now considered an attractive field of nutritional intervention.

During our lifetime, nutrients, bioactive components, or diet can modify many physiologic and pathologic processes through epigenetic mechanisms. However, nutritional epigenetics is a field in its infancy and many questions remain to be answered. Specific time and dose of nutritional exposures and their efficacy on epigenetic regulations need to be examined. Numerous studies have suggested that perinatal nutrition is critical in epigenetic reprogramming of offspring, but few studies exist regarding the epigenetic effects of nutrition on other time periods of the lifecycle. This is particularly critical for the nutritional intervention in aging and age-associated diseases. Investigation into how epigenetic phenotypes acquired by nutrients can be inherited to the next generation independently from the genetic sequence as well as how nutrients select specific genes to be repressed or activated through epigenetic marks needs to be made.

It is not easy to delineate the precise effect of nutrients or bioactive food components on each epigenetic mark and their associations with physiologic and pathologic processes in our body, because the nutrient also interacts with genes, other nutrients, and other lifestyle factors. Furthermore, each epigenetic phenomenon also interacts with each other, adding to the complexity of the system. Nevertheless, we need to evaluate the epigenetic properties of more nutrients or bioactive food compounds to find better ones for our health. Embryonic development and aging are associated with substantial changes in epigenetic patterns and recent work is implicating epigenetic mechanisms in the etiology of pediatric developmental diseases and a majority of age-associated diseases.

Understanding the epigenetic roles of nutrients or bioactive food components in our health and development of these diseases will enable our ability to find a better way to maintain our health through nutritional modulation.
